## INTRODUCTION

The discovery of fullerenes<sup>[1,2]</sup> has disclosed a new wide area of research in fundamental condensed matter physics,<sup>[3,4]</sup> as well as in chemistry<sup>[2,5]</sup> and materials science,<sup>[6]</sup> confirming carbon as the most versatile element of nature. Fullerenes constitute a family of cage-like carbon molecules where each carbon atom is threefold coordinated and forms covalent  $sp^2$  bonds with the three nearest neighbors like in a single graphite sheet. The atoms of fullerenes lie on a closed surface topologically equivalent to a sphere. The actual shapes of fullerene clusters are polyhedra whose structural features can be largely understood from pure topological arguments. The number  $N$  of atoms of a fullerene molecule vary from a minimum of 20 to indefinite large values, presumably in the range of several thousands, although the far most stable fullerene is made of 60 atoms ( $C_{60}$ ) and takes the shape of a soccer ball, otherwise known as a truncated icosahedron. The shape of this highly symmetric polyhedron, having 60 equivalent vertices that can be generated by the 60 operations of the icosahedral point group, was well known to ancient Greek mathematicians, notably to Archimedes who described the 13 possible semiregular polyhedra. Semiregular polyhedra, otherwise known as the Archimedean polyhedra, are made of two different kinds of regular polygons and are obtained by vertex truncation of the five regular (Platonic) polyhedra. The first known representations of the truncated icosahedron have been given by the celebrated Renaissance artists and scholars Piero della Francesca and Leonardo da Vinci (Fig. 1).

In this entry, the structural and topological features of graphite-like carbon are described, with special emphasis on the novel families of graphene materials that have been discovered and thoroughly investigated after the first identification of the fullerenes  $C_{60}$  and  $C_{70}$ . In “Historical Background,” an overview is given on the historical development and the scientific and technical motivations of studies on the different forms of graphite-like carbon. The topology of graphene structures is presented in “Graphene Topology.” This section contains an elementary introduction to the

general topological properties of graphenes, which allows for a classification of the graphene families in terms of topological connectivity. This is followed by four subsections describing the main graphene families: fullerenes, nanotubes, schwarzites, and amorphous  $sp^2$  carbon. “Topology vs. Total Energy and Growth Processes” shows that the energetics and the growth processes of graphene structures can also be related to and, to some extent, understood from general topological arguments.

## HISTORICAL BACKGROUND

The first idea that graphite sheets could be bent, at the cost of replacing a number of six-membered rings with five-membered ones, so as to form graphite balloons, dates back to the mid-1960s and is due to D. E. H. Jones.<sup>a</sup> The conjecture that 60 carbon atoms could arrange themselves in a stable molecule having the shape of a truncated icosahedron was investigated in 1970 by the Japanese chemist Eiji Osawa and confirmed shortly after by the Russian chemists Bochvar and Galpern with a Hückel calculation (1973) and by R. A. Davidson (1980) by means of a group theoretical analysis. It is now recognized that fullerenes are rather frequent in nature, especially in soot and probably in interstellar dust. However, it was in 1985 that the cluster  $C_{60}$  was experimentally identified by Robert F. Curl, Harold W. Kroto, and Richard E. Smalley with their graduate students J. R. Heath and S. C. O'Brien at Rice University.<sup>[1]</sup> The molecule was recognized among the various products of a cluster beam experiment where carbon clusters were generated by laser vaporization of graphite—a technique developed by E. A. Rohlfing, D. M. Cox, and A. Kaldor a year before and then adopted by Richard Smalley for his experiments at Rice. The large abundance of  $C_{60}$  in the cluster beam, as signaled by mass spectra, was indicative of its exceptional stability whereas the

<sup>a</sup>References to this and following historical works are found in Sir H. W. Kroto's introductory paper in Ref.<sup>[2]</sup>.

**Fig. 1** The truncated icosahedron according to Piero della Francesca (*Libellus de Quinque Corporibus Regularibus*, 1492 manuscript at Bibliotheca Vaticana) and Leonardo da Vinci (in L. Pacioli, *De Divina Proportione*, Bologna 1498).

occurrence of a single line in the nuclear magnetic resonance spectrum suggested that all 60 atoms are equivalent, which led to one single possible geometry for the molecule, the truncated icosahedron. Although the number of possible fullerene isomers rapidly increases with the cluster size and many isomers have a comparable cohesive energy per atom, the truncated icosahedron is definitely the most stable form of  $C_{60}$  among its 1812 possible isomers. The resemblance of these new molecules with the geodetic domes invented by the renowned architect Buckminster Fuller led to the general name of buckminsterfullerenes, subsequently abbreviated into fullerenes.

A further breakthrough in the chemistry and physics of fullerenes was made by Wolfgang Krätschmer and Donald R. Huffman (1990) who devised a method for the production of fullerenes in gram quantities.<sup>[7]</sup> This allowed for the growth of fullerene crystals, either pure (fullerite) or in a compound form with other elements (fullerides), and led to the discovery of superconductivity in alkali fullerides at moderately high temperatures (1991).<sup>[8]</sup> Carbon clusters can also be considered as the building blocks for a large variety of carbon-based, cluster-assembled materials and novel nanostructured carbon forms.<sup>[9]</sup> Quite often clusters have peculiar properties, originating from the low dimensionality, which are frustrated in the corresponding three-dimensional solid. The concept behind cluster assembling is that some of the interesting properties and functions that occur in the composing clusters may be preserved in a three-dimensional robust structure. Much of the materials science based on fullerenes relies on their peculiar chemistry and on various functionalization and polymerization processes that have been discovered and extensively studied starting from the early 1990s.<sup>[10]</sup> The chemistry of fullerenes also includes the synthesis of endohedral fullerenes having the formula  $C_n@Me$ , where Me stands for a metal atom inside the fullerene cage. Indeed, these studies have suggested enormous potentialities and a wide range of applications for carbon-based materials,

thanks to the possibility of tailoring their physical properties and performances. It was suggested, for example, that the superconducting critical temperature of doped fullerite increases with the curvature of fullerene cages, namely with the reduction of the cluster size from  $C_{60}$  down to  $C_{36}$ ,<sup>[11]</sup> and perhaps  $C_{28}$  and  $C_{20}$ . Moreover, an unexpected ferromagnetic behavior has been recently described in fullerene materials.<sup>[12]</sup>

The surprising wealth of physical and chemical properties found in fullerenes has stimulated an extensive search for additional forms of carbon.<sup>[13]</sup> The peculiar cage-like geometry of fullerenes has provided a new ingredient for the structural analysis and growth of some widely studied forms of aggregation of  $sp^2$  carbon, such as carbon blacks, which are currently obtained by dehydrogenation of hydrocarbons and modeled as concentric shells of graphitic segments.<sup>[14]</sup> Indeed, single fullerenes may work as templates for the formation of a highly idealized form of  $sp^2$  carbon nanoparticles known as carbon onions. Carbon onions consist of concentric hollow carbon spheres that are produced with a strong electron beam irradiation of carbon nanoparticles such as those present in carbon blacks. Carbon onions have been found to act as precursors for the formation of diamond under suitable high-temperature electron beam irradiation. The low-density aggregation of  $sp^2$  clusters leads to the formation of highly porous, low-density carbon phases (carbon aerogels). Among these structures, schwarzites, discussed below, are of special interest from the topological point of view.

Another important class of  $sp^2$  carbon materials is that of carbon fibers, which can be viewed as assemblies of closely connected carbon nanotubes. A single-wall carbon nanotube (SWCNT) consists of graphite sheet rolled up to form a cylinder of a given constant diameter and indefinite length. The diameter can be as small as about 0.7 nm. When a nanotube is closed (capped) at both extremities, the nanotube can be viewed as a very elongated fullerene, and is indeed topologically equivalent to a fullerene. A single-wall nanotube can be dressed by other coaxial nanotubes in the very same way as a carbon onion grows around a fullerene and forms a multiwall carbon nanotube (MWNT). Carbon nanotubes have been discovered by high-resolution transmission electron microscopy (TEM) by S. Iijima in 1991<sup>[15]</sup> and since then have stimulated an enormous interest for their great mechanical robustness combined with excellent transport properties and potential applications in field emitters, supercapacitors, nanoelectronics, etc. Carbon nanotubes can be grown from the decomposition of hydrocarbons on metal nanoparticles acting as catalysts. Like endohedral fullerenes, nanotubes can be filled with metal ions that modify their one-dimensional properties; for example, their electrical behavior and

functions as nanowires. Indeed, nanotubes are considered as elementary components for nanocircuits, T- and Y-shaped junctions, and possibly semiconducting n-p junctions where the difference between the two sides of the junction is achieved either with two unequal nanotube structures or through doping, e.g., with endohedral metal atoms.

Other exotic morphologies of  $sp^2$  carbon that have been obtained with the use of different catalytic metal particles, laser-ablation processes, or simply by flash chemical vapor deposition techniques are carbon parallelepipeds,<sup>[16]</sup> single-wall<sup>[17]</sup> and multiwall<sup>[18]</sup> ring-shaped nanotubes, graphitic nanocones,<sup>[19]</sup> carbon nanohorns,<sup>[20]</sup> and nanotrees.<sup>[21]</sup> Nanotubes as well as cones and similar morphologies can be obtained in principle by a continuous bending of a graphite sheet without breaking any bond, namely without introducing disclinations. As will be explained in the next sections, from the topological point of view, this kind of deformation keeps the Gauss curvature of the surface constant, in this case zero as for the originally flat graphite sheet. For comparison, the bending of a graphite sheet and its closure into a fullerene implies a change of the Gauss curvature from zero to a positive value and the creation of a certain number of positive disclinations associated with the conversion of some hexagonal rings into smaller polygons.

The synthesis of new  $sp^2$  carbon forms, such as fullerenes and nanotubes, and the observation of important properties, such as superconductivity in alkali metal-doped fullerenes,<sup>[22]</sup> field-emission,<sup>[23]</sup> and supercapacitance<sup>[24]</sup> from arrays of nanotubes, are opening fascinating perspectives for nanostructured carbon as a novel, all-purpose material. However, fullerenes and nanotubes, as well as graphite, aggregate into van der Waals three-dimensional (3-D) solids. For many technological applications, there is a need of highly connected, fully covalent  $sp^2$ -bonded carbon forms, combining the valuable properties of fullerenes and nanotubes with a robust 3-D architecture. A basic question is whether a graphite sheet can be transformed into a surface characterized by a negative Gauss curvature everywhere through the creation of a sufficient number of negative disclinations where some hexagonal rings transform into larger polygons. A special case of negative Gauss curvature occurs when the mean curvature is zero everywhere, which corresponds to what is known in differential geometry as a minimal surface. The conjecture that a minimal surface is particularly stable has stimulated much theoretical work on hypothetical graphite sheets (graphenes) with the shape of a periodic minimal surface.<sup>[25–31]</sup> These structures have been called schwarzites, after the name of the mathematician H. A. Schwarz, who investigated the differential geometry of this class of surfaces at the end of the 19th century.<sup>[32]</sup>

Similar theoretical  $sp^2$  carbon structures such as polybenzenes<sup>[33]</sup> and hollow graphites<sup>[34,35]</sup> can be ascribed to the general family of schwarzites. In the late 1990s, possible routes to the synthesis of schwarzites through the assembling of small carbon clusters in supersonic cluster beam deposition (SCBD) experiments<sup>[36,37]</sup> have been theoretically investigated by means of classical molecular dynamics.<sup>[37,38]</sup> Indeed, there is a clear evidence that *random schwarzites*, characterized by a highly porous, fully 3-D graphite-like carbon, are formed under special conditions.<sup>[28,39]</sup> Recently, periodic structures, with a porosity on the mesoscopic scale and fascinating perspectives in optoelectronics, have been synthesized by chemical methods.<sup>[40]</sup>

While most of the theoretical studies concerned periodic schwarzites, experimental evidence has been recently obtained for an amorphous schwarzitic form of carbon corresponding to the random schwarzite previously envisaged by various authors.<sup>[28,41,42]</sup> This new structure, which is fully covalent in three dimensions, represents the fourth form of  $sp^2$  carbon; the first form, fullerite, is the aggregation of zero-dimensional objects (fullerenes); the second form, nanotubes bundles, is the aggregation of one-dimensional objects (nanotubes); and the third form, graphite, is the aggregation of two-dimensional objects (the graphite sheets or graphenes). Random schwarzites have been obtained by supersonic cluster beam deposition (SCBD) of carbon clusters in the presence of very small catalyst nanoparticles,<sup>[39]</sup> and look like a highly porous spongy carbon. The numerical simulation of the TEM images suggests that random schwarzites grow in the form of a self-affine minimal surface, with relevant and not yet fully understood topological features. The topology and structural properties of the different classes of  $sp^2$  carbon are discussed in “Graphene Topology.”

Supersonic cluster beam deposition experiments have also shown that by increasing the energy per atom of the beam clusters, an increasing  $sp^3$ -to- $sp^2$  bond ratio is observed in the SCBD carbon. A natural question was whether carbon is able to form other *fully covalent, fully three-dimensional*  $sp^3$  solids besides diamond and lonsdaleite, which can be obtained from the coalescence of fullerene cages. Much theoretical work and speculations have been made about the possible geometries and structure of carbon clathrates originating from the coalescence of small fullerenes,<sup>[43–46]</sup> but no experimental synthesis of these interesting materials has been obtained so far. Similar structures, characterized by only a partial saturation of bonds (mixed  $sp^3/sp^2$  forms), have been recently synthesized by linking together through covalent bonds  $C_{36}$  clusters<sup>[11]</sup> or  $C_{20}$  clusters.<sup>[47]</sup> The topology of clathrates is discussed in general terms in Refs.<sup>[48,49]</sup> while some topological algorithms that

generate complex and even fractal clathrate structures can be found in Refs.<sup>[46,50]</sup> together with some topological algorithms that generate complex and even fractal clathrate structures.

## GRAPHENE TOPOLOGY

From the topological point of view, fullerenes as well as graphite sheets, nanotubes, and schwarzites [which we shall group under the general family name of *graphenes* (Fig. 2)] are here described as polygonal tilings of surfaces with only hexagons, pentagons, and heptagons, where each vertex corresponds to a carbon atom, each edge corresponds to a covalent bond, and each polygon corresponds to a carbon ring. The generalization to structures with larger and/or smaller polygons is straightforward. Each atom has a threefold coordination. The surface, covered by a polygonal tiling of carbon rings, defines the shape of a graphene and is characterized by its connectivity or order of connection  $k$ . According to Hilbert and Cohn-Vossen,<sup>[51]</sup> the order of connection is the number plus one of the close cuts that can be made on the given surface without breaking it apart in two pieces. The

**Fig. 2** The four allotropic forms of graphite-like carbon, which are characterized by  $sp^2$  bonds and threefold coordination and are grouped under the general name of *graphenes*: (A) Two lattice planes of graphite crystal, where each plane represents an ideal graphene with only hexagonal rings. (B) The fullerene  $C_{60}$ , formed by 12 pentagons and 20 hexagons. (C) A nanotube, having a cylindrical shape and an indefinite length. (D) A three-periodic, D-type schwarzite, characterized by a lattice with the diamond structure. While the crystalline forms of fullerenes, nanotubes, and graphite are held together by van der Waals forces in three, two, and one space directions, respectively, schwarzite is entirely covalent in three dimensions.

surface topology may be alternatively characterized by the Euler–Poincaré characteristic  $\chi = 3 - k$  or the genus  $g = (k - 1)/2$ . For example, a simple (one-hole) torus can be cut along two closed lines without splitting it in two pieces, and therefore  $k = 3$  or  $\chi = 0$ ,  $g = 1$ . For a sphere,  $k = 1$  ( $g = 0$ ,  $\chi = 2$ ), whereas for an  $n$ -hole torus,  $k = 1 + 2n$ ,  $\chi = 2(1 - n)$ , and  $g = n$ . Thus the genus represents the number of “holes” (or “handles”) of a generalized torus.

While fullerenes are represented by a closed surface topologically equivalent to a sphere ( $k = 1$ ), uncapped nanotubes, graphite sheets, and schwarzites are open surfaces with an infinite extension in one, two, or three dimensions, respectively. However, graphenes characterized by a periodic atomic structure can be conveniently reduced to a closed surface by applying cyclic boundary conditions. In this way, uncapped nanotubes and graphite sheets become topologically equivalent to an ordinary (one-hole) torus ( $k = 3$ ). On the other hand, the connectivity of an infinite periodic surface is infinite. However, if cyclic boundary conditions are applied on a finite portion of the periodic surface, the connectivity is finite, although dependent on the actual number of unit cells of the periodic structure. Thus it is convenient to define the connectivity per unit cell. This is obtained by closing the portion of surface contained in the unit cell on itself as implied by the cyclic boundary conditions, and the number  $g_{\text{cell}}$  of handles generated by the closure operation gives the order of connection per unit cell as

$$k_{\text{cell}} = 2g_{\text{cell}} + 1 \quad (1)$$

There is a fundamental relationship, known as the Gauss–Bonnet theorem, which links the topological properties of a closed surface, expressed by the Euler–Poincaré characteristic, to its differential geometrical properties, expressed by the principal curvature radii  $R_1$  and  $R_2$ :

$$\int_S \frac{dS}{R_1 R_2} = 2\pi\chi \quad (2)$$

where the integral extends over the whole surface  $S$ . For a periodic surface, the theorem applies to any portion of it, notably to a single unit cell, after closure through the periodic boundary conditions. The two principal radii are usually replaced by two more convenient variables, the mean curvature  $H$  and the Gauss curvature  $K$ , defined by

$$H = \frac{1}{2} \left( \frac{1}{R_1} + \frac{1}{R_2} \right), \quad K = \frac{1}{R_1 R_2} \quad (3)$$

respectively, with the convention that radii have a positive or a negative sign according to whether they are oriented on one side of the surface or the other. Thus according to the Gauss–Bonnet theorem, the Euler–Poincaré characteristic is the average Gauss curvature times  $S/2\pi$ .

According to Euler's theorem, the tiling of a closed surface with a Euler–Poincaré characteristic  $\chi$  fulfils the equation

$$v - e + f = \chi = 3 - k = 2(1 - g) \quad (4)$$

where  $v$  is the number of vertices (atoms),  $e$  is the number of edges (bonds) and  $f$  is the number of polygonal faces (atom rings). We shall indicate by  $f_j$  the number of  $j$ -membered rings present in the tiling, so that

$$f = \sum_j f_j \quad (5)$$

and

$$v = \sum_j jf_j/3 = \frac{2}{3}e \quad (6)$$

By inserting Eqs. (5) and (6) into Eq. (4), one obtains

$$\sum_j (6 - j)f_j = 6(3 - k) = 12(1 - g) \quad (7)$$

For a given connectivity (genus) of the surface, this equation provides a condition among the numbers of polygons. It appears that this condition is independent of the number of hexagons, which is therefore arbitrary.

Special cases are the *Platonic tilings*, with a single kind of polygons, and the *Archimedean tilings*, with two different kinds of polygons, one of which is, in the present discussion, the hexagon. In both cases

$$f_j = 6(3 - k)/(6 - j) \quad (8)$$

for  $j \neq 6$ , whereas the number of hexagons is zero for Platonic tilings or any other number  $>1$  for Archimedean tilings. If, besides hexagons, the tiling also includes pentagons and heptagons, then

$$f_5 - f_7 = 6(3 - k) \quad (9)$$

From this equation, it appears that pentagon–heptagon pairs may be added to (or cancelled from) a tiling within the same topology of the surface. Thus if a hexagon is replaced by a pentagon in some thermally induced or stress-induced defect formation process, a heptagon must be formed as well in some other place of the graphene network.

To replace a hexagon in a flat graphite layer with a pentagon with no bond stretching, a whole sector  $60^\circ$ -wide of the surrounding hexagonal lattice has to be removed. This transforms the original flat lattice into a cone truncated by the pentagonal face, where the continuous surface encompassing the atoms acquires a positive Gaussian curvature: The perimeter of a circle of radius  $R$  lying on the surface and centered at the pentagon center is shorter than  $2\pi R$ . This defect is an example of a *positive disclination*. In a similar way, a hexagon can be replaced by a heptagon with no bond stretching by inserting a  $60^\circ$ -wide sector, which transform the original flat lattice into a saddle around the heptagonal face, with a negative Gaussian curvature: The perimeter of a circle of radius  $R$  lying on the surface and centered at the heptagon center is longer than  $2\pi R$ . This defect is an example of a *negative disclination*.

The creation of pentagon–heptagon defect pairs occurs, for example, when a cylindrical nanotube is bent. An ideally infinite cylindrical nanotube is a perfect hexagonal tiling. An elbow bending produces a positive Gauss curvature on the external side and a negative Gauss curvature on the internal side of the elbow, and this is accommodated by the creation of pentagon and heptagon defects on the two sides, respectively. These arguments are easily extended to the case where octagons are considered instead of, or in addition to, heptagons.

The topological features of graphenes are relevant to their cohesive energy and electronic structure. Intuitively, the number of topologically different close electron orbits increases with the order of connection of the graphene surface. The topological structure of the electronic eigenfunctions in graphenes, notably in schwarzites, has been theoretically investigated in some recent works by Aoki et al.<sup>[52]</sup> The electronic energy levels and their degeneracy depend also, and more specifically, on the local point symmetries. The subtle links between topological and point-symmetry properties have been elucidated by Fowler, Ceulemans, and coworkers in a series of seminal works.<sup>[53–56]</sup>

## Fullerenes

For fullerenes ( $k = 1$ ), Eq. (8) gives  $f_5 = 12$  or  $f_4 = 6$  or  $f_3 = 4$ . By excluding energetically unfavorable three- and four-membered rings, it turns out that Archimedean fullerenes must always contain 12 five-membered rings, and the number of atoms grows with the number of six-membered rings as

$$v = 20 + 2f_6 \quad (10)$$

Therefore the most common fullerenes  $C_{60}$  and  $C_{70}$  have 20 and 25 six-membered rings, respectively,

whereas the smallest fullerene is the Platonic dodecahedron  $C_{20}$ . In general, fullerenes with abutting pentagons are less stable. To avoid abutting pentagons, each pentagon must be surrounded by five hexagons, and each hexagon cannot have more than three adjacent pentagons. Thus the smallest fullerene with no abutting pentagons must have  $12 \times 5/3 = 20$  hexagons, and this explains the high stability of  $C_{60}$  in its isomeric form with the 12 pentagons regularly spaced at the vertices of an icosahedron. On the other hand, the carbon atom at the trihedral vertex of three abutting pentagons has three bonds forming angles of  $108^\circ$  and can therefore easily go in an approximate  $sp^3$  configuration as long as its outward dangling bond is saturated, say, by a hydrogen atom, which leads to rather stable forms of hydrogenated fullerenes. Thus  $C_{20}H_{20}$ ,  $C_{28}H_4$ , etc. are particularly stable molecules, unlike the corresponding pure fullerenes that have a very low stability. As regards the possible isomeric forms, even restricting the fullerene isomers to those exclusively made of five- and six-membered rings, their number rapidly increases with  $v$ . As shown by Fowler et al.<sup>[57,58]</sup> in some basic works, the enumeration of isomers and the classification of their electronic structures can be achieved through the so-called spiral algorithm and leapfrog rules. Thus for  $C_{28}$ , there are only two isomers; for  $C_{40}$  this number is 40, whereas for  $C_{60}$  there are 1812 spectrally distinct isomers. Fortunately, because of the geometrical conditions discussed above, there is, in general, at least for not too large fullerenes, only a small number of particularly stable isomers that are largely favored with respect to the others. They are the isomers with no abutting pentagons: only one isomer for  $C_{60}$ , but five for  $C_{78}$ , seven for  $C_{80}$ , etc. The most stable isomers approximate as much as possible the spherical shape to minimize the distortion of the bonds from the ideal  $sp^2$  configuration. For approximately spherical fullerenes, the average diameter  $d_v$  can be evaluated from the equation

$$\pi d_v^2 \cong \frac{f_6 S_6}{1 - S_6/S_p} + \frac{12 S_5}{1 - S_5/S_p} \quad (11)$$

where  $S_5 \cong 1.720r_5^2$  and  $S_6 \cong 2.598r_6^2$  are the areas of pentagons and hexagons of average edge length  $r_5$  and  $r_6$ , respectively, and  $S_p = 12S_5 + f_6S_6$  is the surface area of the fullerene polyhedron. For  $r_5$  and  $r_6$  equal to the bond length in graphite  $r_0 = 0.142$  nm, the diameter of  $C_{60}$  estimated from this equation is  $d_{60} \cong 0.694$  nm, whereas the experimental value is  $0.704$  nm. This small discrepancy is fully accounted for by using the actual average bond lengths  $r_5 = 0.145$  nm and  $r_6 = 0.142$  nm.

Giant fullerenes, with  $v$  in the range  $10^2$ – $10^3$ , are believed to approach an icosahedral shape with the

**Fig. 3** A giant fullerene of 1620 carbon atoms. Rather than spherical, the structure is approximately icosahedral as a result of the positive disclinations induced by the 12 pentagonal rings requested by Euler's theorem and located at the vertices. *Source:* From Ref.<sup>[59]</sup>.

12 five-membered rings at the vertices and the 20 triangular faces made by graphite sheets (Fig. 3). In this limit, the fullerene may be viewed as obtained by folding a single graphite sheet through the insertion of 12 positive disclinations. However, capped nanotubes may also be viewed as giant fullerenes where the 12 five-membered rings are concentrated in the caps, six on each side.

## Nanotubes

A single-wall carbon nanotube can be constructed by rolling up a portion of a graphite sheet into a cylinder so as to bring an atomic site in the unit cell  $(L, M)$  of the graphite sheet to coincide with its equivalent site in the origin unit cell  $(0, 0)$  (Fig. 4A). The structure of the nanotube is entirely defined by the pair of integer numbers  $(L, M)$ . The diameter is given by.<sup>[60,61]</sup>

$$d_{L,M} = \frac{\sqrt{3}}{\pi} r_0 (L^2 + LM + M^2)^{1/2} \quad (12)$$

On pure geometrical grounds, the smallest open-ended nanotube is  $(3, 0)$ ; however, with the requirement of end capping with six pentagons on each side, the smallest possible nanotube is  $(5, 0)$  with a diameter of about  $0.39$  nm.

Nanotubes are classified into three types depending on the indices  $(L, M)$  (Fig. 4B–D): *parallel* nanotubes, with indices  $(L, 0)$  or  $(0, M)$ , where one third of the interatomic bonds is parallel to the nanotube axis; *perpendicular* nanotubes, with indices  $(L, L)$ , where one third of the interatomic bonds is normal to the nanotube axis; and *chiral* nanotubes with either  $L > M > 0$  (right-handed) or  $M > L > 0$  (left-handed).

**Fig. 4** (A) A single-wall carbon nanotube can be obtained by folding a graphite sheet so as to bring the point  $(L,M)$  to coincide with the origin  $(0,0)$ . The vector  $T$ , orthogonal to the circumference  $C$ , defines the periodicity in the axial direction. In this example  $(L,M) = (4,1)$ . (B) An achiral perpendicular nanotube of indices  $(5,5)$ . (C) An achiral parallel nanotube of indices  $(9,0)$ . (D) A chiral  $(7,3)$  nanotube. (Ph. Lambin, private communication.)

From the symmetry point of view, the nanotube axis is a rotation axis of order  $L$  for both parallel  $(L,0)$  and perpendicular  $(L,L)$  nanotubes, whereas chiral nanotubes have a screw axis. In the direction parallel to the axis, nanotubes are periodic with a period of  $3r_0$  for the parallel type,  $\sqrt{3}r_0$  for the perpendicular type and  $\pi d_{LM}/\sqrt{3}D(L,M)$  for the chiral type, where  $D(L,M)$  is the greatest common divisor of  $L$  and  $M$ . Thus for prime pairs, for which  $D(L,M) = 1$ , the period along the axis is  $1/\sqrt{3}$  times the circumference.

Multiple-wall nanotubes grow by sequential addition of layers on an original single-wall nanotube. The interlayer distance is constant and is about 0.34 nm, with a tolerance that keeps, for energetic reasons, within about 1%. Thus the diameters of a multi-wall nanotube with the concentric nanotubes labeled in the outward direction by  $n = 1, 2, 3, \dots$  are given by

$$d_{L'M'} = d_{LM} + 2(n - 1)(0.34 \text{ nm}) \quad (13)$$

It turns out that each layer has indices  $(L',M')$  that differ from the indices  $(L,M)$  of the template ( $n = 1$ ) layer, their values being those that better simultaneously fulfill Eqs. (12) and (13) within a 1% tolerance (Fig. 5).

**Fig. 5** A multiwall nanotube is grown around an initial single-wall  $(9,2)$  nanotube of circumference  $C_1$  by the addition of further layers of circumferences  $C_2 = C_1 + 2\pi$  (0.34 nm),  $C_3 = C_2 + 2\pi$  (0.34 nm), etc. The indices of second, third, etc. layers are those that better match the respective radii with some interatomic distance:  $(15,8)$  and  $(19,16)$  in the present example. (Ph. Lambin, private communication.)

Apart from caps, which contain 12 pentagons each, ideal straight nanotubes are exclusively made of hexagonal rings as in the graphite sheet, with a good conjugation among interatomic bonds. However, as explained above, nanotubes can be bent with the addition of pentagon–heptagon pairs that introduce pairs of disclinations of opposite sign. In particular, an open-ended nanotube can be closed on itself to give a toroidal shape. Ring-shaped and even coiled nanotubes have been experimentally observed.<sup>[17,62]</sup>

Non-ideal nanotubes may have a variety of defects as in ordinary graphite. Of special interest here are the topological defects in which some hexagons are replaced by other polygons preserving the threefold coordination at each atom. Since the connectivity must not change, the number  $f_j^d$  of polygons replacing hexagons in each defect must fulfill the equation

$$\sum_j (6 - j)f_j^d = 0 \quad (14)$$

as a consequence of Eq. (7). The simplest topological defect, which can be entirely accommodated within a 14-membered ring with no alteration outside, is constituted by two pentagon–heptagon pairs ( $f_5^d = f_7^d = 2$ ) and is generated by the so-called Stone–Wales transformation (Fig. 6).

### Periodic Schwarzites

The fourth form of  $sp^2$  (graphite-like) carbon, which we have called schwarzite, may be defined on a pure topological basis as a graphene with a negative average

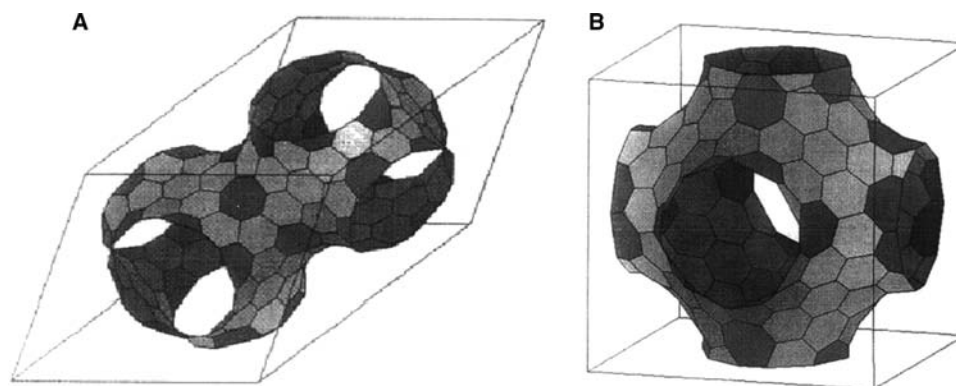

**Fig. 6** Illustration of the simplest topological defect in a nanotube originating from the rotation of the AB bond into A'B'. This operation, known as Stone–Wales transformation, reduces by one the edge number of polygons having AB in common and increases by one the edge number of the two adjacent polygons.

Gauss curvature ( $\chi < 0$ ), unlike fullerenes and capped nanotubes, having  $\chi > 0$ , and graphite, open and toroidal tubulenes, having  $\chi = 0$ . Any periodic surface with a periodicity in two or three space directions has a unit cell that can be closed by the periodic boundary conditions with two or three handles, respectively, and therefore the average Gauss curvature is always negative. As proved in “Topology vs. Total Energy and Growth Processes,” the highest stability of a graphene with a negative  $\chi$  occurs for a shape corresponding to a minimal surface, namely when the principal radii fulfil the condition

$R_1 = -R_2$  everywhere, or equivalently the mean curvature  $H$  vanishes at any point of the surface. Among the possible shapes of minimal surfaces, special attention has been given to branched tubular structures, as an obvious generalization of nanotubes,<sup>[30]</sup> which form two disjoint labyrinths, one complementary to the other. For this special feature, periodic schwarzites have been pictorially termed as the *plumber’s nightmares*.<sup>[30]</sup>

Periodic schwarzites are generated by covalent connections of identical units (elements). The unit cell may contain one or more such elements. The centers of the elements can be viewed as the nodes of a corresponding *dual lattice*. One of the two labyrinths, assumed as the internal one, contains the dual lattice. The dual lattice with the four-coordinated diamond structure defines an important class of cubic schwarzites, with two elements per unit cell (*bielemental* schwarzites). They are tessellations of a D-type Schwarz minimal surface<sup>[28]</sup> (Fig. 7A). *Monoelemental* cubic schwarzites with a *sc*, or *bcc* or *fcc* dual lattice are also possible, in principle, although the negative curvature of the elements becomes large and energetically unfavorable because of the increasing dual-lattice coordination (6, 8 and 12, respectively). However, *sc*(P-type) schwarzites (Fig. 7B) include a special class of structures known as polybenzenes, which have been predicted to be rather stable.<sup>[33]</sup>

Minimal surfaces can be analytically defined by means of the complex Weierstrass–Enneper representation.<sup>[63,64]</sup> However, for visual representation purposes, a minimal three-periodic surface can indeed be sufficiently well approximated by a trigonometric expression corresponding to the lowest-order terms

**Fig. 7** The unit cells of D-type (A) and P-type (B) schwarzites with a tessellation of hexagonal and heptagonal tiles. Schwarzites are three-periodic minimal surfaces. According to Euler’s theorem, heptagons (darker grey) must be 24 in the unit cell of both types, whatever is the number of hexagons (except 1). D-type schwarzites have the structure of a diamond lattice so that the unit cell can be split into two identical elements having 12 heptagons each, whereas P-type schwarzites have the structure of a simple cubic lattice. In principle, schwarzites can be associated to any kind of lattice, either periodic or amorphous (random schwarzites). *Source:* From Ref.<sup>[28]</sup>.

**Fig. 8** The atomic structure of the elements of the smallest D-type schwarzites with a tetrahedral symmetry: (A)  $(C_{28})_2$  with 12 heptagons per element and no hexagon; (B)  $(C_{36})_2$  with 4 hexagons per element; (C)  $(C_{40})_2$  with 6 hexagons per element. The unit cell of D-type schwarzites contains two elements. Note that  $(C_{28})_2$  has a chirality that allows for two enantiomeric lattices, whereas  $(C_{36})_2$  and  $(C_{40})_2$  are achiral.

of a Fourier expansion. For example, D- and P-type surfaces are well described in the  $(x, y, z)$  space by

$$\cos(x) \cos(y) \cos(z) + \sin(x) \sin(y) \sin(z) = 1 \quad (15)$$

$$\cos(x) + \cos(y) + \cos(z) = 0 \quad (16)$$

respectively (Fig. 7).

In D-type schwarzites, each element is linked to four identical elements and therefore has four open terminations. Correspondingly, the unit cell, containing two elements, has six terminations. The closure procedure transforms a single element into a two-hole torus ( $k_{el} = 5$ ), and the unit cell into a three-hole torus ( $k_{cell} = 7$ ). Thus the Platonic tiling of a D type, according to Eq. (8), is obtained with either 12 heptagons or 6 octagons or 4 non-agons per element, and 28, 16, or 12 atoms per element, respectively. The corresponding numbers per unit cell are twice as much.

Each Platonic tiling is the zeroth element of an infinite series of larger schwarzites obtained by inserting in each element an arbitrary number ( $f_6 > 1$ ) of hexagons. The number of atoms per element increases by two units for each additional hexagon (Eq. (6)). Thus the D-type schwarzites with only heptagons and hexagons form a family of crystals with  $2(28 + 2f_6)$  atoms in the unit cell. However, only certain values of  $f_6$ , given by

$$f_6 = 4(3n + m) + 6l \quad (17)$$

with  $l, n$  any integer  $\geq 0$  and  $m = 0, 1$ , are compatible with the tetrahedral symmetry and give a *fcc* crystal. Therefore the smallest member of this family is *fcc*- $(C_{28})_2$  ( $l = n = m = 0$ ). The second member is *fcc*- $(C_{36})_2$  ( $l = n = 0$  and  $m = 1$ ) with 36 atoms per element and four hexagons in each element lying on the faces of the tetrahedron. The third member is *fcc*- $(C_{40})_2$  ( $l = 1$  and  $m = n = 0$ ) with 40 atoms per element and six hexagons lying on the edges of

the tetrahedron, etc. The respective elements are shown in Fig. 8A–C: While the elements of *fcc*- $(C_{36})_2$  and *fcc*- $(C_{40})_2$  have a full tetrahedral point symmetry ( $T_d$ ) with six mirror planes, *fcc*- $(C_{28})_2$  shows an intriguing chirality ( $T$  point group) that allows for two enantiomeric lattice forms. Fig. 9 depicts a portion of the *fcc*- $(C_{36})_2$  lattice.<sup>[65]</sup>

Isomeric forms of schwarzites are possible with rules similar to those applied to fullerenes, although no systematic analysis is presently available. Also, in this case, isomers with non-abutting heptagons are expected to be more stable. The smallest D-type schwarzite with non-abutting heptagons requires seven hexagons around each heptagon and three heptagons adjacent to each hexagon. This makes  $f_6 = 12(7/3) = 28$  hexagons per element, corresponding to the lattice formula *fcc*- $(C_{84})_2$ . Indeed, this structure, analogous to  $C_{60}$  for being the smallest structure with non-abutting odd polygons, was theoretically predicted to be very stable.<sup>[30]</sup> The lattice constant  $a(f_6)$  of the cubic cell for D-type *fcc* schwarzites with only heptagons and hexagons is approximately given by

$$\frac{a(f_6)}{a(0)} \cong \left(1 + \frac{f_6 S_6}{24 S_7}\right)^{1/2} \quad (18)$$

where  $a(0) = 1.5$  nm is the lattice constant of the Platonic member of the family and  $S_7 = 3.634r_7^2$  is the area of the heptagons. It is a simple exercise to extend the above analysis to the family of schwarzites with only octagons and hexagons of both D and P types.

### Amorphous $sp^2$ Carbon

Among the various forms of amorphous graphite-like carbon, random schwarzites are of special interest here for their topological features as well as for the fact that they have been recently synthesized. The synthesis was achieved through SCBD in the presence of a metallorganic catalyst.<sup>[39]</sup> More information can be found in

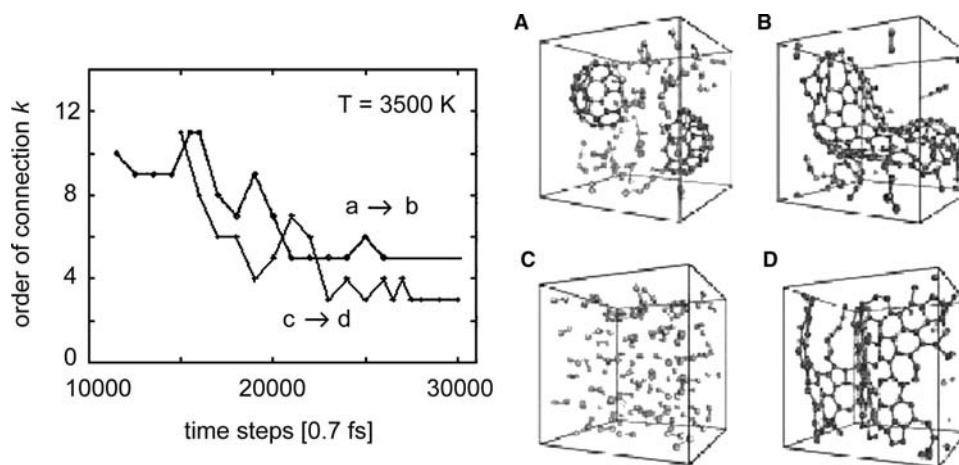

**Fig. 9** The structure of the D-type schwarzite ( $C_{36}$ )<sub>2</sub> shows the distinct features of a face-centered cubic diamond lattice as seen along the  $\langle 100 \rangle$  direction.

“Fullerenes and Carbon Nanotubes,” p. 1322. The SCBD experiments relied on a number of previous theoretical studies based on classical molecular dynamics of the aggregation process of carbon clusters in a gaseous phase<sup>[38]</sup> or during a cluster beam deposition on a substrate.<sup>[37]</sup> The aggregation process can be conveniently understood from a topological point of view, e.g., by following the evolution of the order of connection  $k$  as a function of time, namely as a function of the time step.

Two examples of such simulations, starting from different cluster distributions in the gas phase, are displayed in Fig. 10. The insets show the initial distributions of carbon clusters and the aggregation obtained at the end of the molecular dynamics simulations and after different changes of temperature.<sup>[38]</sup> Although the condensed phases obtained at the end of the simulation look qualitatively similar, the evolution of  $k$  follows different behaviors. In both cases,

**Fig. 10** Simulations by classical molecular dynamics of the condensation process of carbon clusters of various sizes (a) or carbon dimers (c) into a connected graphene structure (b,d). The final condensation temperature is 3500 K. The time evolution, expressed in time steps of 0.7 fsec, of the order of connection  $k$ , allows to distinguish between ill-condensed and well-condensed matter, according to whether the connectivity oscillates or is stable. While a distribution of clusters including fullerene fragments leads to a connectivity corresponding to a schwarzite structure, the dimer gas condenses into graphite (or open nanotube) sheets. The simulation cells shown in A–D should be periodically repeated in three dimensions.

the connectivity, after large oscillations, becomes stabilized at a limit value  $k_{\text{lim}}$ , which is 3 for the aggregation of carbon dimers, or 5 for the aggregation of larger clusters. The first value corresponds to a graphitic layer (or open nanotube); the second value corresponds to a schwarzite. These structures can be better visualized by periodically repeating, in three dimensions, the cubic simulation cells shown in Fig. 10. The clear distinction between two regimes, with either an oscillating or a constant connectivity, has been viewed as the topological definition of an ill-condensed and a well-condensed phase, respectively. However, a constant value of  $k$  does not mean that the system does not evolve any more. However, the interatomic bonds keep breaking and reforming in a way that the connectivity remains constant. In fact, any change of  $k$  would require the sudden creation/annihilation of a fixed number of pentagons/heptagons, as a consequence of Euler's theorem, and this has a substantial cost in terms of free energy. In principle, the evolution at constant  $k = 3, 5$  may gradually transform the above disordered structures into an ideal graphite layer (or an open-ended nanotube) or an ideal schwarzite, respectively.

These examples show that the topological connectivity is a useful parameter for characterizing and monitoring the evolution of a condensed amorphous phase. Another application of this concept is illustrated in Fig. 11 where the thermal dissociation of the D-type schwarzite  $fcc\text{-}(C_{36})_2$  lattice is signaled by the sudden drop at  $T_c = 3800$  K of the order of connection  $k$  from 19, corresponding to eight elements within the cubic

**Fig. 11** Thermal evolution of the D-type schwarzite  $(C_{36})_2$  as monitored by the connectivity for the simulation cell of Fig. 8. By heating up to 3700 K, the connectivity shows a small decrease as a result of a random break of bonds; but suddenly above that temperature, the connectivity drops to a small value, which is indicative of a transition leading to graphitization.

**Fig. 12** (A) A high-resolution transmission electron microscope (HRTEM) image of random schwarzite obtained by supersonic cluster beam deposition compared with (B) an image simulation constructed through a self-affine distortion of an analytical expression for a P-type minimal surface.

simulation cell, to 3, corresponding to a graphite sheet.<sup>[65]</sup> Thus the topological analysis reveals that transition at  $T_c$  corresponds to a graphitization process. This example shows that the order of connection can provide a sort of order parameter and a useful topological picture of a structural phase change.

Series of high-resolution transmission electron microscope (HRTEM) images of this material, such as the one reproduced in Fig. 12A, suggested a novel form of nanostructured carbon consisting of three-dimensional, fully connected  $sp^2$  networks. This form of carbon seemingly consists of multiply connected graphene sheets forming a spongy structure with meso- and macroporosity, and appears to be fully covalent in three dimensions, which ensures a certain robustness as compared to fullerite and nanotube bundles, which are held together by van der Waals forces. An atomic force microscopy (AFM) analysis indicated that SCBD carbon films grow in a fractal self-affine structure<sup>[66–68]</sup> characterized by a growth exponent  $\beta$  of the order of 0.5.

In general, the reconstruction of the detailed three-dimensional structure is not possible from HRTEM images, but a useful comparison can be made with simulated images originating from the projection of a model analytical surface with suitable topological requisites. To simulate extended regions of the observed graphene surfaces as they appear in HRTEM images, analytical surfaces have been generated by applying a self-affine distortion along a given axis  $z$ , assumed as the growth direction, to the approximate Eqs. (15) and (16) for D-type or P-type three-periodic schwarzites through the coordinate transformation

$$x \rightarrow xz^\beta, y \rightarrow yz^\beta, z \rightarrow z^{\beta-1}/(\beta - 1) \quad (19)$$

where the coordinates  $x, y, z$  are in units of a conventional length  $a_0 = 1$  nm and  $\beta = 0.5$ . The direct comparison of the HRTEM images with the simulated

ones (Fig. 12B) gives a convincing evidence that the observed SCBD spongy carbon can be ascribed to a random schwarzite, more precisely a form of fractal self-affine schwarzite.

## TOPOLOGY VS. TOTAL ENERGY AND GROWTH PROCESSES

It has been shown<sup>[69]</sup> that the total energy of a curved single-walled graphene can be written in the form proposed by Helfrich for membranes and foams.<sup>[70–72]</sup>

$$E = \int_S dS(\gamma + \kappa H^2 - \bar{\kappa}K) \quad (20)$$

where  $S$  is the (portion of the) surface which the total energy refers to and  $\gamma = 2.82 \text{ eV}/\text{\AA}^2$  is the energy for a unitary flat surface (a graphite sheet).<sup>[61]</sup> The constants  $\kappa$  and  $\bar{\kappa}$  are two elastic constants associated with cylindrical and elliptical/hyperbolic deformations of the surface, respectively. Density functional calculations in the local density approximation for nanotubes of variable radius  $R$  [where  $H = 1/(2R)$  and  $K = 0$ ]<sup>[73]</sup> and  $C_{60}$  (where  $H = 1/R$  and  $K = 1/R^2$ )<sup>[61]</sup> permit to extract the values  $\kappa = 3.1 \text{ eV}$  and  $\bar{\kappa} = 1.7 \text{ eV}$ . Consistently, a value of  $\bar{\kappa} = 1.5 \text{ eV}$  can be obtained from the available calculations of the cohesive energy of schwarzites<sup>[28,30,42,65]</sup> by means of the Gauss–Bonnet theorem (Eq. (2)). This shows that the above Helfrich's form for the total energy approximately holds also for graphenes. The total energy expressed by Eq. (20) has the important property, if  $\bar{\kappa}$  is constant, that a minimal surface corresponds to a stable local minimum, because for  $\kappa > 0$ , the integral on  $H^2$  is always positive unless  $H = 0$ , while the integral over  $K$  is, according to Gauss–Bonnet theorem, independent of any small continuous deformation of the surface. Thus graphenes taking the shape of a minimal surface, such as schwarzites, are stable forms, up to effects of the contour where  $\kappa$  and  $\bar{\kappa}$  may change, as discussed below. If the negative disclinations yielding a negative Gauss curvature are exclusively because of heptagons, the number of disclinations  $N_d$  is fixed by the Euler characteristic as  $N_d = 6(2 - \chi)$  independently of the length scale of the surface.<sup>[74]</sup> On the other hand, if the Gaussian surface energy density  $-\bar{\kappa}K$  is roughly assumed to be nonzero only at pentagons or heptagons, a local definition of  $\bar{\kappa}$  is obtained as

$$\bar{\kappa} \simeq \frac{\gamma}{2K_5} \frac{5S_6 - 6S_5}{5S_6 + 3S_5} \simeq \frac{\gamma}{2K_7} \frac{7S_6 - 6S_7}{7S_6 + 3S_7} \quad (21)$$

where  $K_5 = 0.0808 \text{ \AA}^{-2}$  and  $K_7 = -0.0783 \text{ \AA}^{-2}$  are the Gaussian curvatures at a pentagon and a heptagon

surrounded by five or seven hexagons, respectively.<sup>[27]</sup> With the polygon areas given above, Eq. (21) yields  $\bar{\kappa} = 2.1 \text{ eV}$  for both pentagons and heptagons. The consistency of this value with that deduced from density-functional calculations for the various types of graphenes confirms the validity of the Helfrich's form of total energy for graphenes of any shape. The residual discrepancy of  $0.4 \text{ eV}$  may be ascribed to the crude approximations implied in Eq. (21), although this equation is useful because it relates  $\bar{\kappa}$  to the actual size of the polygons generating the disclinations, hence to the local electronic structure. The values of  $\kappa$  and  $\bar{\kappa}$  give general indications about whether the growth process of  $sp^2$  carbon preferentially leads to fullerenes, nanotubes, or schwarzites. In an incipient growth process from an initial radius  $R_1$  on the surface of a catalyst, the second principal radius  $R_2$  corresponding to a local energy minimum is obtained from Eqs. (3) and (20) as

$$\frac{R_1}{R_2} = \frac{2\bar{\kappa}}{\kappa} - 1 \quad (22)$$

The surface deformation energy densities for (spherical) fullerenes ( $R_1 = R_2 \equiv R$ ), nanotubes ( $R_1 \equiv R$ ,  $R_2 \rightarrow \infty$ ), and schwarzites ( $R_1 = -R_2 \equiv R$ ) are  $(\kappa - \bar{\kappa})/R^2$ ,  $\kappa/4R^2$  and  $\bar{\kappa}/R^2$ , respectively. Therefore, for any given  $R_1$ , the values of  $\kappa$  and  $\bar{\kappa}$  define three different topological domains: schwarzites are favored for  $\bar{\kappa} < 1/4\kappa$ , nanotubes for  $1/4\kappa < \bar{\kappa} < 3/4\kappa$  and fullerenes for  $\bar{\kappa} > 3/4\kappa$ . When  $\bar{\kappa} \approx \kappa/2$ , as found from density-functional calculations, nanotubes are more likely to occur. However, the local values of  $\bar{\kappa}$  and  $\kappa$  either at the surface termination into vacuum, where the growth takes place by cluster addition, or at the contact with a catalyst where the growth process starts, may be quite different from the above values (which have been fitted to ideal close structures), and therefore other forms can be favored. The expected local changes in the electronic structure, e.g., a  $\pi$  bond-charge depletion or accretion, can substantially modify  $\bar{\kappa}$ . The fact that the growth of schwarzites supersedes that of nanotubes when metallorganic precursors are used<sup>[39]</sup> suggests that the charge redistribution produced by a catalyst, and the consequent change of the incipient  $\bar{\kappa}/\kappa$  ratio, generally depend on the actual size (and shape) of catalyst nanoparticles. Once the growth has started as either a nanotube or a schwarzite, it is likely to proceed within the same topological domain. As mentioned above, simulations of the aggregation process of a fixed number of carbon clusters have shown that after the initial condensation process, the Euler–Poincaré characteristic  $\chi$  stabilizes at a given value (for either the topology of a nanotube or a schwarzite, depending on the initial conditions) during all the subsequent morphological evolution.

On the other hand, the growth of a fully connected schwarzite in the open space with a constant addition of atoms results in a progressive branching and joining of schwarzitic elements with an increase in connectivity and a corresponding stepwise increase  $\Delta\chi$  of  $\chi$ . The process leading to an increase in connectivity is actually favored if the corresponding total energy increase  $-2\pi\kappa\Delta\chi$  is overcompensated by the total energy decrease associated with the reduction in the free contour length. The geometrical constraints on the surface derivatives associated with the minimality conditions and topology (via Gauss–Bonnet theorem) lead to apparently well organized, albeit amorphous structures, through a fairly deterministic, low-entropy process.

## CONCLUSION

Fullerenes, nanotubes, and schwarzites, when considered from the topological point of view, provide a paradigmatic example of the close link between topology and various physical aspects, ranging from thermodynamic stability to electronic and transport properties. In the particular case of schwarzites, the surface minimality condition, implied by the Helfrich form for the total energy, leads to the far-reaching consequence that an extensive property  $E$  (for example, the total energy) is minimal if and only if a local (intensive) condition  $I$  (for example, a vanishing mean curvature) is fulfilled everywhere. If the kinetics of a growth process are such that condition  $I$  is fulfilled at any step, then the property  $E$  turns out to be automatically minimal at any stage of the process. In this case the evolution of the system occurs along the valley bottom of the energy landscape.

The intriguing similarity between graphenes and foams, based on the Helfrich form for the total energy, suggests the existence of a wider class of systems, where the calculation of the total energy can be reduced, through a variable transformation, to the calculation of a surface area. For all of them the search for the stability conditions can be reformulated in the well-established mathematical realm of minimal surfaces. Many complex chemical systems such as supramolecular structures, nanoporous materials, biomembranes, and many other objects which are crowding into the rapidly growing fields of nanostructures and mesoscopic physics are characterized by complicated, highly connected surfaces with a large specific area and a large surface-free energy. A challenging question is whether the morphology and the stability of each of these systems can be reduced to a problem of minimal surfaces and solved with the tools of differential geometry.

# Functionalization of Surface Layers on Ceramics

Toshihiro Ishikawa

Functional Materials Research Department, Ube Research Laboratory,  
Yamaguchi, Japan

## INTRODUCTION

Ceramics are often prepared with surface layers of different composition from the bulk,<sup>[1,2]</sup> to impart a specific functionality to the surface or to act as a protective layer for the bulk material.<sup>[3,4]</sup> Here I describe a general process by which functional surface layers with a nanometer-scale compositional gradient can be readily formed during the production of bulk ceramic components. The first concept regarding this process was established by Ishikawa et al. in 1998.<sup>[5]</sup> The basis of this approach is to incorporate selected low-molecular-mass additives into either the precursor polymer from which the ceramic forms, or the binder polymer used to prepare bulk components from ceramic powders. Thermal treatment of the resulting bodies leads to controlled phase separation (“bleed out”) of the additives, analogous to the normally undesirable outward loss of low-molecular-mass components from some plastics;<sup>[6–10]</sup> subsequent calcination stabilizes the compositionally changed surface region, generating a functional surface layer. This approach is applicable to a wide range of materials and morphologies, and should find use in catalysts, composites, and environmental barrier coatings.

## PREVIOUS METHODS TO OBTAIN SURFACE GRADIENT STRUCTURES

To avoid the concentration of thermomechanical stress at the interface between the surface layer and the bulk material, many materials were developed that had gradually varying properties as the distance into the material increases.<sup>[11]</sup> Such materials can contain gradients in morphology or in composition. For example, gradients in morphology can result in materials that have a graded distribution of pore sizes on a monolith of silica aerogel, and a type of integral plastic. These materials were created by strictly controlling the vaporization of the volatile during the production process.<sup>[12,13]</sup> Gradients in chemical composition have been achieved, for example: 1) chemical vapour deposition;<sup>[14,15]</sup> 2) powder methods such as slip cast or dry processing;<sup>[16]</sup> 3) various coating methods;<sup>[17]</sup> and 4) thermal chemical reaction.<sup>[2,18]</sup> Of these, 1) and 4)

are relatively expensive, complicated and result in damage to bulk substrates. Items 2) and 3) produce stepped gradient structures, and it is difficult to control the thickness of each layer to less than 100 nm. Furthermore, most of these processes are not easily adapted to coating samples in the form of fiber bundles, fine powders, or other materials with complicated shapes.

## A NEW PROCESS FOR CREATING SURFACE FUNCTIONAL LAYERS

We have addressed the issue of establishing an inexpensive and widely applicable process for creating a material with a compositional gradient and excellent functionality. A schematic representative of our new in situ formation process for functional surface layers, which have a gradient-like structure toward the surface, is shown in Fig. 1. The important feature of this method is that the surface layer of the ceramic is not deposited on the substrate, but is formed during the production of the bulk ceramic. We confirmed that our process is applicable to any type of system as long as, in the green-body (that is, not calcined) state, the system contains a resin and a low-molecular-mass additive that can be converted into a functional ceramic at high temperatures. Here the resin is a type of precursor polymer (polycarbosilane, polycarbosilazane, polysilastyrene, methylchloropolysilane, and so on) or binder polymer used for preparing green bodies from ceramic powders.<sup>[19]</sup> Although the former case (using precursor polymers) is explained in detail in this paper, the latter case, using binder polymers, was also confirmed by treating a  $\text{Si}_3\text{N}_4$  body with a TiN surface layer.  $\text{Si}_3\text{N}_4$  can exhibit excellent thermal stability and wear resistance in the high-speed machining of cast iron, but shows poor chemical wear resistance in the machining of steel.<sup>[20]</sup> To avoid this problem, TiN coating, via expensive chemical vapor deposition, was often performed on previously prepared  $\text{Si}_3\text{N}_4$  substrates. But if our new process is appropriately applied, formation of the TiN surface layer could be achieved during the sintering process of the  $\text{Si}_3\text{N}_4$  green body. In this case, titanium(IV) butoxide and polystyrene are used as the low-molecular-mass additive and binder polymer, respectively. By a combination of sufficient

Fig. 1 Schematic diagram of a general process for in situ formation of functional surface layers on ceramics.

maturation (in air at  $100^\circ\text{C}$ ) and subsequent sintering (in  $NH_3 + H_2 + N_2$  at  $1200^\circ\text{C}$ ),  $Si_3N_4$  covered with TiN is successfully produced. This technology would be very useful for producing ceramic materials with complicated shapes and various coating layers. Moreover, our process is advantageous for preparing precursor ceramics (particularly fine particles, thin fibrous ceramics and films). The systems to which our concept is applicable are shown in Fig. 1.

Here I give a detailed account of the results for the precursor ceramic obtained by using polycarbosilane. Polycarbosilane ( $-SiH(CH_3)-CH_2-$ )<sub>n</sub> is a representative preceramic polymer for preparing SiC ceramics—for example, Hi-Nicalon fiber<sup>[21]</sup> and Tyranno SA fiber.<sup>[22]</sup> Furthermore, oxide or nitride can also be produced from the polycarbosilane by firing in air or ammonia, respectively. Our new technology makes full use of the bleed-out phenomenon<sup>[6–10]</sup> of additives intentionally mixed in the polycarbosilane. Here we treated a polycarbosilane with  $Ti(OC_4H_9)_4$  or  $Zr(OC_4H_9)_4$ , and created a strong, fibrous photocatalyst with a surface  $TiO_2$  layer, or a highly alkali-resistant SiC-based fiber with a surface  $ZrO_2$  layer.

#### PHOTOCATALYTIC FIBER PRODUCED BY THIS NEW PROCESS

The preceramic polymer containing  $Ti(OC_4H_9)_4$  (50 wt.%) was shaped into a fiber by melt spinning.

The fiber was then matured in air at  $70^\circ\text{C}$  for 100 h; during this process, the titanium compound oozed from the preceramic polymer. The bleed-out phenomenon was confirmed by using electron spectroscopy for chemical analysis (ESCA). After the maturation, the fiber material was cured in air at  $200^\circ\text{C}$ . The cured material was then calcined in air at  $1200^\circ\text{C}$  to obtain a silica fiber covered with titania. This production process is schematically shown in Fig. 2.

Fig. 3 shows Auger electron spectroscopy (AES) depth analysis of the surface layer of the fiber. The thickness of the surface layer can be controlled in the range 5–500 nm by changing the temperature ( $70$ – $100^\circ\text{C}$ ) and time (10–200 h) of the maturation.<sup>[23]</sup> Furthermore, the composition of the surface layer

Fig. 2 A new process for producing strong photocatalytic fiber with gradient structure.

Fig. 3 Surface gradient compositions of the photocatalytic fiber.

reflects the composition of the low-molecular-mass additives.

According to the results of X-ray diffraction analysis, these fibers were composed of anatase  $\text{TiO}_2$  and an amorphous  $\text{SiO}_2$  phase. Investigation by scanning electron microscopy (SEM) showed that the outer surface of the fiber prepared via maturation for 100 h appeared to be smooth (Fig. 4A) and was covered with titania particles (Fig. 4B). Furthermore, the transmission electron microscopy (TEM) image of the cross section near the surface showed a  $\text{TiO}_2$ -sintered surface and particle-dispersed bulk structures (Fig. 4C). Most of the surface  $\text{TiO}_2$  crystals (crystalline size: 8 nm, Fig. 4D) were directly sintered (directly sintered structure), whereas the internal  $\text{TiO}_2$  crystals were bound

with the amorphous  $\text{SiO}_2$  phase (liquid-phase sintered structure). This result corresponds to the gradient composition shown in the AES data. The gradient-like structure resulted in strong adhesion between the surface  $\text{TiO}_2$  layer and the bulk material, which is different from the behavior of other coating layers formed on substrates via conventional methods. Although in the case of the other  $\text{TiO}_2$ -covered silica fiber, the  $\text{TiO}_2$  layer was easily peeled off, and our  $\text{TiO}_2$ -sintered surface definitely did not drop off after heat-cycling, washing, or rubbing.

Furthermore, a strengthening effect of the fine particles (<10 nm) dispersed in the bulk ceramics can be achieved at the same time by using our technology. Tensile testing of the monofilaments according to the ASTM D3379-75 standard with a 25-mm-gauge length demonstrated that the strength was markedly higher (>2.5 GPa) than that of ordinary sol-gel  $\text{TiO}_2/\text{SiO}_2$  fibers (<1 GPa).<sup>[24]</sup> At present, the reason for this is not clear, but it was assumed that this was caused by less stress concentration at the surface region because of the gradient structure toward the surface.

We subsequently confirmed the objective function (photocatalytic activity) of the above-mentioned fiber (titania fiber) as follows. We prepared a quartz tubular reactor (inner volume:  $7 \text{ cm}^3$ ) with an ultraviolet (UV) lamp. The tubular reactor was filled with 2 g of the felt material (Fig. 5) made of the titania fiber. The photocatalytic activity was confirmed by using air containing 140 ppm of acetaldehyde, at a flow rate of 1 L/min, and UV light at an intensity of  $1\text{--}5 \text{ mW cm}^{-2}$  (wavelength, 352 nm). Under these conditions (single pass), the acetaldehyde was effectively decomposed

*Bleed out, inorganicization, crystallization, and sintering competitively proceed. → Grain growth was prevented.*

Fig. 4 Surface appearances and cross sections of the  $\text{TiO}_2/\text{SiO}_2$  photocatalytic fiber.

Fig. 5 Felt material of the photocatalytic fiber.

accompanied by the generation of  $\text{CO}_2$ . The results are shown in Fig. 6.

It is well known that the catalytic effect of  $\text{TiO}_2$  is attributed to the generation of a strong oxidant, hydroxyl radicals. Following this theory, the quantum efficiency of the felt material prepared from the above titania fiber was calculated from a decrease in the acetaldehyde. In this case, if the number of molecules is significantly larger than the number of photon, acetaldehyde is oxidized to  $\text{CH}_3\text{COOH}$  as follows:

\*Semiconductor (such as  $\text{TiO}_2$ )

+  $h\nu$  (energy of photon)

=  $\text{e}^-$  (electron) +  $\text{h}^+$  (hole)

In this case, the apparent quantum efficiency (QE) of the felt material prepared from the aforementioned

titania fiber is calculated by the following equation:

$$\text{QE} = 2 \times (\text{Number of decomposed molecules}) / (\text{Number of incident photons})$$

$$\begin{aligned} \text{Wavelength} &= 352 \times 10^{-9} \text{ m, Intensity of UV light} \\ &= 1 \text{ mW/cm}^2 = 10 \text{ J/sec/m}^2 \end{aligned}$$

$$\text{Actual irradiation area} = 8.33 \times 10^{-4} \text{ m}^2$$

The calculation result using these values showed an extremely high QE value even at room temperature (over 37%). It is believed that this higher value at high temperatures is attributable to the evaporation of the formed acetic acid adsorbed on the fiber surface. These excellent QE values could be realized by the dense existence of very fine anatase- $\text{TiO}_2$  crystals (8 nm) on the surface. These fine crystals are considered to facilitate the diffusion of excited electrons and holes toward the surface before their recombination.

We also confirmed the coliform-sterilization ability of this fiber as follows. Our fiber (0.2 g) was placed in wastewater (20 mL) containing coliform at a concentration of  $1 \times 10^6 \text{ mL}^{-1}$ . Irradiation by UV light (wavelength: 352 nm,  $2 \text{ mW cm}^{-2}$ ) was performed at room temperature, and a small amount of the wastewater was extracted. After cultivation using the extracted water, the amount of active coliform was calculated from the number of colonies formed. In this experiment, using the desirable fiber covered with very fine titania crystals (8 nm), all of the coliform in the wastewater was completely sterilized within 5 hr, accompanied by the generation of  $\text{CO}_2$ . In the comparative study, using undesirable fibers covered with large titania crystals (9–11 nm), sterilization of

**Fig. 10** Purification test of the water of a circulation bath system using the circulation purifier.

the coliform was markedly slow (Fig. 7). From the results, the size of the titania crystal is found to be closely related to the photocatalytic activity. It is assumed that, in the case of large crystals, the recombination (inactivation) of the hole and excited electron generated by UV irradiation easily occurs (Fig. 8). To suppress the recombination and obtain the good

photocatalytic activity, the creation of the smaller titania crystals is very important. The new process described in this paper is very desirable for controlling the size of fine crystals, because both the bleed-out phenomenon of the low-molecular-mass additive and the crystallization of the led functional material proceed competitively.

**Fig. 11** The results of the purification test using the circulation purifier.

Fig. 12 Decomposition of dioxin using the circulation purifier.

### INDUSTRIAL APPLICATION OF THE PHOTOCATALYTIC FIBER WITH A GRADIENT TITANIA LAYER

A circulation purifier for pollutants (Fig. 9) was developed by using the felt material made of the aforementioned photocatalytic fiber. This is a very simple purifier with a module composed of the cone-shaped felt material (made of the photocatalytic fiber) and UV lamp. Purification of the bath water of a circulation bath system was performed by using the above purifier (Fig. 10). Many bacteria (common bacterium, legionera germ, and coliform), which existed in the bath water before the purification, were perfectly decomposed into  $\text{CO}_2$  and  $\text{H}_2\text{O}$  by using the above purifier (Fig. 11).

Furthermore, the photocatalytic fiber can be used for the purification of the many types of wastewater. Fig. 12 shows the result regarding a decomposition

of dioxin contained in a wastewater. In this case, 95.1% of the dioxin was found to be decomposed after only 2 hr.

### FORMATION OF THE ALKALI-RESISTANT SURFACE LAYER ON SiC

The next fiber was prepared from polycarbosilane containing  $\text{Zr}(\text{OC}_4\text{H}_9)_4$  by the same process as that used for the  $\text{TiO}_2/\text{SiO}_2$  fiber material (the aforementioned photocatalytic fiber), except that the calcination was performed in Ar atmosphere at  $1300^\circ\text{C}$ . In this case, the polycarbosilane and  $\text{Zr}(\text{OC}_4\text{H}_9)_4$  were effectively converted into SiC-based bulk ceramic and zirconium oxide (cubic zirconia), respectively (X-ray diffraction results are given in Fig. 13). Before the conversion, bleed-out of the zirconium compound proceeded effectively. AES depth analysis of the fiber surface showed an increase in the concentration of zirconium toward the surface. This construction was confirmed by the TEM image of the cross section near the fiber surface (Fig. 14A and B). This indicates the direct production of an SiC-based fiber covered with a  $\text{ZrO}_2$  surface layer, which has a gradient-like composition toward the surface. In general, amorphous fibers covered with ceramic crystal do not show high strength.<sup>[25]</sup> However, this fiber showed relatively high strength (2.5 GPa) compared with other SiC fiber (2.1 GPa) coated with zirconia nanocrystals via the sol-gel method. The initial strength of the SiC fiber used for the comparative study was 3.1 GPa. The  $\text{ZrO}_2$  surface layer, a basic oxide material, can provide better alkali resistance for SiC ceramics.

To confirm the better alkali resistance for our  $\text{ZrO}_2$ -covered SiC fiber, the following experiment was

Fig. 13 X-ray diffraction pattern of the SiC fiber covered with zirconia.

**Fig. 14** Surface appearances and cross sections of the SiC fiber covered with  $ZrO_2$ .

performed. The fiber material was immersed for 15 min in deionized water saturated with potassium acetate and then annealed at  $800^\circ\text{C}$  for 100 hr in air after drying. Comparative studies were conducted by using the SiC-based fiber prepared from polycarbosilane, which did not contain zirconium (IV) butoxide, as well as commercial SiC fibers, namely, Hi-Nicalon and an alkali-resistant sintered SiC fiber<sup>[22]</sup> (Tyranno SA fiber). Fig. 15 shows the fractured surfaces of the tested fiber bundles, obtained by using field-emission scanning electron microscopy (FE-SEM). As can be seen from the micrographs, only the  $ZrO_2$ -covered SiC fiber, which was obtained by using our method, retained its intact fibrous shape, whereas the other SiC fibers were extensively oxidized and then bonded together.

## CONCLUSION

Fundamentally, this new process can be applied for preparing functional ceramics with gradient, nano-sized surface structures as long as in the green-body state, the system contains both a polymer component and a low-molecular-mass additive which can be converted into a functional ceramic by heat treatment at high temperatures. Namely, this process does not care about the shape of the precursor materials. Fine particles, thin fibrous ceramics and films ( $\text{SiC}$ ,  $\text{Si}_3\text{N}_4$ ,  $\text{SiO}_2$ ) covered with functional layers ( $\text{BN}$ ,  $\text{TiN}$ ,  $\text{TiO}_2$ ,  $\text{ZrO}_2$ ,  $\text{Al}_2\text{O}_3$ ) could also be synthesized by sufficiently maturing and firing the precursor powders of polycarbosilane or polysilazane including the corresponding additives. The atmosphere and temperature during

**Fig. 15** Alkali resistance of the SiC fiber covered with  $ZrO_2$  with comparative results.

firing would need to be strictly controlled. This process is applicable to a wide range of materials and morphologies, and should find use in catalysts, composites, and environmental barrier coatings.

## Abstract

The attachment pads of some beetles, spiders, flies, and geckos are covered by a dense array of long hairs with characteristic geometries. This curious surface topography allows them to firmly attach to and easily release from almost any kind of surfaces. In a technological context, such reversible adhesion could enable robots to walk along walls or ceilings, or lead to new medical devices, disposable plasters, reusable adhesive tapes, etc. Artificial fibrillar surfaces mimicking nature's design have been recently fabricated. This chapter describes the micro- and nanofabrication strategies that have been applied to generate such systems.

## INTRODUCTION

The ability of some insects and geckos to firmly attach to and rapidly detach from varied types of surfaces in diverse conditions has gathered the attention of zoologists for many centuries.<sup>[1–6]</sup> Microscopic examination of their attachment pads has revealed a complex surface hyperstructure consisting of long hairs, sometimes organized in a hierarchical arrangement spanning the millimeter to nanometer range (Fig. 1). These hairs have characteristic sizes and geometries depending on the animal, and their small dimension seems to be the key factor enabling their strong but reversible adhesion.<sup>[7]</sup> In the particular case of the gecko foot, which shows the best adhesion performance, the keratinous hairs (“setae”) are typically 30–130  $\mu\text{m}$  long and contain hundreds of projections terminating in 200–500 nm spatula-shaped structures.

Recent innovations in the area of micro and nanofabrication with polymeric materials have created a unique opportunity for mimicking natural attachment systems as a new generation of moderately strong but reversible adhesives.<sup>[8–10]</sup> Increasing efforts are being made to establish fabrication technologies, which allow the production of polymeric structured surfaces with greater geometrical complexity, closer to the natural systems in design and performance. These include patterns made of polymer materials possessing elongated fibers (high aspect ratio), ordered in a tilted arrangement, exhibiting several hierarchy levels, or 3D spatula-like terminals. This entry describes a number of micro and nanofabrication approaches that have been applied to generate such structures. The methods are classified attending to the dimensions and complexity of the produced structures (micro-metric, nanometric, hierarchical, or 3D). At the end,

recent developments in the area of switchable adhesives based on structured surfaces and responsive materials will be described.

## MICROSTRUCTURED ADHESIVE SURFACES

### Soft Lithography

The term soft lithography is applied to a collection of pattern-replication methods, which rely on an elastomeric mold.<sup>[11]</sup> This is a negative replica of a micro or nanostructured hard master and is prepared by casting and thermal curing a liquid prepolymer (mostly poly(dimethylsiloxane), PDMS) on the master. The PDMS replica can be considered the final patterned surface (Fig. 2A), or it can also be used as mold (or stamp) for patterning other polymeric materials in subsequent replication processes (Fig. 2B and 2C). The elastomeric character allows the PDMS stamp to be released easily from the master (or molded polymer), even in the presence of complex and fragile structures, like high-aspect ratio fibers. Moreover, its low interfacial free energy and chemical inertness reduce mold sticking.

A prerequisite for soft-molding is the access to masters with the desired geometry. Masters for bioinspired fibrillar adhesives consisting of arrays of holes with predefined dimensions have been typically fabricated by photolithography.<sup>[12–15]</sup> Alternatively, masters have been produced by indenting a wax surface with an AFM tip,<sup>[16]</sup> or by laser ablation of a metallic surface.<sup>[17]</sup> Photolithography using SU-8 photoresist has been proven to be particularly suited for obtaining regular, model surfaces in which the influence of the

**Fig. 1** Terminal elements (circles) in animals with hairy design of attachment pads. Note that heavier animals exhibit finer adhesion structures. Scale bar represents 2  $\mu\text{m}$ . Source: Reused with permission from Ref.<sup>[7]</sup>.

different geometrical parameters in adhesion can be characterized and quantified.<sup>[14]</sup> This resist material has been specially formulated to obtain high-aspect-ratio features, like holes that are required for obtaining long PDMS fibers in the replication process.<sup>[18]</sup> Arrays of fibers with radius between 1 and 25  $\mu\text{m}$  and lengths between 5 and 80  $\mu\text{m}$  have been reported over 25  $\text{cm}^2$  areas (Fig. 3A).<sup>[14]</sup> These systems have been used to analyze the influence of contact radius and aspect ratio of the fibers in the final adhesion performance of the artificial adhesive surface.<sup>[14]</sup>

In theory, soft-molding allows fabrication of fibers of any dimensions. In reality, the aspect ratio of the fibers is limited by the low mechanical stability of PDMS, and fiber collapse typically occurs in microsized fibers with

aspect ratios exceeding 4 (Fig. 3B). This fact is more critical in nanosized fibers and their fabrication requires the use of harder materials.

Soft PDMS stamps can be also applied to generate fibrillar micropatterns of different materials by soft-molding polymer melts, polymer solutions, or polymer precursors (Fig. 2B). For example, PDMS stamps were used to soft-mold liquid polyurethane precursors and fibers with 20  $\mu\text{m}$  diameter, 40–100  $\mu\text{m}$  length, and 40  $\mu\text{m}$  spacing were obtained.<sup>[19]</sup> In addition, PDMS is transparent and can be used to mold UV-curable prepolymers (Fig. 2C). Using this method, hard polyurethane patterns with fibrils of 0.5–4  $\mu\text{m}$  height and diameters between 1 and 4  $\mu\text{m}$  have been generated.<sup>[15]</sup>

Tilted fibrillar structures are required if reversible gecko-inspired adhesives need to be fabricated. The tilted disposition of the fibers allows peeling-off the adhesive and, therefore, easy removal.<sup>[20]</sup> Tilted SU-8 fibrils have been obtained by photolithography by tilting the mask and resist film with respect to the beam during exposure using a tilting stage (Fig. 4A). Soft-molding polyurethane precursors with a PDMS negative replica of the SU-8 master yielded arrays of polyurethane microfibers with a tilting angle of 25 (Fig. 4B).<sup>[19]</sup>

## NANOSTRUCTURED ADHESIVE SURFACES

### Hot Embossing

Thermoplastic materials can be patterned by hot-embossing (Fig. 5). This involves the shaping of a

**Fig. 2** (A) Replication by soft lithography. (B) Soft molding polymer solutions using PDMS stamps. (C) Soft-molding UV curable prepolymers.

**Fig. 3** SEM micrographs showing arrays of fibers made by soft-molding PDMS onto SU-8 photolithographic templates. (A) Fibers have a radius of  $2.5\ \mu\text{m}$  and a height of about  $20\ \mu\text{m}$ . The minimum interpillar distance is  $5\ \mu\text{m}$ . (B) PDMS pillar with higher aspect ratios collapse after demolding due to the low mechanical stability of PDMS. *Source:* Reprinted with permission from Ref.<sup>[14]</sup>.

polymer melt by conformal contact of a micro or nanostructured mold using heat and pressure. The polymer melt is able to flow and fill the mold cavities in the processing conditions. The filling depends on the viscosity, wetting properties, and pattern geometry, as well as on applied pressure or vacuum. Solidification of the polymer after filling is achieved by cooling below the crystallization temperature in semicrystalline polymers, or below the glass transition temperature in amorphous polymers. Removal of the mold releases a structured polymer with features reproducing its particular geometry. This can be done by peeling off (demolding) or by selective dissolution of the template. Demolding is preferred since it permits use of the same mold for additional molding processes. An example of embossed poly(methyl methacrylate) (PMMA) fibrillar surface is given in Fig. 5. The embossing process was performed at temperatures above the glass transition of PMMA ( $\sim 120^\circ\text{C}$ ) using a polyurethane acrylate mold. Arrays of fibers with  $150\ \text{nm}$  diameter and up to  $500\ \text{nm}$  height were obtained.<sup>[21,22]</sup>

The fabrication of high-quality molds is one of the most important requirements in performing successful embossing. These are typically made of silicon or silicon

dioxide by dry etching technologies, or by deposition of nickel or other metals on patterned resist substrates (LIGA process). Mold fabrication is the most time- and cost-consuming step involved in these patterning techniques, and is very likely to constitute the biggest limitation in potential industrial applications.

### Filling Nanoporous Membranes

Track-etched polycarbonate (PC) and anodic alumina (AA) membranes have been used as low-cost alternatives to expensive molds for producing arrays of long, nanosized fibers.<sup>[16,23,24]</sup> These membranes are commercially available with pore sizes ranging from a few nm to a few  $\mu\text{m}$  and different spacings and thicknesses. The pores of the membrane can be filled with polymer precursors, solutions of melts to obtain a structured polymer film possessing cylinders with dimensions reproducing those of the pores (Fig. 6).

PC membranes containing randomly distributed cylindrical pores of  $0.6\ \mu\text{m}$  diameter and spacings  $< 5\ \mu\text{m}$  have been filled with poly(imide) (PI) solutions.<sup>[23]</sup> Since the PC membrane is flexible, it can be

**Fig. 4** Fabrication of tilted fibers by inclined lithography. The SEM picture shows tilted polyurethane pillars obtained after soft-molding with the photolithographic SU-8 masters. Pillars have high aspect ratio, a diameter of  $8\ \mu\text{m}$  and a tilting angle of  $25^\circ$ . *Source:* Reprinted with permission from Ref.<sup>[17]</sup>.

**Fig. 5** Hot-embossing and example of fabricated PMMA fibers with this method. Fibers are 150 nm at base end and 50 nm at top, and 500 nm height.<sup>[22]</sup>

peeled off from the solidified PI film to release dense arrays of high aspect ratio nanofibers. Owing to their large aspect ratio, these fibers were shown to collapse laterally and therefore reduced adhesion is expected. AA membranes with pores between 200 and 400 nm have been also filled with two-parts epoxy resin,<sup>[23]</sup> with a PS solution,<sup>[25]</sup> and with UV curable precursors.<sup>[26]</sup> Because of their rigidity, AA membranes cannot be removed from the polymer by peeling off but need to be selectively dissolved in NaOH solution. This represents a strong disadvantage for fabrication, since the template is destroyed and dissolution takes long times and may cause polymer swelling. In addition, wet etching is followed by a drying step during which capillary forces usually may cause fiber's lateral collapse and, consequently, reduced adhesion (Fig. 6).<sup>[26]</sup>

### e-Beam Lithography

Arrays of PI fibers have also been microfabricated using electron-beam lithography followed by pattern transfer by dry etching in oxygen plasma (Fig. 7A).<sup>[27]</sup> The etching step is necessary to obtain high aspect ratio structures, since the maximum penetration depth of low energy electrons is about 100 nm. Fiber diameters ranged between 0.2 and 4  $\mu\text{m}$ , heights from 0.15 to 2  $\mu\text{m}$ , and spacings from 0.4 to 4.5  $\mu\text{m}$ . This method is appropriate to obtain model nanostructures with smaller dimensions than those obtained by optical photolithography.

However, patterning is slow and restricted to small areas, and requires the availability of e-beam facility.

### Carbon Nanotubes

Microfabrication techniques strongly restrict material's selection to a few resists, all of them quite expensive. In addition, patterning can only be performed in specialized laboratories and requires costly equipment and long processing times. For this reason, scientists have started to look for alternative patterning techniques, which do not require a template (e.g. the mold in soft-lithography or the mask in photolithography). Arrays of vertically aligned carbon nanotubes (CNTs) have been reported as an interesting alternative (Fig. 7B).<sup>[28–31]</sup> Carbon nanotubes have smaller diameters (10–20 nm) than gecko spatulae ( $\sim 200$  nm) and can be made very long (above 65  $\mu\text{m}$ ).<sup>[29]</sup> Having an extremely high aspect ratio, exceptional mechanical strength, and excellent electronic and thermal properties, the CNTs show great potential for dry adhesion applications with additional electrical/thermal management capabilities (e.g., electroswitching, through-thickness thermal transport, high temperature use).<sup>[28]</sup> Arrays of CNTs are fabricated by chemical vapour deposition on Si substrates. In the reported systems, the nanotubes aligned almost normal to the substrate surface and have a fairly uniform tubular length. However, they tend to stick to their closest neighbors

**Fig. 6** Fabrication of high aspect ratio fibers by filling porous AA membranes. Fibers collapse after removal of the membrane (dissolution) because of the large capillary forces acting during the drying process. *Source:* Reprinted from Ref.<sup>[26]</sup> with kind permission of Springer Science and Business Media.

**Fig. 7** SEM micrographs of fibrillar surfaces fabricated by different methods. (A) Arrays of PI pillars fabricated using e-beam lithography and pattern transfer by dry etching.<sup>[27]</sup> Source: Reprinted by permission from Macmillan Publishers Ltd.: Nature Materials. (B) Side-top view of an array of CNTs.<sup>[28]</sup>

forming loosely packed “bundles.” This reduces the overall adhesion force of the CNT layer owing to the reduced number of contact points.

The array of CNTs can be transferred from the Si wafer to flexible backing substrates.<sup>[29,30]</sup> For this purpose, the patterned silicon wafer was embedded in a polymer precursor. After curing, the CNTs were peeled off from the wafer. By etching the silicon-facing side of the polymer matrix by solvents or plasma treatment, a smooth layer of CNTs on a flexible backing was generated.

### Drawing Polymer Fibers

Arrays of nanofibers have been obtained by drawing fibers from polymer drops on non-wettable surfaces by contacting them with a hot plate and then moving both surfaces apart.<sup>[32]</sup> The process is based on surface tension and capillary forces and is available in a number of versions. For example, films of thermoplastic polymers can be brought in contact with a hot structured master possessing pillars. When pulling the master apart, fibers will be drawn from the contacting points (Fig. 8). Alternatively, structured polymer films with large features can be brought in contact with a hot surface and then removed to obtain elongated fibers on the top of the features.<sup>[32]</sup> Other authors have miniaturized this method by using an AFM tip to draw nanosized fibers from a melt polymer film.<sup>[33]</sup> These fabrication

methods seem to be more suitable for large area patterning, and are therefore more likely to be applied in manufacture. However, this requires severe alignment between hot plate (or a roll) and the polymer film across large areas, if nanosized fibers need to be obtained.

An ingenious alternative has been reported recently, which allows alignment problems by combining molding and fiber drawing processes to obtain high aspect ratio nanofibers from thin PS and PMMA films.<sup>[34]</sup> This was achieved by performing the demolding step at temperatures above the glass transitions of the materials. Capillary forces induced deformation of the polymer melt into the void spaces of the mold, and the filled nanofibers were elongated on removal of the mold because of tailored adhesive force at the mold/polymer interface (Fig. 8).

### HIERARCHICAL ADHESIVE SURFACES

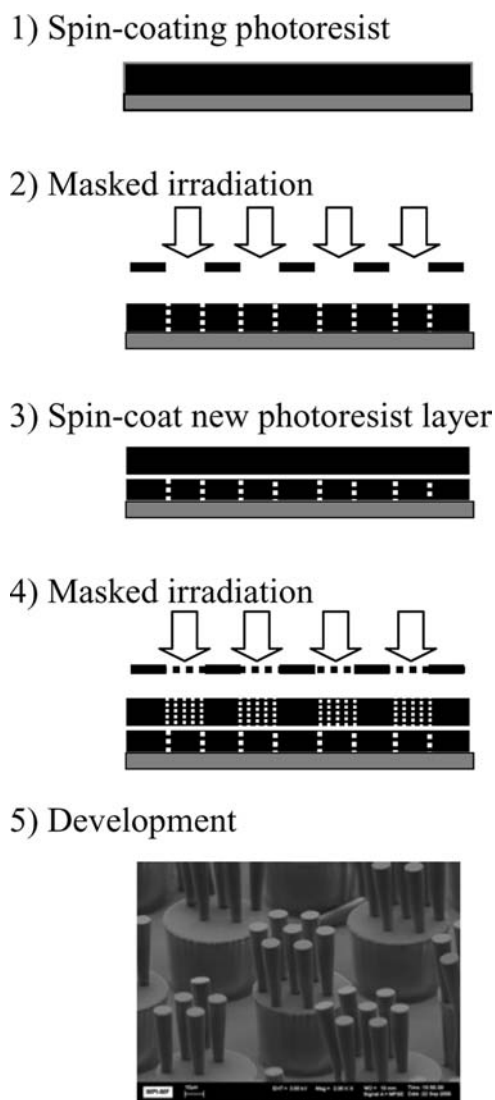

A hierarchical organization of fibers over different length scales (mm to nm) mimicks the multiple levels of compliance present in the gecko setae, which is required for adaptability and adhesion to rough surfaces of any kind.

### Multistep Exposure in Photolithography

Lithographic fabrication by superposition of coating and irradiation steps enables fabrication of structures

**Fig. 8** Fabrication of structured surfaces by fiber drawing method. The SEM picture shows an example of obtained PMMA fibrillar surface. Source: Reprinted with permission from Ref.<sup>[34]</sup>.

**Fig. 9** Hierarchical structures by double exposure photolithography.

with several organization levels using traditional 2D setups and alignment markers on the mask for guiding superposition. Figure 9 shows the fabrication procedure and an example of micrometric adhesive structure with two hierarchical levels obtained by SU-8.<sup>[18]</sup> Additional levels are possible by just increasing the number of coating and irradiation steps. Geometries are not restricted to cylindrical fibers and depend only on the mask used for irradiation. This can also be replicated using soft-molding methods and transferred to other materials.

### Microfabrication Technologies

Hierarchical structured surfaces have also been obtained by combining photolithography and dry etching methods, as typically used in MEMS fabrication.<sup>[35,36]</sup> Single

crystal silicon posts (1  $\mu\text{m}$  in diameter and height up to 50  $\mu\text{m}$ ) supporting microsized silicon dioxide platforms (2  $\mu\text{m}$  thick and 100–150  $\mu\text{m}$  on a side) were coated by photoresist fibers with  $\sim 250$  nm diameter and  $\sim 4$   $\mu\text{m}$  height in average (Fig. 10A and 10B).

### Filling Stacked Membranes

Hierarchical patterns were also obtained by filling stacked micro and nanoporous AA membranes with different pore diameters.<sup>[37]</sup> The nanoporous membrane (pore diameter  $\approx 60$  nm and interpore distance  $\approx 100$  nm) was generated by the anodization of an aluminum film in an oxalic acid solution. The microporous alumina was produced by conventional lithography and anisotropic chemical etching of the thick film of anodic alumina pores. The micro- and nanoporous alumina membranes were subsequently brought into intimate contact and filled with PMMA solution. Hierarchical polymeric microfibrils (fibril diameter  $\approx 10$   $\mu\text{m}$ ; fibril length  $\approx 70$   $\mu\text{m}$ ) with nanofibril arrays at their tips were obtained after removal of the solvent by heating and selective etching of the AA membranes (Fig. 10C and 10D).<sup>[37]</sup> The nanofibril has a lateral dimension of approximately 60 nm with length-to-diameter aspect ratios as high as 100:1.

### Two-Step Embossing

By performing two sequential embossing steps, hierarchical patterns with micrometric fibers decorated with nanosized fibers of various sizes and spacings were obtained (Fig. 10E and 10F).<sup>[21]</sup> A PMMA film was patterned with microfibers using a PDMS stamp. Subsequently, nanofibers were patterned on the top of the preformed microfibers using a hard polyurethane acrylate (PUA) mold. The PUA mold replaces the PDMS mold for sub-100 nm lithography since high-aspect ratio sub-100 nm features in a PDMS mold do not retain dimensional stability due to the low Young's modulus of PDMS. The resulting micro/nanoscale combined structures were robust and demonstrated enhanced water-repellent properties as a consequence of the hierarchical arrangement.

### 3D STRUCTURED ADHESIVE SURFACES

The 3D geometry of the tip seems to be crucial for the adhesion performance of the fibrillar surface. Spherical, conical, filament-like, band-like, sucker-like, spatula-like, flat, and toroidal tip shapes have been observed in different animals.<sup>[38]</sup> The role of the contact geometry has been analyzed in artificial

**Fig. 10** (A) Multiscale microfabricated structures consisting of single crystal silicon pillars supporting a silicon dioxide platform and coated by nanometer-sized polymer fibers (B). (C) Hierarchical microfibril array fabricated by filling porous AA. Microfibers are  $10\ \mu\text{m}$  wide and  $70\ \mu\text{m}$  long, and each branches into nanofibrils about  $60\ \text{nm}$  wide and  $0.5\ \mu\text{m}$  long (D). (E) and (F) Hierarchical PMMA pattern fabricated by superposition of two embossing steps. *Source:* Reprinted from Ref.<sup>[36]</sup>. Reprinted with permission from Ref.<sup>[37]</sup>. Reprinted with permission from Ref.<sup>[21]</sup>.

model systems.<sup>[39]</sup> Using a modification of the soft-molding method, arrays of PDMS fibers with spherical and spatula-like tips have been reported.<sup>[39–41]</sup> Figure 11 shows the fabrication methods. Arrays of pillars with spherical and spatular tips were obtained by inking PDMS fibrillar surfaces (Fig. 11A) in a thin film of PDMS precursor. A small drop of precursor remained on the top of the pillars. Curing of the array in upside-down orientation yielded hemispherical tips as a consequence of gravity and surface tension acting on the fluid drop (Fig. 11B). Alternatively, the inked stamp can be pressed against a flat substrate and then cured. This renders pillars with a flexible and flat roof with a diameter that depends on the thickness of the spin-coated film. The roofs can be symmetric or asymmetric depending on the tilt

of the substrate during curing (Fig. 11C and 11D). Other authors have used this method to obtain a continuous thin film of PDMS on the top of a fibrillar surface, which also seems to be advantageous for adhesion purposes.<sup>[42]</sup>

Spatula-like fibers have also been fabricated by filling prefabricated 3D masters with the negative profile with Teflon, followed by etching the master away.<sup>[43]</sup>

## SWITCHABLE ADHESIVE SURFACES MADE OF RESPONSIVE MATERIALS

Patterning technologies can be combined with responsive polymer materials to create microstructured surfaces with switchable adherence. Application of an

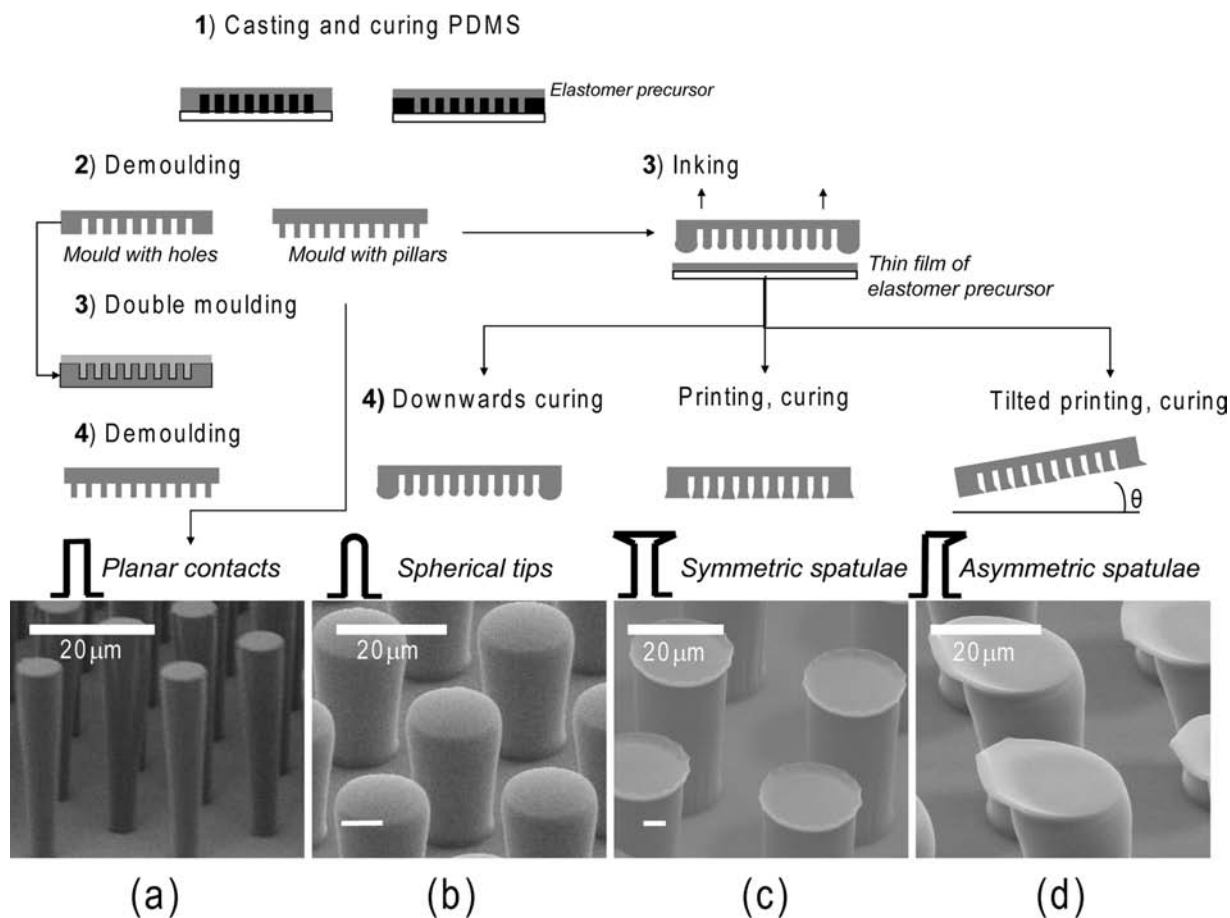

Fig. 11 3D structuring methods.<sup>[40]</sup>

Fig. 12 SEM images of pillars made by soft molding a shape memory polymer with a masters with holes of radius of  $10\ \mu\text{m}$ , height of  $100\ \mu\text{m}$ , and  $20\ \mu\text{m}$  interpillar spacing.<sup>[44]</sup> (A) Top and side views of tilted pillars after deformation above the shape memory transition temperature and fixation in the deformed state by cooling (non-adhesive state). (B) Top and side views of recovered pillars after reheating the sample above the transition temperature (adhesive state).

external field (e.g. temperature) causes changes in the topographical design and this influences the final adhesion performance. A shape memory polymer was selected for this purpose. Arrays of microfibers with diameters between  $0.5$  and  $50\ \mu\text{m}$  and heights between  $10$  and  $100\ \mu\text{m}$  were patterned by soft molding in the molten state.<sup>[44]</sup> Mechanical deformation of this topography at the shape-memory transition temperature, followed by cooling to room temperature in the deformed position yielded a temporary non-adhesive surface consisting of pillars in a tilted position (Fig. 12A). By reheating above the transition temperature, the patterned surface switches from the temporary non-adhesive state to a permanent adhesive surface with at least a 200-fold increase in adherence (Fig. 12B).

## CONCLUSIONS

Fibrillar adhesive surfaces with increasing complexity have been generated by different micro and nanofabrication methods. The achieved geometries still represent

a coarse simplification of natural systems and this may limit their adhesion performance. Combination of different techniques is required if the geometrical design spans over three dimensions and in different length scales (from mm to nm). Material parameters like the viscosity during embossing, or the mechanical stability of the fibers after processing, also limit the fabrication procedure. Large-scale manufacture has not yet been demonstrated with any of the reported technologies.

# Gene Delivery via Polymer Nanoparticles

Jie Wen

Kam W. Leong

*Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, Maryland, U.S.A.*

## INTRODUCTION

Gene therapy, a therapeutic modality designed to introduce an extraneous gene into the patient's cells to produce a specific protein, potentially can treat a variety of inherited and acquired diseases. Gene medicines are composed of a gene expression vector that encodes a therapeutic protein and a gene delivery system that delivers the gene to the desired tissue and subcellular compartments. The specific and efficient delivery of DNA to the diseased sites and to the nuclei of particular cell populations is the key for successful gene therapy. Gene delivery system plays a central role in fulfilling this mission.

## OVERVIEW

Traditionally, DNA delivery systems fall into two categories, viral-mediated and non-viral-mediated. In addition, naked DNA can be directly injected into the target tissue to produce the transgenes. Viral vectors such as retrovirus, adenovirus, adeno-associated virus, lentil virus, and herpes-simplex virus are usually much more efficient than non-viral vectors in both gene delivery and expression because of their highly evolved and specialized mechanisms in infecting cells. However, viral vectors have inherent disadvantages such as immunogenicity, restricted targeting of specific cell types, size limit of the DNA packaged into a virus, and scale-up difficulties.<sup>[1]</sup> The safety issue takes on new significance in light of the tragic event in recent clinical trial.<sup>[2]</sup> Consequently, non-viral delivery systems have been increasingly proposed as alternatives to viral systems. However, non-viral systems are inefficient and produce only transient transgene expression.

Nonviral gene delivery systems rely on condensing DNA to a compact size that can be internalized by cell and protecting the DNA from enzymatic degradation until the DNA reaches the nucleus. However, this tight binding and protection must be balanced by the ability of the gene carrier to release the DNA. The non-viral gene carriers include cationic liposomes, cationic

polymers, and neutral polymers. They are able to condense DNA to nanoparticles with a size of 20–500 nm in diameter for cellular internalization. The term nanoparticle is used in this review to cover particulate carrier systems that are less than 1  $\mu\text{m}$  in size and normally below 500 nm, including liposomes and solid nanocapsules.

Most cationic liposome formulations are composed of a cationic lipid and a neutral helper lipid. The cationic lipid binds the DNA through electrostatic interaction to form a complex termed lipoplex, while the helper lipid helps to stabilize the liposome and improve the cytoplasmic delivery of DNA.<sup>[3]</sup> Cationic polymers are usually nitrogen-rich polymers and have been used in much the same way as cationic liposomes with the polymer interacting electrostatically with DNA to yield a transfection-competent complex, termed polyplex. Polyplex is generally more stable than lipoplex in a physiological environment. The neutral polymer system usually involves encapsulating DNA in nanoparticles using biodegradable polymers, such as PLA and PLGA, to obtain sustained release characteristics. Recently, an inorganic system based on calcium phosphate nanoparticle has also been reported for gene delivery.<sup>[4]</sup>

Although most non-viral gene carriers can efficiently condense and protect the DNA, delivering the intact DNA to the nucleus remains a major challenge in the field. Poor mechanistic understanding of the whole gene transfer process makes it difficult to develop an optimal delivery system with all the desirable features for gene delivery. This review focuses on the application of cationic polymer-based nanoparticles for gene delivery.

## NANOPARTICLE FORMATION

Because of large electrostatic repulsion, free or naked DNA remains in an expanded state. Free DNA is too large and too polar a molecule to cross cell membranes by passive diffusion. The condensation of DNA into compacted nanoparticles is essential for

the transport of DNA through the cell membrane, although recent studies suggest that naked DNA can be taken up by muscle cells via receptor-mediated endocytosis.<sup>[5]</sup> Multivalent cations such as polyamines, positively charged polymers, and peptides are known to be capable of condensing DNA via electrostatic interaction with the negatively charged phosphate groups of DNA. A valence of  $\geq 3$  is required for the multivalent cations to condense DNA because the Coulombic interactions should be stronger than the entropic interactions so the entropy loss can be overcome.<sup>[6]</sup> The condensed DNA nanoparticles appear as rods, toroids, or spheroids under electron microscope.<sup>[7]</sup>

In understanding the mechanism of DNA condensation, the most extensive work has been conducted using small cations, such as spermidine [ $\text{H}_2\text{N}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}_2$ ],<sup>[8]</sup> spermine [ $\text{H}_2\text{N}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}(\text{CH}_2)_3\text{NH}_2$ ],<sup>[9]</sup> and cobalt hexamine [ $\text{Co}(\text{NH}_3)_6^{3+}$ ].<sup>[10]</sup> A variety of techniques, such as microscopy, light scattering, fluorescence, and calorimetry, have been used. Two models, the spool model and the constant loop model, have been proposed to explain how the DNA is compacted within the toroid.<sup>[9,11]</sup> The cations instigate localized bending or distortion of DNA at a critical extent of charge neutralization, which facilitates the formation of rods and toroid-like structures.<sup>[12,13]</sup> The cations can also induce DNA condensation by rendering the DNA-solvent interactions less favorable.<sup>[14,15]</sup> Formation of a highly ordered liquid crystalline phase of DNA is believed to be involved in DNA condensation.<sup>[16]</sup>

Many factors affect the formation of DNA nanoparticles, such as chemical structure of cations, ionic strength of the medium, and molar ratio of the

polycation and DNA. The study on the structural arrangement of DNA condensed by polyamine homologues indicates that the number of positive charges and the charge density of polyamine molecules affect the size of DNA nanoparticles as well as the ability to induce the formation of liquid crystalline phase of DNA.<sup>[17,18]</sup> In high ionic strength solution, DNA nanoparticles may aggregate because the salt overcomes the repulsive interaction between particles. Excess positive charge on the surface can prevent the nanoparticles from aggregating under the salt condition. The surface charge of the nanoparticles is characterized by  $\zeta$ -potential and can be adjusted by changing the reactant ratio of DNA to polycations.

A better understanding of the relationship between the physicochemical properties of the DNA nanoparticles, their ability to be taken up by cells, and the chemical structure of agents that cause the condensation of DNA is needed for the development of non-viral gene delivery vehicles.

## DELIVERY OBSTACLES FOR NON-VIRAL SYSTEMS

Ultimately, DNA has to be delivered to the nucleus for successful gene expression, after overcoming a number of obstacles on the way (Fig. 1). These delivery obstacles are both extracellular as well as intracellular. The biodistribution of nanoparticles in the extracellular space is determined by their interaction with the physiological environment, based on their physicochemical and biological properties, such as size, electrical charge, hydrophilicity-hydrophobicity, and possible ligand conjugation.

Fig. 1 Obstacles of nonviral gene delivery.

Of all the properties, particle size is of crucial importance in determining the biodistribution.<sup>[19]</sup> Any particle aggregation during the gene delivery is detrimental for DNA to get to the final site, the nucleus. In fact, negatively charged proteins such as albumin tend to bind with the positively charged nanoparticles, leading to a size increase of the particles and a reduced positive charge on the particle surface, which may diminish the affinity of the nanoparticles to the negatively charged cell surface. Therefore the nanoparticles must first be stable in the extracellular fluid so that they can be delivered to the target tissue or cells. It should be noted that the immune cells might recognize the particles as foreign materials and phagocytose them, which may be attractive for genetic vaccination but may not be desirable for other gene therapy applications.

Once the nanoparticles reach the target cells, they bind with the negatively charged cell membrane and are subsequently taken up by endocytosis. The rate of entry into the cells varies with cell type and is relatively slow.<sup>[20]</sup> In order to achieve cell-specific gene transfer, cell-specific targeting ligands such as monoclonal antibodies, peptides, and sugars can be conjugated to the gene carriers to promote receptor-mediated endocytosis. After the non-specific or receptor-mediated endocytosis, most DNA complexes are internalized into the endosomes/lysosomes and are eventually degraded. Cytoplasmic release of the DNA complex is the first barrier in the intracellular transport. Efficient destabilization of the endosomes/lysosomes is believed to enhance gene expression. Some endosomolytic reagents such as chloroquine,<sup>[21]</sup> lipids,<sup>[22]</sup> and peptides<sup>[23]</sup> have been used to disrupt the endosome membrane, leading to an enhanced gene expression. The buffering capacity of amine-containing polymers has also proved to reduce the acidification of the endosome, triggering endosome swelling and rupture or collapse.<sup>[24]</sup> Some anionic lipids in the endosome may compete with the DNA and dissociate the DNA complexes, leading to the release of the DNA into the cytoplasm.<sup>[25]</sup>

Cytosol is not a friendly environment for DNA because of the presence of nuclease. Microinjected plasmid DNA is rapidly degraded in the cytoplasm with an apparent half-life of 50–90 min.<sup>[26]</sup> The translocation of released or “unpacked” DNA from cytosol to nucleus is probably through diffusion, a relatively slow process compared to cytoplasmic degradation. It is understandable that the DNA would be more stable in cytosol if it were still complexed with cationic carrier. However, only certain synthetic polymers, such as polyethylenimine (PEI), can show protection of DNA in the cytoplasm and also promote nuclear transport. The pathway of the transport of DNA complexes from cytoplasm to nucleus is not well understood. Some hypothesis leans toward the involvement of

anionic phospholipids. The inclusion of viral nuclear localization signals (NLS) has been demonstrated to be an efficient strategy to facilitate nuclear transport.<sup>[27,28]</sup> Typically comprising several positively charged lysines and arginines, a NLS is a peptide signal sequence that directs a protein from the cytosol into the nucleus.

As stated above, eventually the DNA has to be released from the complexes to allow transcription. The dissociation of complexes may occur either in the endosome, cytosol, or nucleus. Other than enzymatic degradation of the gene carrier, anionic membrane components and other intracellular substances may also be responsible for the dissociation by carrier substitution.

## POLYMERIC GENE CARRIERS

The poor transfer efficiency and transient gene expression of polymer–DNA complexes continue to stimulate the development of more effective and less-toxic polymeric gene carriers. A number of polycations have been tested to transfer genes *in vitro* or *in vivo*, including poly-L-lysine (PLL) (Fig. 2A), PEI (Fig. 2B), polyamidoamine (PAMAM) dendrimers (Fig. 2C), poly( $\alpha$ -(4-aminobutyl)-L-glycolic acid) (PAGA) (Fig. 2D), poly((2-dimethylamino)ethyl methacrylate) (PDMAEMA) (Fig. 2E), chitosan (Fig. 2F), etc. Our group has been interested in investigating polyphosphoester as a new polycationic gene carrier (Fig. 2G).

### Poly-L-Lysine

Poly-L-lysine has been widely used in the early days as a gene delivery carrier because of its excellent DNA condensation ability and efficient protection of DNA from nuclease digestion. However, its cytotoxicity and low transfection problems remain to be solved. Moreover, PLL–DNA complexes tend to aggregate under physiological conditions. Efforts have focused on improving the solubility of PLL by the introduction of hydrophilic groups, such as dextran<sup>[29]</sup> and PEG.<sup>[30,31]</sup> Both PEG-g-PLL and PEG-b-PLL have shown lower cytotoxicity and enhanced transfection efficiency than PLL. A polymeric micelle, PLGA-g-PLL has also been proposed as an effective carrier for gene delivery.<sup>[32]</sup>

### Polyethylenimine

Polyethylenimine–DNA complex is one of the most potent synthetic gene transfer vectors. They can also transfect a wide variety of cells. The high transfection efficiency of PEI has been postulated to relate to its buffering capacity, which leads to the accumulation

cell membranes. Moreover, PEI is not degradable and high molecular weight PEI may accumulate in the body. Several approaches have been explored to reduce the cytotoxicity, such as PEGylation<sup>[34]</sup> and conjugation of low molecular weight PEI with cleavable cross-links such as disulfide bonds, which can be cleaved in the reducing environment of the cytoplasm.<sup>[35]</sup>

### Polyamidoamine Dendrimers

Starburst polyamidoamine dendrimers with either ammonia or ethylenediamine as core molecules have been used for gene delivery. These molecules are highly defined in terms of molecular weight and geometry. They are spherical polymers, with primary amine groups on the surface, which can be used to condense DNA. Dendrimers can transfect a wide variety of cells in culture,<sup>[36]</sup> with an efficiency matching that of PEI under optimal conditions. The higher generation dendrimers (G6 and G7) are effective at disrupting anionic vesicle membranes, which may explain the high transfection efficiency.<sup>[37]</sup> The advantage of these dendrimers over PEI remains to be established.

### Poly( $\alpha$ -(4-aminobutyl)-L-glycolic acid)

Poly( $\alpha$ -(4-aminobutyl)-L-glycolic acid) is an analogue of PLL with a degradable ester linkage in the main chain.<sup>[38]</sup> Poly( $\alpha$ -(4-aminobutyl)-L-glycolic acid) efficiently condenses and protects DNA and shows enhanced transfection efficiency in culture compared to other PLL-based systems. It is also less cytotoxic than Lipofectamine and SuperFect (a dendrimers). Although PAGA generates positive results in producing cytokines as an immunoadjuvant in a murine cancer model, its biodegradation rate of the polymer may be too rapid for some in vivo gene transfer applications.<sup>[39]</sup>

### Poly((2-Dimethylamino)Ethyl Methacrylate)

Poly((2-dimethylamino)ethyl methacrylate) is a water-soluble cationic polymer capable of binding plasmid DNA and transfecting different cell types.<sup>[40]</sup> The complexes with a slightly positive  $\zeta$ -potential (25–30 mV) and a size around 200 nm possess the highest transfection efficiency.<sup>[41]</sup> Study on the structure–activity relationship of a number of water-soluble cationic methacrylate/methacrylamide polymers with structures closely related to PDMAEMA shows that among these polymers, PDMAEMA has the highest transfection efficiency and cytotoxicity.<sup>[42]</sup> The high transfection efficiency of PDMAEMA is probably due to its high buffering capacity to destabilize endosome, combined with its ability to release the DNA in the cytosol

and/or the nucleus. Its strength and shortcomings are similar to those of PEI.

### Chitosan

Chitosan, a biodegradable polysaccharide composed of D-glucosamine repeating units, has been explored by several research groups as a non-viral gene carrier.<sup>[43–45]</sup> Chitosan can efficiently bind DNA and protect DNA from nuclease degradation. Moreover, chitosan has good biocompatibility and toxicity profile, rendering it a safe biomedical material for clinical applications. Chitosan–DNA nanoparticles can transfect several different cell types. However, the transfection efficiency is relatively poor. Chitosan can be readily modified. For example, trimethylated chitosan can be prepared with different quarternization degree to increase the solubility of chitosan at neutral pH,<sup>[46]</sup> or chitosan can be conjugated with deoxycholic acid to become a colloidal gene carrier.<sup>[47]</sup> Both quaternarized chitosan and deoxylic acid-modified chitosan can efficiently transfect COS-1 cells. Chitosans with different molecular weights have different DNA binding affinities and exhibit different transfection efficiencies, indicating that particle stability may be one of the rate-limiting steps in the overall transfection process.<sup>[43]</sup> The effect of degree of deacetylation on the stability of chitosan–DNA nanoparticles is being investigated.<sup>[48]</sup>

### Polyphosphoester

We have been working on polyphosphoesters (PPE) for more than 15 years, particularly the ones with a backbone analogous to nucleic acids and teichoic acids. They show promise in different biomedical applications because of their biocompatibility, biodegradability, and pendent chain functionality. Several polyphosphoesters with positive charges either in the backbone or in the side chain were synthesized and evaluated as non-viral gene carriers.<sup>[49–51]</sup> These polyphosphoesters can efficiently bind DNA and protect DNA from nuclease degradation. Efficient transfection was found in a number of cell lines, with some of them comparable to Lipofectamine. The transfection is cell-type dependant and can be improved with the incorporation of chloroquine. All the polyphosphoesters exhibit a significantly lower cytotoxicity than PLL or PEI in vitro and in vivo. With the structural versatility, polyphosphoester can be designed to have different hydrophilicity–hydrophobicity properties. One interesting feature is that the PPE can provide extracellular sustained release of the DNA, leading to prolonged and enhanced transgene expression in the muscle compared to naked DNA administration.<sup>[50]</sup> An amphiphilic polyphosphoester,

poly{[(cholesteryl oxocarbonylamido ethyl) methyl bis(ethylene) ammonium iodide] ethyl phosphate} (PCEP), was synthesized and investigated for gene delivery.<sup>[51]</sup> Carrying a positive charge in its backbone and a lipophilic cholesterol structure in the side chain, PCEP self-assembles into micelles in aqueous solution at room temperature with an average size of 60–100 nm. This is one of the few polymeric lipids for gene delivery that are biodegradable.

## TARGETING

Drug targeting can be achieved with different levels of sophistication: first-, second-, and third-order targeting. First-order targeting can be defined as the delivery of a drug to a particular organ; second-order targeting is where the drug is internalized in a specific cell type; and third-order targeting is where the drug is localized in a specific cellular compartment.<sup>[52]</sup> Gene delivery is indeed a third-order targeting challenge with nucleus as the targeting site.

The use of polymeric nanoparticles for targeted drug and gene delivery system has gained increasing attention and importance.<sup>[53]</sup> Targeting can be achieved either by passive route, where the particles are captured by a physiological uptake mechanism such as filtration or macrophage sequestration, or by active route, where the particles are recognized by the host molecule through the targeting moiety conjugated on the surface of the particles.

### Passive Targeting

Normally, after the nanoparticles are injected into the blood stream, they are rapidly coated by circulation elements, such as plasma proteins and glycoproteins. This process renders the particles easily recognized by the major defense system of the body, the reticuloendothelial system. The macrophage (Kupffer) cells of the liver play a critical role in removing these coated foreign particles.<sup>[54]</sup> Thus Kupffer cells specificity can be achieved by passive targeting. Particles with a more hydrophobic surface, which can be efficiently coated with plasma elements, are more desirable for this targeting. This strategy can be used to achieve gene delivery to the blood circulation.

The lymph nodes are of great interest because of their vital role in the staging of anticancer and anti-infection immune responses.<sup>[52]</sup> A subcutaneous administration of nanoparticles can be an efficient way of reaching local draining lymph nodes. Particle size and surface property are two decisive parameters for such targeting. Generally, particles with a size less than 100 nm are preferable for such targeting. The

particles with intermediate hydrophilicity–hydrophobicity in nature appear to have the most lymph node accumulation. This type targeting is particularly useful for DNA vaccination applications.

### Active Targeting

To increase the specificity of DNA uptake by target cells, transferrin,<sup>[55]</sup> monoclonal antibodies,<sup>[56]</sup> mannose,<sup>[57]</sup> galactose,<sup>[58]</sup> lactose,<sup>[59]</sup> folic acid,<sup>[60]</sup> low-density lipoproteins,<sup>[61]</sup> and RGD peptides<sup>[62]</sup> have been conjugated to the polymer backbone to achieve receptor-mediated endocytosis. Poly-L-lysine and PEI are popular candidates for the conjugation because of the readily available primary amine groups. After endocytosis, the DNA nanoparticles are internalized in the vesicles within the cells. Two strategies are used to help cytoplasmic release of DNA. One is to use fusogenic peptides derived from fusion-active virus to destabilize the endosomal membrane. Another approach is to use a carrier with a high buffering capacity to promote the escape of the complexes into the cytosol, with mechanisms discussed above. The next target is then the nucleus. The cut-off size of nuclear pores is 9–10 nm, which allows proteins up to 60 kDa and nucleotides up to 300 bp to enter freely.<sup>[63]</sup> However, larger molecules can still get through the nuclear pores via an active process, which can be modulated by NLS. Enhanced gene transfection efficiency has been achieved by the conjugation of NLS peptide to the gene carriers such as PLL<sup>[64]</sup> and PDMAEMA,<sup>[65]</sup> or plasmid itself.<sup>[66]</sup> If the NLS peptide is conjugated to the gene carrier, the DNA has to stay complexed before nuclear translocation takes place. It has been reported that the number of NLS peptides conjugated to DNA plays an important role in the nuclear transport. Too many NLS peptides may actually inhibit nuclear translocation.<sup>[67]</sup>

## IN VIVO APPLICATION

Targeted delivery is the ultimate goal of gene therapy. Local administration so far presents a more feasible approach as systemic barriers are bypassed. Significant gene expression has been found in a variety of tissues/organs, such as muscle, lung, liver, brain, tumor, and gastrointestinal (GI) tract using polymeric gene carriers.

### Muscle

Muscle has been of interest as a target for gene therapy since Wolff et al. demonstrated that intramuscularly injected naked plasmid DNA can be expressed in myofibers in 1990.<sup>[68]</sup> Naked DNA has poor bioavailability in muscle due to the degradation by extracellular nucleases and the rapid elimination from the muscle.

In order to protect DNA from degradation cationic agents are used to condense DNA. However, the use of condensed DNA particles to achieve higher transfection in muscle rather than naked DNA has not been successful. This is possibly because the connective tissue surrounding myofibers and muscle fasciculus could limit the diffusion of rigid condensed DNA particles through the muscle.<sup>[69]</sup> Recently, a sustained release system using PPE-EA as a carrier has been proved to enhance gene expression in mouse muscle compared to naked DNA.<sup>[50]</sup> Lower N/P ratios of 0.5 and 1 were used in the study. The intramuscular delivery of plasmid encoding antigens can induce antibody and cytotoxic T-lymphocyte (CTL) responses, which is desirable for DNA vaccination.

## Lung

Gene delivery to the lung has the potential to treat several life-threatening genetic diseases such as cystic fibrosis (CF) and  $\alpha_1$ -antitrypsin ( $\alpha_1$ AT) deficiency. Cystic fibrosis is the result of mutations in a single gene (CF transmembrane conductance regulator, CFTR), and the gene delivery target is the airway epithelial cell.  $\alpha_1$ AT is another lung disease resulting from a single gene mutation; however,  $\alpha_1$ AT is a secreted product that does not need to be expressed in lung epithelium. Pulmonary gene delivery can be achieved through different administration methods, such as lung instillation, aerosol delivery, and intravenous injection. The method of application greatly influences the extent of gene expression in the lung as well as the cell type that is transfected. Instillation usually leads to significant but inhomogeneous gene expression in epithelial cells lining the bronchioles and distal airways, while aerosol delivery enables a more uniform distribution of gene expression.<sup>[70,71]</sup> By intravenous injection, transfection is mainly restricted to pulmonary endothelium.<sup>[72]</sup> Cationic polymers such as PEI and PAMAM have been proposed for pulmonary gene therapy.<sup>[73,74]</sup> Several problems including avoidance of biological barriers, suppression of immune response, and increase of transfection efficiency and specificity need to be solved before successful pulmonary gene therapy becomes a reality.

## Tumor

Cancer gene therapy can take the form of the administration of a good copy of a mutated tumor suppressor gene, a gene encoding an enzyme that activates an anticancer prodrug, or a gene that encodes an antigen designed to generate a protective immune response.<sup>[75]</sup> There are two general methods for tumor treatment. One is the direct injection of DNA particles into

arterial blood vessels that supply the tumor. Another method is the direct injection of the particles into the tumor.<sup>[76]</sup> In this case, the mobility of the particles within the tissue is very important to the transfection efficiency and is affected by the particle size, charge, and concentration. Liposomal and naked DNA formulations are two intensively investigated intratumoral gene delivery systems. Polyethylenimine,<sup>[77]</sup> poly( $\alpha$ -(4-aminobutyl)-L-glycolic acid),<sup>[78]</sup> and poly-amidoamine<sup>[79]</sup> have been the polymeric gene carriers studied for cancer gene therapy.

## Liver

Gene delivery to the liver involves intravenous administration of DNA containing formulations, either into a systemic or the portal vein. The stability of DNA complexes in the blood and the dilution of DNA dose by the blood are two major challenges for this application. Interestingly, naked DNA has been found to transfect hepatocytes by intravenous delivery under some special circumstances. Hydrodynamic injection of a large volume of naked DNA solution via the tail vein in 5–8 sec can induce potent gene expression in internal organs, especially the liver.<sup>[5]</sup> Significant gene expression can also be achieved in the liver by transiently restricting blood flow through the liver immediately after peripheral intravenous injection of naked DNA.<sup>[80]</sup> The hypothesis is that naked DNA is taken up by hepatocytes through receptor-mediated pathway and pressure can increase cellular uptake. However, these methods are not practical in clinical application. Condensed systems, such as poly-L-lysine<sup>[81]</sup> and PEI,<sup>[82]</sup> have been reported to achieve transfection in the liver.

## Brain

Gene therapy of the brain is hindered by the presence of the blood–brain barrier (BBB), which only allows permeation of small lipophilic molecules. Exogenous genes have been expressed in the brain after invasive routes of administration, such as craniotomy<sup>[83]</sup> or intracarotid arterial infusion of noxious agents causing BBB disruption.<sup>[84]</sup> Taking advantage of receptor-mediated transport, a non-invasive gene delivery system using transferrin as receptor to cross the BBB has been described.<sup>[85]</sup> PEI has been shown to be a versatile and efficient vector in the mammalian brain.<sup>[86,87]</sup> As neurons are capable of taking up exogenous particulates from the muscles they innervate, a non-invasive strategy for gene delivery to the brain stem has been developed via peripheral intramuscular injection of PEI/DNA complexes. It is hypothesized that the complexes can reach the neuronal cell bodies in the

brain stem by retrograde axonal transport after being internalized by nerve terminals in the tongue muscle.<sup>[88]</sup>

## Gastrointestinal Tract

Oral gene delivery is by far the most attractive of administration. The efficiency of chitosan–DNA nanoparticles has been explored as an oral gene delivery system in a peanut allergy vaccine model.<sup>[44]</sup> The study demonstrates that transgene expression can be achieved in the small intestine of the mouse after oral administration of chitosan/DNA nanoparticles. Using pCMVArh2 plasmid encoding a dominant anaphylaxis-inducing antigen identified in mice sensitized with peanut, nanoparticle immunization elicits a relatively high IgG2a immune response and protects the animals from an allergic challenge.

## CONCLUSION

Successful non-viral gene therapy will rely on the development of efficient vectors that can overcome the multitude of delivery barriers, including targeted cellular uptake, cytoplasmic release, and nuclear transport. An ideal non-viral vector would be non-immunogenic, non-toxic, biodegradable, able to condense DNA into nanoparticles, and amenable to conjugation of ligands, endosomolytic agents, and NLS peptides. The DNA complex should possess stability before and after cellular uptake, but instability after nuclear transport. Although significant progress has been made in the development of DNA condensing agents, poor understanding of the relationship between the structure of gene carriers and transfection efficiency has rendered the design of non-viral gene delivery systems suboptimal. Systematic mechanistic studies to identify the rate-limiting steps in the non-viral gene transfer process will undoubtedly produce the next generation of efficient and safe non-viral vectors.

# Germanium Nanoparticles

Boyd R. Taylor

Louisa J. Hope-Weeks

*Chemistry and Chemical Engineering Directorate, Lawrence Livermore National Laboratory, Livermore, California, U.S.A.*

## INTRODUCTION

The interest in semiconductor nanoparticles is primarily because of disparities in electronic properties from the bulk material they exhibit because of their extremely small size. However, the preparation method used and the ability to manipulate them make an enormous impact on the applications of semiconductor nanoparticles. In the case of Ge nanoparticles, interest in their preparation and properties traces back to the proposal by Canham<sup>[1]</sup> in 1990 that the luminescence of porous Si was caused by quantum confinement (QC) of charge carriers. Because both bulk Si and Ge are diamond-lattice semiconductors with indirect band gaps in the near infrared, it seemed natural that the great interest in Si nanoparticles triggered by Canham's paper would cause a similar interest in Ge nanoparticles. This level of interest has not materialized because of the desire to link with the microelectronics community, which focuses so intensely on Si. Physically, the larger exciton Bohr radius of Ge of 11.5 nm,<sup>[2]</sup> its higher dielectric constant, and its higher refractive index make Ge the material of choice for some applications. Unlike Si, very little work has been performed on nanoparticles derived from porous Ge<sup>[3,4]</sup> or spark processed Ge.<sup>[5]</sup> The purpose of this entry is to discuss methods for preparation of Ge nanoparticles by colloidal chemistry; we will first discuss the initial methods and point out their strengths and weaknesses. A discussion of more recent preparation methods will follow. Finally, a comparison of the recent methods will point to some possible improvements in the colloidal preparation of Ge nanoparticles.

## PREPARATION OF Ge NANOPARTICLES

The preparation methods of Ge nanoparticles, such as those of other semiconductors, separate naturally into physical or "top-down" approaches and colloidal chemistry or "bottom-up" approaches. The colloidal chemistry approach mentioned here refers to preparing

the nanoparticles using conventional synthetic chemistry and preparing a suspension of them in a solvent. The dividing line between a colloidal suspension and a solution is literally a murky one because one may think of a solution as a suspension that shows minimal light scattering. In the case of the very small particles considered here, the strong scattering characteristic of most colloids is seen only at high concentrations, where they agglomerate. Colloidal preparation of nanoparticles offers several advantages; the colloidal chemistry offers better control over the surface chemistry of the nanoparticles and their size distribution, and the particles are produced with no surrounding matrix. Because surface effects can change the properties of nanoparticles, control over the surface chemistry is vital to understanding their properties. To date, physical preparation methods such as various chemical vapor deposition (CVD) techniques and co-sputtering rely heavily on clean high-vacuum conditions to exclude impurities from the nanoparticles produced. These "top-down" techniques were developed to prepare thin films of bulk materials. Layers of nanoparticles were produced only by mixing these films with an inert matrix. Although many different techniques have been developed to both control and narrow the size distribution of semiconductor nanoparticles prepared by "top-down" methods, the best systems prepared through colloidal chemistry are nearly monodisperse,<sup>[6]</sup> far better than particles prepared by physical methods. In the case of compound semiconductors, particularly the II–VI semiconductors, the colloidal chemistry approach has been much more successful in preparing nanoparticles than "top-down" methods. The colloidal chemistry preparation of Si and Ge nanoparticles is much more difficult because of the greater sensitivity to oxidation and the difficulty of preparing anions with these elements.

Because there is enough literature on the preparation of Ge nanoparticles to infer an interest in this area, one might naturally ask why there is an interest. This question has been partially addressed previously. Because the microelectronics industry drives a continuing interest in Si as a semiconductor, and QC is widely

seen as a way of obtaining visible light from Si, the desire to integrate optical and electronic components drove early work on Si nanoparticles. Because Ge has a larger dielectric constant than Si (15.9 vs. 11.5) and smaller effective masses for the electron and hole, which give it a larger exciton Bohr radius, QC effects should be easier to observe in Ge nanoparticles than Si nanoparticles. Additionally, colloids of Ge nanoparticles have been predicted to have exceptional non-linear optical properties.<sup>[7,8]</sup>

### Colloidal Preparative Methods

Several methods have been used to prepare colloidal suspensions of Ge nanoparticles. Previous colloidal synthesis of both Ge quantum dots and wires has been reported to utilize the reduction of alkylchlorogermanes by NaK alloy.<sup>[9–11]</sup>

where  $\text{NaK}_{\text{disp}}$  means a dispersion of NaK alloy in hexane and  $\text{Ge}_{\text{diam}}$  means diamond-cubic Ge, the crystal structure of bulk Ge. The NaK dispersion was prepared by sonicating NaK alloy under anaerobic conditions. This reduction was performed in a bomb at 275°C and 200 atm, rather harsh synthetic conditions. Additionally, the reaction offered little control over size or surface termination, typically produced mixtures of quantum dots and wires, and had relatively low recoveries of Ge as nanoparticles. Previous attempts at liquid solution synthesis of Ge, Si, or SiGe quantum dots under less-forcing conditions all led to amorphous material. Another interesting liquid solution synthesis of Ge nanoparticles used ruby laser light to crystallize amorphous Ge particles from a colloidal solution after terminating the surface of the particles with alkylsilanes.<sup>[12]</sup> The reaction used to produce a colloidal solution of Ge particles was

The particles initially produced are amorphous, requiring annealing with ruby laser light to crystallize. However, this reaction takes place at 60°C and atmospheric pressure, and the resulting particles show some evidence of size selection because particles between 6 and 10 nm absorb the laser light, heating, and annealing. The amorphous particles still present must be separated, but the crystalline particles are produced in a reasonably narrow size range.

### Recent Colloidal Preparations

More recent colloidal preparative methods for Ge nanoparticles include the metathesis of  $\text{GeCl}_4$  with the Zintl salts NaGe, KGe, and  $\text{Mg}_2\text{Ge}$  and the reduction of  $\text{GeCl}_4$  in inverse micelles. Both methods offer the ability to prepare Ge nanoparticles in quantity. The Zintl salt metathesis permits reasonable control over the surface termination and limited control over size distribution.<sup>[13]</sup> The reduction of  $\text{GeCl}_4$  in inverse micelles permits excellent control over size distribution, but limited control over surface chemistry.<sup>[14]</sup> Because these more recently developed colloidal preparations offer better control over size distribution and surface chemistry than the previously mentioned methods, more detailed examination of both methods is in order.

#### Zintl salt metathesis

Zintl salts<sup>[15]</sup> are named for Eduard Zintl, who first prepared and characterized them in the 1930s. They consist of polyanions of elements to the right of the Zintl line, which divides groups 13 and 14 with cations from the left of the Zintl line.<sup>[16]</sup> These polyanions follow the octet rule, with cations from groups 1, 2, or the lanthanides providing charge balance. Zintl characterized these unusual air-sensitive compounds by X-ray diffraction (XRD) of the crystalline phases prepared and potentiometric titrations of solutions of Zintl salts in liquid ammonia.<sup>[15]</sup> It must be kept in mind that the structure of the polyanions in the crystalline phases need not closely resemble the structure of anionic clusters in solutions prepared from them.

To begin the Zintl salt metathesis, a suspension of the salt in a glyme (ethylene glycol dimethyl ether) is prepared under water- and air-free conditions by heating to reflux. While the Zintl salts used to prepare Ge nanoparticles, NaGe, KGe,  $\text{Mg}_2\text{Ge}$ , and CaGe, do not dissolve well in the glyme solvents used, enough dissolves to support the metathesis reaction with  $\text{GeCl}_4$ . Because the Cl-terminated Ge nanoparticles produced by the initial reaction dissolve freely in glyme solvents, the reaction is driven to completion. The reaction between the Zintl salts and a 3-fold excess of  $\text{GeCl}_4$  takes from 4 to 6 hr in diglyme and from 1/2 to 2 hr in triglyme, judged by the suspension changing from opaque gray-blue to clear and colorless. A 3-fold excess of  $\text{GeCl}_4$  is needed to drive the reaction to completion, and both the Zintl salt used and the  $\text{GeCl}_4$  are consumed in the reaction. It is not known why a 3-fold excess of  $\text{GeCl}_4$  is needed to drive the reaction to completion, but neither reactions performed with a 10-fold excess of  $\text{GeCl}_4$  nor those performed with less than a 3-fold excess of  $\text{GeCl}_4$  reacted completely. The ability

of Li alkyls and Grignard reagents to alkylate the surface of the nanoparticles also points to the chloride termination of the surface mentioned above.

Of course, reaction with Li alkyls and Grignard reagents has permitted surface termination with more interesting groups than alkyls. To date, surfaces with methyl, butyl, octyl,<sup>[13,17]</sup> *p*-chlorophenyl,<sup>[18]</sup> vinyl, and allyl groups have been prepared with varying success. Ge nanoparticles with alkyl-terminated surfaces are remarkably stable and relatively simple to separate. Nanoparticles with vinyl- and allyl-terminated surfaces have been proven to be both unstable and difficult to purify. The primary failing of this preparative method is the limited control over size distribution and the difficulty of separating sizes. While different concentrations of reactants, reaction time, or reaction temperature changed the mean nanoparticle size, no control over size distribution is apparent.

### Reduction in inverse micelles

In the inverse micelle preparation of Ge nanoparticles, both size control and size separation are incorporated into the preparative method. The partial separation of the halide salt and reductant into hydrophilic and hydrophobic regions of the inverse micelles permits some control over size distribution, which is greatly enhanced by the use of high-performance liquid chromatography (HPLC) to size-separate the nanoparticles. In essence, GeX<sub>4</sub> (X = Cl, Br, or I) was more soluble in the tetrahydrofuran (THF) portion of inverse micelles formed in THF/octane or THF/decane mixtures than in the hydrocarbon portion of the reaction mixture. The micelles form at the interface of the THF and alkane phases, with aliphatic polyethers or quaternary ammonium salts acting as phase transfer catalysts and stabilizing the micellar phase. Small regions of THF/GeX<sub>4</sub> are formed with octane or decane separating them. This was followed by the introduction of the reductant, typically 1 M LiAlH<sub>4</sub> in THF. The micelles determine the size of nanoparticles produced, although thinking of micelles as pores or cavities is an oversimplification. Rather than act as cavities, which directly limit the size of the nanoparticles, the micelles slow the rate of reaction, perhaps separating crystallite nucleation from growth. Similar to all of the other reactions discussed, this reduction was carried out under water-free, anaerobic conditions. However, the use of alkaline N<sub>2</sub>H<sub>4</sub> as a reductant was suggested, indicating that as long as hydrolysis was slower than reduction, the presence of a small amount of water could be tolerated. Although no attempt to characterize or manipulate the surface chemistry has yet been made for Ge nanoparticles prepared with this method, the surface is most likely terminated by H. The strengths of this method are that it is generally

applicable to main group nanoparticles and that the reaction mixture can be size-separated by HPLC. However, because the nanoparticles produced are terminated by H, they are not stable in air, making characterization difficult.

## DISCUSSION

### Quantum Confinement

Because most of the interest in Si nanoparticles can be traced back to Canham's proposal that quantum confinement is responsible for the observed photoluminescence in porous Si, it may be assumed that most of the interest in Ge nanoparticles also arises from an interest in QC. Because the changes in electronic properties as a result of QC are observable only at radii  $\leq R_{\text{Bohr}}$  of the exciton, or equivalently, when the particle size is approximately the same as the mean free path of charge carriers in the material, measuring the size of the nanoparticles produced is crucial.

Quantum confinement changes all of the electronic properties of nanoparticles relative to the bulk material. The best-known example of this is the change in optical properties. The absorption onset of bulk Ge lies in the near infrared, at 0.67 eV, and it photoluminesces in the near infrared, with an efficiency of less than 10<sup>-4</sup>%. Quantum confinement predicts that the band gap, the photoluminescence (PL), and the photoluminescence excitation (PLE) maxima will shift to higher energies with decreasing size. It also predicts that the efficiency of an optical transition will increase with decreasing size.

### Size Measurement

Because the properties of nanoparticles depend primarily on size, measurement of both the mean size and size distribution is vital to understanding their properties. It has been proven to be more difficult than expected to establish reliable size measurements. Size measurements of Ge nanoparticles have been made by high-resolution transmission electron microscopy (HRTEM), selected area electron diffraction (SAED), X-ray diffraction (XRD), or atomic force microscopy (AFM). Size measurements by HRTEM have been used most widely because one may image the d-spacing of the lattice of the nanoparticles while imaging them. This ability to measure d-spacing and obtain an image simultaneously permits looking for a phase change at extremely small sizes. Size measurements based on diffraction rely on the broadening of diffraction lines for both XRD and SAED observations. However, the need to assume a particle shape in the Debye-Scherrer

formula and the low intensity of diffraction maxima for these measurements make them uncertain and difficult. More importantly, line-broadening measurements provide no information about the size distribution. Atomic force microscopy provides a quick measurement of both mean size and size distribution, providing that the nanoparticles are equiaxial because AFM measurements are precise only in  $Z$ .

### Surface Termination

The issue of surface termination is often overlooked because most of the interesting properties of nanoparticles depend primarily on their size. However, particles from 2 to 10 nm in diameter, which is the size range of interest for quantum-confined nanoparticles, have enormous surface areas. They also oxidize more rapidly than bulk material because they have so many atoms near the surface. To prevent the nanoparticles from oxidizing, one must passivate the surface in some way. Unlike Si nanoparticles, the surface oxide of Ge does not effectively passivate the nanoparticle surface. For Ge nanoparticles prepared by the Zintl salt metathesis, reacting the chlorides on the surface with Grignard reagents or Li alkyls is a natural method of passivating the surface. For Ge nanoparticles prepared in inverse micelles, some other coupling chemistry must be devised. Hydrogen-terminated Si surfaces have been prepared by reaction with 1-alkenes.<sup>[19]</sup> Similar chemistry should work on Ge nanoparticles with H-terminated surfaces.

### RESULTS

As predicted by quantum confinement models, the optical properties of quantum-confined nanoparticles differ greatly from those of the bulk material. The plot of absorption onsets vs. mean diameter in Fig. 1 demonstrates the change in absorption onset with size for Ge nanoparticles prepared by the Zintl salt metathesis. Although the UV-Vis spectra in this figure are not presented as measurements of band gaps, the absorption onsets seen in this figure are of similar energy and scale inversely with mean particle size as expected from quantum confinement models. The size-selected PL spectra in Fig. 2 demonstrate luminescence in the blue-to-violet region of the spectrum. The shift in energy of the PL maxima is over 2 eV. However, this large energy shift is reproducible and consistent between samples of similar mean size. While some of the shift may be a result of surface effects, it is primarily because of quantum confinement. Ge nanoparticles 2–4 nm in diameter prepared in inverse micelles using  $\text{LiAlH}_4$  as a reductant show a similar shift in

**Fig. 1** Absorption onset vs. mean diameter for alkyl-terminated Ge nanoparticles.

energy in PL spectra.<sup>[14]</sup> Recent X-ray absorption measurements of butyl-terminated Ge nanoparticles prepared by the Zintl salt metathesis also showed approximately a 2-eV shift of the conduction band.<sup>[20]</sup> The XAS data do not rule out solvent-nanoparticle interactions, defects, or electronic transitions involving the butyl groups, but the resemblance of the XAS spectra of the nanoparticles to bulk Ge rather than

**Fig. 2** Size-selected photoluminescence spectra of butyl-terminated Ge nanoparticles. The figure legend labels the excitation wavelength of each spectrum. The wide range of photoluminescence wavelengths is due to a broad range of sizes for this sample.

**Fig. 3** High-resolution TEM image of butyl-terminated Ge nanoparticles. The lattice spacing is 3.27 Å, as expected for the  $\langle 111 \rangle$  face for bulk Ge.

Ge oxide or carbide supports quantum confinement as the primary cause of the large conduction band shift.

Transmission electron microscopy (TEM) is the most widely used size measurement for nanoparticles because diffraction and chemical information are available in tandem with the images obtained. High-resolution TEM (HRTEM) permits direct imaging of the lattice spacing of the nanoparticles, providing some composition information. The HRTEM micrograph in Fig. 3 of several Ge nanoparticles shows the  $\langle 111 \rangle$  plane of the crystallites, with a d-spacing of 3.27 Å,

as expected for bulk Ge. This lattice plane is both the easiest to image by HRTEM because of its relatively large d-spacing and the most commonly seen plane for a diamond cubic lattice. A phase change from diamond cubic to tetragonal has been predicted in Ge nanoparticles and observed in nanoparticles prepared in co-sputtered Ge/SiO<sub>2</sub> at diameters  $\leq 4$  nm.<sup>[21]</sup> However, no such phase change has been observed in Ge nanoparticles prepared colloiddally. There is no evidence for this cubic-to-tetragonal phase change in colloidal Ge nanoparticles.

An atomic force microscope (AFM) measurement of butyl-terminated Ge nanoparticles is presented in Fig. 4. The height measurements by AFM were performed in tapping mode, on colloid spin-coated onto mica substrates, which provided a nearly atomically flat surface. Another sample from this same preparation had a mean diameter of 6.5 nm by HRTEM compared with 6.1 nm by AFM. Because HRTEM imaging is based on interference<sup>[22]</sup> and will inherently overestimate the size of objects, some size difference is to be expected. The agreement between HRTEM and AFM measurements is surprising and suggests equiaxial, although not necessarily spherical nanoparticles.

The surface termination of Ge nanoparticles prepared from the Zintl salt metathesis is seen clearly in Fig. 5. This Fourier transform infrared (FTIR) spectrum of butyl-terminated Ge nanoparticles was obtained by evaporating a hexane colloid onto a CsI plate followed by heating to 120°C in air for 4 hr. The alkyl stretches and bends are clearly seen, while there is no evidence of GeO<sub>2</sub> in the spectrum. The absence of the broad, intense peak for GeO<sub>2</sub> at 870–940 cm<sup>-1</sup> in this FTIR spectrum does not rule out the presence of small amounts of surface oxide in the

**Fig. 4** Atomic force micrograph of butyl-terminated Ge nanoparticles with a mean height of 6.1 nm. The nanoparticles appear as small bright spots against the mica substrate.

**Fig. 5** FTIR spectrum of a film of butyl-terminated Ge nanoparticles on a CsI plate. The vibrations correspond closely to those of  $\text{Ge}(n\text{-C}_4\text{H}_9)_4$ .

nanoparticles. However, the ability to handle the nanoparticles in air and heat them for several hours at  $T > 100^\circ\text{C}$  demonstrates excellent surface termination.

## CONCLUSION

Most semiconductor nanoparticles are prepared by colloidal chemistry because of the superior optical properties and control of size distribution. Colloidal preparation of Ge nanoparticles is far more difficult than the compound semiconductors. The early colloidal preparation methods for Ge nanoparticles offered low yields and little or no control over size and surface termination. More current colloidal preparation methods offer better yields; nearly 80% of the Ge in the reaction was recovered in the inverse micelle synthesis, and yields as high as 60% have been obtained for the Zintl salt metathesis. The inverse micelle synthesis also permits good control over the size distribution, which is greatly enhanced by HPLC. The Zintl salt metathesis offers limited control over size distribution, but good control over surface termination, according to the choice of reagents used. While no perfect method for colloidal Ge nanoparticle preparation yet exists, progress continues in this area.

## ACKNOWLEDGMENTS

# Gold Nanoclusters: Structural Disorder

Ignacio L. Garzón

*Instituto de Física, Universidad Nacional Autónoma de México, Mexico City, Mexico*

## INTRODUCTION

One of the main goals of researchers working on Nanoscience and Nanotechnology is the design and the fabrication of nanostructured materials with novel and perhaps unexpected properties.<sup>[1]</sup> These systems are defined as materials constructed from structural elements (clusters, crystallites, or molecules) with dimensions in the range of 1–100 nm. The case of gold-based nanostructured materials has been especially relevant because of the potential applications in nanoelectronics<sup>[2]</sup> and in biological diagnostics.<sup>[3]</sup> An important contribution in this area was the self-assembly of two- and three-dimensional superlattices of nanometer-diameter gold particles linked to each other by organic interconnects.<sup>[4–6]</sup> Thiol-passivated gold nanoclusters, assembled in closed-packed arrays, showed interesting electronic transport properties, such as single-electron tunneling at room temperature, and are expected to be useful for the development of nanoscale electronics.<sup>[5,6]</sup> It was also shown that although the self-organization of nanoparticles is a powerful route to grow these materials, imperfections in the superlattice can result from incorrect chemical recognition between the constituents.<sup>[2]</sup> This can be a serious limitation in making nanostructured materials for electronic applications, where long-range order is important. On the other hand, biological systems are able to solve complex recognition problems. In particular, DNA transmits well-defined chemical information through the pairing properties of nucleotide bases. A major advance in controlling the self-assembly of metal particles was achieved by using oligonucleotides to organize colloidal gold nanoclusters into superlattices, allowing for the controlled growth of hybrid DNA-gold nanostructured materials.<sup>[7,8]</sup>

Although the main mechanisms to synthesize and to isolate hybrid DNA-gold nanostructured materials have been discovered,<sup>[7,8]</sup> further studies continue to fully characterize the structural, electronic, optical, transport, and other physical and chemical properties. This research represents a challenge for future investigations in Nanoscience and Nanotechnology because of the complexity of these materials, which are a complex mixture of inorganic and biological structures.<sup>[9]</sup> The first investigations toward a full characterization

of gold-based nanostructured materials have already begun. In a first stage, valuable information on the properties of each subsystem, metal particles and DNA, is being obtained. These separate properties will be fundamental in understanding the behavior of the hybrid materials.<sup>[9]</sup> Along this direction, theoretical and experimental information on the shape and morphology of bare and passivated gold nanoclusters will be fundamental to fully predict and understand their electronic, optical, and other physical and chemical properties. This information is essential to optimizing their utilization as building blocks of the new molecular nanostructured materials.

## OVERVIEW

The objective of this entry is to describe recent theoretical advances on the study of the shape and morphology of bare and passivated gold nanoclusters of different sizes. A detailed knowledge of the most stable structural configurations of these nanostructures is a very active field of research because the cluster geometries are the starting point to study their electronic, optical, and other physical and chemical properties, which are relevant for the design and fabrication of gold-based nanostructured materials. The main trend emerging from recent theoretical studies on structural optimizations of bare Au clusters in the size range up to 200 atoms indicates that many topologically interesting low-symmetry, disordered structures exist with energy near or below the lowest-energy ordered isomer.<sup>[10,11]</sup> Moreover, chiral structures have been obtained as the lowest-energy isomers of bare Au<sub>28</sub> and Au<sub>55</sub> clusters,<sup>[12]</sup> whereas in the size range of 75–212 atoms, defective Marks decahedral structures are nearly degenerate in energy with the ordered symmetrical isomers.<sup>[11,13]</sup> For methylthiol-passivated gold nanoclusters [Au<sub>28</sub>(SCH<sub>3</sub>)<sub>16</sub> and Au<sub>38</sub>(SCH<sub>3</sub>)<sub>24</sub>], structural relaxations have shown that the ligands are not only playing the role of passivating molecules, but their effect is strong enough to distort the metal cluster structure.<sup>[12,14]</sup> These predictions on the existence and the stability of disordered configurations for bare and passivated gold nanoclusters have opened the possibility of constructing gold-based nanostructured

materials, where the amorphous-like character of the gold nanoparticles could generate interesting electronic and optical behavior with potential nanotechnological applications.

In the next section, we briefly describe the theoretical methodologies utilized to study the structural properties of bare and passivated gold nanoclusters, as well as the existing experimental techniques that provide useful information to complement the structural characterization of these systems. The trends on the most stable geometries of bare and passivated gold nanoclusters are then discussed including a recent prediction on the existence of chirality in such systems. Finally, some concluding remarks are presented.

## THEORETICAL AND EXPERIMENTAL METHODOLOGIES

Several experimental studies have reported results on the properties of bare and thiol-passivated gold nanoclusters that constitute the building blocks of gold-based nanostructured materials. For example, structural information of bare and passivated gold nanoclusters of different sizes has been obtained using high-resolution transmission electron microscopy (HRTEM),<sup>[15–19]</sup> X-ray powder diffraction (XRPD),<sup>[20–23]</sup> scanning tunneling microscopy (STM),<sup>[24,25]</sup> and extended X-ray absorption fine structure (EXAFS).<sup>[26,27]</sup> Furthermore, optical spectrum measurements on the smallest gold particles (1–2 nm) have shown discrete electronic transitions indicating the existence of quantum size effects in these systems.<sup>[20]</sup> Despite the existence of these sophisticated experimental tools, several questions concerning the physical and chemical properties of bare and passivated gold nanoclusters remain unsolved or under debate.<sup>[9,11,12,14]</sup> For example, the current approach to determine nanocluster structures is based on the comparison between experimental HRTEM images<sup>[16,19]</sup> or XRPD and EXAFS structure factors<sup>[20,21,26]</sup> with those calculated from geometrical models of these nanostructures. However, the actual experimental resolution is not sufficient to resolve the broad features shown in the XPRD patterns,<sup>[21,23]</sup> neither have the HRTEM images<sup>[16,19]</sup> allowed for a clear discrimination of the atomic positions of gold nanoclusters in the size range of 1–2 nm.

An effective theoretical approach to determine the lowest-energy configuration (global minimum) and the structures of low-energy isomers (local minima) of clusters combines genetic algorithms and many-body potentials (to perform global structural optimizations over the cluster potential energy landscape),<sup>[9–12,28–32]</sup> with first-principles density functional theory (to confirm the stability and the energy ordering of the local minima).<sup>[9–14,33–36]</sup> This method has been recently

utilized to study the structural properties of bare and passivated gold nanoclusters. In the initial stage of this approach, global unconstrained structural optimizations of bare gold nanoclusters of different sizes are performed using semiempirical many-body potentials, such as the Gupta potential,<sup>[37,38]</sup> and a genetic-symbiotic algorithm.<sup>[29,31,39,40]</sup> With this procedure, it is possible to obtain the distribution of lowest-energy isomers in a range of potential energy values for each cluster size.<sup>[28,29]</sup> From this distribution, representative isomers such as those with the lowest energy are selected, together with those isomers that are considered good candidates to be the lowest-energy minima, based on the existence of well-known symmetric structures for certain cluster sizes such as the truncated octahedron, icosahedron, or decahedron configurations.<sup>[12]</sup>

In the second stage of this approach, the first-principles methods, which do not depend on empirical parameterizations and have a reliable predictive power, are used to locally reoptimize the representative isomers obtained at the first stage. Specifically, unconstrained relaxations are performed using the forces calculated from density functional theory (DFT) in the local density (LDA) and generalized-gradient (GGA) approximations. The DFT calculations are performed using scalar relativistic norm conserving pseudopotentials and numerical atomic orbitals<sup>[41]</sup> or plane waves<sup>[42]</sup> as basis sets. For these quantum mechanical calculations, the atomic coordinates of each cluster, obtained from the global optimizations realized at the first stage, are used as initial conditions for the DFT relaxations.

The lowest-energy structures of passivated gold clusters are obtained by performing local relaxations, using the forces calculated from the DFT–LDA–GGA first principles method, and starting from different cluster-ligands configurations.<sup>[9,11,12,14,43–48]</sup> These include the lowest energy bare gold cluster geometries obtained by the procedure described above, with the passivating molecules placed on different adsorption sites (top, bridge, and hollow), as well as on random positions over the metal cluster surface.<sup>[9,11,12,14]</sup> For passivated gold clusters, a global structural optimization, of the type mentioned above for bare gold clusters, is more difficult to perform because of the lack of adequate model potentials that describe appropriately the interaction between the metal cluster and the organic passivating molecules. Nevertheless, some calculations of this kind have been reported in connection with gold-based nanostructured materials.<sup>[49]</sup>

## STRUCTURAL PROPERTIES OF BARE GOLD NANOCLUSTERS

Extensive theoretical studies on the geometrical structures of the most stable isomers of bare gold clusters

have shown that these systems have interesting and perhaps unique peculiarities. For example, in the small-size regime ( $n \leq 13$ ), quantum mechanical calculations of neutral and charged gold clusters<sup>[34,36,50–54]</sup> indicate that the lowest-energy configurations correspond to planar (two-dimensional) structures. These results have been attributed to the non-additivity of the many-body forces existing in small noble metal clusters<sup>[50,51]</sup> and to the strong *sp-d* hybridization caused by the large relativistic effects present in the bonding and structure of gold clusters.<sup>[52,53]</sup> This planarity in the structures of small gold clusters is being considered as an important factor for the appearance of unusual catalytic activity, recently observed in these systems.<sup>[52,53]</sup>

In the intermediate-size regime ( $n = 12–55$ ), structural optimizations of  $Au_n$  clusters have shown that many topologically interesting low-symmetry, disordered structures exist with energy near or below the lowest-energy ordered isomer.<sup>[9–12,29,30,32,33,35,36,55]</sup> This is especially surprising because the calculations include “magic” cluster sizes for which very compact ordered structures exist. Fig. 1 shows the lowest-energy structures calculated for the  $Au_{55}$  cluster.<sup>[55]</sup> In this case, there are several amorphous-like structures, such as those shown in the three upper panels of Fig. 1, that have higher stability than the ordered icosahedral and cuboctahedral structures.

It was shown that the analysis of the cluster local stress can be used to understand the physical origin of the higher stability of disordered clusters with respect to their ordered isomers.<sup>[33,35]</sup> Specifically, it was found that the compact ordered structures are destabilized by the tendency of metallic bonds to contract at the surface because of the decreased coordination. The cluster amorphization is also favored by the relatively low energy associated with bond length and coordination disorder in metals.<sup>[33,35]</sup> Although these are the general effects of the metallic bonding, they are especially large in the case of gold because of the short range of the many-body forces existing in this system as compared with other metals.<sup>[55]</sup> The low spatial symmetry or lack of symmetry at all in the most stable configurations of intermediate-size gold nanoclusters opened the possibility of having distinct electronic and optical properties in such systems that are of interest for the fabrication of gold-based nanostructured materials.<sup>[10]</sup> In fact, the atomic disorder in the gold nanocluster structures is reflected in the broad features present in their vibrational and electronic density of states (DOS), as compared with the sharper structure found in the DOS corresponding to high-symmetry ordered structures.<sup>[10]</sup> Such differences could lead to distinct optical responses according to the cluster size and structural symmetry. Fig. 2 displays a comparison of different physical properties,

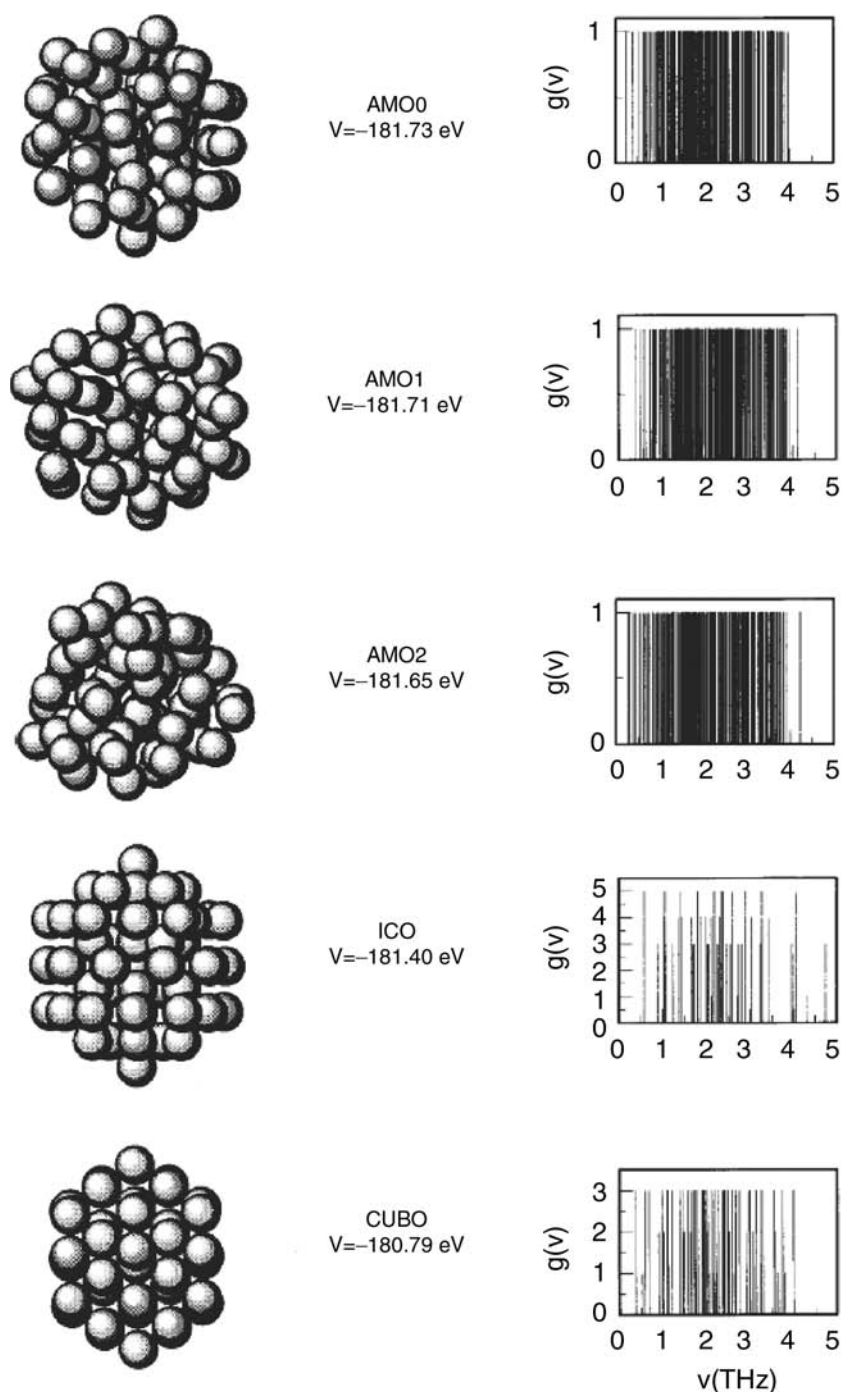

including the vibrational and electronic DOS, between disordered and ordered gold nanoclusters of different sizes.<sup>[10]</sup>

In HRTEM studies<sup>[56,57]</sup> on Au and Pd nanoparticles, images of polycrystalline and amorphous structures have been reported in the size range of a few nanometers, providing experimental evidence for the existence and the stability of disordered metal nanoclusters. Further experimental evidence in this direction was obtained through the qualitative agreement between the XRPD patterns measured for  $Au_{38}$  and  $Au_{75}$  clusters and those calculated using their disordered configurations.<sup>[28,29]</sup> It can be noticed in Fig. 3 the level of agreement with the experimental results between the structure factors corresponding to the disordered and ordered clusters. However, the above comparisons are not completely fair because the experimental samples corresponded to thiol-passivated gold nanoclusters, whereas the calculated structures corresponded to bare gold particles. In fact, an obvious question is what the effect is of the thiol-passivating monolayer on the physical and chemical properties of gold nanoclusters.

More recently, it was also found using DFT calculations that in larger gold nanoclusters ( $Au_n$ ,  $n = 75, 101, 146, 192,$  and  $212$ ), defective decahedral structures are nearly degenerate in energy with the highly symmetrical Marks decahedron isomer.<sup>[13]</sup> These results are in agreement with another experimental study on Au clusters of 2–4 nm in size, where complex and defective structures have been detected using XRPD.<sup>[23]</sup>

## STRUCTURAL PROPERTIES OF THIOL-PASSIVATED GOLD NANOCCLUSERS

Several theoretical studies have been performed to investigate the effect of thiol passivation on gold nanoclusters.<sup>[9,11,12,14,43–49]</sup> One approach consists of performing conjugate gradient structural DFT relaxations starting from different cluster-thiol monolayer configurations. Specifically, the  $Au_{28}$  and  $Au_{38}$  clusters coated with 16 and 24 methylthiol ( $SCH_3$ ) molecules, respectively, have been investigated.<sup>[9,11,12,14]</sup> These passivated gold clusters with diameters of 0.8 and 1.1 nm have been isolated and characterized by XRPD and other experimental techniques.<sup>[20,58]</sup> According to the DFT calculations performed on these passivated clusters, the effect of the thiol monolayer is strong enough to drastically distort the structure of the bare gold cluster. In one calculation, a truncated octahedron  $Au_{38}$  cluster (with fcc symmetry) was dramatically distorted upon relaxation with 24 methylthiol molecules, symmetrically positioned on the (111) facets close to the hollow sites.<sup>[14]</sup> The relaxed structure of the  $Au_{38}(SCH_3)_{24}$  cluster corresponds to a disordered,

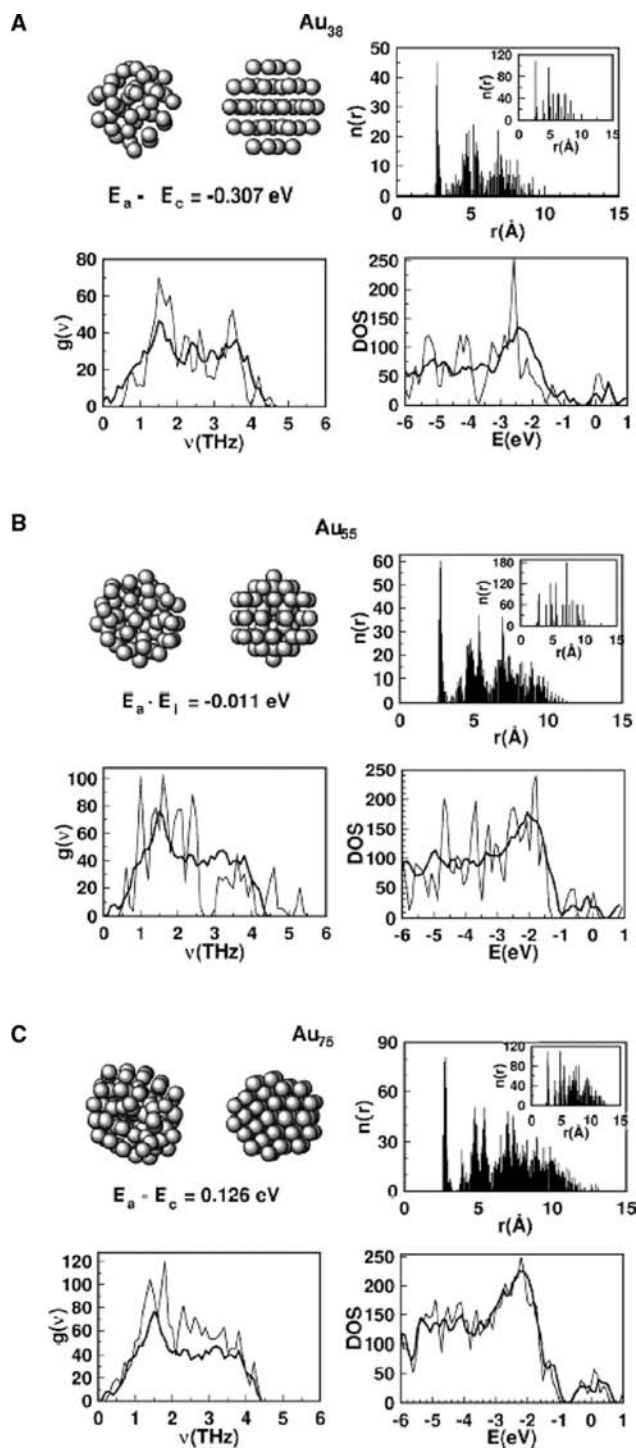

**Fig. 1** Left: stable isomers and their energies (in eV) of the  $\text{Au}_{55}$  cluster. The three upper configurations correspond to amorphous gold clusters. The cluster shown on the top was the lowest-energy configuration obtained in the optimization procedure. The icosahedron and octahedron structures are local minima with higher potential energy. passivated nanocluster where the sulfur atoms of the thiol heads are incorporated within the cluster surface. Fig. 4 shows the clearly separated gold and sulfur atomic shells of the fcc structure and their distortion and overlap in the disordered configuration.<sup>[14]</sup> Different patterns of charge transfer are expected to occur on this disordered, alloyed cluster surface.<sup>[14]</sup>

The lowest-energy structure obtained from DFT structural relaxations of  $\text{Au}_{28}(\text{SCH}_3)_{16}$  also corresponds to a highly disordered passivated nanocluster with an ill-defined gold–thiol interface.<sup>[12]</sup> It was obtained by

the relaxation of the lowest-energy disordered structure of the bare  $\text{Au}_{28}$  cluster, with the methylthiols placed close to three-atom hollow sites.<sup>[12]</sup> In the top panel of Fig. 5, the gold and sulfur atomic shells of the  $T$  structure and the most stable disordered configuration of the bare  $\text{Au}_{28}$  cluster are compared.<sup>[12]</sup> The bottom panel of Fig. 5 shows the gold and sulfur atomic shells for the most stable disordered configuration of the passivated  $\text{Au}_{28}(\text{SCH}_3)_{16}$  cluster.<sup>[12]</sup> From different DFT studies on thiol–gold cluster systems, it has been found that the main driving force

producing the metal cluster distortion is the gold-sulfur interaction.<sup>[45-47]</sup> This corresponds to a strong covalent-like (directional) bond between the sulfur atom of the passivating thiol and the gold atoms in the metallic cluster core.<sup>[45-47]</sup>

## CHIRALITY IN GOLD NANOCLUSTERS

Although most of the theoretical results mentioned above on the degeneracy in energy of amorphous or

**Fig. 4** Distances of the gold ( $i = 1-38$ ) and sulfur ( $i = 39-62$ ) atoms from the cluster center of mass for the  $\text{Au}_{38}(\text{SCH}_3)_{24}$  nanocluster in the disordered (closed circles and stars) and the truncated octahedron fcc (open circles and diamonds) structures. The inset shows the relaxed disordered structure. Sulfur atoms are depicted as darker spheres and only one  $\text{CH}_3$  group is shown. Source: From Ref.<sup>[14]</sup>.

disordered isomers with ordered structures for intermediate-size gold clusters have been obtained by several research groups,<sup>[9-14,28-33,35,36,55]</sup> and the calculated XRPD structure factors of the disordered gold clusters are in qualitative agreement with the experimental data,<sup>[28,29]</sup> direct confirmation of the existence of bare and thiol-passivated gold nanoclusters with low or no spatial symmetry has not been possible. This is mainly because of the lack of enough experimental resolution in HRTEM and XRPD measurements for cluster in the size range of 1–2 nm.<sup>[20,21]</sup> Nevertheless, a recent study using circular dichroism techniques found strong optical activity in the metal-based electronic transitions (across the near-infrared, visible, and near ultraviolet regions) of size-separated glutathione-passivated gold clusters in the size range of 20–40 atoms.<sup>[58]</sup> In this work, it was pointed out that the most plausible interpretation of these results is that the structure of the metal cluster core of the gold glutathione cluster compound would be inherently chiral.<sup>[58]</sup> Moreover, because the most abundant cluster in the experimental samples corresponds to the passivated cluster  $\text{Au}_{28}(\text{SG})_{16}$ , where SG denote the glutathione adsorbate, a chiral structure with  $T$  point group for the  $\text{Au}_{28}$  cluster was proposed.<sup>[58]</sup>

In earlier studies, several structural, vibrational, and electronic properties of disordered gold nanoclusters have been reported.<sup>[10-12,55,59]</sup> Although an initial quantification of the amount and type of local disorder present in amorphous-like structures of  $\text{Au}_{55}$  was obtained,<sup>[55]</sup> no attempt to theoretically investigate the existence of chirality in gold nanoclusters has been

**Fig. 5** Top panel: distances of the gold atoms from the center of mass and cluster geometry for the lowest-energy disordered [closed diamonds and inset (A)] and the  $T$  [open circles and inset (B)] isomers of the bare  $\text{Au}_{28}$  cluster. Bottom panel: distances of the gold (open diamonds) and sulfur (stars) atoms from the center of mass for the lowest-energy structure of the thiol-passivated  $\text{Au}_{28}(\text{SCH}_3)_{16}$  cluster. The closed diamonds denote the same gold atom distances as in the top panel. They are included to show at the same scale the degree of distortion and expansion of the gold metal cluster core upon passivation. reported. Very recently, a theoretical study on the existence and quantification of chirality in bare and thiol-passivated nanoclusters was published.<sup>[11,12]</sup> In this study, the asymmetrical structures corresponding to the lowest-energy configurations of several cluster sizes, obtained by the theoretical approach described above, have been analyzed to calculate their index of chirality.<sup>[11,12]</sup> This information is relevant for a proper interpretation of the circular dichroism measurements performed on glutathione-passivated gold nanoclusters.<sup>[11,12]</sup>

Because chirality is a geometrical property of the system, independent of its chemical and physical manifestations, it is possible to quantify chirality without reference to experimental measurements, but using

the inherent structural symmetry of the clusters. Although in recent years several approaches have been developed to measure chirality,<sup>[60,61]</sup> the Hausdorff chirality measure (HCM) has emerged as the general method of choice for the quantification of chirality.<sup>[62,63]</sup> Within this approach, the degree of chirality is found by calculating the maximum overlap between the actual molecular structure and its mirror image, using the Hausdorff distance between the sets of atomic coordinates. By rotating and translating one structure with respect to the other, the optimal overlap can be calculated. The HCM is a continuous and similarity-invariant function of the molecular shape and is zero only if the molecule is achiral.<sup>[62,63]</sup> The advantage of this approach is that its numerical implementation for large cluster sizes in a three-dimensional space is straightforward.<sup>[11,12]</sup>

The HCM for the lowest-energy structures of the bare and passivated gold nanoclusters can be calculated using their relaxed Cartesian coordinates measured with respect to the cluster center of mass.<sup>[11,12]</sup> Through an inversion operation, the coordinates of the mirror-image clusters are obtained. By calculating the maximum overlap between a given cluster and its mirror image, the HCM is obtained. This corresponds to the minimum value of the Hausdorff distance between the sets of atomic coordinates of both structures. To obtain the minimum Hausdorff distance, the mirror cluster is translated and rotated around the original cluster in the three-dimensional space generating different configurations. For each configuration, the Hausdorff distance with respect to the original cluster is calculated. The minimum of these values, normalized by the largest interatomic distance in the cluster, corresponds to the HCM.<sup>[11,12]</sup>

Chiral structures, with HCM values different from zero, have been obtained for the lowest-energy isomers of bare (Au<sub>28</sub> and Au<sub>55</sub>) and thiol-passivated [Au<sub>28</sub>(SCH<sub>3</sub>)<sub>16</sub> and Au<sub>38</sub>(SCH<sub>3</sub>)<sub>24</sub>] gold nanoclusters using the HCM approach.<sup>[11,12]</sup> For the lowest-energy isomers of bare Au<sub>38</sub> and Au<sub>75</sub> clusters, the HCM index of chirality is zero. These values are expected because the lowest-energy structures corresponding to these sizes have one plane of symmetry and therefore are achiral. By comparing the HCM index of chirality of bare and passivated gold nanoclusters, an interesting theoretical prediction,<sup>[11,12]</sup> to be confirmed experimentally, indicates that the effect of the passivating thiol monolayer is strong enough to distort the bare cluster geometry, producing chiral metal cores that give rise to intense chiroptical activity. This effect could change an achiral cluster into a chiral one as in the Au<sub>38</sub> case or increase the index of chirality in an already chiral structure as in the Au<sub>28</sub> cluster.<sup>[11,12]</sup>

The HCM values calculated for bare and passivated clusters have been compared with the corresponding values of other chiral nanostructures such as the D<sub>2</sub>-C<sub>78</sub> and D<sub>2</sub>-C<sub>84</sub> fullerenes. It shows that the chiral gold clusters are as chiral as those fullerenes.<sup>[11,12]</sup> However, it remains to be seen if clusters with different chirality can be detected experimentally. In this respect, circular dichroism spectroscopy seems to be an appropriate technique to study the above effect, as has been suggested by the optical activity measurements in passivated gold-glutathione cluster compounds.<sup>[58]</sup> At present, it is expected that novel and interesting properties emerge from the chiral character of metal clusters that could be useful for new applications.

## CONCLUSION

Along this entry, several trends and predictions on the most stable configurations of bare and passivated gold nanoclusters, obtained through a theoretical approach that incorporates “state-of-the-art” techniques,<sup>[39–42]</sup> have been discussed. The main conclusion emerging from these studies indicates the existence of many topologically interesting low-symmetry, disordered structures, nearly degenerate in energy.<sup>[9–14,28–36]</sup> Specifically, planar,<sup>[34,36,50–54]</sup> low-symmetry,<sup>[9–12,28–33,35,36,55,59]</sup> chiral,<sup>[11,12]</sup> and defective<sup>[13]</sup> structures have been obtained as the most stable configurations for bare gold clusters in the size range of 3–200 atoms. On the other hand, highly distorted structures were found for gold clusters with 20–40 atoms upon passivation with thiol monolayers.<sup>[9,11,12,14]</sup> Experimental techniques such as HRTEM,<sup>[16,56,57]</sup> XRPD,<sup>[23]</sup> and circular dichroism<sup>[58]</sup> have now been used to provide further evidence to support the above predictions.

The existence and the stability of disordered structures of bare and passivated gold nanoclusters have opened the possibility of using these amorphous-like nanostructures as building-blocks of gold-based nanostructured materials, where the nanoscale disorder may produce interesting behavior with potential nanotechnological applications. Although most of the results on disordered nanostructures described in this entry have focused on gold nanoclusters, other metals may have similar structural behavior as indicated by recent theoretical studies.<sup>[59]</sup> One important characteristic of the structural nanoscale disorder existing in gold clusters is that it is not a result of kinetic or temperature effects,<sup>[64]</sup> but of the complexity of the cluster potential energy landscape generated by the special bonding mechanisms involving Au atoms, where nonadditive,<sup>[50,51]</sup> relativistic,<sup>[52,53]</sup> and strong *sp-d* hybridization<sup>[52,53]</sup> effects are present.

# Gold Nanoparticles on Titania: Activation and Behavior

Jose A. Rodriguez

Chemistry Department, Brookhaven National Laboratory,  
Upton, New York, U.S.A.

## INTRODUCTION

Gold nanoparticles supported on titania show a high activity in many catalytic processes, including the oxidation of CO and the destruction of SO<sub>2</sub>. This is a remarkable phenomenon because surfaces of bulk metallic gold are not good catalysts. In recent years, many experimental and theoretical studies have been focused on understanding the high catalytic activity of gold nanoparticles supported on titania. Quantum effects related to the small size of the particles could be responsible for the enhancement in catalytic activity with respect to bulk gold, but it is becoming increasingly clear that interactions between the gold nanoparticles and the titania support plays a very important role. In this contribution, a review is presented of studies dealing with the behavior of a well-defined system such as Au/TiO<sub>2</sub>(110). The edge and corner sites of a gold nanoparticle (i.e., sites having three to four metal atom neighbors) can bond well adsorbates such as CO, O<sub>2</sub>, and SO<sub>2</sub>. They can even perform the catalytic oxidation of CO, but for more demanding reactions, the chemical activity of the isolated Au nanoparticles is not enough. A comparison of the DeSO<sub>x</sub> activity for the Au/TiO<sub>2</sub>(110) and Au/MgO(100) surfaces illustrates the important role played by gold–titania interactions. The titania support is not a simple spectator.

## CATALYTIC ACTIVITY OF BULK GOLD AND GOLD/TITANIA

Bulk metallic gold typically exhibits a very low chemical and catalytic activity.<sup>[1–4]</sup> Among the transition metals, gold is, by far, the least reactive and is often referred to as the “coinage metal.” Fig. 1 shows a valence photoemission spectrum for metallic gold.<sup>[5]</sup> The zero of binding energy represents the Fermi level of the system. States with Au 6s,p character appear from 0 to 2 eV, while the Au 5d states extend from 2 to 8 eV.<sup>[5]</sup> The low reactivity of metallic Au is a

consequence of combining a deep-lying valence 5d band and very diffuse valence 6s,p orbitals.<sup>[3,4,6]</sup>

In the last 10 years, gold has become the subject of considerable attention because of its unusual catalytic properties when dispersed on some oxide supports.<sup>[7–29]</sup> The Au/TiO<sub>2</sub> system is particularly interesting.<sup>[8,14–20,23,25,28,29]</sup> Gold particles supported on titania are active catalysts for the low-temperature oxidation of CO, as shown in Fig. 2. This phenomenon was originally discovered by Haruta and coworkers in the early 1990s,<sup>[8]</sup> and has been corroborated by many subsequent studies.<sup>[7,10,19,25,27,29]</sup> The exact catalytic activity of the Au/TiO<sub>2</sub> system depends on the method of preparation and the dispersion of the metal on the support,<sup>[8,10,25,29]</sup> but in general, Au particles with sizes between 2 and 4 nm display a catalytic activity for CO oxidation much larger than that of bulk metallic gold. New preparation methods aim for the synthesis of very small Au particles (<2 nm) with an extremely high catalytic activity.<sup>[25]</sup> The Au/TiO<sub>2</sub> systems lose catalytic activity over time as a consequence of the sintering of the Au particles.<sup>[8,25]</sup> The smaller the initial size of the particles, the more dramatic the negative effects of sintering.

Au particles supported on titania are also efficient catalysts for the complete oxidation of methane, the selective or partial oxidation of propene, the hydrogenation of CO and olefins, the reduction of NO with hydrocarbons, and the decomposition of SO<sub>2</sub>.<sup>[8,9,11,24,28–31]</sup> Depending on the conditions, Au/TiO<sub>2</sub> is a useful catalysts for the destruction of the three major contaminants produced during the combustion of fossil-derived fuels: CO, NO, and SO<sub>2</sub>.<sup>[8,29,31]</sup> Several models have been proposed for explaining the activation of supported gold:<sup>[8,10,17–19,23,29,31]</sup> ranging from special electronic properties resulting from the limited size of the active gold particles (usually less than 10 nm),<sup>[8,10,19,31]</sup> to the effects of metal–support interactions (i.e., charge transfer between the oxide and gold).<sup>[15,18,23,31]</sup> In principle, the active sites for the catalytic reactions could be located only on the supported Au particles or on the perimeter of

**Fig. 1** Valence photoemission spectrum for metallic gold. *Source:* From Ref.<sup>[5]</sup>.

the gold–oxide interface.<sup>[8,10,12,16,31]</sup> The Au/TiO<sub>2</sub>(110) surface appears as an ideal and well-defined system to examine some of these hypothesis in a controlled manner.<sup>[10,12,14–18,22,23,28]</sup>

## GOLD NANOPARTICLES ON TiO<sub>2</sub>(110)

Fig. 3 shows a schematic model for the (110) face of titania in its rutile phase. The surface exposes pentacoordinated Ti cations, while O atoms are present

**Fig. 2** Turnover frequencies for CO oxidation at 300 K on Au/TiO<sub>2</sub> as a function of the mean particle diameter of Au. *Source:* From Refs.<sup>[8]</sup> (curve a) and <sup>[29]</sup> (curve b).

**Fig. 3** Schematic model for the TiO<sub>2</sub>(110) surface. Dark spheres represent Ti atoms, while white spheres represent O atoms.

at in-plane and bridging positions. O vacancies are usually created by the removal of O atoms from bridging positions. Several studies indicate that gold grows on TiO<sub>2</sub>(110) epitaxially, forming two- or three-dimensional particles (Volmer–Weber growth mode).<sup>[10,12,16]</sup> The formation of two-dimensional (2-D) clusters has been detected only at low gold coverages [ $<0.2$  monolayers (ML)] and moderate temperatures ( $<350$  K).<sup>[10,16]</sup> Although, thermodynamically, gold would prefer to form three-dimensional (3-D) islands from the onset of growth, kinetic limitations constrain the growth initially to two-dimensional (2-D) islands.<sup>[16]</sup> The critical gold coverage for a 2-D  $\rightarrow$  3-D transition decreases with temperature, and increases with the defect density of the TiO<sub>2</sub> surface.<sup>[10,16]</sup> At elevated temperatures ( $\sim 750$  K), 3-D particles are usually present on the oxide surface, without encapsulation of the Au islands by Ti suboxides.<sup>[10,12,16]</sup>

Fig. 4 shows an image of scanning tunneling microscopy (STM) for 0.25 ML of Au on TiO<sub>2</sub>(110)

**Fig. 4** STM image for 0.25 ML of Au on TiO<sub>2</sub>(110). *Source:* From Ref.<sup>[10]</sup>.

after deposition of Au at 300 K and annealing at 850 K for 2 min.<sup>[10]</sup> The TiO<sub>2</sub>(110) surface consists of flat (1 × 1) terraces separated by monoatomic steps. The Au clusters are imaged as bright protrusions with a relatively narrow size distribution.<sup>[10]</sup> The clusters preferentially nucleate on the step edges of the TiO<sub>2</sub>(110) substrate and have an average size of ~2.6 nm in diameter and ~0.7 nm in height (two to three atomic layers). Studies of scanning tunneling spectroscopy (STS) indicate that the clusters have a small band gap (0.2–0.6 V) and electronic properties different from those of bulk metallic Au.<sup>[10]</sup> This is important, because such difference could be responsible for the variation in chemical activity when going from the nanoparticles to bulk gold.<sup>[10]</sup>

The nature of the interactions between Au and TiO<sub>2</sub>(110) has been examined in several theoretical studies.<sup>[15,17,18,23]</sup> In agreement with experimental observations, density-functional (DF) calculations show weak bonding interactions between Au atoms and stoichiometric TiO<sub>2</sub>(110). Au–Au bonds are stronger than Au–TiO<sub>2</sub> bonds, which explains the formation of mostly 3-D particles in Fig. 4. The results of STM and DF calculations show that Au adatoms prefer to interact with the O-vacancy sites present on the oxide support.<sup>[18,23,30]</sup> Theoretical studies<sup>[18,23]</sup> and photoemission measurements<sup>[15,23]</sup> indicate that the Au atoms bonded to these sites receive electron density from the oxide substrate. Fig. 5 displays Ti 2p photoemission spectra collected before and after dosing Au to a TiO<sub>2</sub>(110) surface.<sup>[23]</sup> The surface without gold (top) was initially annealed at 750 K for 2 min to induce the formation of O vacancies. In this way, one obtains a distribution of vacancies from the surface to the bulk of the sample. The Ti 2p spectrum for this system is well fitted<sup>[23]</sup> by a set of two doublets with p<sub>3/2</sub> components at 458.03 eV (Ti<sup>4+</sup>) and 455.96 eV (Ti<sup>3+</sup>). Under these conditions, the near surface region contains O vacancies with a density of ~7%. When Au is deposited on this surface at 300 K, the features between 454 and 456 eV gain relative intensity with respect to the main feature at ~458 eV and the resulting Ti 2p spectrum needs three doublets for a good fit (center of Fig 5). The p<sub>3/2</sub> components of these doublets appear at 458.06, 456.93, and 455.41 eV. The first peak is attributable to Ti<sup>4+</sup> cations, the last one corresponds to Ti<sup>3+</sup> species, and the middle one can be assigned to Ti<sup>3+</sup> ions weakly oxidized (Ti<sup>δ+</sup>) by interaction with Au.<sup>[23]</sup> Final annealing of the Au/TiO<sub>2</sub>(110) surface at 750 K produces a clear increase in the signal covering the 454–456 eV region because of a rise in the intensity of the Ti<sup>3+</sup> and Ti<sup>δ+</sup> peaks. This phenomenon is not a consequence of the oxidation of Au, or the evolution of O<sub>2</sub> into gas phase. It originates in the migration of O vacancies or Ti<sup>3+</sup> interstitial sites from the bulk to the surface of the oxide.<sup>[23]</sup> One has a

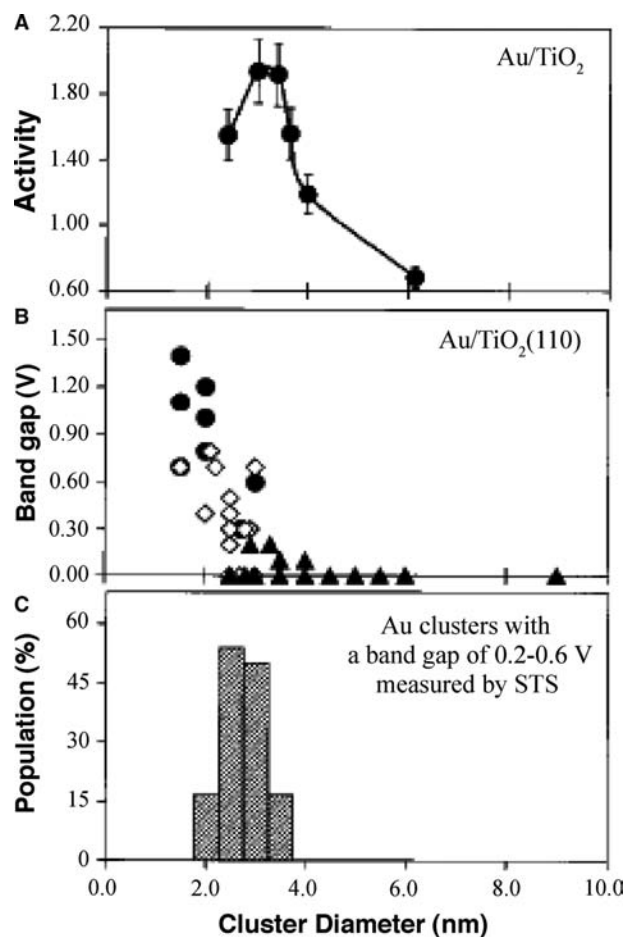

**Fig. 5** Ti 2p photoemission spectra taken before and after dosing 0.5 ML of gold to a TiO<sub>2</sub>(110) surface. In the first step, the clean oxide was annealed at 750 K, and then the top spectrum was recorded. This was followed by the dosing of Au at 300 K, middle, and final heating to 750 K, bottom. *Source:* From Ref.<sup>[23]</sup>.

complex situation, in which the admetal modifies the rate of exchange of defects between the bulk and surface of the oxide, and at the same time, the presence of O vacancies in the surface electronically perturbs the gold, probably making it more chemically active.

### OXIDATION OF CARBON MONOXIDE ON Au/TiO<sub>2</sub>(110)

High surface area Au/TiO<sub>2</sub> catalysts are very efficient for the oxidation of CO.<sup>[8,25]</sup> The top panel in Fig. 6 shows how the CO oxidation activity of a Au/TiO<sub>2</sub>(110) surface changes as a function of particle diameter.<sup>[10]</sup> There is a marked size effect on the catalytic activity, with Au clusters in the range of 3.5 nm exhibiting the maximum reactivity. For this size, most of the particles have a band gap of 0.2–0.6 V according to STS (Fig. 6B and C). Particles with a larger band gap (>1 V) display a lower reactivity, and particles with metallic character (band gap ~0 V) are the least active. Thus there is a correlation between the electronic and chemical properties of the supported Au

**Fig. 6** (A) The activity for CO oxidation at 350 K as a function of the Au cluster size supported on TiO<sub>2</sub>(110). (B) Cluster band gap measured by STS as a function of the Au cluster size supported on TiO<sub>2</sub>(110). (C) Relative population of the Au clusters that exhibited a band gap of 0.2–0.6 V as measured by STS. *Source:* From Ref.<sup>[10]</sup>.

nanoparticles. Studies of STM indicate that exposure to CO has no effect on the morphology of the Au/TiO<sub>2</sub>(110) surface.<sup>[10]</sup> On the other hand, significant morphological changes occur after exposure to O<sub>2</sub> or CO:O<sub>2</sub> mixtures. In these cases, the Au cluster density is considerably reduced as a result of sintering. The Au/TiO<sub>2</sub>(110) surfaces exhibit an exceptionally high reactivity toward O<sub>2</sub> at 300 K that promotes the sintering of the Au nanocrystallites.<sup>[10,14]</sup> This sintering eventually leads to a decrease in the CO oxidation activity of the Au/TiO<sub>2</sub>(110) systems.<sup>[10]</sup>

A transfer of electrons from the titania support to atoms in the Au nanoparticles could help to explain the high catalytic activity of Au/TiO<sub>2</sub><sup>[10,15,18]</sup> DF calculations have been used to study the CO oxidation process on an isolated (i.e., nonsupported) Au<sub>10</sub> cluster.<sup>[19]</sup> The results are summarized in Fig. 7. Two different reaction paths were considered: one where O<sub>2</sub> dissociates and one where adsorbed O<sub>2</sub> directly reacts

**Fig. 7** Calculated reaction profile for CO oxidation on a Au<sub>10</sub> particle. All energies are given with respect to CO and O<sub>2</sub> in gas phase. Black color, direct path; gray, indirect path. Thicker lines represent stable states, while thinner lines correspond to transition states. Light gray spheres represent Au atoms, dark spheres represent O atoms, and gray spheres represent C atoms. *Source:* From Ref.<sup>[19]</sup>.

with adsorbed CO. Both reactions were found to be extremely facile on the Au<sub>10</sub> particle, with reaction barriers of less than 0.4 eV indicating that the CO oxidation reaction should be possible well below room temperature.<sup>[19]</sup> This is contrary to the behavior found for a Au(111) surface. The small Au<sub>10</sub> cluster offers special geometrical configurations (corner and edge sites) that cannot be found on the extended surface.<sup>[19]</sup> The size and shape of the Au particle are important parameters. Also, the electronic structure of the Au atoms in the cluster is different from that of the Au atoms at the surface of a large crystal. The d states of Au<sub>10</sub> are 0.75 eV higher in energy than the d states of the surface atoms of an Au(111) surface.<sup>[19]</sup> These DF results show that an isolated Au nanoparticle could catalyze the oxidation of CO.

No theoretical study has been published examining the role of the oxide support during the oxidation of CO on Au/TiO<sub>2</sub>(110). Similar studies have been carried out in the case of the Au/MgO(100) system.<sup>[26,27]</sup> It appears that the smallest gold cluster that catalyzes the CO oxidation reaction is Au<sub>8</sub>.<sup>[26]</sup> A key aspect for the reactivity of this particle is its structural fluxionality that allows the adsorption and activation of O<sub>2</sub>.<sup>[26]</sup> DF calculations indicate that the active sites for CO oxidation on Au/MgO(100) involve low-coordinated Au atoms and Mg cations.<sup>[27]</sup> The oxide stabilizes a peroxolike intermediate, CO·O<sub>2</sub>, and then the oxidation reaction proceeds in the metal–oxide interface.<sup>[27]</sup> Such a reaction pathway is consistent with studies for Au/TiO<sub>2</sub> high-surface area catalysts,<sup>[31]</sup> which show that a strong contact between the Au

nanoparticles and oxide support is indispensable for high catalytic activity because the periphery sites probably carry out the oxidation of CO.

### DECOMPOSITION OF SULFUR DIOXIDE ON Au/TiO<sub>2</sub>(110)

Surfaces of metallic gold interact very weakly with SO<sub>2</sub> and the molecule desorbs intact at temperatures below 200 K.<sup>[23]</sup> Titania is the most common catalyst used in the chemical industry and oil refineries for the removal of SO<sub>2</sub> through the Claus reaction: SO<sub>2</sub> + 2H<sub>2</sub>S → 2H<sub>2</sub>O + 3S<sub>solid</sub>.<sup>[1,2,32]</sup> The main product of the adsorption of SO<sub>2</sub> on stoichiometric TiO<sub>2</sub>(110) are SO<sub>3</sub> and SO<sub>4</sub> species.<sup>[23,33]</sup> A substantial concentration of O vacancies on the oxide surface is necessary to induce the decomposition of SO<sub>2</sub> at high temperatures (>400 K). In contrast, Au/TiO<sub>2</sub>(110) surfaces fully dissociate SO<sub>2</sub> at room temperature.<sup>[23]</sup> Fig. 8 shows S 2p photoemission spectra for the adsorption of SO<sub>2</sub> on TiO<sub>2</sub>(110) and Au/TiO<sub>2</sub>(110) at 300 K. The Au/TiO<sub>2</sub>(110) surfaces were prepared following a procedure similar to that used to obtain the surface in Fig. 4.<sup>[10]</sup> The S 2p spectra indicate that upon adsorption of SO<sub>2</sub> on Au/TiO<sub>2</sub>(110), SO<sub>4</sub> and atomic

S (produced by the full dissociation of SO<sub>2</sub>) coexist on the surface. For the systems in Fig. 8, the larger the Au coverage on titania (0.05–0.5 ML range), the bigger the amount of atomic S deposited. This trend points to a direct involvement of gold in the dissociation of SO<sub>2</sub>. A large shift in the corresponding Au 4f core level spectra also supports this idea.<sup>[23]</sup>

Fig. 9 compares S 2p areas measured for atomic S after dosing the same amount of SO<sub>2</sub> to Au/TiO<sub>2</sub>(110) and Au/MgO(100) surfaces at 300 K.<sup>[28]</sup> Neither TiO<sub>2</sub>(110) nor MgO(100) is able to dissociate SO<sub>2</sub> on their own. On both oxide supports, the largest activity for the full dissociation of SO<sub>2</sub> is found in systems containing Au coverages smaller than 1 ML when the average diameter of the nanoparticles is below 5 nm.<sup>[10,28]</sup> Clearly, the Au/TiO<sub>2</sub>(110) systems are much more chemically active than the Au/MgO(100) systems. Catalytic tests also show that Au/TiO<sub>2</sub> is substantially more active than Au/MgO for the Claus reaction or the reduction of SO<sub>2</sub> with CO.<sup>[23,28]</sup> These data indicate that titania either play a direct active role in the dissociation of SO<sub>2</sub> or modifies the chemical properties of the supported Au nanoparticles.

DF calculations have been used to examine the adsorption of SO<sub>2</sub> on Au(100) and a series of clusters: Au<sub>6</sub>, Au<sub>8</sub>, and Au<sub>14</sub>.<sup>[28]</sup> Very weak bonding interactions were observed on the extended Au surface with adsorption energies smaller than 0.15 eV. On the other hand, the corner atoms in the Au clusters were able to interact reasonably well with SO<sub>2</sub>, giving adsorption energies of 0.43–0.65 eV. However, none of the isolated clusters was able to dissociate the SO<sub>2</sub> molecule. The DF calculations indicate that such a process is very

**Fig. 8** S 2p photoemission spectra for the adsorption of SO<sub>2</sub> on TiO<sub>2</sub>(110) and Au/TiO<sub>2</sub>(110) at 300 K. *Source:* From Ref.<sup>[23]</sup>.

**Fig. 9** Relative amounts of atomic S formed by the full dissociation of SO<sub>2</sub> on Au/MgO(100) and Au/TiO<sub>2</sub>(110) surfaces at 300 K. Each surface was exposed to the same amount of SO<sub>2</sub>. The S coverage is assumed to be proportional to the area under the corresponding S 2p XPS features. *Source:* From Ref.<sup>[28]</sup>.

endothermic on Au<sub>6</sub>, Au<sub>8</sub>, and Au<sub>14</sub>.<sup>[28]</sup> One of the most favorable cases found is shown in Fig. 10.<sup>[28]</sup> The adsorption of SO<sub>2</sub> on the Au<sub>14</sub> particle is an exothermic process but, upon heating, the molecule should desorb instead of dissociating. The chemistry observed experimentally for SO<sub>2</sub> on Au/MgO(100) seems to reflect mainly the intrinsic reactivity of Au nanoparticles with the oxide support playing only a minor role.<sup>[28]</sup>

Variations in the strength of metal–support interactions are probably the key to the large difference in chemical activity seen in Fig. 9 for Au/MgO and Au/TiO<sub>2</sub>. During the preparation of the active Au/TiO<sub>2</sub>(110) surfaces, the system is annealed to temperatures as high as 700–750 K to induce the formation of O vacancies and migration of bulk defects to the surface of the oxide.<sup>[23]</sup> Au particles like to interact with O vacancies,<sup>[15,18,23,30]</sup> and on these adsorption sites an oxide → gold charge transfer has been predicted from theoretical studies<sup>[15,18,23]</sup> and X-ray photoelectron

spectroscopy (XPS) measurements.<sup>[10,15,23]</sup> The active Au/TiO<sub>2</sub>(110) surfaces combine electronically perturbed Au atoms and an oxide substrate with a significant amount of defects. Both factors probably contribute to the high activity of these surfaces for the dissociation of SO<sub>2</sub>.<sup>[23]</sup> DF calculations for SO<sub>2</sub>/Au/TiO<sub>2</sub>(110) systems show several bonding conformations in which Au- and O-vacancy sites work in a cooperative way to dissociate the SO<sub>2</sub> molecule.<sup>[23]</sup> Thus the active sites should be at the Au–TiO<sub>2</sub> interface. In the case of MgO(100), the formation of O vacancies is a highly endothermic and difficult process.<sup>[34]</sup> In the Au/MgO(100) surfaces, a negligible number of O vacancies is expected and this probably leads to a low activity for the dissociation of SO<sub>2</sub>.

## CONCLUSION

Gold nanoparticles supported on titania show a high activity in many catalytic processes not seen for bulk metallic gold or titania. Quantum effects related to the small size of the particles could be responsible for the enhancement in catalytic activity with respect to bulk gold. The edge and corner sites of a gold nanoparticle have distinctive electronic properties and can bond well adsorbates such as CO, O<sub>2</sub>, and SO<sub>2</sub>. They can even perform the catalytic oxidation of CO, but for more demanding reactions, it is becoming increasingly clear that interactions between the gold nanoparticles and the titania support can play a very important role in determining chemical activity.

**Fig. 10** Bottom: Diagrams showing an isolated Au<sub>14</sub> cluster and the cluster with the SO<sub>2</sub> molecule bonded. The molecule is bonded via the oxygen atoms ( $\eta^2$ -O,O). Each oxygen atom is bonded to a corner site of the Au<sub>14</sub> cluster. Top: Change in energy for the dissociation of a SO<sub>2</sub> molecule on the Au<sub>14</sub> cluster. The zero of energy corresponds to an initial state with SO<sub>2</sub> and the Au<sub>14</sub> separated. Then, the SO<sub>2</sub> molecule is adsorbed in the configuration shown at the bottom of the figure. This is followed by cleavage of a S–O bond, and at the end, the molecule is fully dissociated into one S and two O atoms. *Source:* From Ref.<sup>[28]</sup>.

## ACKNOWLEDGMENTS

The author would like to thank Profs. D.W. Goodman, M. Haruta, and J. Nørskov for kindly allowing the reproduction of figures from their work. Many of the studies described here were done in collaboration with Z. Chang, J. Dvorak, J. Evans, L. González, J. Hrbek, F. Illas, T. Jirsak, G. Liu, A. Maiti, M. Pérez, and J.M. Ricart. I am very grateful to all of them. This research was supported by the U.S. Department of Energy, Division of Chemical Sciences.

# Guests within Hydrophobic Pockets: Conventional Synthesis

**Bruce C. Gibb**

*Department of Chemistry, University of New Orleans,  
New Orleans, Louisiana, U.S.A.*

## INTRODUCTION

According to Cram, a “guest” is a molecule or ion that possesses divergent binding sites, while a “host” is a molecule containing convergent binding sites.<sup>[1]</sup> The combination of the two is a host–guest complex, an incredibly large number of which have been identified and studied. The paradigm of “guests within large synthetic hydrophobic pockets” represents a small subset of host–guest chemistry. Hence, using the adverb “within” limits the discussion to systems in which the (smaller) guest can actually reside inside the host. Likewise, the adjective “large” narrows the coverage further by focusing on sizable cavities that by the laws of physics bind sizable guests. In this review, “sizable guests” refers to those of at least seven non-hydrogen atoms. The term “hydrophobic” is used to focus only on organic guest molecules undergoing solution phase complexations. Finally, and perhaps most importantly, the term “pocket” narrows the review somewhat to focus on hosts that possess well-defined, highly concave surfaces or enclosed surfaces. An arbitrary value of greater than approximately 50% encapsulation has been set. Thus, crown ethers and other “2-D” macrocycles, as well as simple resorcinarenes, calixarenes, and other bowl-shaped cavities do not fall within the purview of this work. Although setting the bar at this height is undoubtedly subjective, it seems reasonable, bearing in mind that the general movement of the field is toward greater “percent encapsulation” and maximal guest control. Finally, one more proviso must be added. The general topic of hosts binding guests within hydrophobic pockets have been reviewed—albeit in several separate contributions—within the major publication, *Comprehensive Supramolecular Chemistry*.<sup>[2]</sup> This review is therefore primarily interested with the literature since this publication.

For chemists, the underlying rationale for placing molecules or guests within synthetic hydrophobic pockets is straightforward: control. Chemists are interested in placing guest molecules within hydrophobic pockets to gain complete control of the immediate

environment around the guest molecule. Why do this? There is a variety of potential applications: protecting the guest from reacting with the surrounding environment, or at the opposite extreme, orchestrating non-covalent or covalent interactions to affect a precise conversion of the guest into a product. Alternatively, the goal may be to bring about a change in the host so that the guest can be detected. These applications—storage/delivery, catalysis, and detection—are powerful motivators for the field of host–guest chemistry in general.

There are three ways in which synthetic hydrophobic pockets can be synthesized. First, they can be constructed in a method analogous to the way Nature does it. In other words, a polymer can be folded into a distinct conformation that possesses the required cavity. At the moment the protein-folding problem is just that, a problem. Consequently, the normal way to build a cavity using polymers is to use one with relatively few conformational degrees of freedom so that some preferred conformation is “guaranteed.” Because there is a distinct qualitative difference between a well-defined hydrophobic pocket and the microenvironment within a dendrimer, dendrimers do not fall under the auspices of this review. Instead, we will focus on systems that possess one principle conformation to define their hydrophobic cavity.

The second approach is to use conventional synthetic techniques and build up the hydrophobic pocket, “brick-by-brick.” This circumnavigates the problem of protein folding and in theory allows precise control of the shape of the cavity. No approach is perfect, however, and this strategy suffers from the problem of hydrophobic pocket collapse. By constructing a “mere” shell to define the pocket, it is hard to build into it design elements that inhibit collapse. The conformational minimum of the target must possess the desired cavity.

The third approach is to use self-assembly. This strategy is treated in a separate review titled “Guest Within Large Hydrophobic Pockets: Synthesis Using Self-Assembly.”

## THE POLYMER APPROACH

The term “foldamer” has been used by Gellman to describe any polymer with a strong tendency to adopt a specific conformation.<sup>[3]</sup> From a hydrophobic pocket perspective, polymers get interesting when they adopt specific conformations that engender a hydrophobic pocket. As we shall see, some polymers need only possess local conformational preferences, or what is called defined secondary structure, to create a pocket. On the other hand, many foldamers cannot form a suitable pocket from secondary structure alone, and these elements of secondary structure must combine to form a tertiary structure. Unfortunately, to date no synthetic polymer with a defined tertiary structure analogous to a compact folded protein has been synthesized. Not that this is a problem if your interests lie out with hydrophobic pocket design. For example,  $\beta$ -peptides, foldamers built from  $\beta$ -amino acids such as *trans*-2-aminocyclohexanecarboxylic acid **1**, or  $\beta$ -homo amino acids **2**, have been intensively studied.<sup>[3–6]</sup> These investigations revealed unusual protease-resistant peptidomimetics,<sup>[7]</sup> novel inhibitors of fat and cholesterol absorption,<sup>[8]</sup> and new antibiotics.<sup>[9]</sup> Other polymer systems with exciting possibilities, including vinylogous peptides **3**,<sup>[10]</sup>  $\beta$ -sulfonepeptides **4**,<sup>[11,12]</sup> and aedamers **5**,<sup>[13–15]</sup> have also been investigated, but if hydrophobic pockets are your goal then more time is needed to develop variations on these themes that possess tertiary structure.

**1****2****5****3****4**

A central theme of the Moore group is the development of foldamers that form hydrophobic pockets.<sup>[16–18]</sup> Thus, all-*meta* phenylacetylene oligomers **6** have been shown to fold into distinct helical conformations when  $n > 8$ . The formation of secondary structure, driven in part by nonspecific solvophobic forces, engenders a cylindrical cavity the length of which is dependent on the number of residues in the polymer. Fig. 1 shows a space-filling model of the polymer ( $n = 18$ ), where the side chain ester groups have been “reduced” to methyls. The binding properties of the corresponding 12-mer have been investigated.<sup>[18]</sup> In mixed water/acetonitrile, the polymer exists as a pair of helical enantiomers (P and M) that possess the requisite pocket for binding small bicycles such as (–)- $\alpha$ -pinene **8** or (+)- $\beta$ -pinene **9**. The binding constants for several enantiopure, chiral guests were recorded at between 1790 and 6830 M<sup>-1</sup>. Each of these  $K_a$ s represent an amalgam of the association constants for the diastereomeric complexes formed when the chiral guest forms a complex with the two helices, e.g., **8**-P and **8**-M. Interestingly, the molecular volume of these guests corresponds to about 55% of the volume of the pocket, a criterion for binding suggested by Rebek.<sup>[19]</sup> Circular dichroism (CD) spectroscopy demonstrated that the ratio of each pair of diastereomeric complexes varied considerably with only small changes in the structure of the guest. Thus, **8** was 20 times more selective for

Fig. 1 Perpendicular views of the 18-mer of polymer 6.

one helical enantiomer than **9** was, even though the association constants were very similar. The dynamic nature of these hosts was emphasized by determining the association constants for the same guests to polymer **7**. Although the methyl groups in this derivative essentially fill its pocket, the association constants for the bicycles examined decreased only by two orders of magnitude. In contrast, such changes to less conformationally flexible hosts generally cause a more dramatic drop in association constants.

Larger guests can be incorporated into longer *meta*-phenylacetylene polymers. Hence, the association constants between rodlike guest **10** and a range of polymers ranging in length from a 10-mer to a 24-mer

have been determined.<sup>[17]</sup> In these studies, the 10-mer proved to be the weakest host ( $K_a = 5600 M^{-1}$ ), with binding increasing rapidly to 30 times this level for the 20-mer and 22-mer. Binding was weaker for slightly larger hosts. However, even larger *n*-mers will be required to confirm that maximal binding occurs in the region of  $n = 20$  or 22. The volume of guest **10** was calculated to be 58% of the volume of the pocket of the 22-mer, again suggesting that at least to a first approximation, a cavity should be between 1.5 times and twice the volume of the intended guest for maximal binding.

## THE SYNTHESIS APPROACH

In the earlier days of host design, the diversity of approaches to synthesizing hosts was inspiring. The field “scanned” the different possible approaches to host architectures to identify workable systems of molecular curvature. Phase II, for want of a better phrase, built on those systems that proved to be the most utilitarian, those that were easily synthesized and easily adapted. Thus, the bulk of the literature concerning the synthesis of hydrophobic pockets since 1995 has focused in relatively few systems. These are described below.

In 1983, Cram proposed the concept of a molecular container.<sup>[20]</sup> He suggested hypothetical structure **11** as an interesting possible target. An important design feature of **11** is that it cannot readily collapse. Just as an architect must use the known gamut of architectural rules to build, say a dome, so a chemist must carefully choose the different hybridization states and connectivities of the atoms involved to synthesize a cavity that cannot collapse under its own “weight.” The target must be conformationally flexible to bestow it with reasonable solubility and recognition properties, and unless the idea is to permanently entrap a guest, the shell of the cavity must possess at least one portal. At the same time, however, the cavity-possessing

conformer must be at, or close to, the thermodynamic minimum. Since this seminal paper, advances in molecular host design has progressed to the point that new entrants to the field have a range of starting materials with which to induce molecular curvature. Of these different kinds, arguably the two richest sources of molecular curvature are the calixarenes<sup>[21–24]</sup> **12** ( $R =$  various,  $n = 4–20$ ) and the resorcinarenes<sup>[1,23,25]</sup> **13** ( $n = 4$ ). In terms of general utility to supramolecular chemistry, the former has proven most engaging, primarily because they are available in a larger range of sizes. However, for the construction of large hydrophobic pockets the resorcinarenes have perhaps proven of greater utility.

**12****13**

Many of the larger hosts that have been synthesized are obtained by combining multiple copies of molecular subunits in self-assembly processes. These are discussed in the aforementioned accompanying paper. Here the focus is on hosts derived from calixarene or resorcinarenes, as well as other hosts such as the cucurbiturils, which are formed via traditional synthetic means. Note that this is a subjective means of demarcation. If self-assembly is considered in terms of probability,<sup>[26]</sup> cucurbiturils, calixarenes, and resorcinarenes themselves could also be discussed under the banner of self-assembly. Their placement here is the result of their nomenclature; cucurbiturils are considered as monomers, not  $n$ -mers, of glycoluril and resorcinarenes are considered as monomers, not as  $n$ -mers, of resorcinol, etc.

### Hosts Based on Resorcinarenes

Resorcinarenes have themselves been used as hosts for sugars and *bis*-carboxylic acids.<sup>[27–30]</sup> However, the cavity of these hosts is too small to encapsulate large guest molecules. One way to increase the cavity is to add long chains to each phenol oxygen. This produces a poorly preorganized cavity that we will review only

briefly. Hence, by attaching sugar chains to resorcinarenes, the Aoyama group has generated a series of hosts that bind large molecules.<sup>[31–33]</sup> Water-soluble host **14** can bind both nucleotides and 8-anilino-naphthalene-1-sulfonate (ANS). In the latter case, if a quartz plate is immersed in a solution of ANS and the host, the complexed guest is delivered to the quartz surface by the host, as it irreversibly binds. Similar systems have also been used to deliver guests to proteins.<sup>[31]</sup>

**14****15****16**

To synthesize cavities that are more preorganized, the phenol groups of resorcinarenes must be “bridged” to form cavitands, molecules possessing rigid, enforced cavities. The first attempt at bridging was with bromochloromethane and 2,3-dichloro-1,4-diazanaphthalene to give, respectively, **15** and **16** ( $R = \text{Me}$ ).<sup>[34]</sup> Although capable of binding guests,<sup>[35]</sup> the cavity of the former is still rather small. However, the cavity of **16**, the first example of what can be termed a deep-cavity cavitand,<sup>[36]</sup> is capable of binding large guests. One of the obstacles to confirming this point was solubility. Thus, longer “feet,” the  $R$  groups in structure **16**, were appended to these cavitands to bestow them with

by a porphyrin, also bound suitably shaped guests. Studies revealed that a rod-shaped guest, with an adamantyl group at each end and a pyridine moiety in the center, bound strongly. Interestingly, binding was only slightly stronger than with guests possessing only two (pyridine and adamantyl) recognition points, suggesting that perhaps for entropic reasons the second adamantyl group did not contribute significantly to binding. Host **20** can also form ternary complexes by binding two guests. Variations on this theme of two deep-cavity cavitands tethered together to make a large, nanoscale cavity have also been investigated.<sup>[55,56]</sup>

Most recently, these types of cavitands have been modified to include other metal ion binding sites. Cavitand **21** is one such example capable of binding amines that coordinate to the zinc center.<sup>[53]</sup> Going one step further, Gibson and Rebek have also investigated a cavitand that promotes allylic alkylations.<sup>[54]</sup> This palladium(0) cavitand, complex **22**, was shown by mass spectrometry to be capable of subtly discriminating among various allyl acetates of general structure  $R'\text{CH(OAc)CHCH}_2$ . As a result, the rate of 1,4-addition to these substrates, using the conjugate base of dimethyl malonate as nucleophile, was dependent on the nature of the hydrocarbon  $R'$  group.

Scheme 1 Synthesis of deep-cavity cavitand **25**.

In the aforementioned examples, hydrogen bonding constrained the aromatic rings in the “second row” to conformations that defined a hydrophobic pocket. An alternative way to preorganizing deep-cavity cavitands is to add a further covalent link between the aromatic rings in the second row. One way that this has been accomplished is to first bridge resorcinarenes with benzal bromides.<sup>[57–59]</sup> The resulting cavitands such as **23** are amenable to a range of strategies for preorganizing their hydrophobic pockets. One approach is to perform an eightfold Ullman ether reaction on octabromide **24** with *bis*-nucleophiles such as resorcinol (Scheme 1).<sup>[60]</sup> The resulting series of hosts, e.g., **25**, possesses highly preorganized cavities that are ca. 1 nm in diameter and depth and capable of binding guests as large as adamantane and camphor derivatives. One of the more significant non-covalent interactions that can form between host and suitably appended guest are C–H···X–R hydrogen bonds.<sup>[60–63]</sup> Each of the benzal hydrogens at the base of the cavity is electron deficient, and the geometry of the array is such that halogen atoms on a guest can fit within it. This is especially true for iodine groups, which snugly fit within the crown and interact with all four benzal hydrogens simultaneously. As a result, guests such as iodoadamantane bind strongly ( $\Delta G^\circ -7.3 \text{ kcal mol}^{-1}$ ) in non-competitive solvents such as DMSO. Binding of such highly complementary guests is enthalpically driven. Smaller guests—down to bromocyclobutane—also bind if DMSO is used to study complexation.<sup>[61,64]</sup>

These hosts cannot undergo a “flowering process” to release their guests. Consequently, those guests that are highly complementary to the shape of the cavity exchange in a dissociative mechanism that is slow on the (500 MHz) NMR timescale.<sup>[65]</sup> On the other hand, the small weaker binding guests undergo exchange much more rapidly.

It is relatively straightforward to modify these hosts by dangling functional groups from the rim of the pocket. These can control what type of guest binds in the pocket, how the guest is oriented once inside, and if several orientations are available to the guest, the equilibria between the different isomeric complexes.<sup>[65]</sup> The placement of a methyl group at the rim greatly decreases the strength of association between the resultant host **26** and adamantyl guests. Indeed, binding to **26** is completely shut down if the adamantane guest is so shaped that a substituent is forced to impact the methyl group on the wall of the cavity. On the other hand, host **27** is selective for guests that can form salt bridges or hydrogen bonds with the phenol group. In these situations, the guest binds functional group up. Finally, placing four methyl groups at the rim of cavity drastically alters the properties of the pocket. Thus, tetramethyl cavitand **28** binds halocycloalkanes as large as bromocycloheptane but has a strong preference for halocyclopentanes.<sup>[61]</sup>

A third way in which cavitands can be deepened is to directly add a new layer of moieties to the 3-position of the resorcinol rings. This strategy<sup>[66]</sup> allows cavitands such as *tetra*-amidinium **29** to be synthesized.<sup>[67]</sup> By necessity, the second row of aromatic rings must be at right angles to the first. This makes for a rather

open cavity, which in this case can bind a variety of nucleotides.

### Hosts Based on Calixarenes

Although calixarenes **12** ( $\text{R} = \text{various}$ ) as large as 20-mers have been synthesized and characterized,<sup>[68]</sup> the larger examples are too “ropey” to construct discrete hydrophobic pockets. The smaller calixarenes are capable of binding guests if they are constrained in the cone conformation, a task readily accomplished by the alkylation of the phenols with groups of sufficient size to inhibit the interconversion between the different possible conformations. As was the case with resorcinarenes, simple calixarene hosts are ideally suited for complexing relatively small guests, with some of the most recent endeavors focusing on the development of concave reagents and enzyme mimics.<sup>[69–75]</sup> Readers interested in these examples and the bigger calixarene picture are directed to an excellent resource.<sup>[23]</sup>

Extending the cavity of calixarenes by attaching amino acids or sugars to their rim leads to a range of fascinating hosts on the verge of this summary. These hosts have been recently reviewed.<sup>[76]</sup> Adding a “roof” to such derivatives makes for a much more defined pocket that can encapsulate guests more fully. By way of example, **30** has been characterized by solution and solid-state techniques and has been shown to bind benzoate ions and N-acyl amino acid derivatives with  $K_{\text{a}}$ s up to  $44,000 \text{ M}^{-1}$ .<sup>[77]</sup> Examples where cavitands<sup>[78]</sup> or porphyrins<sup>[79]</sup> have been used as roofing material have also been reported. As expected, the zinc-containing derivatives of the latter hosts bind Lewis basic guests such as 4-methylpyridine.

Perhaps the most common approach to synthesizing large hydrophobic pockets using calixarenes is to join two or more calixarenes together. Saadioui and Böhmer have recently written an excellent review on this topic.<sup>[80]</sup> The most common strategies are to join two calixarene “hemispheres” via either one or two linking groups. We focus here on illustrative examples

that show a high degree of guest encapsulation. For a more comprehensive review of covalently linked polycalixarenes, readers are directed toward the latest calixarene compendium.<sup>[23]</sup>

Turning first to singly linked calix[4]arenes, compound **31** (Fig. 2) binds methylpyridinium and methylquinolinium guests.<sup>[81]</sup> Binding is strongest for methylpyridinium iodide ( $K_{\text{a}} = 480 \text{ M}^{-1}$ ) while NMR shift data suggest that methyl quinolinium iodide is a little too large to be fully included into the  $\pi$ -rich cavity.<sup>[81]</sup> Related hosts,<sup>[82]</sup> including those from the Arduini group in Parma,<sup>[83]</sup> show similar binding profiles. For example, the olefin-linked calixarene **32** also binds pyridinium and quinolinium guests.<sup>[82]</sup> In contrast, directly connecting calix[4]arenes with an aryl–aryl bond reduces the size of the cavity so that only methylpyridinium species may bind.<sup>[84]</sup> Linking the two hemispheres together with a ferrocenoyl group generates host **33**, capable of sequestering benzoate ions. In this case the aromatic ring binds into the hydrophobic cavity, while the carboxylate group interacts with the ferrocenoyl linker.<sup>[85]</sup>

*Bis*-linked calix[4]arenes have more preorganized cavities. Two related examples are **34** and **35** (Fig. 3), both of which are capable of binding methylpyridinium and methylquinolinium guests.<sup>[86,87]</sup> As anticipated, the binding of methylpyridinium iodide to **34**

**30**

**31:**  $\text{X} = \text{CH}_2$

**33:**  $\text{X} =$

**32:**  $\text{X} = \text{CH}=\text{CH}$

**Fig. 2** Mono-linked *bis*-calixarenes.

Fig. 3 Bis-linked bis-calixarenes.

is stronger than its association to **31**. Additionally, unlike host **32**, exchange of *N*-methyl- $\gamma$ -picolinium iodide and other guests into and out of the cavity of **34** is slow on the (500 MHz) NMR timescale. It is less feasible for the host to adopt a conformation possessing a large portal for guest entry or egression. NMR peak shifts of the guest suggest that it is predominantly in an orientation in which the methyl group protrudes out of the cavity at the “equator” of the host. The larger cavity of **35** does not bind pyridinium guests strongly. Instead, its preferences are for methylquinolinium guests. Furthermore, because of the larger portals in the host the kinetics of guest exchange are faster than in **34**.

A series of bis-calixarenes with larger and more open cavities has been reported by Kim's group.<sup>[88,89]</sup> In this work, several bis-calixarenes with aromatic linkers were investigated for their ability to bind viologens and other bis-pyridinium derivatives. In this regard, one of the best hosts was bis-thiophene **36** (Fig. 3).

Calix[5]arenes or larger are capable of binding fullerenes. Indeed, the early successes in developing facile means of C<sub>60</sub> purification<sup>[90,91]</sup> resulted in a flurry of activity as analogous methods for purifying other fullerenes were sought. Many open hosts consisting of one calixarene moiety have been investigated, as a recent review by Zhongm Ikeda, and Shinkai will testify to.<sup>[92]</sup> Our focus here is on the less common hosts capable of encapsulating C<sub>60</sub>, rather than binding to the surface of it. Host **37** is one such example.<sup>[93]</sup> This host was shown to weakly bind both C<sub>60</sub> and C<sub>70</sub>; with *K<sub>a</sub>* values of 43 and 233 M<sup>-1</sup>, respectively, the *K<sub>C70</sub>*/*K<sub>C60</sub>* ratio was 5.4. Stronger binding was observed for host **38**. However, the recorded association constants of 1300 and 625 M<sup>-1</sup> for C<sub>60</sub> and C<sub>70</sub>, respectively, gave a *K<sub>C70</sub>*/*K<sub>C60</sub>* ratio of only 0.48. An even stronger binder of C<sub>60</sub> and C<sub>70</sub> is host **39**, which presumably exists in solution as a mixture of interconverting *meso* and enantiomeric stereoisomers.<sup>[94]</sup> In toluene, the association constants for C<sub>60</sub> and C<sub>70</sub> were 76,000 and 163,000 M<sup>-1</sup>, respectively. NMR experiments revealed that the poles of C<sub>70</sub> bind deeply into

the calixarene cavities of the host. Hence, the spherical C<sub>60</sub> cannot form as intimate a series of contacts as C<sub>70</sub> can. Studies on a closely related host reveal that the complexation of C<sub>60</sub> is entropically penalized.<sup>[95]</sup>

37

38

39

## Hosts Based on Glycoluril

Another source of molecular curvature is glycoluril **40**. This simple bicycle has been polymerized with formaldehyde to form a series of fascinating, gourdlike macrocycles, the cucurbiturils. It has also served as the foundation for the syntheses of a family of hosts known as molecular clips. We will review each of these in turn.

In 1981, Freeman, Mock, and Shih reported the structure of cyclic hexamer **41**, the main product from the acidic condensation of glycoluril with excess formaldehyde.<sup>[96]</sup> This reaction had been investigated 75 years earlier by Behrend, Meyer, and Rusche<sup>[97]</sup> but without the benefit of modern instrumentation the remarkable structure of what is now termed cucurbit[6]uril could not be identified. More recently, several other cucurbiturils possessing five, seven, and eight glycoluril moieties, have been synthesized and characterized.<sup>[98]</sup> A space-filling model of cucurbit[8]uril is shown in Fig. 4. As a rule, cucurbiturils are rather rigid and so are only significantly soluble in aqueous acidic media or aqueous solutions of alkaline metal salts. In the latter, the capping of each portal with two sodium metal ions is responsible for the noted solubility.<sup>[99]</sup> Because of these solubility limitations, most of the organic guests that have been shown to form host-

Fig. 4 Space-filling model of cucurbit[8]uril.

guest complexes with cucurbiturils are ammonium species.<sup>[100–104]</sup> For the cyclic hexamer **41**, the largest guests observed in the hydrophobic pocket are *para*-substituted aromatic derivatives such as *p*-methylbenzylammonium. A telltale sign that the cavity of **41** is filled by this guest is that the corresponding *ortho*- and *meta*-substituted isomers do not bind. The *para*-oriented substituents are apparently poking out of the portals when such guests bind. Another indicator is that the  $K_a$  for *p*-methylbenzylammonium is  $3.2 \times 10^2 \text{ M}^{-1}$ , while the strongest binding guests such as  $\alpha,\omega$ -alkanediammonium ions bind with  $K_a$ s in the region of  $2.4 \times 10^6 \text{ M}^{-1}$ . The shell must distort to accommodate the bulkier guest. For these and other guests, the rates of exchange in and out of the pocket is independent of the structure or concentration of the displacing molecule; that is, the rate-determining step is the egression of the occupant. Rate constants varied by seven orders of magnitude depending on the guest. The binding properties of the larger cucurbiturils have also been examined. Cucurbit[7]uril has been shown to bind 4,4-bipyridinium (viologen) dications, guests that can be reduced while bound inside the cavity,<sup>[105]</sup> whereas the larger cucurbit[8]uril has been shown to bind two dissimilar guests that form a charge transfer complex within its cavity.<sup>[106]</sup> The latter has also been shown to bind aza-crowns, which, once bound, can be metalated by treatment with copper or zinc salts. Encapsulation of copper within the aza-crown, within the cucurbituril, stabilizes the Cu(I) state and considerably slows the electron transfer rate between electrode and redox center.<sup>[107]</sup>

The Nolte group's approach to pocket design is to use glycoluril as a foundation and build up hosts possessing narrow slitlike cavities.<sup>[108–110]</sup> For example, the combination of benzil and urea yields foundation **42**,

whereas a further two-step process leads to hosts **43** ( $R = H, OH, OMe$  or  $OAc$ ).<sup>[111]</sup> The two walls of the cavity of **43** ( $R = H$ ), the *ortho*-xylylene units, can adopt *anti* or *syn* orientations with respect to the phenyl groups. NMR experiments reveal that the host can adopt three possible conformers: *aa* (the conformation with an actual cavity), *as*, or *ss*, but that the former is generally preferred.<sup>[111]</sup> Examining many systems demonstrates that the precise conformer population depends on the structure of the host and occasionally even the type of guest.

**44**

Host **44** binds metal ions and *bis*-ammonium or paraquat guests,<sup>[112]</sup> while variations on this structure, e.g., **45**, have been shown to bind dihydroxybenzene derivatives.<sup>[113]</sup> The order of guest affinity for **45** is resorcinol > hydroquinone > catechol. Hydrogen bonding and  $\pi$ - $\pi$  stacking are important to binding,

**45**

the latter being apparent from color changes upon complexations and the observation that electron-withdrawing groups on the guest increase association. Thus, 2,3-dicyanohydroquinone binds more strongly ( $K_a = 3 \times 10^5 \text{ M}^{-1}$ ) than hydroquinone or even resorcinol. To separate the contributions of hydrogen bonding and  $\pi$ - $\pi$  stacking, complexation has been examined in a series of related hosts.<sup>[114]</sup> By and large, hydrogen bonding is the larger contributor. A “cavity effect,” the result of an entropy effect and a solvation effect, was also found to be important.

The Nolte group has also investigated how their hosts can act as shape-selective catalysts. For example, the copper (II) complex of pyrazole derivative **46** is capable of the shape-selective oxidation of benzyl alcohols.<sup>[115]</sup> Dihydroxybenzene derivatives bind into the cavity of **46**, and if these guests also possess a benzyl alcohol group it is quickly oxidized. The rate of formation of the corresponding aldehyde varies by over  $5 \times 10^4$ , with complementary guests being oxidized fastest.

**46**

More recent technologies have allowed the synthesis of a variety of molecular clips possessing two different cavity walls.<sup>[116,117]</sup> This had led to examples such as **47** ( $R = t\text{-Bu}$ ), possessing one porphyrin wall and capable of binding resorcinol derivatives.<sup>[116]</sup> Guest binding was shown to influence both the electrochemistry and the fluorescence of **47**. The latter was quenched upon binding because of a photoinduced electron transfer process, an observation of interest because in the photosynthetic reaction center,

aromatic residues are thought to play a role in the electron transfer process.

Molecular clips have also been designed and synthesized in which a porphyrin moiety is used to “roof” the cavity. Host **48** is an example.<sup>[118]</sup> The pocket of this molecule is capable of binding viologens, resorcinols, and pyridine derivatives. Some of the strongest binding guests are the viologens, whose pyridinium moieties can interact with the crown ether functionality of the host. Pyridine guests can also bind strongly via N-coordination to the zinc center. 3-Hydroxy pyridine binds particularly strongly as a hydrogen bond between host and guest can also be established. Resorcinols, which can only bind primarily with the aid of hydrogen bonding, bind more weakly.

The Mn(V)-oxo derivative of **48** has been shown to catalyze the epoxidation of alkenes.<sup>[119]</sup> Epoxidation can be accomplished from either porphyrin face. Thus, when pyridine was added to a solution of the Mn(III)-Cl complex, it was shown to enter the cavity and bind axially to the metal. The addition of oxygen and substrate led to epoxidation of the latter on the outer face, and decomposition of the catalyst. In contrast, when a bulky pyridine derivative was used it coordinated to the metal center on the open face of the porphyrin,

and hence epoxidation occurs within the pocket. Under these conditions, the observed conversion rates are intimately tied to the shape of the substrate. For example, *trans*-stilbene was oxidized almost twice as fast as *cis*-stilbene, a reversal of the results observed for the simple porphyrin. Furthermore, under these conditions no decomposition of the catalyst occurred. Related, two-cavity systems in which molecular clips are covalently attached to each face of a porphyrin have also been synthesized.<sup>[120]</sup> One example of these hosts demonstrated negative homotropic allosteric binding; a viologen guest can bind to each compartment, but the binding of the first is 15 kJ mol<sup>-1</sup> stronger than the second.

Recent research from the Nolte group includes the synthesis of alternative hosts. Thus, molecular clips based on propanediurea **49** (R = R' = H, or R = H, R' = Me, or R = R' = Me) have been synthesized and analyzed.<sup>[121,122]</sup> Propanediurea hosts such as **50** possess U-shaped rather than V-shaped clefts. In addition, the distance between the hydrogen bond acceptor carbonyl groups in **50** is ca. 0.3 Å shorter than the glycoluril-based hosts. As a result, these two families of hosts possess slightly different binding properties. Generally, guests can form stronger hydrogen bonds and make more intimate contacts with the walls of **50** than they can in the corresponding glycoluril host **43** (R = OMe). Hence, in CDCl<sub>3</sub> the *K*<sub>a</sub>s between 5-cyanoresorcinol and hosts **50** (R = R' = H) and **43** (R = Me) are 2.4 × 10<sup>6</sup> and 1.0 × 10<sup>5</sup> M<sup>-1</sup>, respectively.

### Hosts Based on Steroids

The incidents of steroids in molecular recognition have been reviewed.<sup>[123]</sup> In terms of steroids being used to

construct hydrophobic pockets, molecular curvature can be introduced by two architectural approaches. If the steroid of choice has all *trans*-A/B, B/C, and C/D ring junctions, then each unit is essentially flat and the curvature must be introduced by the groups that link them together. If on the other hand the steroid possesses, e.g., a *cis*-A/B ring junction, then the steroid framework itself possesses a degree of curvature that can be used to construct hydrophobic pockets. Examples of the latter approach predominate. Many of the steroid-based host systems that have been reported do not form hydrophobic pockets as such. Work from the Regen group is illustrative in this regard, where one of the main thrusts of their research is the synthesis of facial amphiphiles called molecular umbrellas.<sup>[124–126]</sup> Structure **51** is one example that, under aqueous conditions, can envelop guests and transport them across membranes.<sup>[125]</sup>

Steroids have been used to construct large macrocycles. Hosts **52–54** are representative examples of what have been termed cholaphanes, cyclophanes derived from the  $5\beta$  steroid, cholic acid.<sup>[127,128]</sup> These hosts have been shown to bind octyl  $\beta$ -D-glucoside **55** with association constants of 1305, 600, and  $1560\text{ M}^{-1}$ , respectively.<sup>[129]</sup> No binding of **55** to analogues **56**<sup>[130,131]</sup> has been noted, but the corresponding host with a *para*-substituted aromatic ring was noted to bind this guest.<sup>[127]</sup> A triply bridged cholaphane **57** has also been synthesized and its properties examined. This host was shown to bind several guests including *p*-nitrophenol, triethanolamine, benzyloxycarbonyl-protected amino acids, as well as glycoside **55**.<sup>[132]</sup> Smaller guests formed 1:2 complexes, with the second association constant being about one-fourth the value of the first. Cholic acid roofed porphyrin **58**<sup>[133]</sup> has also been examined for their ability to bind several alkyl-chained glycosides.<sup>[134]</sup> In this regard, a

semiquantitative two-point binding model was developed with the strength of binding rationalized in terms of the number of hydrogen bonds between host and guest. An interesting feature of these systems is that glycoside binding was noted to increase in the presence of small traces of methanol or water. A detailed analysis revealed that “gap filling” by the methanol or water was occurring. Host and guest are not perfectly complementary in the 1:1 complex, but the overall fit is greatly improved if a methanol or water molecule joins the glycoside inside the cavity and forms a 1:1:1 complex. The binding properties of porphyrin hosts “roofed” on both faces with *bis*-cholic acid moieties have also been examined in micelles. Chiral discrimination of hydrophobic amino acids was noted.<sup>[135]</sup>

**52** ( $n = 2$ ), **53** ( $n = 1$ ), **54** ( $n = 0$ )

**55**

**51**

56

57

**Scheme 2** The base-promoted decomposition of 5-nitrobenzoxazole.

pyridine nitrogen removes the requisite proton and triggers the ring-opening process. The overall reaction can be described in terms of a fast preequilibrium, a slow intramolecular reaction, product release, and subsequent product reuptake. It was shown that the product bound much more strongly to **59** than the starting material. Nevertheless, host **59** accelerated the reaction in question by 6000-fold relative to a cavityless pyridine analogue.

59

## Cyclophane Hosts

Early cyclophanes were rather open and bound relatively small guests. However, as synthetic approaches to these unique types of hosts have been honed, so have their size and complexity increased.<sup>[2]</sup> Our first example is host **59**, capable of catalyzing the ring opening of isoxazoles (Scheme 2).<sup>[136]</sup> The 5-nitrobenzoxazole binds into the cavity of **59**, whereupon the

Inouye et al. have also recently investigated the properties of cyclophanes. By way of example, they synthesized host **60**.<sup>[137]</sup> The two pyrene rings are held about 4.5 Å apart, just the right distance for binding aromatic rings. Guests that bind to **60** included the four nucleotides: adenine, uracil, guanine, and cytosine. Presumably, the base moiety of each enters the cavity leaving the phosphate sugar free in solution. The strongest binding guest examined was 4-hydroxy-2,7-naphthalenedisulfonic acid sodium salt.

58

60

When bound, the naphthalene ring of this “ideal” guest was completely shielded from the water/ethylene glycol solvent, leaving the charged groups at the portals of the cavity.

Cyclophanes have also figured prominently in the recent research endeavors of the Dougherty group. Chiral cyclophane **61** forms the foundation of much of this work.<sup>[138]</sup> Both slim guests such as quinoline and methylquinolinium chloride, as well as more rotund guests such as *N,N,N*-trimethyl-1-adamantanammonium chloride, bind into **61**. The free energy of complexations for these guests,  $\Delta G_{298^\circ} = 5.3, 8.4,$  and  $6.7 \text{ kcal mol}^{-1}$ , respectively, were typical values observed for a wide range of similarly shaped guests. Slim guests bind best, especially so if they possessed a positive charge that interacts with the walls of the cavity. When fluorine atoms are added to the structure of the host, i.e., **62**, binding is reduced relative to **61** by  $2 \text{ kcal mol}^{-1}$  if the guest is charged, and  $1 \text{ kcal mol}^{-1}$  if the guest is neutral.<sup>[139]</sup> This result was attributed to the electron-withdrawing fluorine atoms that essentially reverse the quadrupole moment of the benzene moieties. In other words, the walls of the cavity of **62** are relatively electron deficient and any cation- $\pi$  interaction diminished. Hosts **63** and **64** have also been examined.<sup>[140]</sup> The binding of neutral guests to **63** differed little from host **61**. Thus, even though it is conceivable that the additional carboxylate group would decrease the hydrophobicity of the pocket, this does not seem to be the case. Additionally, a more detailed comparison between **61** and **63** suggested that the carboxylate group had little influence on the conformation of **63**. The strength of association between **63** and cationic guests was generally stronger, but this was not always the case. For some guests, e.g., *N,N,N*-trimethyl-1-adamantanammonium iodide, the salt bridge between the host and guest was not strong in pure water, and the binding of this guest to **61** and to **63** were identical. However, in 10% aqueous acetonitrile, this and other charged guests were noted to bind more strongly to **63**. In contrast to **63**, host **64** showed

a general decreased affinity for neutral guests, a diminution attributed to a decrease in the hydrophobicity of the cavity. For charged guests complexing with **64**, binding was considerably stronger if the guest was flat, but slightly reduced with quasi-spherical guests. This difference arises because aromatic and adamantyl guests induced different host conformations. The rhomboidal-shaped cavity ideal for binding the former allowed the formation of salt bridges between host and guest, whereas the toroidal form ideal for binding rotund guests did not.

61

62

A rather open, chiral cavity is engendered by the unusual structure of host **65** synthesized by the Diederich lab.<sup>[141]</sup> With six converging hydroxy groups, this  $C_3$  symmetry host was designed to recognize pyranosides. Thus, binding of guest **55** and other sugars was demonstrated in  $CDCl_3$ . The addition of phenethyl groups to each naphthalene moiety and the development of a successful strategy to engender  $C_2$  symmetry isomers has expanded the size of the family of these hosts.<sup>[142]</sup> In these cases, guest binding was rather weak. However, stronger binding was realized

with hosts such as **66**. Possessing eight converging phosphodiester groups, this cyclophane was capable of sequestering mono- and disaccharides from deuterated acetonitrile/methanol mixtures. Binding constants as high as  $41,000 M^{-1}$  were recorded.<sup>[143]</sup>

The Diederich group has also synthesized cyclophane **67**.<sup>[144]</sup> This rather complicated host is a mimic of the enzyme pyruvate oxidase, a flavin adenine dinucleotide (FAD)-dependent enzyme that within lactobacteria catalyzes the reaction from pyruvate to acetyl phosphate. The mimic consists of three essential features, the first of which is a slot-shaped cavity for binding aromatic guests. It also possesses two pieces of catalytic machinery “taken” from the enzyme, which in this model study were used to oxidize aldehydes to carboxylic acids/esters. First, it possesses a thiazolium moiety that readily forms an ylide by deprotonating of the C-2 atom. This nucleophile

68

initiates conversion by attacking the carbonyl group of the substrate. The mimic also possesses a flavin moiety that oxidizes the resulting intermediate to form an activated ester. In the last step of the reaction either water or an alcohol reacts with this activated ester to generate the product. The naphthalene ring is ideal for binding to **67**. Thus, the binding constant for 2-naphthaldehyde to **67** was  $2900 \text{ M}^{-1}$ . By comparison, binding of 2-naphthaldehyde to the corresponding cyclophane without a thiazolium ring was  $5300 \text{ M}^{-1}$ , indicating a small amount of self-complexation occurs in **67**. In methanol, and in the presence of triethylamine, **67** smoothly converts 2-naphthaldehyde to the corresponding ester. A comparison with reactions using mixtures of the individual components, e.g., a flavinless cyclophane plus flavin, demonstrated the increase in efficiency when all the catalytic machinery are brought together in one reagent. Unfortunately, attempts to complete the catalytic cycle by running the reaction under aerobic conditions to allow reoxidation of the flavin were not successful.

We finish off with some more encapsulating cyclophanes. Host **68** is a water-soluble cyclophane whose conformational motions are relatively slow because of its many amide bonds.<sup>[145]</sup> Its binding properties were examined with fluorescent guests such as ANS. In aqueous acetate buffer, a  $K_a$  between **68** and ANS of  $20,000 \text{ M}^{-1}$  was recorded. The complexation and preferred orientation of the more sizable guest, pamoic acid **69**, was also examined. Related cyclophanes have also been used for complexing steroids.<sup>[146]</sup> Cyclophane **70** is also capable of sequestering sizable guests.<sup>[147]</sup> This host from the Davis group was examined for its ability to bind a range of monosaccharides and disaccharides. Of the different guests examined, the host was shown to bind only the all-equatorially substituted *n*-octyl- $\beta$ -D-cellobioside **71**. Monosaccharides, or disaccharides with axial substituents, did not fit within the cavity.

69

70

71

## CONCLUSION

Both selected polymers and traditional synthetic techniques can engender the formation of discrete hydrophobic pockets. Each approach is associated with considerable diversity and offers many opportunities for new strategies in storage/delivery, catalysis, and detection. Many of these goals are currently being addressed by rather open, solvated, supramolecular tools. And what successes there have been! Nevertheless,

it is surely the case that soon the more encompassing hydrophobic pockets highlighted here will ultimately herald even more powerful supramolecular tools.

# Guests within Hydrophobic Pockets: Self-Assembly

Bruce C. Gibb

Department of Chemistry, University of New Orleans,  
New Orleans, Louisiana, U.S.A.

## INTRODUCTION

This review focuses on how self-assembly can form hosts capable of binding large guests. Its sister article, “Guests within Large Synthetic Hydrophobic Pockets Synthesized Using Polymer and Conventional Techniques,” reviews like-minded work using either polymers or hosts synthesized by traditional synthetic approaches. As described in more detail in that paper, the focus here is on hosts capable of binding organic molecules of more than seven non-hydrogen atoms. Likewise, a similar definition of a “pocket” is retained, with the focus on hosts possessing well-defined, highly concave or enclosed surfaces. An arbitrary value of greater than approximately 50% encapsulation has been set. “Comprehensive Supramolecular Chemistry” covers much of our discussion topic up to 1995.<sup>[1]</sup> This review is therefore primarily interested with the literature since that time.

Motivators for supramolecular chemists include molecular storage/delivery, the detection of substances, and the conversion of one substance into another via catalytic processes. All these processes include at some point the binding of a guest to a host. The hard part in these endeavors is the synthesis of the host, with all the required functionality gathered in a converging array. One approach uses self-assembly, whereby molecular subunits are designed to merge in a specific pattern that possesses a hydrophobic pocket. In this regard, both self-assembly and self-assembly with covalent modification have been used. As with the polymer and traditional synthetic strategies, the self-assembly approach has pros and cons. Normally, relatively rigid subunits are used and so a common worry in cavity design—hydrophobic pocket collapse—is generally avoided. On the other hand, at our current level of understanding we are limited to relatively symmetrical subunits and assembled structures. Nevertheless, testimony to the power of this approach is found in the large cavities formed, some in the order of thousands of cubic Ångströms.

The bulk of recent self-assembly research has focused on understanding the rules that govern how one product can arise out of a reaction mixture that, if all things were equal, would lead to a highly complex

mixture. Hence in a manner analogous to contemporary polymer research, the emphasis is on understanding how the structure of the product is reached, rather than on understanding the properties of any cavity in the product. As a result, many of the very large cavities created by self-assembly are “simply” filled with a large number of (small) solvent molecules. Such examples are not dealt with explicitly here but can be found in citations throughout the text.

## HOSTS BASED ON RESORCINARENES

In the last seven or so years it has become apparent that resorcinarenes, **1** ( $n = 4$ ), a family of molecules<sup>[2–5]</sup> held in much regard for their hosting properties and their use in the synthesis of a plethora of cavitands, also possess a spectacular flair for self-assembly. Two general assembly products have been identified (Fig. 1). Either two molecules can come together in a pseudo  $C_{4h}$  symmetric host, or six assemble into a pseudo-octahedral array. A second component, usually solvent, is necessary to “glue” the subunits together. The first hint of this supramolecular chemistry was pinpointed by MacGillivray and Atwood, who identified the pseudo-octahedral complex both in the solid and the solution state.<sup>[6]</sup> The total assembly consists of six resorcinarenes, eight water molecules and has a solvent-filled cavity. Shortly thereafter, the dimer, again in part held together by 2-propanol/water molecules, was identified independently by the Rose and Aoki groups.<sup>[7,8]</sup> The latter identified a tetraethylammonium ion within the cavity. A third such structure, this time hosting triethylammonium, was identified shortly thereafter.<sup>[9]</sup> Recently, Atwood, Barbour, and Jerga identified a more robust pseudo-spherical hexamer derived from pyrogallol[4]arenes **2**,<sup>[10]</sup> while Shivanyuk and Rebek have determined that the corresponding dimeric assembly also forms and encapsulates large guests.<sup>[11]</sup> Thus, in deuterated methanol or aqueous acetonitrile, NMR evidence suggests that **2** ( $R = Pr$ ) is monomeric. However, the addition of tropylium tetrafluoroborate results in an intense red color indicating a charge transfer complex between **2** ( $R = Pr$ ) and guest. Furthermore, at host/

**Fig. 1** Dimeric and hexameric assemblies of resorcin[4]arenes.

guest ratios larger than two, the  $^1\text{H}$  NMR at 233 K demonstrates that a 2:1 complex of **2** ( $\text{R} = \text{Pr}$ ) and tropylium tetrafluoroborate exists. At this temperature, the kinetics of guest exchange is slow on the (600 MHz) NMR time-scale. Further experiments revealed that 1) at higher equivalents of guest a 1:1 complex was formed, and 2) a protic solvent was necessary for assembly of the dimer host. This latter point was noted when more lipophilic **2** ( $\text{R} = \text{C}_{11}\text{H}_{23}$ ) was shown to only assemble in deuterated chloroform when a trace of methanol was present. Interestingly, resorcinarenes **1** ( $\text{R} = \text{Me}$ , or  $\text{Et}$ ) did not undergo this encapsulation of the tropylium ion.

The octahedral assemblies of **1** ( $n = 4$ )<sup>[12,13]</sup> have demonstrated some fascinating encapsulation properties. For example, in water saturated, deuterated chloroform, the hexamer of **1** encapsulates a range of ammonium ions in a manner that is intimately tied to the size and concentration of the guest.<sup>[14]</sup> Tetrahexylammonium bromide is an ideal guest and exchanges slowly, relative to the 600-MHz NMR

time-scale, between cavity and free solution. Nuclear magnetic resonance evidence suggests that the larger guest tetraheptylammonium bromide is cramped within the confines of the assembly, while the still larger tetrahexadecylammonium bromide was not complexed. With smaller guests, things became even more interesting. Thus, in the case of  $\text{Bu}_4\text{N}^+\text{BF}_4^-$ , the small counter ion is coencapsulated along with cation. In such cases, solvent is also present in the cavity but leaves when a more suitable space-filler is present. Hence, at the expense of bound water 4-phenyltoluene is also encapsulated along with  $\text{Bu}_4\text{N}^+\text{BF}_4^-$ . Still smaller ammonium ions instead template the assembly of the dimeric host.  $\text{Bu}_4\text{SbBr}$ , along with a variety of co-encapsulated aromatic guests, is also seen within the hexameric assembly.<sup>[15]</sup> Co-guests included are benzene, *p*-xylene, 4-phenyltoluene, and naphthalene. In contrast, 4,4'-dimethylbiphenyl was not encapsulated with the antimony guest, suggesting that adding an extra methyl group to 4-phenyltoluene was enough to destabilize the complex. Size, however, is not the only important factor for encapsulation. Neither hexafluorobenzene, cyclohexane, nor pentane was coencapsulated. Rather, the antimony guest and presumably some solvent molecules occupied the cavity.

As the basis of cavitands, resorcinarenes have also been instrumental in the synthesis of carceplexes such as **3** (Scheme 1).<sup>[16–18]</sup> As defined by their inventor, Donald Cram, carceplexes are closed surface compounds that permanently entrap guest molecules or ions within their shell, such that guest escape can only occur by rupture of covalent bonds. Since their initial synthesis,<sup>[19]</sup> their self-assembly (with covalent modification) has been intensively investigated; as has the relationship between host shell (the carcerand) and guest. As it transpires, these two facets are intimately tied. Early work focusing on small guests established that templation<sup>[20]</sup> is essential for successful synthesis. The best yields arise when a template stabilizes the transition state of the rate-determining step (rds) for the synthesis. Furthermore, the transition state at the rds has a similar cavity to the product.<sup>[21–29]</sup> Hence good templates for assembly make good guests for the carcerands. In these initial studies, the best guest identified was pyrazine, while the worst guest, and hence the solvent of choice for many of these studies, was *N*-methylpyrrolidinone (NMP).

Scheme 1 Synthesis of carceplex 3.

4

Carceplexes can be increased in size to allow the encapsulation of large guests. One way is to use wide-bodied cavitands—cavitands derived from resorcin [5]arenes—in the carceplex reaction.<sup>[30]</sup> Another is to join several “normal”-sized cavitands together.<sup>[31–33]</sup> To date, only relatively small molecules have been observed within hosts synthesized by these methods. A more common approach is to increase the size of the linker groups that join the two “hemispheres” of the shell, i.e., replace bromochloromethane in the synthesis shown in Scheme 1 with a compound with two separate electrophilic centers.<sup>[34]</sup> The resulting products, such as **4** ( $R = -(CH_2)_4-$ ),<sup>[35]</sup> are called hemicarceplexes; so named because the portals in the shell, or hemicarcerand, are large enough for guests to exit or enter the cavity without covalent bond rupturing.<sup>[36]</sup> The ability of over 68 molecules to template the formation of **4** ( $R = -(CH_2)_4-$ ) has been recently studied.<sup>[37]</sup> Of these, 30 proved capable of templation, with the best template *p*-xylene proving to be 3600 times better than the worst *N*-formylpiperidine. However, in contrast to carceplex **3**, the final host structure **4** did not appear to be a reasonable model of the transition state of the rds in its synthesis.

Although many hemicarceplexes can be assembled via templation, most have been synthesized by inserting the desired guest post-assembly. This has provided information about how solvent and the shape of the

portals or guest influence thermodynamic stability, and complexation and decomplexation rates. For example, after synthesizing hemicarceplex **4** ( $R = -(CH_2)_4-$ , guest = solvent), the guest solvent can be exchanged using the law of mass action. Either heating the hemicarceplex in the presence of 100 equivalents of new guest in a solvent too large to enter the cavity, or more simply heating the complex in neat guest, leads to exchange. Using this technique, it is possible to synthesize a range of hemicarceplexes.<sup>[38]</sup> In general, long, thin guests complexed the fastest, while for disubstituted aromatic guests a general order of complexation was demonstrated by the xylene isomers; *p*-xylene  $\gg$  *m*-xylene > *o*-xylene. Computational studies on a related hemicarceplex indicated that two type of gating processes, involving conformational changes in the intra-hemispherical linker groups, affect guest entry or egression.<sup>[39,40]</sup>

How do guests inside the cavity interact with species in free solution? Host **4** ( $R = -(CH_2)_4-$ ) was used to study the first  $S_N2$  reactions of inner-phase guests with outer-phase reactants.<sup>[41]</sup> For example, when the complexes **4** ( $R = -(CH_2)_4-$ , guest = either 4-HOC<sub>6</sub>H<sub>4</sub>OH or 2-HOC<sub>6</sub>H<sub>4</sub>OH or 3-HOC<sub>6</sub>H<sub>4</sub>OH) were exposed to THF/NaH/CH<sub>3</sub>I, three different reaction outcomes were noted. The encapsulated *para*-isomer gave no reaction, the *meta*-isomer was doubly methylated, while the *ortho*-isomer gave a mixture of mono- and dimethylated guest. Different reactivity profiles were noted because each guest prefers a different orientation within the cavity. In the case of the 1,4-isomer for example, the two OH groups can reside deep within the “poles” of the host and cannot be readily alkylated. A similar rationale explains the observed alkyllithium additions and borane reductions of **4** ( $R = -(CH_2)_4-$ , guest = benzaldehyde, benzocyclobutenone, and benzocyclobutenedione).<sup>[42]</sup> If a reactive species is generated within the cavity, it can sometimes react with the hemicarcerand shell. For example, reaction at 0°C between **4** ( $R = -(CH_2)_4-$ , guest = benzocyclobutenedione) and an excess of MeLi gave diol **5** (Scheme 2). Experiments revealed

**Scheme 2** Synthesis of diol **5** via an inner-molecular reaction.

that a possible mechanism for this conversion begins with the addition of one equivalent of MeLi to a C=O group of the guest. The basic lithiate complex **6** can then induce a  $\beta$ -elimination in one of the linkers. This produces a butene ether derivative **7** that can then undergo a further elimination to yield the *bis*-phenoxide. Workup yields **5**. The tetramethylene linkers are not the sole reactive sites in this hemicarceand. Thus the methylene bridges in each hemisphere undergo reaction with the guest derived from methyl lithium addition to encapsulated *N*-methyl-2-pyrrolidinone.<sup>[42]</sup>

By carrying out a two-step (hemi)carceplex reaction, lower symmetry hydrophobic pockets can be synthesized.<sup>[43,44]</sup> To point out just two examples, hosts such as **4** (R =  $-\text{CH}_2-$ , or R =  $-(\text{CH}_2)_6-$ ) were synthesized and their corresponding hemicarceplexes examined by X-ray crystallography, NMR, and computational studies.<sup>[45]</sup> As anticipated, introducing a dissimilar linker between the hemispheres altered the shape of the pocket, the orientation of the guest, and hence the thermodynamic and kinetic stability of the corresponding complexes. The kinetics of exchange were measured at different temperatures for 1,4-dimethoxybenzene vacating **4** (R = 1,3- $(\text{CH}_2)_2\text{C}_6\text{H}_4$ ), to show how  $\Delta H^\ddagger$ ,  $\Delta S^\ddagger$ , and hence  $\Delta G^\ddagger$  varied as a function of solvent.<sup>[43]</sup> These studies revealed that solvation plays an important role in decomplexation. Hence decomplexation rates in  $\text{CDCl}_3$  were 800 times faster than in deuterated 1,1,2,2-tetrachloroethane. An examination of different hemicarceplexes showed that the structure of the unique linker also has a considerable effect on egression rates. For example, changing the dissimilar linker R in **4** from pentamethylene to hexamethylene increased the rate constant for egression by a factor of 177. Lower symmetry cavities can also be made by using two different cavitands to construct a hemicarceplex. For example, in hosts **8** and **9** methylene and dimethylene bridges link the phenol oxygens of the former, while dimethylene and

trimethylene linkers are used in the latter.<sup>[46,47]</sup> Nuclear magnetic resonance evidence demonstrates that these subtle changes in the host are manifest in how the guest moves within the pocket. Hence when the guest in **8** is 1,2,3-trimethoxybenzene three signals are observed for the methoxy groups. The 1- and 3-methoxy groups reside within different hemispheres, and the movement of the guest that allows them to exchange is slow on the (500 MHz) NMR time-scale; in contrast, the slightly bigger cavity of **9** means that the corresponding process is fast on the NMR time-scale. Although no simple rules were discernable, the size of the bridges between the phenolic O-atoms undoubtedly influences guest movement and decomplexation rates.

10

Building on these developments, Cram moved the carceplex and hemicarceplex field into the realms of aqueous solution, while at the same time synthesizing chiral hosts. The first water soluble hemicarceplexes were isolated from hemicarcerand **10**.<sup>[48]</sup> In aqueous solution, this host is capable of sequestering a number of guests including naphthalene and 1,3-dimethoxybenzene. Guests such as alkyl ammonium salts that are well solvated by water did not bind. Chiral hemicarceplexes can be synthesized by using the two-step process discussed above. Hosts **11** and **12** are two examples.<sup>[49]</sup> Introducing the chiral linker group of **11** in the presence of a racemic mixture of selected chiral guests resulted in ratios of the diastereomeric complexes of up to 1:1.5. Alternatively, higher diastereomeric ratios could be attained if the chiral hemicarceplex **11** containing chloroform was heated either in the presence of pure, racemic guest, or in diphenylether with an excess of racemic guest. By this approach the highest diastereomeric ratio observed was >20:1 in favor of the *R*-isomer of 4-MeC<sub>6</sub>H<sub>4</sub>-S(O)Me binding to **11**. In contrast, the diastereomeric ratio observed for complexing racemate C<sub>6</sub>H<sub>5</sub>S(O)Me was only 1.6:1 in favor of the *R*-isomer. Overall, the hemicarcerand **12** (guest = chloroform) was less discriminating than **11**. This was attributed to the two “non-chiral,” 26-membered ring portals in **12** being less encumbering than its two chiral portals.

11

As a rule, the shape and functionality of the guest can be transferred through a hemicarceplex shell to the external environment. A simple thin layer chromatography experiment is usually sufficient to demonstrate this point. Furthermore, hemicarceplex shells allow the transfer of triplet energy from aryl ketone guests to free naphthalene.<sup>[50]</sup> These results notwithstanding, guests in carceplexes or hemicarceplexes are in relatively sheltered waters, and this has allowed these unique hosts to be used as storage containers for highly reactive guests.<sup>[34,51,52]</sup> The first example, involving a small guest, was carried out over 12 years ago. Nevertheless, the trapping and room temperature analysis of cyclobutadiene **13** (Fig. 2), the Mona Lisa of organic chemistry as Cram described it, is always worth mentioning.<sup>[34]</sup> Equally as exciting was the trapping by Warmuth of *o*-benzynes **14** inside the cavity of **4** (R = -(CH<sub>2</sub>)<sub>4</sub>-).<sup>[51]</sup> This remarkable feat was accomplished by the photolysis of **4** (R = -(CH<sub>2</sub>)<sub>4</sub>-, guest = benzocyclobutenedione) and allowed its <sup>1</sup>H and <sup>13</sup>C NMR analysis. The former suggested that “free” benzyne would possess <sup>1</sup>H NMR chemical shifts of  $\delta = 7.0$  and 7.6 ppm, while <sup>13</sup>C-<sup>13</sup>C coupling in the latter suggests that **14** is best described as a cumulene. Interestingly, when warmed up to room temperature, the guest reacted with the hemicarcerand in an intermolecular Diels-Alder reaction.<sup>[53]</sup> Following on from this work, Warmuth and Marvel successfully trapped an enantiomeric mixture of 1,2,4,6-cycloheptatriene **15** inside hemicarceplex **4** (R = -(CH<sub>2</sub>)<sub>4</sub>-), by first encapsulating phenyldiazirine and then irradiating the resulting hemicarceplex.<sup>[54]</sup> Protected by the host shell, **15** could not dimerize and was stable for weeks at ambient temperature. By carrying out the same chemistry within chiral host **12**, a 3:2 ratio of the two resulting diastereomeric complexes was formed.<sup>[55]</sup> No coalescence of NMR signals could be observed when heating these complexes up to 100°C, which puts a lower limit to the enantiomerization barrier of >19.6 kcal mol<sup>-1</sup>. This value was collaborated with a parallel experiment using the diastereomeric complex of **12** (guest = **16**). Thus using line broadening analysis

12

Fig. 3 Cartoon of the two, heterodimeric assemblies in the  $20_2$  toluene and  $\gamma$ -picoline complex.

heterodimeric assemblies is shown in Fig. 3. In these assemblies, each toluene molecule tumbles freely whereas the methyl pyridine can only adopt one of two, thermodynamically equilibrated orientations. Replacing the toluene guest with another guest alters this equilibrium.<sup>[67]</sup> This intriguing supramolecular isomerism is not of course restricted to two guests. For example, in more recent work, the isomers that can result when three guests are encapsulated within the dimer of **20** have also been identified.<sup>[68]</sup>

Host **20** can also be used as a means of storage and delivery. Thus, capsule-bound dibenzyl peroxide was shown to be incapable of oxidizing triphenylphosphine. However, normal peroxide reactivity is restored when dimethylformamide is added and the

capsular assembly broken.<sup>[63]</sup> The same host can also be used to control the regioselectivity of cycloaddition reactions.<sup>[69]</sup> The 1,3-dipolar cycloaddition between phenylacetylene and phenyl azide can lead to two isomeric triazoles, the 1,4 isomer or the 1,5-isomer (Scheme 4). At ambient temperature and millimolar concentration this reaction is negligible on the human time-scale. In the presence of **20** though, a heteroassembly formed, the effective molarity of the two reactants greatly increased, and the reaction accelerated. Furthermore, the shape of the cavity directs the reaction only toward the 1,4-isomer.

The capsule formed by the dimerization of **20** can engender more complex kinetic systems (Scheme 5).<sup>[70]</sup> When free in solution, acids **21a** and **21b** can react with amine **22** via the activated ester formed between the acid and dicyclohexylcarbodiimide **23**. The main products are amides **24a/24b** and urea **25**. Both acids are observed to react at about the same rate. Adding a stoichiometric amount of **20** slows these reactions down because **23** is encapsulated, leaving little to promote the formation of the amide bond. The two acids **21a** and **21b** do not, however, react at the same rate. The smaller acid **21a** reacts faster because both products **24a** and **25** fit within the confines of the capsule. Indeed, they associate more strongly with the capsule than **23** does. Thus, for each peptide bond formed, two molecules that bind to the capsule are generated and two equivalents of encapsulated reagent **23** are expelled into free solution. In contrast, **24b** is a poor guest, so for each peptide bond made only one molecule of **25** can liberate one carbodiimide **23**. As a result, in the presence of **20**, the formation of **24b** is slower than the formation of **24a**.

The kinetics of exchange into and out of dimer **20** have been examined for both pairs of small guests and singular large guests.<sup>[71]</sup> Using  $^1\text{H}$  magnetization transfer experiments it was shown that the substitution of a benzene guest in the dimer of **20** containing one benzene and one *p*-xylene molecule occurred without the capsule breaking in two. Instead, two walls of one subunit can flap open to allow the guest to be displaced either by an incoming benzene molecule or by the resident *p*-xylene guest. For singular guests, a

Scheme 4 Reaction between phenyl acetylene and phenyl azide.

Scheme 5 Synthesis of amides **24a** and **24b**.

mechanism was proposed in which solvent displaces the guest, before it in turn is displaced by either a copy of the original guest or a competing species.

Tetra-glycoluril derivative **26** is another resorcinarene-based host that self-assembles into a hydrophobic cavity.<sup>[72]</sup> The dimer of this molecule features a cavity of volume 950 Å<sup>3</sup>, sufficiently large enough to complex cryptates such as **27**. Furthermore, the potassium thiocyanate salt of **27** is also encapsulated within the dimer of **26** to form a complex within a complex.

Metal ion coordination is a powerful means to synthesize hydrophobic pockets via self-assembly. Most examples utilize planar subunits (vide infra); however,

metal ions have also been used to assemble resorcinarenes and calixarenes. The Dalcanale group in Parma investigated several such resorcinarene-based systems, including using palladium ions to assemble **28** and **29**.<sup>[73–75]</sup> To date, however, only triflate ion binding in the former has been reported.<sup>[75]</sup> Related systems have also been developed by the Harrison group. The tetra-cobalt derivative **30**, as well as the corresponding iron complex, has been shown to bind 40 guests.<sup>[76–78]</sup> The largest of these were bromobenzene, *p*-xylene, and their ilk. One interesting feature of **30** is that it acts as a NMR shift reagent. <sup>1</sup>H NMR signals for a guest shift as much as –30 and –40 ppm, and can cover a range of 12 ppm. The Beer group has also been active in this area. Host **31** (R = *n*-butyl or *n*-propyl, M = Cd<sup>2+</sup> or Zn<sup>2+</sup>) possesses a cavity large enough to bind C<sub>60</sub>.<sup>[79]</sup> The binding constants between each variant and C<sub>60</sub> were similar, with the host **31** (R = *n*-propyl, M = Cd<sup>2+</sup>) showing the strongest association (log K<sub>a</sub> > 6).

29

30

31

Although cavitands have played a large role in the field of self-assembling resorcinarene derivatives, they are not alone. For example, Shivanyuk, Paulusn, and Böhmer, have noted that regioselectively acetylated resorcinarenes also undergo self-assembly.<sup>[80]</sup> Thus in  $\text{CDCl}_3$  tetra ester **32** dimerizes around a templating tropylium salt. The intense red color observed is indicative of a charge transfer complex, and indeed the forces in such a complex are essential for assembly as neither benzene nor toluene is capable of affecting a similar assembly. The combination of the charge transfer forces and eight  $\text{CO}\cdots\text{HO}$  hydrogen bonds (as evidenced by X-ray crystallography) is sufficient to form a thermodynamically and kinetically stable complex.

### HOSTS BASED ON CALIXARENES

The self-assembly of calixarenes, **33** ( $R$  and  $n =$  various), is another active area of cavity synthesis research. Most of this research has utilized calix[4]-arenes ( $n = 4$ ). For example, independently the Rebek and Böhmer groups devised a family of upper-rim, urea-functionalized calixarenes of general structure **34** ( $R$  and  $R^1 =$  various). These molecules dimerize to produce a quasi-spherical host in which the two hemispheres are  $45^\circ$  out of register, and the urea arms interdigitated.<sup>[81,82]</sup> By meshing in this manner, the subunits form interstrand hydrogen bonds between the carbonyl of one strand and the two  $\text{N-H}$  donors

of an adjacent strand. Thus, the host is held together by a circular array of 16 hydrogen bonds. The first examples, **34** ( $R = \text{Bn}$ ,  $R^1 = \text{Ph}$  or *p*-fluorophenyl), were shown to bind both deuterated benzene, deuterated toluene, as well as chlorobenzene and 1,4-difluorobenzene.<sup>[83,84]</sup> More recently, selected ammonium salts, including tetra-alkyl ammonium, pyridinium, and *N*-methylquinuclidinium, were also encapsulated.<sup>[85]</sup> The multitude of noncovalent forces between the three species induces each hemisphere to clamp down on the guest, with the result that guest exchange is slow on the NMR time-scale. At the same time, the conformation of each individual hemisphere is also altered. For example, calixarenes with small *R* groups, e.g., **34** ( $R = \text{Me}$ ), can adopt several conformations because the *R* group can pass through the annulus of the macrocycle. Thus, each of the precursors to **34** ( $R = \text{Me}$ ,  $R^1 = p$ -tolyl) is in partial cone conformations. Contrastingly, each hemisphere in the dimer is 100% cone conformation.<sup>[86]</sup>

All things being equal, the combination of two different calixarenes should lead to a statistical distribution of the three possible products ( $A_2$ ,  $2 \times AB$ ,  $B_2$ ). However, the combination of **34** ( $R = \text{Me}$ ,  $R^1 = \text{C}_6\text{H}_4$ -*p*- $\text{C}_7\text{H}_{16}$ ) and **34** ( $R = \text{Me}$ ,  $R^1 = \text{SO}_2\text{C}_6\text{H}_4$ -*p*- $\text{CH}_3$ ) led exclusively to the heterodimer; a supramolecule that, because the seam of hydrogen bonds can run in either a clockwise or anticlockwise manner, exists as a pair of enantiomers.<sup>[87]</sup> Encapsulation of a chiral guest

therefore leads the formation of two diastereomeric complexes, complexes that only reach equilibrium at ambient temperature after several days. Chiral calixarenes such as **34** ( $R = \text{C}_{10}\text{H}_{21}$ ,  $R^1 = \text{CH}(\text{Me})\text{Ph}$ ) also dimerize around guests.<sup>[88]</sup> In these cases  $^1\text{H}$  NMR chemical shifts suggested that different heterodimers possessed the opposite sense of directionality to their respective hydrogen-bonding seam. Building on this work, a close examination of the ability of chiral calixarenes to form heterodimers with achiral calixarene **34** ( $R = \text{C}_{10}\text{H}_{21}$ ,  $R^1 = \text{Ph}$ ) was undertaken to determine the influences that control heterodimerization.<sup>[88]</sup> Solvent was found to be important in the percentage of homo- vs. heterodimeric assemblies, with benzene promoting the formation of the latter. Structural influences were subtler, and although selected derivatives were identified for optimal heterodimer formation, pinpointing the rules governing assembly proved elusive.

In an effort to identify a more capacious system, Cho, Rudkevich, and Rebek synthesized calixarene **35** ( $R = \text{CH}_2\text{C}(\text{O})\text{NEt}_2$ ,  $R^1 = p$ -tolyl).<sup>[89]</sup>  $^1\text{H}$  NMR revealed that this calixarene did indeed dimerize in solution. By mixing **35** ( $R = \text{CH}_2\text{C}(\text{O})\text{NEt}_2$ ,  $R^1 = p$ -tolyl) with **35** ( $R = \text{CH}_2\text{C}(\text{O})\text{NEt}_2$ ,  $R^1 = p$ -(*n*-hexyl)-phenyl) and identifying the three possible complexes, it was apparent that dimerization was slow on the NMR time-scale; N-H signals could be observed for each individual dimer. Neutral guests did not bind to these assemblies, but charged species including pyridinium and quinuclidinium salts did. In these cases, exchange rates were faster than the rate of assembly, indicating that guests can vacate the cavity through portals in the host.

Böhmer's group also investigated dimerizing calix[4]arenes that possess urea functionality at the wide rim. As the first to observe heterodimerization of calixarenes with general structure **34**,<sup>[90]</sup> their research lent credence to the dimer structure initially put forward by Shimizu and Rebek on the basis of N-H and guest NMR signal shifts.<sup>[83]</sup> The case for a dimer assembly was clinched with the crystal structure of the dimer of **34** ( $R = \text{CH}_2\text{C}(\text{O})\text{OEt}$ ,

$R^1 = p\text{-tolyl}$ ).<sup>[82]</sup> Furthermore, the synthesis of a lower symmetry calixarene with two different R groups in an A/C arrangement provided a handle for an intense NMR investigation and the determination of the rate constants for assembly.<sup>[91]</sup> Recent studies show how the nature of the guest influences the rates of assembly. Although the bulk of the  $\Delta G^\ddagger$  for dissociation presumably arises through the breaking of hydrogen bonds, the shape and electronics of the guest nevertheless have a considerable effect. For example, the half-lives of guest exchange for cyclohexane, fluorobenzene, and toluene were measured at 78 days, 3 days, and 4.2 hr, respectively.<sup>[92]</sup> The nature of the  $R^1$  groups influences assembly, with large groups both reducing the range of homo- and heterodimers that can form, as well as slowing down the rate of assembly.<sup>[93]</sup> In deuterated benzene, discerning monomer **34** ( $R = \text{Me}$ ,  $R^1 = \text{trityl}$ ) does not form homodimers, nor heterodimers with calixarenes such as **34** ( $R = \text{Me}$ ,  $R^1 = 3,5\text{-di}(t\text{-butyl})\text{phenyl}$ ). It does, however, form a heterodimer with **34** ( $R = \text{Me}$ ,  $R^1 = 4\text{-tritylphenyl}$ ), one that is particularly stable in deuterated cyclohexane. As well as increasing the kinetic stability of the dimer, increasing the size of the  $R^1$  group also decreases the size of the cavity. Thus, the homodimer of **34** ( $R = \text{Me}$ ,  $R^1 = \text{trityl}$ ) forms a homodimer by encapsulating a relatively small tetramethyl ammonium ion, but the complex is kinetically stable even in neat  $d_6\text{-DMSO}$ .<sup>[94]</sup> The motion within the cavity of such relatively small guests has also been examined.<sup>[95]</sup>

With urea-substituted calix[5]arenes, it has been possible to encapsulate  $C_{60}$ .<sup>[96]</sup> Urea groups are not, however, the only functionality that can be used to promote the assembly of calixarenes. For example, metal ion coordination has also been used to encapsulate both  $C_{60}$  and small chiral amines between assembling homooxacalix[3]arenes.<sup>[97–99]</sup> In addition, carboxylic acids have been used to promote the assembly of calixarenes. Tri-acid **36** is one such example.<sup>[100]</sup> This compound has been shown to dimerize around molecules such as *N*-methyl-4-picolinium iodide, but not *N*-methyl-2-picolinium iodide. Functionalization of the lower rim of calixarenes also leads to subunits capable of self-assembly. Thus **37** ( $R = C_8H_{17}$ ) was shown to dimerize around benzene and toluene.<sup>[101]</sup> In these cases some of the  $^1\text{H}$  NMR signals were broad, an indicator that these

solvents are not good guests. In contrast, the  $^1\text{H}$  NMR signals of the same complex in  $CDCl_3$  were well resolved, suggesting that this guest did complement the cavity.

## HOSTS BASED ON GLYCOLURIL

The Rebek group has worked with a number of glycoluril-based assembly systems for the generation of hydrophobic pockets. One of the richest systems devised is **38**, a molecule possessing 14 fused rings and an overall “C” shape (Fig. 4). In suitable organic solvents, this molecule forms a hollow, pseudo-spherical dimer in which the two halves are held together by hydrogen bonds between the glycoluril termini and the amide carbonyl groups. The first examples of these “soft-ball” hosts, e.g., **38** ( $R = \text{phenyl}$ ,  $X = \text{H}$ ), were shown to bind various guests, the strongest binder being 1-adamantanecarboxylic acid.<sup>[102,103]</sup> Subtle modifications to **38** ( $R = 4\text{-}n\text{-heptylphenyl}$ ,  $X = \text{OH}$ ) generated a self-assembling system that was both more soluble, thanks to the heptyl groups, and more robust, thanks to the phenol groups which contributed to the total number of hydrogen bonds between the subunits.<sup>[104]</sup> As expected, in both these systems assembly and guest complexation was highly dependant on the solvent.<sup>[105]</sup> Interestingly, in all solvents examined, binding of guests was entropically driven. To rationalize this observation it was proposed that two or more solvent molecules occupied the cavity and that the addition of a large guest liberated these. By such a mechanism, the system could become more disordered upon complexation and release up to

**Fig. 4** Perpendicular views of space filling model of subunit **38** (R groups omitted for clarity, X = OH).

6.0 kcal mol<sup>-1</sup> of free energy when 1-adamantane-methanol was encapsulated. Once a guest is encapsulated, exchanging it for another is a relatively slow process. The mechanism, at least in the case of [2.2]paracyclophane substituting adamantane in a deuterated xylene solvent, has been examined.<sup>[106]</sup> The guest vacates the cavity via a conformational change in one subunit that opens a “flap” in the side of the host. The new guest can then exchange with the resident, potentially via an intermediate that possesses a solvated cavity. One of the remarkable properties of host **38** (R = 4-*n*-heptylphenyl, X = OH) is its ability to accelerate<sup>[107,108]</sup> and even catalyze Diels–Alder reactions.<sup>[109]</sup> The first experiments highlighting these properties involves the reaction in Scheme 6, a process that at millimolar concentrations in xylene has a half-life of about 1 year. In contrast, the reaction greatly accelerates in the presence of capsule **38** (R = 4-*n*-heptylphenyl, X =

OH) because the host can encapsulate both reagents and hold them at an effective concentration 1000 times that of the free reagents. The capsule is not, however, a catalyst. That bane of catalyst designers, product inhibition, raises its head and prevents catalytic turnover. On the other hand, no such problem was observed with the Diels–Alder reaction involving *p*-quinone and 2,5-dimethylthiophene dioxide (Scheme 7).<sup>[109]</sup> In this system, *p*-quinone binds more strongly to the cavity formed by host **38** (R = 4-*n*-heptylphenyl, X = OH). Consequently, the product is driven out of the cavity by the starting material and so each dimer can induce many transformations.

Analogous systems have also been used for chiral recognition. Host **39** (X = H) possesses one symmetry plane and is therefore achiral ( $C_S$ ).<sup>[110]</sup> In the softball-type assembly, however, the two subunits are orthogonal to each other and each plane bisects and therefore violates the other. The result is a chiral capsule ( $C_2$ ) that racemizes via a process of disassembly and reassembly. Upon the addition of a chiral guest two diastereomeric complexes form, with diastereomeric excesses ranging from 0% for guest **40**, to 35% for the more complementary **41**. The latter value corresponds to  $\Delta\Delta G^\circ$  of 0.4 kcal mol<sup>-1</sup>. A more extensive examination revealed diastereoselective excesses as high as 50%.<sup>[111]</sup>

The additional hydrogen bonds in the dimer of **39** (X = OH) slow its rate of isomerization down somewhat so the  $t_{1/2}$  is approximately 10–20 hr. In contrast, the rate of guest exchange in this system is much faster because the subunits do not need to completely dissociate for exchange to occur. As per **38**, a flap can open to allow guest egression. These points lead to an unusual memory effect. If a deuterated *p*-xylene solution of the dimer of **39** (X = OH) is charged with (+)-pinanediol **41**, then after equilibration an excess of one diastereomeric complex is observed. The addition of an excess of the enantiomer of **41** rapidly leads to guest exchange. As this process is so much quicker than racemization, the enantiomeric shells of the original major and minor complexes find themselves with a mismatched and a matched guest, respectively. The major diastereomeric complex is now the least stable complex, and only through the slow racemization

**Scheme 6** The Diels–Alder reaction between *p*-hydroquinone and cyclohexadiene.

**Scheme 7** The Diels–Alder reaction between *p*-quinone and 2,5-dimethylthiophene dioxide.

can equilibrium be reestablished. Until then, the system finds itself “remembering” the shape of the first guest.

Another way to introduce chirality is to make assemblies using **38** ( $X = H$ ) in which the pairs of R groups on each glycoluril are different. This approach has to date been less successful in chiral recognition, presumably because the chirality is associated with the outer surface rather than the inner cavity.<sup>[112]</sup>

The glycoluril subunit has been used by the Rebek group to synthesize other assembling systems. The “jelly doughnut,” a dimer of *tri*-glycoluril **42**

**39**

**40**

**41**

**42**

**43**

( $R = CO_2$ -*i*-pentyl) capable of encapsulating benzene and cyclohexane, lies at the edge of our review. Readers interested in its hosting properties, and its ability to slow the ring inversion of encapsulated cyclohexane, are directed toward Refs.<sup>[113]</sup> and<sup>[114]</sup>. Building upon these studies, a modular approach to self-assembling subunits such as **43–45** ( $G =$  glycoluril) has been proposed.<sup>[115]</sup> By a combination of NMR and mass spectrometry, the smaller of these three hosts, **43**, was shown to bind *N*-methylquinuclidinium, while the large guests built from cavitands could bind 2,2′bipyridine and metal complexes of cryptates such as **27**.

A final self-assembling host based on glycoluril is built from monomer **46** ( $R = 4$ -*n*-dodecylphenyl,  $X = H$ ).<sup>[116]</sup> This molecule possesses curvature, and at each end, an acidic H-bond donor (the sulfamide N–H) and a basic acceptor (the glycoluril carbonyl). Because the sulfamide N–H/glycoluril C=O hydrogen bond is the strongest possible noncovalent interaction between subunits, the molecules assemble into a barrel-shaped tetramer of  $D_{2d}$  symmetry where each stave is antiparallel to its neighbors. The monomer has low solubility in  $CD_2Cl_2$  and toluene- $d_8$ , but the addition of adamantane derivatives results in a homogeneous solution. Diketone **47** was the strongest binding guest initially screened ( $K_{app} = 3200 M^{-1}$ ), and exchanged slowly (relative to the 600-MHz NMR time-scale) between the free and the bound states. Subsequent competition experiments between neutral guests and cationic species such as **48** revealed that the latter bind more strongly.<sup>[117]</sup> The barrel assembly is chiral ( $D_2$  symmetry) if the staves used to construct it are **46** ( $R = 4$ -*n*-dodecylphenyl,  $X = OH$ ).<sup>[118]</sup> This monomer is itself chiral—it possesses a plane of chirality—and was therefore resolved upon synthesis. Choosing one enantiomer and investigating its ability to bind racemic guests revealed a range of diastereoselective recognitions. For example, the diastereomeric excess in binding ( $\pm$ ) 3-methylcyclohexanone **49** was 60%, while for its constitutional isomer ( $\pm$ ) norcamphor **50** there was no diastereomeric excess. Shape is everything! The binding profiles of these hosts have recently been investigated as a dynamic combinatorial library. By examining mixtures of seven different staves in

the presence of a series of guests, it was possible to identify the different assembly products, often in distributions far from statistical, that arose from matched and mismatched assembly components.<sup>[119]</sup>

44

45

Even larger guests can be encapsulated with the host arising from **51** ( $R = 4$ -*n*-heptylphenyl).<sup>[120]</sup> This monomer again forms a tetrameric, barrel-shaped assembly and is capable of binding guests such as adamantane **52** and congressane **53**. These assemblies are very secure structures in solvents such as  $CD_2Cl_2$  or  $CCl_4$ . In the latter, EXSY NMR experiments revealed a lower limit for the activation energy of the dissociation of tetramer of **51** ( $R = 4$ -*n*-heptylphenyl) containing **52** to be  $20 \text{ kcal mol}^{-1}$ . Two possible mechanisms of this exchange were identified. Either one or two staves flip up to allow the guest to escape, or the barrel breaks in two before the guest enters solution.

46

47

48

49

50

51

52

53

are also many ways that planar subunits can be used to form quasi-spherical hosts. The majority of these assemblies use metal ion coordination to join subunits with Lewis basic sites. As arguably the most powerful approach to self-assembly, an important goal of this field has been to garner the rules that govern assembly.<sup>[121–124]</sup> Thus a great deal of metal coordination assembly has not been directly concerned with guest binding within hydrophobic pockets. Here the focus is on assemblies in which large guest molecule binding properties have been studied. For more general reviews readers are directed to Refs.<sup>[125–131]</sup>

The Fujita group investigates using heterocycles and palladium complexes in self-assembly. Their research has led to some of the largest hydrophobic cavities reported to date.<sup>[127]</sup> A particularly rich seam of research emerged from the triazine-based subunit **54**, which assembles into tetrahedral structure **55** in the presence of palladium or platinum ions (Scheme 8). This host is spacious enough to complex four adamantane guests.<sup>[132]</sup> Guests can be sequestered by stirring an aqueous solution of **55** ( $M = Pd^{2+}$ ) with a saturated hexane solution of the desired target.<sup>[133–135]</sup> Adamantane is one such example; another is tri-*tert*-butylbenzene. The latter is larger than the portals in the host and therefore is encapsulated very slowly. Only at  $80^\circ C$  is the 1:1 complex formed at an appreciable rate. For the smaller guests, a “ship-in-a-bottle” mechanism is in operation whereby each guest enters the cavity sequentially, and the contents of the cavity assembled into the lowest free-energy packing arrangement; an assembly within an assembly! Not all guests can pack with equal efficiency though. Thus in competition experiments between *cis*- and *trans*-dimethylazobenzene only two molecules of the former are taken up by **55** ( $M = Pd^{2+}$ ).<sup>[136]</sup> Residency within

## HOSTS BASED ON PLANAR SUBUNITS

As just described, hydrophobic pocket design via self-assembly often utilizes curved subunits. However, as MacGillivray and Atwood have observed,<sup>[121]</sup> there

**Scheme 8** The metal-ion assembly of ligand **54** into host **55**.

**55** ( $M = \text{Pd}^{2+}$ ) alters the properties of the *cis*-4,4'-dimethylazobenzene guests, in so much as they do not isomerize to the more stable *trans* form even after a few weeks of exposure to visible light. Interestingly, two molecules of unsubstituted azobenzene do not bind to **55** ( $M = \text{Pd}^{2+}$ ). It was suggested that  $\text{CH}-\pi$  interactions between the methyl protons of the guest and the walls of the cavity are important in the packing process. Host **55** ( $M = \text{Pd}^{2+}$ ) recognized *cis* and not *trans* isomers via shape-recognition. Shape complementarity is not, however, the only important factor in determining guest complexation. For example, although 1,3,5-trimethoxybenzene is a good guest, electron deficient guests such as 1,3,5-tribromobenzene were not taken up by the host.<sup>[134]</sup>

Host **55** ( $M = \text{Pt}^{2+}$ ) has also been used to assemble cyclic siloxanes that are presumed to be ephemeral intermediates in the so-called sol-gel condensation; the polycondensation of trialkoxysilanes that leads to siloxanes.<sup>[137,138]</sup> Guest **56** is one such example. It is a kinetic intermediate en route to a thermodynamic product in the sol-gel process, the cyclic "tetramer." In contrast, **56** is kinetically stable when synthesized inside host **55** ( $M = \text{Pd}^{2+}$ ). This is determined by hydrolyzing phenyltrimethoxysilane in a solution of the host. A NMR spectrum after only 5 min of reaction suggested that three or four molecules of phenyltrihydroxysilane were initially incorporated into the cavity, while within 1 hr NMR spectroscopy demonstrated that the complex **55**·**56** had been formed. Once encapsulated, a consideration of the NMR spectrum of the shell and variable temperature NMR experiments told a good deal about the mobility of the guest.<sup>[139]</sup>

Host **55** ( $M = \text{Pd}^{2+}$ ) can also accelerate and control reactions (Scheme 9).<sup>[140]</sup> When acenaphthylene guest **57** ( $R = \text{H}$ ) was heated with **55**, two guests were encapsulated. Irradiation of this sample led to a near

quantitative yield of *syn*-dimer **58** ( $R = \text{H}$ ), in a considerably shorter time than is required for reaction in free solution. On a related note, normally guest **57** ( $R = \text{Me}$ ) does not undergo dimerization. However, inside **55** ( $M = \text{Pd}^{2+}$ ) the  $C_{2v}$  product was quickly formed in near quantitative yield. No  $C_s$  symmetric dimer was observed. Similar rate accelerations and stereoselectivities were seen for the dimerization of naphthoquinones, and cross-photodimerizations (Scheme 10).<sup>[141]</sup> Thus when 5-ethoxy-naphthoquinone **59** ( $R' = \text{Et}$ ) and acenaphthylene **57** ( $R = \text{H}$ ) were heated with host **55** ( $M = \text{Pd}^{2+}$ ) a 1:1:1 complex formed. Irradiation of this complex gave a 92% yield of the cross *syn* product **60** ( $R = \text{Et}$ ,  $R' = \text{H}$ ). Surprisingly, with **59** ( $R' = \text{Me}$ ) this yield dropped to 44%, and a considerable amount of the homodimers were observed. More dramatically, with **59** ( $R' = \text{H}$ ) only a 35% yield of the cross product was observed, along with 21% of the dimer of **59** and 14% of the dimer of **57**.

**56**

Another family of subunits from the Fujita group are the oligo(3,5-pyridine)s such as **61** (Scheme 11). In the presence of palladium ions this subunit forms square prism or "nanotube" **62**.<sup>[142-144]</sup> To affect this formation, a rod-like template, e.g., 4,4'-biphenylene-carboxylate **63**, is required. In the final assembly product the dicarboxylate resides within the hydrophobic tube. In fact, it is rather hard to remove. Only at elevated temperatures was (weaker binding) biphenyl

Scheme 9 A [2 + 2] photodimerization of acenaphthylenes.

Scheme 10 A [2 + 2] cross-photodimerization of olefins.

slowly extracted from the pocket by chloroform. The smaller subunit **64** ( $n = 1$ ) undergoes an analogous assembly, whereas the even-numbered pyridine ligand **64** ( $n = 2$ ) forms two assembly products, **65** and **66**. These products have  $C_{2h}$  and  $D_{2h}$  symmetry, respectively, and are formed in a 1:1 ratio in the presence of template **63**.<sup>[143]</sup> The rate of isomerization between **65** and **66** is slow. Two weeks were required for one isolated product to form an equilibrium mixture. The movement of guests within these nanotubes was examined by synthesizing the complex between **62** and

4-phenylbenzoic acid.<sup>[144]</sup> This lower symmetry guest induced desymmetrization of the host framework at room temperature. As the temperature was raised, coalescence of the NMR signals at 47°C demonstrated that the guest vacated the cavity via an activation barrier of 16 kcal mol<sup>-1</sup>. This coalescence temperature varied as a function of guest concentration suggesting two mechanisms of exchange, a dissociative one at low concentrations and an associative mechanism at higher guest concentrations. Guest egression depends on the length of the nanotube—the shorter the tube

Scheme 11 Assembly of nanotube **62**.

the lower the activation energy—and the nature of the guest.<sup>[138,144]</sup>

A subtle change to **54** leads to a family of bowl-shaped hosts. Thus subunit **67** assembles into cavitand **68** (Scheme 12).<sup>[145]</sup> Binding studies revealed that this host can hold two molecules of *m*-terphenyl.<sup>[146]</sup> At room temperature, guest motion within the cavity is slow on the NMR time-scale. Interestingly, the solid-state structure of this complex revealed a dimeric capsule of **68** encapsulating four guests. Whether this is the case in solution could not be determined. The encapsulation of *cis*-stilbene in **68** was equally interesting. Six molecules were trapped in a dimeric capsule in the solid state. In solution, the garnered evidence suggested that a monomeric host containing one or two guests was in equilibrium with the dimeric capsule containing six. Host **68** has also been used to stabilize sol-gel condensation intermediates, in particular the condensed “dimer” of naphthyltrihydroxysilane.<sup>[138]</sup>

The assembly properties of tripodal ligand **69** have been examined.<sup>[147]</sup> In the presence of palladium ions, this subunit assembles into one of two forms: dimer **70** that exists as a pair of enantiomers, and **71** (Scheme 13). Addition of 1,3,5-benzenetricarboxylic acid to the assembly reaction leads to **70**, whereas addition of a more spherical guest leads to **71** with the more spherical cavity. Furthermore, each assembly product can be converted to the other by the addition of a suitable excess of the requisite guest. Hence this system constitutes a dynamic receptor library. This library can be taken to the “next level” by mixing ligands **69** and **72**. This leads to up to four products whose ratios depend on the guest present in the assembly mixture.<sup>[148]</sup>

Hexahedral capsule **74** (Scheme 14), formed by the assembly of 18 palladium ions and six copies of subunit **73**, is a remarkable structure that, at least for host/guest applications, was designed too well.<sup>[149]</sup> The shell possesses little in the way of portals and, with six connections between each of the organic subunits, is of very high kinetic stability. Guest exchange is hard. For this reason **75**, a subunit that possesses a “N-defect,” was synthesized.<sup>[150]</sup> This molecule assembles into an analogous structure, but with one less coordination site, there are fewer linking groups between each subunit and the shell is a bit more forgiving. To date, only guests as large as CBr<sub>4</sub> have been stored in this capsule.

Subunit **76** follows different assembly paths than **75**. Using four subunits and eight metal ions, this triangular subunit forms either a tetrahedron-shaped capsule, or an open pocket of square pyramidal architecture.<sup>[151]</sup> The assembly is again template dependant. Benzil promotes the formation of the open pocket, which in aqueous conditions is filled with one guest. In contrast, the smaller CBr<sub>4</sub> leads to the sealed, tetrahedral-shaped host. In the absence of a template, two products form in a 3:2 ratio. The major component was tentatively identified as a trimer of **76** possessing an open, trigonal pyramid structure, while the minor component was the open, square pyramidal pocket.

Porphyrin derivative **77** also undergoes self-assembly with palladium ions; three subunits assemble

Scheme 12 Assembly of cavitaand **68**.Scheme 13 Assembly of **69** to form **70** and **71**.

into a trigonal prism capable of encapsulating pyrene.<sup>[152]</sup> Porphyrin dimers have also been reported that bind bipyridines.<sup>[153]</sup> Subunit **78** forms a square prism assembly.<sup>[154]</sup> By using a biphenyl template, it was possible to switch this assembly to a trimer of trigonal prism architecture, while crystallization led to the formation of an alternative (lower symmetry) square pyramid structure.

The Raymond group has also utilized Lewis acid/Lewis base coordination processes to drive the assembly of subunits into hydrophobic pockets. One of their more successful systems in this regard is based on ligand **79**, which, in the presence of a variety of metal ions, assembles into the distorted tetrahedron **80** (Scheme 15). Host **80** is chiral (symmetry group T) and therefore exists as a pair of enantiomers. The helical twist of the three ligands around each metal center induces chirality. In each enantiomer, all these

centers possess the same twist sense,  $\Delta\Delta\Delta\Delta$  or  $\Lambda\Lambda\Lambda\Lambda$ . In the absence of a guest, water fills the cavity of host **80** ( $M = \text{Ga}^{3+}$ ) and the counterion of the base used in the assembly, e.g.,  $\text{K}^+$ , is not incorporated into the cavity.<sup>[155]</sup> If a guest such as  $\text{Et}_4\text{N}^+\text{Cl}^-$  is added to the assembly process, it is encapsulated within the racemic mixture of host.<sup>[156]</sup> As expected, there is a dramatic upfield shift of the  $^1\text{H}$  NMR signals of the encapsulated guest. Furthermore, the signal from each methylene proton, enantiotopic in the free state but diastereotopic in the assembly, appears as a complex multiplet rather than a quartet. Other guests can be encapsulated within the confines of **80**. A study of the entrapment of  $\text{Me}_2\text{Pr}_2\text{N}^+$ ,  $\text{Pr}_4\text{N}^+$ , and  $\text{Me}_2\text{NCH}_2\text{CH}_2\text{NMe}_2\text{H}^+$  revealed that  $\text{Et}_4\text{N}^+$  is the best guest and that the assembly processes were endothermic (for a cation binding to a host of charge  $-12!$ ).<sup>[155]</sup> The endothermic nature of this process was rationalized in terms of the necessity to desolvate both host and guest. However, desolvating the host is not at all bad. As the authors pointed out, the release of the solvating waters from the cavity is probably at the root of the enthalpic gain of guest complexation. A mono-charged guest does, however, appear to be a necessity. Neither  $\text{Et}_4\text{Si}^+$ —isosteric with  $\text{Et}_4\text{N}^+$ —nor doubly charged  $N,N,N',N'$ -tetramethyl-1,3-propanediamine was observed to bind to the cavity of **80** ( $M = \text{Ga}^{3+}$ ).

Host **80** ( $M = \text{Ga}^{3+}$ ) is also capable of stabilizing reactive species in aqueous solution. For example, the phosphonium salt  $[\text{Me}_2\text{C}(\text{OH})\text{PEt}_3][\text{Br}]$  has been trapped in its cavity.<sup>[157]</sup> This salt can be formed by the reversible addition of triethylphosphine to acetone

**72**

**Scheme 14** Assembly of **73** to form hexahedral cage **74**.

in the presence of HBr, but in an aqueous solution devoid of acetone this compound rapidly decomposes to its constituent parts. The combination of a water-free cavity, a high effective concentration of the components, and shielding by the cavity walls, stabilizes the normally reactive phosphonium salt. The proposed formation involved triethylphosphine entering the confines of the cavity and undergoing reaction with an acetone guest.

Complex **80** ( $M = \text{Ga}^{3+}$ ) is large enough to act as a host for a host.<sup>[158]</sup> Thus mixing **80** with either [12]crown-4, [15]crown-5, or [18]crown-6 led to the appearance of new  $^1\text{H}$  NMR signals that corresponded to the encapsulated crown ether complex. That the crowns were carrying a metal ion was revealed using  $^7\text{Li}$  NMR on the lithiated host  $\text{Li}_{12}[\text{Ga}_4\text{L}_6]$  containing one of the two smaller crown complexes. In these experiments, with the signal from the crown complex free in solution referenced at 0 ppm, the signal for the encapsulated complexes appeared at  $-4.0$  ppm. The association constants for the three  $\text{Na}^+$  complexes of [12]crown-4, [15]crown-5 and [18]crown-6 binding to **80** ( $M = \text{Ga}^{3+}$ ) were calculated at 2700, 18,  $<0.1 \text{ M}^{-1}$ , respectively. Nuclear magnetic resonance

evidence also suggested that one or two water molecules were incorporated into the host along with the crown complex.

As discussed above, host **80** ( $M = \text{Ga}^{3+}$ ) exists as a pair of enantiomers. These do not interconvert with any apparent haste. The activation energy for flipping a tris(catecholate)gallium(III) center from  $\Delta$  to  $\Lambda$  has been measured at about  $67 \text{ kJ mol}^{-1}$ .<sup>[159]</sup> Hence incorporation of a guest that possesses an element of chirality should result in the formation of readily separable diastereomeric complexes. This was accomplished with the guest, *N*-methyl(-)nicotinium **81**.<sup>[160]</sup> The separated complexes were indeed very stable; they retained their diastereomeric purity in alkaline aqueous solution over a period of at least 8 months. The isolation of each enantiomer of **80** ( $M = \text{Ga}^{3+}$ ) allowed experiments that revealed a chiral memory effect.<sup>[161]</sup> Thus host **80** ( $M = \text{Ga}^{3+}$ ) was prepared with the *N*-methyl(-) nicotinium **81** guest, and the  $\Delta\Delta\Delta$  diastereomer isolated. Cation exchange with excess  $\text{Et}_4\text{N}^+$  gave the enantiomerically pure  $\Delta\Delta\Delta$  ( $\text{Et}_4\text{N}^+$ )<sub>12</sub> salt,

Scheme 15 Assembly of **79** to form T-symmetry cage **80**.

with one of the ammonium ions acting as guest by occupying the cavity; guest exchange did not affect the chirality of the shell. Addition of an excess of helicate complex **82** led to the gradual replacement of the naphthyl ligands in **80** with the phenyl biscatecholamide ligands of **82**. The tetraethyl ammonium guest was a good reporter group for this exchange process, but it was CD spectrometry that revealed that the original chirality of host **80** ( $M = \text{Ga}^{3+}$ ) was retained even after all six ligands had been exchanged!

## CONCLUSION

Self-assembly is a powerful technique for hydrophobic pocket design. Although contemporary technologies mean that the pockets so synthesized must be of relatively high symmetry, this strategy allows access to very large host molecules and supramolecules. As a result, inroads are already being made in terms of molecular storage and catalysis. As the field's ability

to synthesize increasing lower symmetry hosts improves, self-assembly is likely to play an increasing role in the development of new tools for molecular-storage/delivery, detection, and catalysis.

# Halide Transport through Biological Membranes

Lars-Oliver Essen

Department of Chemistry, Philipps University, Marburg, Germany

## INTRODUCTION

The transport of chloride and other halides through lipid membranes is crucial for many cellular processes, but the molecular basis of this important phenomenon is still poorly understood. One reason for this is the lack of small model compounds such as valinomycin or gramicidin A which have played a major role in elucidating the specificity of cation transporters since decades. Of the estimated 19 protein families which are involved in halide transport, structural information exists for three families at high resolution. This review focuses on the recent progress in the structural biology of chloride channels and pumps and what kind of lessons can be learned now for the chemical engineering of synthetic chloride transporters. The design of such chloride-conducting compounds may have profound implications in the treatment of several hereditary diseases such as cystic fibrosis or hypothyroidism.

## CHLORIDE—AN UNUSUAL ANION

Chloride transport through biological membranes might be expected to set different structural restraints on ion translocation pathways than the transport of protons. Proton transport often goes along chains of water molecules and (de)protonable groups via the Grotthus mechanism<sup>[1]</sup> and does not require structural changes in a H<sup>+</sup>-conducting membrane protein per se, except that unidirectionality of H<sup>+</sup> transfer and energy conservation needs to be established. In contrast, chloride ions are sterically rather demanding with a Pauling radius of 1.81 Å and impose high energetic penalties on desolvation.<sup>[2]</sup> Their translocation through lipid bilayers requires at least some dehydration and rearrangement of the hydration shell surrounding the ion. However, the precise structure of the hydration shell around chloride ions in bulk solution is still a matter of debate.<sup>[3]</sup> Several X-ray and neutron diffraction studies suggested coordination numbers of six water molecules, but other reports indicated that the hydration structure around chloride and the more voluminous halides such as Br<sup>-</sup> and I<sup>-</sup> is not so

uniform and might comprise up to 14 water molecules.<sup>[3]</sup> Besides this quantitative uncertainty for the halide solvation shell, several studies of the gas-phase behavior of solvated halides gave conflicting results whether Cl<sup>-</sup> and Br<sup>-</sup> are more stable on the surface of neutral water clusters than in their interiors.<sup>[2]</sup> A preferential surface location of halides on water clusters might be particularly important for transmembrane conductance because it would imply that the partial desolvation of halides in the apolar environments of the transmembrane regions is energetically more favorable as compared to other ion species.

So far, there are only a few theoretical approaches to the structural rearrangements imposed on chloride and its hydration shell during the transfer through biological membranes. Computer simulations of the liquid-to-liquid transfer of hydrated chloride ions from an aqueous to an apolar phase such as 1,2-dichloroethane or CCl<sub>4</sub><sup>[4,5]</sup> might be considered to be representative for the transmembrane transport of halides, because in both cases a transfer of the chloride is firstly implied from a high to a low dielectricity medium (water:  $\epsilon = 81$ , hydrophobic regions of biological membranes:  $\epsilon \approx 2$ ). These simulations showed that the hydration shell is successively reduced and deformed during transfer. The intrusion of chloride into the apolar phase is accompanied by a tailing (“fingering”) of attached water molecules.<sup>[4,5]</sup> Similar calculations using lipid bilayers indicated that the “fingering” effect may increase the permeabilities of membranes by 14 orders of magnitude as compared to a rigid lipid bilayer model.<sup>[6]</sup> As membrane proteins represent natural, for purpose-optimized distortions of the lipid bilayer structure, one may predict that this “fingering” of water molecules will be reflected by their structures.

Another factor besides the effects on halide solvation is the electrostatic contribution of the biological membrane to the transfer process. The arrangement of a dipole layer along the membrane–water interface was postulated to cause a steep electrostatic potential of up to +300 mV in the hydrophobic membrane interior.<sup>[7]</sup> This effect rationalizes why hydrophobic anions partition better to the apolar membrane region

than hydrophobic cations. Consequently, the energetic barrier for anions crossing the lipid bilayer through an integral membrane protein might be considerably smaller than for cations.

Specific interactions between the anion and the membrane protein might be predominantly of enthalpic nature, e.g., by the formation of salt bridges and hydrogen bonds from protein side chains or the peptide backbone in or close to the selectivity filter. Such a stabilization of the transported ion in the transmembrane region of the protein could be further supplemented by size or shape complementarity between the solute and the selectivity filter or by interactions with the electrostatic field of the lipid bilayer. Another theory that deals with the preferential conductance of large over small ions might be relevant for halide selectivity.<sup>[8]</sup> This theory of large-ion selectivity postulates a preferential adsorption of the solute by entropic size exclusion effects which are created by small energetic penalties for the entrance of solvent into the channel. One consequence of the unfavorable water/channel interactions postulated by this theory is that no steric rigidity in the selectivity filter is required to induce large-ion selectivities.<sup>[9]</sup> Furthermore, this theory is also capable to explain the nonlinear conductivities which are particularly often observed for halide channels.

## OVERVIEW OF HALIDE-SPECIFIC MEMBRANE TRANSPORT SYSTEMS

The currently known families of chloride-conducting membrane proteins are summarized in Table 1 using the transporter classification (TC) of Busch and Saier.<sup>[10]</sup> A common functional aspect of these proteins is their rather broad specificity as other halides such as Br<sup>-</sup> or I<sup>-</sup>, or even polyatomic anions such as nitrate, phosphate, or organic acids are often transported. However, chloride is among the most abundant physiological anions and its equilibrium potential of -90 mV is near the resting potential, so that the transport of chloride is energetically not demanding and often contributes to the stabilization of the resting potential.<sup>[11]</sup>

Despite the diversity and the physiological roles of chloride transport, only a few families have been extensively studied in molecular and structural terms. Among the chloride channels (for review, see Ref. <sup>[12]</sup>) whose number of transmembrane spans can be between 1 and 18  $\alpha$ -helices, there are only three major, well-characterized families: the chloride channels of the ClC family (see below), the cystic fibrosis transmembrane regulator (CFTR), which is the only known ion channel of the ABC-transporter family, and the neurotransmitter-gated chloride channels (LIC family) such as the GABA or glycine receptor (Table 1). At least one family, the volume-regulated anion channels

(VAC or VRAC), has not even been cloned, although members of this family are responsible for important cellular responses such as cell volume regulation.<sup>[13]</sup>

Many of the secondary halide transporters exploit the energizing effect of the Na<sup>+</sup>/K<sup>+</sup>-ATPase on the extracellular and intracellular sodium and potassium distribution because these symporters catalyze the electro-neutral symport of K<sup>+</sup> or Na<sup>+</sup> together with halide ions. Symporters such as the (Na<sup>+</sup>/K<sup>+</sup>/2Cl<sup>-</sup>), NaCl, or KCl symporters belong to the CCC family (Table 1),<sup>[14]</sup> but several other transporters such as the NaI-symporter, whose defect may cause congenital hypothyroidism<sup>[15]</sup> or the pendrins, which are implied in hereditary deafness,<sup>[16]</sup> are found in different transporter families (Table 1). Anion-coupled antiporters include the famous HCO<sub>3</sub><sup>-</sup>/Cl<sup>-</sup> exchanger of blood erythrocytes (AE1) or the sodium-driven, electroneutral NaHCO<sub>3</sub>/HCl exchangers of the mammalian tissues (NCBE).

Often, the chloride-conducting channels and the secondary transporters act in concert. For example, the developmentally controlled coexpression of the K<sup>+</sup>/Cl<sup>-</sup> cotransporter KCC2, a member of the CCC family, decides whether the chloride currents mediated by the GABA receptor cause hyperpolarization of neuronal membranes as usually found in the adult or depolarization as found at birth.<sup>[17]</sup> A special class of passive chloride transporters is represented by cryptdin-3 that belongs to the defensin family and appears to be a natural, peptide-based chloride channel maker.<sup>[18]</sup> This peptide, 35 amino acids long, is secreted into the small intestine by the Paneth cells which are located at the base of the crypts. Besides its antimicrobial function, a regulatory role for the intestinal secretion of water and salt was suggested for these small compounds.

Primary active halide transport has been reported several times in animal tissues or algal cells.<sup>[19]</sup> However, evidences for the molecular nature and mechanism of ATP-driven chloride transport are still mostly indirect. In the absence of sequence information, it was concluded from biochemical and electrophysiological data that the chloride-ATPase of the snail *Aplysia* belongs to the P-type,<sup>[19]</sup> whereas such ATPases from the green algae *Acetabularia* were assigned to the F-type.<sup>[20]</sup> Another active chloride transporter that is commonly found in Haloarchaea is halorhodopsin.<sup>[21]</sup> This member of the microbial rhodopsins mediates the conversion of light energy into the intracellular accumulation of chloride and is discussed in detail below.

## STRUCTURALLY CHARACTERIZED HALIDE TRANSPORTERS

Only four structures are now deposited in the RCSB protein database for halide-conducting membrane

**Table 1** Chloride-conducting membrane proteins as classified by Saier's TC nomenclature

TC	Family name	Type	# TM spans	Typical sizes (amino acids)	Occurrence	Comments
1.A.9	Ligand-gated ion channel family of neurotransmitter receptors (LIC)	Channel	4	400–500	Eukaryotes	Pentameric, chloride channels exist for GABA, serotonin, glutamate, glycine as ligands
<b>1.A.11</b>	Chloride channel (ClC)	Channel	18	395–998	Eukaryotes, eubacteria	Dimeric, often voltage-gated
1.A.12	Organelle chloride channel (O-ClC)	Channel	2	241–437	Eukaryotes, eubacteria	Similar to glutathione-S-transferase family, also named as CLIC family
1.A.13	Epithelial chloride channel (E-ClC)	Channel	4	420–917	Eukaryotes, eubacteria	Activated by CaM-dependent protein kinase II
1.A.27	Phospholipid (PLM)	Channel	1	88–92	Eukaryotes	Anion-selective channels formed in planar bilayers
1.A.36	Intracellular chloride channel (ICC)	Channel	4	508	Vertebrates	Only 2 of the 4 $\alpha$ -helices are strongly hydrophobic
<b>1.B.8</b>	Mitochondrial and plastid porin (MPP)	Channel	16 ( $\beta$ -barrel)	275–283	Eukaryotic organelles	Voltage-dependent anion channels (VDAC), several eubacterial homolog, member of porin superfamily
1.C.9	Vacuolating cytotoxin (VacA)	Channel	1	1290	<i>Helicobacter pylori</i>	Channel-forming toxin of <i>H. pylori</i> , also transports $\text{HCO}_3^-$ , pyruvate
1.C.19	Defensin	Channel	?	35–95	Mammals	Cryptdin-3 and -10 form chloride-selective ion channels
2.A.21.5.1	NaI-symporter	Symport	13	643	Animals	Import of sodium iodide, belongs to solute:sodium symporter family (SSS)
2.A.22	Neurotransmitter: sodium symporter (NSS)	Symport	12	600–800	Animals	Some family members cotransport $\text{Cl}^-$
2.A.29	Mitochondrial carrier (MC)	Uniport	6	288	Eukaryotic organelles	Dimeric, only UCP-1 conducts chloride besides other substrates
2.A.30	Cation-chloride cotransporter (CCC)	Symport	12	1000–1200	Eukaryotes, eubacteria	Symport of $\text{Na}^+$ , $\text{K}^+$ , $2\text{Cl}^-$ , or $\text{NaCl}$ or $\text{KCl}$
2.A.31	Anion exchanger (AE)	Antiport	10, 14	900–1250	Animals	Exchange of $\text{HCO}_3^-$ and $\text{Cl}^-$
2.A.53	Sulfate permease (SulP)	Antiport	13–14	434–893	Ubiquitous	A few family members, e.g., the pendrins, catalyze the exchange of $\text{I}^-$ or $\text{Cl}^-$
3.A.1.202	ABC-type chloride channel	Channel	11	1480	Mammals	cAMP-Dependent chloride channel, CFTR defects cause cystic fibrosis
3.A.3	P-type ATPases	Ion pump	?	?	Eukaryotes	No $\text{Cl}^-$ -pump yet cloned, although presence is shown in vivo
<b>3.E.1</b>	Microbial rhodopsins	Ion pump	7	248	Archaea	The trimeric halorhodopsin is the only chloride-transporting member of this family, pump is powered by light energy absorbed by a retinal chromophore

The 9.C.2 family which corresponds to volume-sensitive anion channels (VAC) is not included because this family is not yet characterized on a molecular level. Another family omitted in this table is the bestrophin family for which chloride channel activity was very recently shown.<sup>[77]</sup> Conflicting reports about the number of transmembrane spans exist for the anion exchanger (AE) family. 3-D structural information about the transmembrane domains of halide-conducting membrane proteins is only present for the boldly printed TC-families.

Source: From Ref. <sup>[10]</sup>.

proteins (April '03): the anion-selective porin Omp32 (PDB-code: 1E54), two prokaryotic members of the CIC family of chloride channels (1KPK, 1KPL), and halorhodopsin, the light-driven chloride pump (1E12). A few other structurally well-characterized membrane proteins of the porin family such as PhoE also conduct halides, but they are omitted from further discussion because of their lack of specificity. In the following sections, the different characteristics of these structurally highly diverse membrane proteins are discussed in terms of their structural base for ion specificity and transport.

### Omp32, an Anion-Selective Channel of the Porin Superfamily

Omp32 (molecular weight: 34.7 kDa, 332 amino acids) belongs to the porin superfamily and resides as a trimer in the outer membranes of the eubacterium *Delftia acidovorans*.<sup>[22]</sup> Unlike the unspecific porins which generally facilitate the transport of solutes of a molecular mass of less than 600 Da along large, 10-Å-wide water-filled pores, the Omp32 porin exerts a pronounced selectivity for anions. Its permeability is 17-fold higher for chloride than for potassium cations, at least under low ionic strength conditions.<sup>[23]</sup> The voltage–current curve is nonlinear and varies as a function of the salt concentration. This effect was interpreted as partial shielding of charged residues in the selectivity filter by salt ions. Among the halide-conducting proteins discussed in this review, Omp32 is the least specific case because its *in vivo* role is presumably the transport of nonhalide anions such as organic acids which are the preferred carbon sources of *D. acidovorans*. However, its simple structure exemplifies convincingly several principles of anion selectivity such as electrostatic adaptation and the presence of a selectivity filter.

The 2.1-Å X-ray structure of the Omp32 porin<sup>[22]</sup> shows a 16-stranded, antiparallel  $\beta$ -barrel (Fig. 1A) whose widely opened, water-filled pore narrows down to a cross section of  $5 \times 7$  Å at the central constriction zone of the protein (Fig. 1B). Consequently, steric restriction alone is not considered to be a major factor for the observed anion selectivity of Omp32. In addition to the nonpolar belts which line the extracellular and periplasmic transmembrane regions of the porin, a highly basic girdle is found comprising 10 lysine and 1 arginine residues along the extracellular membrane surface. However, this belt is obviously not important for anion selectivity as its charge is counterbalanced by an almost equal number of acidic residues. This region was hence implied to interact with the anionic head groups of lipopolysaccharides of the outer membrane.<sup>[22]</sup> In contrast, a ladder of four

arginines (R38, R75, R92, and R133) and one lysine residue (K74) transverses the inner side of the  $\beta$ -barrel that lines the pore (Fig. 1B and C). Because of the large positive potential at the constriction site of the Omp32 porin that is devoid of acidic residues, cations are thought to be electrostatically repelled from this selectivity filter, whereas anions should be attracted. The dimension of the constriction zone implies that the permeation of halides proceeds without a loss of their hydration shell. The selectivity filter is partly walled by hydrophobic residues (L94, I132). Whether this serves for enforcing the hydrated ions into closer contact to the charged residues or for imposing a slight energetic penalty for the intrusion of water molecules into the pore<sup>[9]</sup> is unclear.

The electrostatic features of Omp32 might be also at least partially present in the highly related, eukaryotic voltage-dependent anion channel (VDAC) that is present in the outer membranes of mitochondria and shares high sequence similarity with Omp32.<sup>[22]</sup>

### The CIC Family of Chloride Channels

Chloride channels of the CIC family were firstly discovered by Miller in the electric organs of *Torpedo marmorata* during 1979<sup>[24]</sup> and therefrom cloned a decade later.<sup>[25]</sup> CIC-like chloride channels were subsequently found in eubacteria, archaea, and eukaryotes (for concise reviews, see Refs. [12] and [26]). In eukaryotes, the CIC channels have manifold biological functions such as the regulation of electrical membrane excitability, the maintenance of electroneutrality during cation uptake, e.g., for the acidification of endosomal compartments, or the transepithelial chloride transport, e.g., across the nephron segments of kidneys. This range of functions correlates with the presence of at least nine CIC channel isoform in mammals which can be present in either the plasma membrane or the intracellular compartments.<sup>[26]</sup>

Although first structural studies by cryoelectron microscopy utilized the CIC channel EriC from *Escherichia coli*,<sup>[27]</sup> the function of the prokaryotic CIC channels remained enigmatic. Iyer et al.<sup>[28]</sup> recently found that the CIC-like chloride channel of *E. coli* is essential for the extreme acid resistance (XAR). This resistance allows the enterobacteria to survive up to 1 hr under the highly acidic conditions of the stomach (pH 2–3). As XAR apparently depends on the electrogenic countertransport of decarboxylated amino acids (GABA, agmatine) in exchange for glutamate and arginine, the prokaryotic chloride channels act as electrical shunts so that hyperpolarization of the inner membrane is avoided.

Despite the different functions, the prokaryotic and eukaryotic CIC channels share significant sequence

[22] and reproduced with permission of *Structure*.

similarities ( $\approx 21\%$ ) and many of them resemble in their selectivity sequences for anions:  $\text{Cl}^-$ ,  $\text{Br}^- > \text{NO}_3^- > \text{I}^- > \text{F}^-$ .<sup>[29,30]</sup> The observed high conductance for nitrate might be surprising in terms of the structural differences between nitrate and halide anions, but at least in plants, an eminent physiological role of a ClC homologue for nitrate uptake was shown.<sup>[31]</sup> Interestingly, a similar specificity order is observed for the halorhodopsins (see below), which might indicate that the structural restraints for the transport of

partially dehydrated halides and nitrate ions are very similar.

The X-ray structures of the ClC channels from the enterobacteriae *E. coli* and *Salmonella typhimurium* (Fig. 2A) were solved at 3.0- and 3.5-Å resolution by Dutzler et al.<sup>[32]</sup> and confirmed earlier electrophysiological,<sup>[33,34]</sup> biochemical,<sup>[29]</sup> and electron-microscopic reports<sup>[27]</sup> that the ClC channels form dimers with each pore acting independently from each other. Within the membrane, the triangularly shaped

[32] with permission of *Nature*.

subunits (*E. coli*—molecular weight: 46.6 kDa, 438 amino acids) form a large dimer interface of about  $2300 \text{ \AA}^2$ . Despite the large dimer interface, a functional interaction between the two 40- $\text{\AA}$  distant pores is restricted to slow gating<sup>[35]</sup> because fast gating is a property of the individual pores.<sup>[12]</sup> The CIC dimer protrudes by at least 15  $\text{\AA}$  from each membrane side and has a rhombus shape with dimensions of  $100 \times 55 \text{ \AA}$  when viewed along the membrane normal.

Compared to other chloride channel families (Table 1), the CIC family excels by a topologically highly complex transmembrane architecture. Each CIC channel subunit comprises 18  $\alpha$ -helices (numbered from A–R). These helices do not assume a simple helical bundle architecture as mostly found for membrane proteins, but are highly inclined relative to the membrane normal and vary in length between 6 and 55  $\text{\AA}$ . Analogously to the structurally unrelated aquaporin

family,<sup>[36]</sup> a pseudo-twofold relates the N- and C-terminal halves of the ClC monomer (Fig. 2B). As a consequence of this complex topology, four  $\alpha$ -helices (D, F, N, and R) point their N-terminal ends toward a central selectivity gate that is occupied in the ClC structures by a single chloride.<sup>[32]</sup> Three of these helices are capped by conserved, but different GxxxP motifs and apparently stabilize the chloride electrostatically by their helix dipole moments because no basic residues are found close to the selectivity gate (Fig. 2C).

Surprisingly, a conserved glutamic acid, E148, positions its carboxylate only 4 Å away from the chloride so that its passage to the extracellular side is blocked. Dutzler et al.<sup>[32]</sup> interpreted this intimate location of two anionic groups in the selectivity filter as the structural base for Cl<sup>-</sup>-dependent gating. According to their model, high concentrations of extracellular chloride cause a displacement of the side chain of E148. In such an open state, two closely spaced chloride ions would be found in the selectivity filter: one from the cytosolic side as observed in the crystal structure and one at the position of the carboxylate group of E148. This intriguing model resembles the mechanism of K<sup>+</sup> selectivity in kcsA-like potassium channels.<sup>[37]</sup> Alternatively, the protonation state of E148 might be a function of the halide concentration, i.e., invasion of extracellular chloride into the selectivity filter would cause protonation of E148 and thereby a disruption of the electrostatic barrier for halide translocation. This model is consistent with the strong pH dependence of the selectivity order Cl<sup>-</sup> > Br<sup>-</sup> > I<sup>-</sup> which can be reversed in several ClC channels by low pH values.<sup>[12]</sup>

Besides the interactions with the helix dipole moments, the chloride forms two hydrogen bonds with the side chains of the conserved residues S107 and Y445 and the amide nitrogens of the peptide bonds next to I356.<sup>[32]</sup> The chloride also contacts the methylene groups of G355 and F357. Because of the low resolution and high average B-factor of the ClC structures, there is no structural information about putative water ligands for the chloride, although the structure provides sufficient space for at least one water ligand. The access to the selectivity gate that is in the midst of a narrow, 12-Å-long tunnel is provided by wide, water-filled vestibules which are partly lined by basic residues (Fig. 2D). This feature is at least analogous to the wide pore architecture of the anion-selective porin Omp32 and obviously provides some electrostatic guidance for incoming anions.

## Halorhodopsin

In 1980, halorhodopsins (HRs) were for the first time described in the plasma membranes of *Halobacterium*

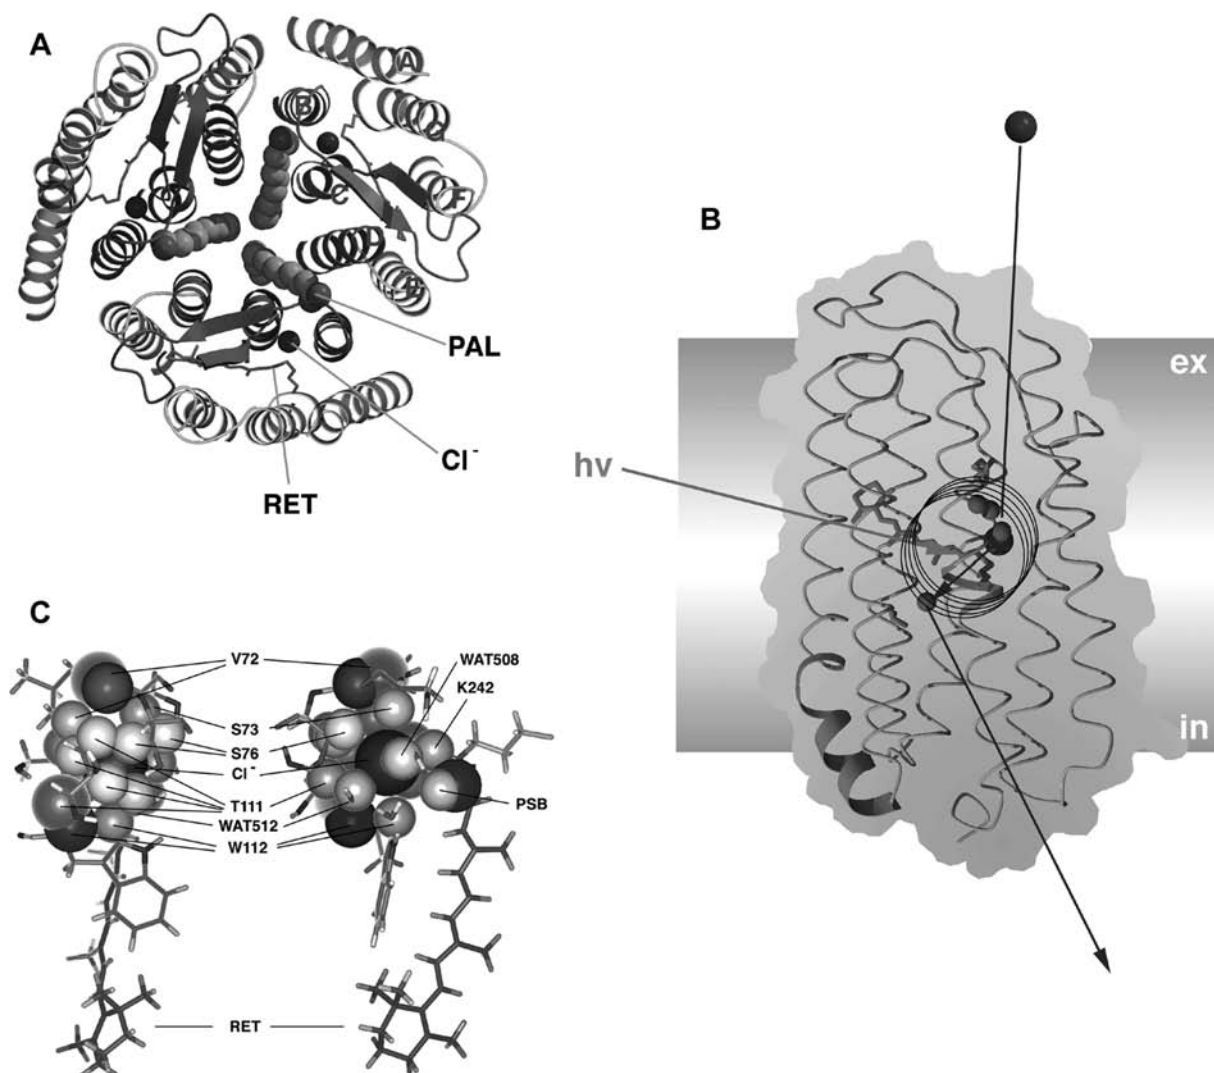

*salinarum*<sup>[38]</sup> and in other haloarchaea such as *Natronomonas pharaonis*. For these haloarchaeal extremophiles, chloride is a crucial growth parameter because the viability of haloarchaea depends on hypersaline environments like salt ponds or salinas. In the cytosol, the high osmolarity of the environment is counterbalanced by almost iso-osmolar KCl concentrations that can be as high as  $\approx 4$  M. During cell growth, the uptake of potassium chloride occurs actively by the combined action of potassium channels and halorhodopsins. The latter energize this process by acting as light-driven, inwardly directed chloride pumps.<sup>[39]</sup> Apparently, the light energy that is converted by HR contributes substantially to the maintenance of an osmotic balance during cell growth. Alternatively, passive salt import can be mediated in the dark by potassium and chloride channels.

Halorhodopsins exert slightly different affinities for the halides (Br<sup>-</sup> > Cl<sup>-</sup>, I<sup>-</sup>) which are pumped against their electrochemical gradients.<sup>[40]</sup> The halorhodopsins of *H. salinarum* and *N. pharaonis* can be produced by homologous and heterologous overexpression in large amounts.<sup>[41,42]</sup> Therefore a plethora of biophysical techniques was applicable in the past to reveal details about the transport mechanism, the photocycle kinetics, and the primary photoreaction of the chromophore (reviewed in Refs. [21], [40], and [43]).

Halorhodopsins define one subfamily of the microbial rhodopsins which also comprise subfamilies like the light-driven, proton-pumping bacteriorhodopsins (BR) and the sensory rhodopsins with sequence identities to each other of 25–35%.<sup>[44]</sup> The structural similarity to other microbial rhodopsins, i.e., an architecture with seven transmembrane  $\alpha$ -helices (numbered from A to G), was initially proven by cryoelectron microscopy on 2-D crystals of halorhodopsins<sup>[45–47]</sup> which were spontaneously formed in vivo during the homologous overexpression in *H. salinarum*.

High-resolution data at 1.8 Å were obtained by X-ray crystallographic analysis of *H. salinarum* halorhodopsin 3-D crystals<sup>[48]</sup> which were grown in a lipidic cubic phase.<sup>[49]</sup> In these crystals, halorhodopsin (molecular weight: 27.0 kDa, 253 amino acids) assembles to trimers (Fig. 3A). The layer-like crystal packing highly resembles the organization of purple membranes which are formed in vivo by bacteriorhodopsin. The quaternary structure of the HR trimer differs significantly from the bacteriorhodopsin trimer because the monomers are tilted by 11° relative to the BR trimer and involve van der Waals packing between the C helices in addition to interactions between the B and D helices.<sup>[48]</sup> The halorhodopsin structure shows that a lipidic plug consisting of the fatty acid palmitate is encircled by the HR trimer (Fig. 3A). This surprising association of halorhodopsin with a fatty acid was shown before by biochemical analysis,<sup>[50]</sup> but its

**Fig. 3** Halorhodopsin. (A) Trimeric arrangement of halorhodopsin as viewed from the extracellular side. The bound retinal (stick representation), chloride (green sphere), and palmitate groups (CPK model) are highlighted. Helix assignments are shown in blue. (B) Side view on halorhodopsin showing the translocation pathway of chloride.  $\Pi$ -Helical distortions in the  $\alpha$ -helix bundle are shown in blue. (C) Chemical environment of the chloride that is bound in the transport site. Hydrogens are shown as white spheres, chloride in green, and the nitrogens of the protonated Schiff base (PSB) and W112 in blue. *Source:* Figure C was reprinted with permission of *Nature*.

implication for the action of halorhodopsin is unclear. At least, a change in the photocycle kinetics and the  $pK_a$  of the protonated Schiff base was found upon the removal of palmitate<sup>[51]</sup> whose carboxylate group is approximately 11 Å away from the chloride that is bound to the transport site.<sup>[48]</sup>

The most appealing feature of the ion- and signal-translocating microbial rhodopsins is the presence of

an all-trans retinal chromophore that is bound as a protonated Schiff base to a conserved lysine residue, K242 in helix G (Figs. 3B and 4B). This chromophore causes the purple-like color of the unphotolyzed HR state with an absorbance maximum  $\lambda_{max}$  of 578 nm. Illumination of this HR state causes the formation of a red-shifted intermediate, the K-state ( $\lambda_{max} \approx 600$  nm), by photoisomerization of the retinal from the all-trans to

**Fig. 4** Steric restraints on the chloride translocation pathway through halorhodopsin. The location of the cross sections through halorhodopsin is indicated by a red line. The chloride ion in the transport site is highlighted as green sphere; the retinal chromophore is shown in blue and buried water molecules are shown in red. (A) View from the extracellular side. (B) The transport site for chloride. (C) The putative chloride release site. Surfaces of the internal cavities are marked in purple.

a 13-cis, 15-anti configuration and an accompanying flip of the N–H dipole of the protonated Schiff base. The 23 kcal/mol of remaining photon energy are mostly stored in the K-state by a twisted conformation of the retinal chromophore and drive the on-going conformational changes of the protein which accompany unidirectional ion transport. The flip of the Schiff base N–H dipole was indicated by a small, negative electrogenic charge shift upon K-state formation.<sup>[52]</sup>

The structure of the HR state of halorhodopsin shows that next to the protonated Schiff base a chloride is bound at a distance of 3.8 Å (Fig. 3C,<sup>[48]</sup>). Consequently, pumping of chloride from this transport site to the cytosol is directly linked to conformational changes of the chromophore and its vicinity which are organized in a well-ordered series of spectroscopically distinguishable photointermediates.<sup>[21,40]</sup> The observed electrostatic interactions between the chloride and the protonated Schiff base and another essential residue nearby, R108, were concluded before from the halide dependence of FTIR<sup>[53]</sup> and UV/VIS spectra.<sup>[54,55]</sup>

Because of the long distance and the relative geometrical arrangement, a strong hydrogen bond between the chloride and the Schiff base nitrogen is not expected in the HR state. However, the stabilization of the chloride in this central transmembrane portion involves the additional coordination to a cluster of three water molecules in the transport site (Figs. 3C and 4B). As in the structure of the ClC channel, the partial hydration around the Cl<sup>−</sup> anion is supplemented by an H bond to the hydroxyl of the conserved serine S115 and a cluster of aliphatic hydrogens which are derived from protein side chains (Fig. 3C). Here electrostatic calculations suggested that these aliphatic side chains might contribute enthalpically to halide binding because of the numerous interactions between the C–H dipoles and the chloride.<sup>[48]</sup> However, the affinities of chloride to the transport site of HR are not very high. Chizhov and Engelhard<sup>[56]</sup> estimated them from kinetic experiments to be in the millimolar range (*N. pharaonis*: ≈2.5 mM; *H. salinarum*: 10 mM).

Large conformational changes of the protein are required during the photocycle to open a transient pathway for chloride conduction because the retinal environment and the cytosolic half of HR are tightly packed (Fig. 4B and C). These changes might be transmitted by distortions in three of the  $\alpha$ -helices (Fig. 3B): a  $\Pi$ -helical segment in helix G (V239–F245), a  $\Pi$ -helical segment at the cytosolic end of helix E (A178–W183), and a  $3_{10}$ -like helical segment in helix C (L110–A113). After photoisomerization, the peptide planes of the first  $\Pi$ -helical segment, which are adjacent to K242, reorient and change the H-bonding pattern of the transport site in the early photocycle intermediates. The second  $\Pi$ -helical segment was suggested to be a hinge for the movements of helix F

that accompany the formation of late photocycle intermediates.<sup>[57]</sup>

The only  $\alpha$ -helical distortion that is not found in other microbial rhodopsins is the  $3_{10}$ -like helical segment of helix C.<sup>[21]</sup> This stretch includes T111 which corresponds to D85 in bacteriorhodopsin, the primary proton acceptor. Compared to D85 of bacteriorhodopsin, the T111 residue is retracted by 1.8 Å out of the chloride-occupied transport site of halorhodopsin. Recently, it was suggested that T111 might drive like a piston the chloride toward the cytosolic side of the chromophore by restoring the regular  $\alpha$ -helical H-bonding pattern after photoisomerization.<sup>[21]</sup> Interestingly, the hydroxyl of T111 is not contributing to Cl<sup>−</sup> binding as shown by the crystal structure of HR and transport studies of the T111V mutant.<sup>[58]</sup>

While K-state formation occurs within picoseconds and is too fast to cause a major displacement of the chloride from the transport site, the subsequently, in about 1  $\mu$ sec, reversibly formed *L-state* ( $\lambda_{\max}$  ≈ 520 nm) coincides with the movement of the halide to a second chloride binding site in the cytoplasmic half of HR.<sup>[21,48]</sup> The putative, second chloride binding site is empty in the HR state (Fig. 4C), but borders directly to the Schiff base and is completely occluded from cytosolic access.<sup>[48]</sup> Consequently, after light-triggered movement of a chloride into this cytoplasmic release site, substantial conformational changes are required in the cytoplasmic half to establish free exchange with the cytosolic milieu. In *N. pharaonis* halorhodopsin, the transport site lowers its chloride affinity from 2.5 mM to 1.1 M after photoexcitation,<sup>[56]</sup> while the affinity of the cytoplasmic release site is almost unchanged (≈5.7 M.<sup>[59]</sup>).

Interestingly, the transport specificity Br<sup>−</sup> > Cl<sup>−</sup> arises from the better binding of Br<sup>−</sup> to the cytoplasmic release site, but not to the transport site.<sup>[54]</sup> Alternative or in addition to the piston model, where movements of the T111 residue drive the ion translocation, some form of “ion-dragging” was considered before where the halide ion follows the flipped dipole of the N–H Schiff base bond and keeps a strong hydrogen bond with the protonated Schiff base.<sup>[48]</sup> A subsequent opening of an extracellular pathway from the cytoplasmic release site toward the protein surface was attributed either to a transition between the L2 and O states<sup>[60]</sup> or to a spectroscopically silent transition between two L-like intermediates.<sup>[56,61]</sup> The chloride transport along the extracellular pathway occurs by passive diffusion during the later part of the photocycle.<sup>[62]</sup> However, the precise order of the further photocycle intermediates is still unclear and might be, for halorhodopsin, even a function of the halide concentration and the source organism. Chloride uptake occurs presumably along an access channel whose outer rim on the extracellular side is lined by aliphatic side chains (Fig. 4A)

which may support the deformation of the hydration shell of the incoming halide ion.

### Converting Proton Pumps to Chloride Pumps

A single mutation in bacteriorhodopsin, aspartate 85 to serine or threonine, suffices to convert the specificity of bacteriorhodopsin from proton to chloride transport.<sup>[63]</sup> The photocycles of halorhodopsin and these mutants resemble each other, but the photocycle of the D85T mutant additionally indicates that chloride uptake becomes a rate-limiting step compared to halorhodopsin.<sup>[64,65]</sup> This might be caused by a sterically hindered access of chloride from the extracellular side to the transport site or by the lack of a hydrophobic ridge around the extracellular entrance site as in HR. Besides the 10-fold reduced transport efficiency, the D85T mutant also exhibits a 20-fold relaxed affinity to  $\text{Cl}^-$ ,<sup>[64,65]</sup> for which the structural reasons are not delineated. Furthermore, in the D85T mutant, the  $\text{Cl}^-$  translocation is accompanied by a deprotonation of E204, which belongs to the extracellular proton release group of bacteriorhodopsin but is missing in halorhodopsin, as this residue is there replaced by a neutral threonine.<sup>[21]</sup>

Apart from T203 in halorhodopsin which is predicted to line the cytosolic release site for  $\text{Cl}^-$  (Fig. 4C), no other residues essential for halide transport were identified by mutagenesis in the cytoplasmic half of halorhodopsin<sup>[58]</sup> or the bacteriorhodopsin D85T mutant.<sup>[65]</sup> Consequently, the walling of the postulated cytosolic exit pathway for  $\text{Cl}^-$  can be rather unspecific to promote the passive diffusion of  $\text{Cl}^-$  into the cytosol.<sup>[62]</sup>

Halorhodopsin is converted to an outwardly directed proton pump, if the chloride in the transport site was replaced by an  $\text{N}_3^-$  anion.<sup>[66]</sup> As a result of a  $\text{p}K_a$  of 4.75 in solution, this azide can act as a proton-accepting group such as D85 in bacteriorhodopsin. The possibility to convert the transport specificities of both bacteriorhodopsin and halorhodopsin from proton to chloride transport and vice versa implies that in these proteins, proton and halide transports depend on similar mechanisms. During the L→M transition of bacteriorhodopsin, a proton is transferred from the protonated Schiff base to the deprotonated D85. Among the models that have been suggested to rationalize the unidirectionality of this step (summarized in Ref. [67]), the so-called hydroxide hypothesis can reconcile these observations. This hypothesis states that a water molecule next to the Schiff base becomes firstly deprotonated by D85 after photoisomerization of the chromophore. The hydroxide then moves toward the cytosolic side of the chromophore like  $\text{Cl}^-$  in halorhodopsin.<sup>[67]</sup> There, it abstracts a proton from the protonated Schiff base so that as a net result, a water molecule is pumped inwardly and a proton outwardly.

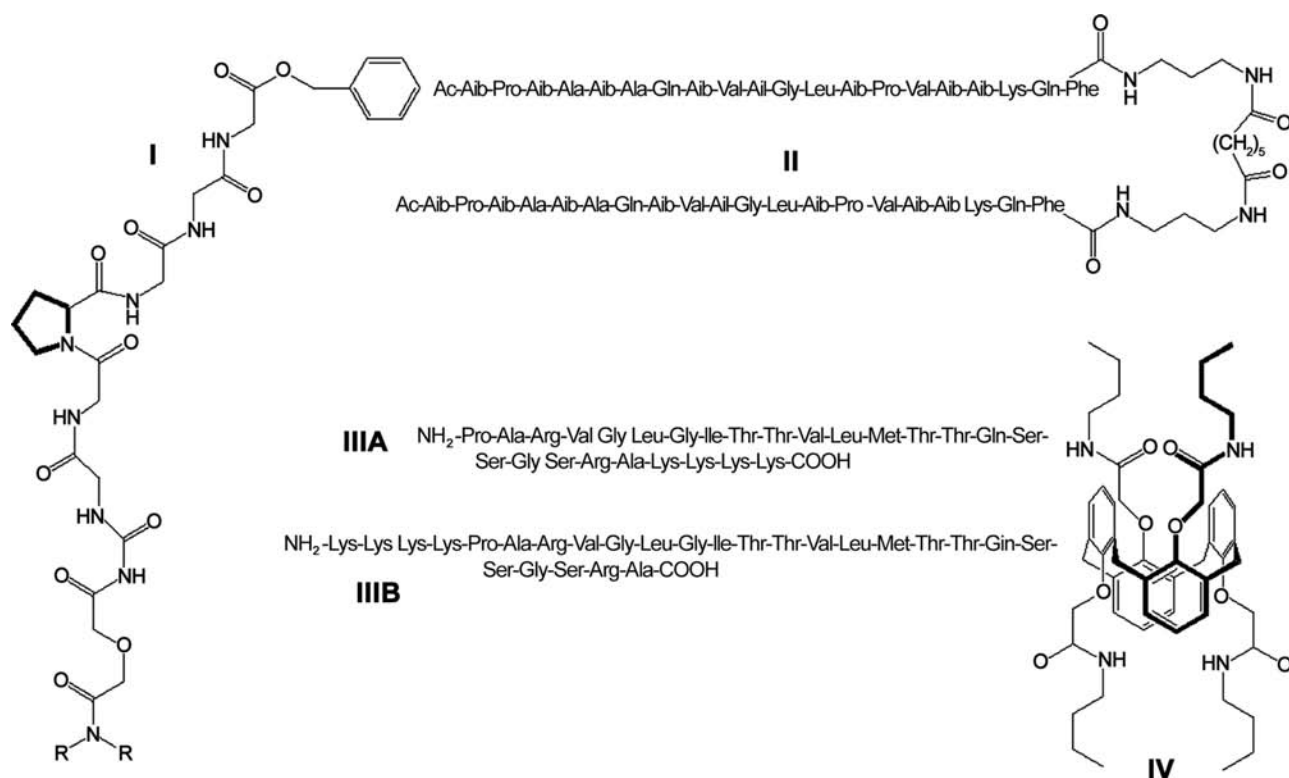

The hydroxide hypothesis suggests that the ion-translocating archaeal rhodopsins generally catalyze the passage of anionic species across the photoisomerized retinal where only steric and electrostatic properties of the transport site determine the  $\text{OH}^-$  vs.  $\text{Cl}^-$  specificity.

### CONCLUSION

The structural studies on natural, halide-conducting membrane proteins show that halides are stabilized in the central region of lipid bilayers by similar mechanisms as postulated before for the transfer of halides from aqueous to apolar phases, i.e., “fingering” of the aqueous solvent into the transmembrane region and electrostatic compensation of the halide’s charge. The charge compensation involves arginine side chains such as in halorhodopsin or the Omp32 porin or at least the alignment of the dipole moments of several helices toward the bound anion such as in the ClC channels. Apart from this, the chloride binding in these proteins occurs without a highly ordered coordination shell as observed before in cation channels. For the potassium channels, it was noted that  $\text{K}^+$  ions are highly regularly coordinated in the selectivity filter in two alternative coordination geometries:<sup>[37]</sup> a square-antiprismatic coordination sphere with eight oxygen atoms and an octahedral geometry with six oxygen ligands which are derived either from water or from carbonyl groups of the selectivity filter. These coordination geometries coincided with structural data from potassium-selective antibiotics such as nonactin or valinomycin and confirmed that there are common principles for the stabilization and the conductance of cations in lipid bilayers by  $\text{K}^+$ -selective ionophores and channels.

A common feature of the structures discussed above is certainly the partial lining of the selectivity filter by hydrophobic residues. According to the theory of large-ion conductance, such an apolar channel lining might impose an energetic penalty for water intrusion into the selectivity gate and induce the observed anion specificity by excluded volume effects.<sup>[9]</sup> Unfortunately, this theory might be hard to prove by mutagenesis and biophysical analysis of natural membrane proteins because small differences in the geometry of the channel could exert large differences for the energetics of water intrusion. What is needed is hence a much simpler and, in steric terms, more stringently defined system than the ClC-like chloride channels or the porins.

Biochemical and biophysical data about small, natural transporters such as cryptdin-3<sup>[18]</sup> or synthetic model compounds capable of transmembrane halide transport<sup>[68]</sup> have been reported since only a few years

**Fig. 5** Synthetic halide transporters. I = SCMTRs,<sup>[70]</sup> II = alamethicin derivative alm-K16,<sup>[69]</sup> IIIA = C-K<sub>4</sub>-M2GlyR,<sup>[75]</sup> IIIB = N-K<sub>4</sub>-M2GlyR,<sup>[78]</sup> IV = calix[4]arene tetrabutylamide. *Source:* From Ref. [76].

(Fig. 5). The design of most of the synthetic halide transporters is based on peptidic backbones. In the case of a specificity-modified, dimeric alamethicin derivative, a mild anion preference was built in by introducing a lysine residue close to the C-terminal end.<sup>[69]</sup> However, the observed anion preference was caused by a drop of the cation conductance, while anion permeability was unaffected in comparison to the parental alamethicin. Another more promising strategy followed by Schlesinger et al.<sup>[70]</sup> was inspired by the conserved motif GKxGPxxH that is present in the anion pathway of ClC chloride channels. By attaching the heptapeptide GGGPGGG to a lipidic anchor (Fig. 5), these authors obtained chloride conductivities with  $> 10 \text{ Cl}^-/\text{K}^+$  selectivity. Furthermore, they could show that these synthetic chloride membrane transporters (SCMTRs) exhibit voltage gating similar to natural chloride channels. Their conductance crucially depends on the presence of the proline kink<sup>[71]</sup> and the precise length of the lipidic moiety.<sup>[72]</sup> Interestingly, this design lacks a direct electrostatic compensation of the chloride charge. The distortion in the lipid bilayer by the proline kink might hence indicate a mechanism which relies on the “fingering” of partially dehydrated chlorides into the apolar region.

Another evidence for the relaxed structural requirements for transmembrane halide conductance is the observation that peptides which are derived from the transmembrane regions of CFTR or the GABA receptor readily form chloride channels *in vitro*.<sup>[73,74]</sup> As these peptides might have a pharmaceutical potential in the treatment of CFTR deficiency, i.e., cystic fibrosis, they are momentarily subject to further optimization in terms of solubility and conductance properties.<sup>[75]</sup> While these approaches to halide channels used peptidic backbones for the transmembrane region, one of the first successful designs of a nonpeptidic chloride transporter utilized a calix[4]arene as chemical scaffold (Ref. [76], Fig. 5).

Certainly, further high-resolution structural studies on synthetic and natural halide transmembrane transporters will be needed before our view about the transport of halides is similarly concise as it is nowadays for the transport of cations.

## INTRODUCTION

In this entry, we will describe an analytical atomic-resolution scanning transmission electron microscopy (STEM) study of supported nanoscale systems. The combination of high-resolution Z-contrast imaging and electron energy loss spectroscopy (EELS) provides an analytical tool with unprecedented chemical and spatial sensitivity that is vital for studying interfaces in heterogeneous catalyst systems. We study three examples of heterogeneous catalyst systems: Pt/SiO<sub>2</sub>, Pd/Al<sub>2</sub>O<sub>3</sub>, and Cu/Al<sub>2</sub>O<sub>3</sub> and the in situ reduction of PdO. In Pt/SiO<sub>2</sub>, the presence of a few monolayers of platinum oxide and changes in the chemistry of the SiO<sub>2</sub> support are characterized as a function of the catalyst preparation conditions. In Pd/Al<sub>2</sub>O<sub>3</sub>, electron transfer from the alumina toward the Pd particles appears to be dependent on the metal particle size that is observed. The Cu/Al<sub>2</sub>O<sub>3</sub>, reduced at various temperatures, exhibits increasing oxidation of the Cu particles upon higher temperature reduction. The in situ reduction of PdO upon heating in the microscope column confirms that the reduction to metallic Pd occurs through a shellwise mechanism, and the effects of beam damage are studied briefly on this system.

Heterogeneous metal catalysts are routinely used in a variety of chemical processes, including dehydrogenation, naphtha reforming, oxidation and automotive exhaust catalysis (e.g., see Ref.<sup>[1]</sup>). Although they have been successfully used for many years, a fundamental understanding of the mechanism behind their activity and selectivity remains elusive. This is

primarily because the bulk materials typically contain a wide range of metallic cluster sizes,<sup>[1–3]</sup> and the majority of experimental techniques, such as infrared absorption spectroscopy extended X-ray absorption fine structure (EXAFS)<sup>[4]</sup> do not have the required combination of spatial resolution (to see individual clusters) and chemical sensitivity (to see changes in composition and bonding). Although accurate information on the electronic structure can be obtained from these techniques, they all lack the ability to define the spatial location from which the information is obtained. The ability to characterize the structure, composition, and properties of individual clusters represents a key advance in the development of a fundamental understanding of existing heterogeneous catalysts and the future engineering of new and improved catalyst systems, as the chemical activity/selectivity in many systems is known to be intimately related to the cluster size.<sup>[5]</sup>

Since it has become increasingly clear that in many cases the core phenomena occur at interfaces between the metal clusters and the support,<sup>[6]</sup> the traditional method of investigating interfaces, transmission electron microscopy (TEM),<sup>[2,7]</sup> is not sensitive to small local changes in composition and electronic structure. There is therefore an “information gap” between what can be learned from spectroscopy and what can be obtained from microscopy. The combination of Z-contrast imaging and EELS can potentially fill this information gap. Here, we describe the combination of Z-contrast imaging<sup>[8]</sup> and EELS<sup>[9]</sup> in the STEM that permits the characterization of individual nanoclusters in heterogeneous catalyst systems on the atomic scale.

The Z-contrast technique routinely provides atomic resolution images of the interface between the support and the metal cluster.<sup>[10]</sup> Using this image to position the probe, one can acquire an energy loss spectrum from any location in and around the interface,<sup>[11,12]</sup> allowing local changes in electronic structure to be correlated directly with the size and composition of the metal cluster. If this analysis is performed on catalysts whose preparation and reaction history is known, then this characterization tool can be used, in conjunction with the surface techniques mentioned above, to derive a fundamental understanding of the mechanism behind activity/selectivity in heterogeneous catalysts.

The metal–support interaction (MSI) is studied in three different systems, Pt/SiO<sub>2</sub>, Pd/Al<sub>2</sub>O<sub>3</sub>, and Cu/Al<sub>2</sub>O<sub>3</sub>. There are two reasons to choose these three systems. One is that they are all important catalysts used in environmental catalytic technologies.<sup>[13–27]</sup> Another is that there are still controversies on some main issues of these catalysts. For example, the activity and selectivity of these Pd catalysts are strongly affected by the support material used.<sup>[28]</sup> Hence, the interaction with the support can alter the electronic properties of palladium. Although a strong metal support interaction (SMSI)<sup>[29,30]</sup> was not seen, it was suggested that the MSI originates from the formation of Pd–Al alloys at the metal–support interface.<sup>[31]</sup>

Furthermore, the reduction behavior of PdO is investigated in situ by EELS to clarify its reduction mechanism. In addition, it is treated as a model system to study the beam effect on the metal oxides in our experiments.

## EXPERIMENTAL TECHNIQUES

The STEM and EELS results presented in this entry were obtained using a JEOL 2010F STEM/TEM, having a Schottky field emission gun source and being operated at 200 kV.<sup>[32–34]</sup> The microscope is equipped with a standard ultra high resolution objective lens pole piece, a JEOL annular dark-field detector, a post column Gatan imaging filter (GIF), and a piezo stage for drift control.<sup>[33,34]</sup> The key to atomic resolution in STEM<sup>[33–35]</sup> is the formation of the smallest possible electron probe with sufficient probe current (~40 pA) to obtain statistically significant images and spectra (Fig. 1). The electron probe is optimized using the electron “Ronchigram,” or “shadow image,”<sup>[33,36]</sup> to obtain a probe size of ~0.2 nm.

The Z-contrast image is formed by collecting the scattered intensity on a high-angle detector (35–100 mrad). The high angles and large angular range of this detector effectively average out the coherent effects in the image, thereby allowing it to be regarded as a simple convolution of the average scattering cross section located at

**Fig. 1** Schematic of the detector arrangement for STEM imaging and analysis.

the position of the atomic columns and the incoming electron probe intensity profile.<sup>[34]</sup> As the scattering amplitude at high angles is essentially Rutherford scattering,<sup>[35]</sup> the measured intensity is proportional to the average atomic number of the column (i.e.,  $\sim Z^2$ ). If the atomic spacing in a zone-axis orientation is larger than the probe size, a direct atomic resolution image can be obtained.<sup>[32–35]</sup>

The experimental setup of this microscope allows us to use the low-angle scattered electrons that do not contribute to the Z-contrast image for EELS.<sup>[37]</sup> As the two techniques do not interfere, the Z-contrast images can be used to position the electron probe at the desired spot in the sample to acquire spectra.<sup>[9,33,38]</sup> The physical principle behind EELS relates to the interaction of the fast electrons with the sample to cause either collective excitations of electrons (plasmons), or discrete transitions between atomic energy levels.<sup>[11,12]</sup> Here, only the highly localized, discrete atomic transitions commonly known as core losses, which allow both compositional analysis and the degree of bonding hybridization to be determined, will be considered.

The in situ heating experiments that are performed here utilize a double tilt heating stage with a variable temperature range between 20° and 1000°C. The oxygen partial pressure in the microscope column is  $P_{O_2}^{gas} \sim 5 \times 10^{-8}$  Pa during the experiment, which means that at 300°C the samples are in a highly reducing environment (for a more detailed description see Ref.<sup>[39]</sup>). To compensate for the continuous drift of the heating holder a piezoelectric driver is used. The piezo-stage drift control was originally developed to eliminate the systematic specimen drift in HRTEM imaging mode. The computer-controlled stage can also be used to compensate for drift in STEM mode. Using the Ronchigram,<sup>[33,45]</sup> the autocorrelation algorithm computes and corrects for the specimen drift.

One side effect of irradiation on the sample with high-energy electrons is that ionizing radiation can damage the specimen. Although STEM is generally considered a low-dose technique with beam currents of  $\sim 40$  pA, radiation damage remains the major challenge in analytical high-resolution STEM analyses. Some aspects of beam damage are particularly pronounced at higher voltages. The most common radiation damage mechanism in oxide materials is the loss of oxygen because of the ionization of the bulk structure. We will study this effect on the PdO system. In amorphous support oxides and especially at the metal–oxide interfaces, radiation damage is hard to detect. The only way to monitor radiation damage effects is to acquire a set of EEL spectra with very short exposure times and observe the continuous changes in the near-edge fine structure. Therefore, it remains very difficult to distinguish the genuine reduction of the interfacial support region from radiation damage effects that take place predominately at the interface.

Because of the specimen preparation techniques, the catalyst system exhibits an uneven surface topology. The spherical oxide support and small, suspended

metal cluster cause the region of interest to be at various different heights with respect to the focal plane of the objective lens system. Consequently, the images of particles that are not in the focal plane appear blurred. For regions out of the focal plane, the height of the sample will be changed until it appears in focus rather than changing the objective lens excitation, as changing the objective lens excitation will result in a decreased spatial resolution. The effects of varying sample heights is particularly pronounced at the metal–support interface for larger metal particles, and it is essential that the ideal height is found to obtain the ideal spatial resolution.

## APPLICATIONS

### Pt/SiO<sub>2</sub>

These catalytic systems were prepared by impregnating colloidal amorphous SiO<sub>2</sub> microspheres (Nissan Chemical Snowtex ZL) of  $\sim 80$  nm diameter with platinum tetraamine hydroxide (pH = 9.3). After an overnight drying at 120°C, the resulting Pt/SiO<sub>2</sub> catalyst was exposed to two different calcination treatments at 350° and 250°C, respectively.

The first set of Pt/SiO<sub>2</sub> sample was heated in an oven to a temperature of 350°C in air. The calcination process was completed after 3 hr and the catalyst was then prepared for TEM analysis. To achieve the appropriate electron transparent samples, the catalyst was crushed to a fine powder. A pure copper grid was then dipped into the fine crushed powder, and a considerable amount of material stuck to the grid for TEM investigations. The average metal particle size is measured by conventional phase contrast imaging to be  $\sim 20$  nm (average dispersion  $\sim 4.5\%$ ).

Fig. 2A shows a high-resolution STEM image of a particle edge on the supporting SiO<sub>2</sub> sphere in a

**Fig. 2** Pt/SiO<sub>2</sub> (calcined at 350°C) at room temperature. (A) Z-contrast image with locations of EELS analysis indicated. (B) EEL spectra showing oxygen K edges with acquisition time  $t = 10$  sec. The dotted lines indicated the edge onsets. Spectra c and d are magnified by a factor of 2. (C) EEL spectra showing Si L edges with acquisition time  $t = 0.3$  sec.

**Fig. 3** Pt/SiO<sub>2</sub> (calcined at 250°C) at room temperature. (A) Z-contrast image with locations of EELS analysis indicated. (B) EEL spectra showing Si L edges with acquisition time  $t = 0.3$  sec. Spectrum e reflects a model spectrum of pure silicon. The interface spectra are magnified by a factor of 2–3 to observe the changes in the fine structure. The dotted lines indicated the edge onsets with an edge-onset shift of  $\Delta = 3.5$  eV.

random orientation (i.e., atomic resolution images of the lattice are not possible). The examination of several edge on particles reveals that the bright core of the particle is surrounded by a darker ring of material that seems to be of a different nature than the center.

A series of EEL spectra (Fig. 2B) were acquired from the positions indicated in Fig. 2A. The spectrum labeled “a” from the bulk of the amorphous SiO<sub>2</sub> sphere has an edge onset of 539 eV. The spectrum taken from the interface does not show any obvious changes, except for a lower intensity of the oxygen peak, which is caused by the decreasing amount of SiO<sub>2</sub> under the beam. The Pt particle bulk spectrum, magnified by a factor of 2, does not show any contribution from oxygen in the spectrum. The spectrum labeled “d” is taken from the lower contrast edge of the particle. In this spectrum, the onset of the edge is shifted toward a lower energy (532 eV) and the main peak is shifted from 548 to 546 eV. The Si L edge spectra (Fig. 2C) are taken from the same positions. The support bulk spectrum displays the fine structure expected for amorphous SiO<sub>2</sub>,<sup>[46]</sup> with an edge onset of 105 eV, and the L<sub>3</sub>, L<sub>2</sub>, and L<sub>1</sub> edges at 108, 112, and 160 eV, respectively. For the interface spectrum b, the same peaks are visible, although the intensity ratios are slightly different. This small change is attributed to the thinner illuminated edge of the SiO<sub>2</sub> sphere. The spectrum c shows no obvious modulation of the background. The particle surface spectrum (not displayed here) exhibits similar features as spectrum c. This indicates that no Si is in or on the surface of the metallic particle.

The combination of the oxygen and silicon near-edge fine structure analyses unambiguously shows that an ordered oxide layer surrounds the Pt particles. The very low intensity of the spectral changes indicates that the thickness of this layer is in fact only around a few monolayers. The changes in the energy loss spectra are so significant that a modulation because of contamination or artifacts can be excluded. This structure can be explained by a partial surface oxidation or

chemisorption of oxygen on the Pt–metal particle during the calcination at high temperatures. An adsorbed layer of oxygen after calcination would not be stable under the electron beam, hence a Pt–O surface layer seems the best explanation. The fact that bulk platinum is regarded as a noble metal and therefore very hard to oxidize does not contradict this observation, because small metal particles often exhibit a completely different behavior with decreasing particle size.<sup>[4]</sup> The second set of Pt/SiO<sub>2</sub> system was heated in air from room temperature to 250°C and kept at this temperature for 3 hr. The TEM sample was prepared in the same manner as the previous one. TEM measurements reveal that the average particle size is ~15 nm with a dispersion of ~6%.

The room temperature Z-contrast images (Fig. 3A) show a similar particle structure to the previous sample, with the bright core and the darker halo around the center. The positions where the EEL spectra are acquired are indicated in Fig. 3A and the corresponding spectra are displayed in Fig. 3B. The oxygen edges were detected only at the supporting oxide and the interface. The SiO<sub>2</sub> bulk spectrum (spectrum a) looks similar to the bulk spectrum of the amorphous support in the previous section. For the center of the interface between the support and the Pt particle (spectrum b), all the edges are still visible, and the peak intensity ratios are different because of the decreased specimen thickness. The spectra from the edge of the interface show some interesting changes in the fine structure. Here, the L<sub>1</sub> and L<sub>3</sub> edge intensities decrease and a shift in the edge onset from 105.5 to 102 eV can be measured. Spectrum e shows the energy loss spectrum from a different bulk crystalline Si sample. Because of the unavoidable surface oxidation of Si, this spectrum represents a mixture of amorphous SiO<sub>2</sub> surface layers and crystalline Si. Spectrum b as well as spectrum c show a remarkable similarity to the Si–SiO<sub>2</sub> reference spectrum. All interface spectra are

**Fig. 4** Pt/SiO<sub>2</sub> (calcined at 250°C) at 300°C in  $5 \times 10^{-8}$  Pa after 3 hr of heating. (A) Z-contrast image showing the heated metal particle and locators for EEL spectra. (B) Si L edges from the indicated positions with acquisition time  $t = 0.3$  sec. Spectrum e reflects a model spectrum of pure silicon. The interface spectra are magnified by a factor of 2–3 to observe the changes in the fine structure. The dotted lines indicated the edge onsets with an edge-onset shift of  $\Delta = 3.5$  eV.

magnified by a factor of 4 to enhance the visibility of the fine structure.

To investigate further these changes in the fine structure of the Si L edges, the sample was then heated in the microscope column to a temperature of 300°C for 3 hr. Afterward, the same set of measurements was repeated on a different particle with similar bulk and interfacial features. The structure of the particles seems to be unchanged (Fig. 4A) and the heating holder is stable enough at these temperatures to acquire even atomic resolution Z-contrast images. The SiO<sub>2</sub> bulk spectrum onset (spectrum a) is located at 105 eV, similar to the unheated bulk spectrum, but the spectra b, c, and d display an enhanced decrease in the L<sub>3</sub>, L<sub>2</sub>, and L<sub>1</sub> edge intensity than was previously observed. In addition to the nearly total disappearance of the L<sub>3</sub> and L<sub>1</sub> peaks, there is also an extra intensity below this onset of the bulk spectrum. An EEL spectrum taken from crystalline bulk Si (with SiO<sub>2</sub> surface layer) is displayed as spectrum e. Furthermore, we acquired a series of spectra under similar conditions close to the surface of Si spheres without any Pt particles attached and no change in the L<sub>3</sub>, L<sub>2</sub> intensity was observed.

The integrated Si/O ratio<sup>[40]</sup> was calculated for the bulk and interface spectra at room and elevated temperatures, and a decrease in the oxygen content toward the interface was determined. At room temperature the Si:O intensity ratio (note that this is not the chemical composition ratio, as the scattering cross sections are not taken into account) increased from  $0.9 \pm 0.1$  in the support to  $1.2 \pm 0.1$  at the heterointerface, whereas at 300°C this difference is further enhanced ( $0.9 \pm 0.1$  in the support and  $1.9 \pm 0.1$  at the interface).

The monolayer of surface oxide around the Pt clusters was not observed for the sample calcined in air at 250°C (this suggests that the oxidation of these Pt particles occurs at higher temperatures). However, the more interesting result in this sample is the change in

the fine structure of the silicon L edges, which can be attributed to the transformation of amorphous SiO<sub>2</sub> in the bulk of the spheres toward a reduced form of SiO<sub>2</sub> at the interface. Furthermore, the spectra that are observed at the interface can be reconstructed from a linear combination of SiO<sub>2</sub> and Si. In addition, the interface spectra exhibit a very similar prepeak intensity with respect to the white-line intensities as the reference Si/SiO<sub>2</sub> spectrum.

The reason for the formation of such an interface layer remains unsolved. One possible explanation might be that a thermally induced PtSi<sub>x</sub> layer, very similar to the CoSi<sub>x</sub> interface structure observed in Co/SiO<sub>2</sub>/Si<sup>[41]</sup> can build up at the heterointerface. The fact that the Si prepeak increases upon in situ reduction suggests a growing amount of Si present in the interface. Therefore, we cannot rule out this formation mechanism. Further investigations of similar systems and the correlation of these data to other conventional techniques will help to solve the origin of this effect and lead to an understanding of the influence of this interface layer on the overall performance of the catalytic system.

### Pd/Al<sub>2</sub>O<sub>3</sub>

A gamma alumina ( $\gamma$ -Al<sub>2</sub>O<sub>3</sub>) powder (BET SA 160 m<sup>2</sup>/g and Hg pore volume 2.3 mL/g) and sufficient solution of Na<sub>2</sub>PdCl<sub>4</sub> (adjusted to pH = 4) was used to prepare the catalyst, thus giving a Pd loading of 2 wt.%. The samples were dried overnight at 393 K and portions were reduced at temperatures of 250°, 500°, and 800°C with 4% H<sub>2</sub> in Ar (for more details, see Ref.<sup>[42]</sup>).

To obtain the particle size distribution for the catalyst reduced at 250°, 500°, and 800°C, 200 particles from different areas of each specimen of the catalyst were examined. At the reduction temperature of

**Fig. 5** (A) Z-contrast image showing the locations of EEL spectra. (B) EEL spectra acquired from a Pd particle in the Pd/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalyst reduced at 250°C.

250°C, the statistical results indicate that most particles are less than 7 nm (in the size range of 2–5 nm). The overall size distribution at 500°C is increased slightly. At the reduction temperature of 800°C, the distribution of the particle sizes is dramatically altered. Most of the particles have grown into the size range of 7–30 nm with several very large particles (>30 nm) observed because of sintering at these high temperatures. Unlike the samples reduced at lower temperatures, the particle size distribution in the sample reduced at 800°C is very wide. Furthermore, most of the particles are faceted with flat surfaces, which is significantly different from those samples reduced at lower temperatures.

Fig. 5A shows a high-magnification Z-contrast image of the catalyst reduced at 250°C, in which a small particle coexisting with an alumina crystal is clearly observed. The corresponding energy-loss spectra are shown in Fig. 5B. Spectra 1 and 2 are acquired from the surface and center of the particle. The spectra consist of delayed Pd M<sub>4,5</sub> (for metallic Pd with onset at 335 eV) and the M<sub>2,3</sub> (at 532.3 eV for metallic Pd) edges, or the oxygen K edge (onset at around 532 eV). It is obvious that the Pd M<sub>2,3</sub> edges overlap with the

oxygen K edge, which makes the identification of the oxidation state of the Pd particles difficult. Nevertheless, no obvious peaks showing up at around 532 eV in the two spectra suggests that this particle is primarily composed of metallic Pd. Comparing spectrum 3, acquired from the interface with spectrum 4 from the support, we can see there is no obvious chemical shift of the oxygen K edge or Pd M<sub>2,3</sub> edges in the interface spectrum. This is the case for all interfaces studied, except for the one large particle, where a 4.8-eV negative chemical shift was observed in the M<sub>2,3</sub> interface spectrum.

Fig. 6A shows the catalyst reduced at 500°C in which a Pd particle coexists with the alumina support. Energy-loss spectra acquired from the positions marked in Fig. 6A are shown in Fig. 6B. Spectra 1 and 2 show metallic Pd features, which suggest that the small clusters formed at this temperature are metallic Pd. No obvious oxygen K edge (or Pd M<sub>2,3</sub> edges) shift for the interfacial spectrum 3 relative to the support spectrum 1 was observed. However, chemical shifts larger than 2.4 eV were observed for the spectra acquired from the interfaces between the large particles and the alumina support.

**Fig. 6** (A) Z-contrast image showing the locations of EEL spectra. (B) EEL spectra acquired from a Pd particle in the Pd/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalyst reduced at 500°C.

**Fig. 7** (A) Z-contrast image showing the locations of (B) EEL spectra acquired from a Pd particle in the Pd/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalyst reduced at 800°C, (C) oxygen K edges of the interface spectrum 4, the support spectrum 5, and a spectrum acquired from PdO.

Fig. 7A shows a high-magnification Z-contrast image of the catalyst reduced at 800°C. Here the particle sizes are much larger than in the previous two specimens. The spectra (1 to 3, Fig. 7B) acquired from the large particle indicate that it is metallic Pd. However, spectrum 4 is noticeably different from these three spectra. The onset of oxygen K edge (or Pd M<sub>2,3</sub> edges) exhibits a shift of  $3.6 \pm 0.6$  to 528.4 eV in the interface spectrum. These large chemical shifts are the same as have been observed in interfacial spectra acquired from the interfaces involving larger particles in the previous specimens. Fig. 7C shows only the oxygen K edges (Pd M<sub>2,3</sub> edges) of the interface spectrum along with reference spectra from PdO, together with  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (spectrum e) and a spectrum that is a combination of the PdO and  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>. It can be seen that the full width at half maximum (FWHM) of the main peak in the spectrum 4 is larger than those of the reference spectra and it has a  $3.6 \pm 0.6$ -eV negative shift in the edge onset. The fact that the fine structure of the interface spectrum is similar to the addition of the PdO and  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> spectra suggests that this shift is due to a downward shift in energy of the Pd M<sub>2,3</sub> edge.

The above results show that there exist chemical shifts in the interface spectra acquired from the interfaces between larger (>10 nm) Pd particles and the support. This may be because of an interaction between the metal clusters and support that is size dependent. The edge shifts are much larger than those in known Al–Pd alloys, which have been reported to be 1.7–1.9 eV for AlPd and 2.5 eV for Al<sub>3</sub>Pd,<sup>[18]</sup> indicating that the observed shifts are not due to the formation of an Al–Pd alloy. Furthermore, the shifts appear not to be due to the oxidation of Pd, as the Pd 3d<sub>5/2</sub> binding energy for metallic Pd is smaller than that for PdO.<sup>[19,20]</sup> This indicates that once oxidized, the Pd 3d<sub>5/2</sub> binding energy will shift to a higher energy—the reverse of what is observed. Moreover, electronic structure calculations of Pd–alumina interfaces also showed that the Pd–O interaction is relatively weak, while the Pd–Al interaction plays a more important role in metal–alumina bonding.<sup>[21]</sup>

The negative energy shift therefore suggests that the Pd particles are negatively charged. This may be because of the charge transfer from the support to the Pd particles during reduction; a mechanism that is consistent with general chemistry principles.<sup>[22]</sup>

**Fig. 8** (A) Low-magnification Z-contrast image of the catalyst reduced at 250°C. (B) EEL spectra collected from different parts of the specimen.

It means that the support can act as an electron donor to the Pd particles, resulting in negatively charged Pd clusters.

### Cu/Al<sub>2</sub>O<sub>3</sub>

Gamma alumina powder with a BET surface area and pore volume of 160 m<sup>2</sup>/g, and 1.3 mL/g, respectively, was used as the catalyst support. A 10% aqueous slurry of the alumina and an aqueous solution as CuCl<sub>2</sub> · 2H<sub>2</sub>O to get 1.0 wt.% Cu loading were prepared. The slurry was heated (70°C for 30 min), filtered, and dried in an oven in air at 120°C overnight. This dried catalyst was reduced in a tube furnace by a stream of 4% H<sub>2</sub>/Ar (at a flow rate of 40 mL/min) for 2 hr at various temperatures (250°, 500°, and 800°C) (for more details, see Ref.<sup>[43]</sup>). Specimens were prepared for electron microscopy analysis by placing the powders on holey carbon-coated copper grids.

Fig. 8A shows low-magnification images taken from the Cu/γ-Al<sub>2</sub>O<sub>3</sub> catalyst reduced at 250°C. From the images we can see that the catalyst consists of mainly needlelike particles and some small irregular

particles. No separated copper species can be resolved from the Z-contrast images, although there exists a great Z difference between Cu and Al and O. Moreover EEL spectra collected from different particles do not show the expected copper L<sub>2,3</sub> edges (see the insert shown in Fig. 8B). As the Cu M<sub>2,3</sub> edges (onset: 74 eV) overlap with the Al L<sub>2,3</sub> edges (onset: 78 eV), we could not identify whether or not the EEL spectrum shown in Fig. 8B contains the copper peaks. However, energy dispersive X-ray spectroscopy (EDS) clearly shows the presence of copper in the catalyst. The fact that no obvious copper species can be directly resolved indicates that copper species is highly dispersed within the catalyst when reduced at 250°C.

Fig. 9 shows results obtained from the catalyst reduced at 500°C with two types of morphological particles, ringlike besides the needlelike particles. One interesting feature is that bulklike particles always coexist with ringlike particles, although they are not completely encapsulated by the ringlike particles. The Z-contrast image with several particles marked as “a” and “b” (ringlike), “c” (bulklike), and “d” (needlelike).

**Fig. 9** (A) Z-contrast images with ringlike feature of the catalyst reduced at 500°C, (B) corresponding EEL spectra.

**Fig. 10** (A), (B), and (C) Z-contrast images and (D) EEL spectra from a particle having a core-shell structure formed when the catalyst was reduced at 800°C.

As the white-line intensity of the Cu  $L_{2,3}$  edges is inversely proportional to the occupancy of the Cu 3d orbitals, the intensity of the white lines gives an accurate indication of the copper valence. For metallic copper, the white lines are not present and the intensity in the spectrum corresponds to transitions to the relatively flat region of the density of states with d character. Upon oxidation, electrons are transferred from these orbits to oxygen atoms and the white-line intensity increases.<sup>[44–46]</sup> The white-line intensity can thus simply be used to fingerprint the oxidation state of the Cu atoms. Based on the  $L_3/L_2$  intensity ratios calculated from reference spectra, the CuO and Cu valence states can be obtained. Fig. 9B shows that a mixture of metallic Cu and  $\text{Cu}^{1+}$  is present in the metallic clusters. Copper species in the ringlike particles (spectra a, b) exists as  $\text{Cu}^{2+}$  state.

Several very large spherical particles were observed in the catalyst reduced at 800°C (Fig. 10A). The image clearly shows this particle has a core-shell structure (Fig. 10B). To identify the structure of this particle, an EELS profile across the particle was acquired. Fig. 10C shows the positions of the particle from which EEL spectra were collected and the corresponding EEL spectra are shown in Fig. 10D. Based on the

obtained  $L_3/L_2$  intensity ratios, spectra a and b are identified as  $\text{Cu}^{1+}$  (spectrum b may indicate a mixture between  $\text{Cu}^{1+}$  and metallic Cu) and spectrum c was acquired from an overlapped area of  $\text{Cu}^{1+}$  and metallic Cu species and spectrum d mainly metallic Cu.

For comparison, the catalyst prerduced at 250°C was also in situ heated at 550°C in the microscope and small particles are formed. These particles grow larger with increased heating times as shown in the image in Fig. 11A (which was acquired after the specimen had been kept at 550°C for about 40 min). Analysis of the EEL spectra (Fig. 11B) ( $L_3/L_2$  intensity ratios  $a = 2.44$  and  $b = 1.7$ ) indicates that the particle again contains metallic cores with a partially oxidized surface layer. This is an intriguing result as oxygen partial pressure in the microscope column is about  $5 \times 10^{-8}$  Pa during the experiment, i.e., it is a highly reducing atmosphere. This experiment clearly indicates that reduction at higher temperatures can result in partially oxidized states of copper.

The data demonstrate that no separated copper species were detected in the catalyst reduced below 250°C. Upon reduction at 500°C, the catalyst is reduced to  $\text{Cu}^{1+}$  and metallic Cu species, and the redistribution of these species occurs. At the temperatures higher

**Fig. 11** Z-contrast images taken from the prerduced copper catalyst at 250°C, (A) during in situ heating at 550°C K in the microscope for 40 min. (B) EEL spectra acquired from different parts are shown in (A).

than 800°C,  $\text{Cu}^{1+}$  species still exists in shells of some big spherical particles having core-shell structures with metallic Cu in the cores.

It should be noted that we did not avoid exposure of the catalyst to air after the catalysts had been reduced in the catalyst and specimen preparation procedures. Therefore, the possibility that the  $\text{Cu}^{1+}$  species in the reduced catalyst are formed because of the reoxidation of metallic Cu when the catalyst was exposed to air cannot be completely ruled out.<sup>[47]</sup> X-ray absorption near-edge spectroscopy (XANES) of  $\text{Cu}/\gamma\text{-Al}_2\text{O}_3$  shows that the catalyst did not change markedly on exposure to air at 21°C.<sup>[48]</sup> This means that for a similar system, the reduced metallic copper species did not react with the oxygen in air, and the in situ heating experiment indicated that upon reduction in the microscope at high temperatures, partially oxidized copper species are obtainable.

Based on these results, it is probable that the  $\text{Cu}^{1+}$  species in the reduced catalysts are formed by the interaction of copper species with the  $\gamma\text{-Al}_2\text{O}_3$  support. Such a mechanism is supported by the observations in several studies of the formation of a  $\text{Cu}_2\text{O}$  phase between metallic copper and alumina substrates.<sup>[45,49,50]</sup> It was found that the oxidation state of copper at the interface is nominally  $\text{Cu}^{1+}$ , i.e., the bonds at the interface being preferentially established between Cu–O rather than Cu–Al and the formation of  $\text{Cu}_2\text{O}$  at the interface is independent of oxygen partial pressure. Given the propensity of metallic Cu to form bonds with oxygen, it may well be that the oxide surface is formed from an interaction with the support oxide and acts as a protective skin against further oxidation when exposed to air afterward.

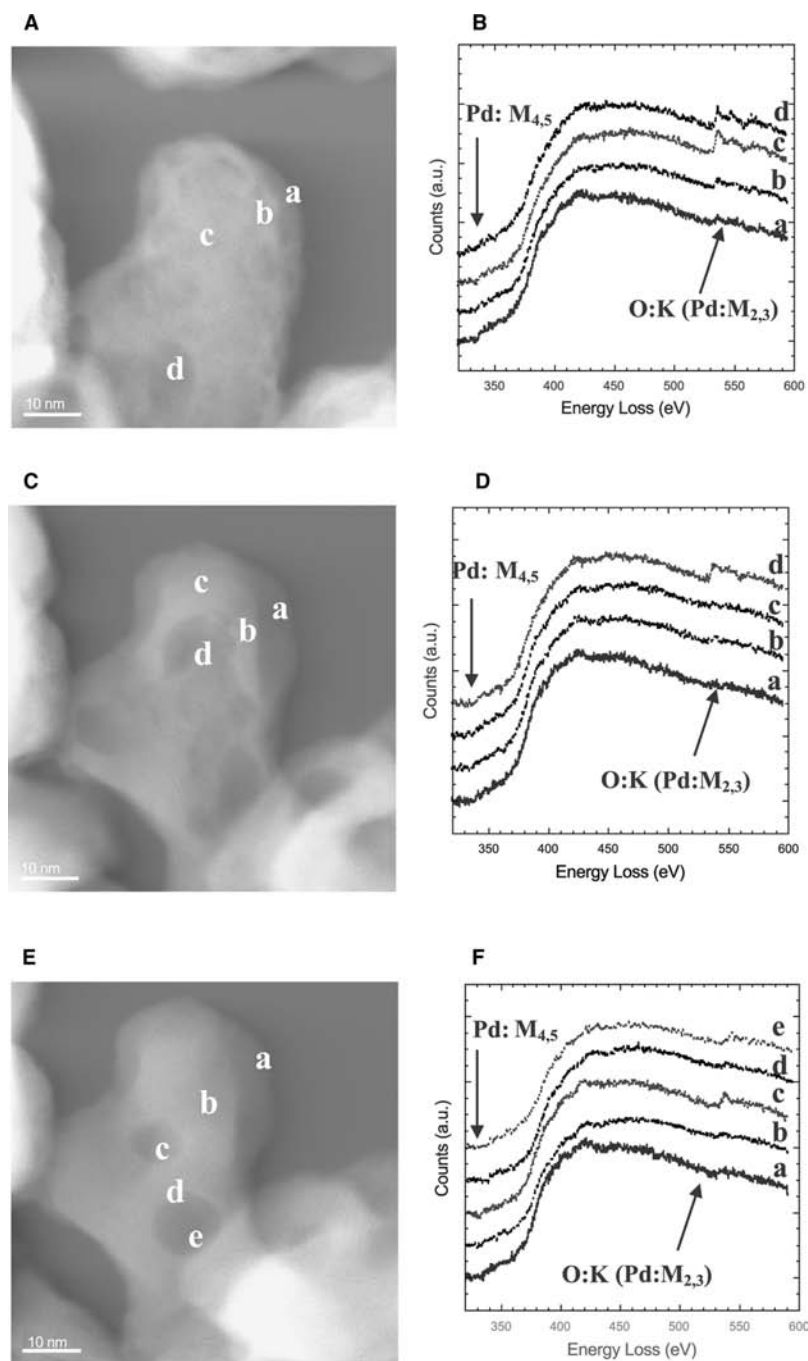

## PdO

PdO specimens were prepared by placing some powder (Aldrich) on holey carbon-coated molybdenum grids

directly. Fig. 12A, C, and E shows Z-contrast images of a PdO particle upon heating at the temperature of 300°C for about 15, 30, and 90 min, respectively. These images show that the morphology of the particle changed after the specimen has been kept at 300°C for 90 min. Shrinkage of the whole particle and also two dark areas, which suggests the formation of voids inside the particle, can be observed. Fig. 12B, D, and F shows corresponding EEL spectra. The features of the EEL spectra show that upon heating at the temperature of 300°C in the microscope, PdO has been reduced to metallic Pd from the surface. The whole PdO particle seems to have been reduced to metallic Pd when it has been heated for about 90 min.

The above in situ EELS studies directly indicate that PdO reduces upon being heated in the microscope via the shellwise manner as previously reported.<sup>[51,52]</sup> First, a metallic shell is formed, and then the whole particle is reduced to metallic Pd at further reduction. Moreover, it demonstrates that this atomic resolved spectroscopic technique is much suitable for the study of nanoparticles with core-shell structures.

It has been known that metal oxides may experience damage under electron beam irradiation.<sup>[53]</sup> Here, the behavior of the PdO phase under electron beam irradiation at room temperature was studied. Fig. 13A is a Z-contrast image taken from a PdO particle. A series of EEL spectra (Fig. 13B) was acquired by placing the electron probe at the position marked as 1 in Fig. 13A for different duration times of 3, 60, 180, and 240 sec, respectively. It shows that the intensity of the oxygen K ( $\text{Pd M}_{2,3}$ ) edges decreases after the sample has been irradiated by the probe for about 60 sec, which indicates that PdO started to be reduced. Once the irradiation time has reached about 240 sec, PdO has been reduced completely to metallic Pd. Fig. 13C shows the oxygen K and the Pd M edges for the corresponding irradiation times, and the changes in the near-edge fine-structure clearly show the reduction of PdO.

**Fig. 12** (A), (C), and (E) show Z-contrast images of a PdO particle upon heating at the temperature of 300°C for about 15, 30, and 90 min, respectively. (B), (D), and (F) are corresponding EEL spectra.

From the in situ EELS study of the PdO phase under a strong focused-beam irradiation, it is clear that if a relatively long dwelling time was used for EEL spectra collection, we could not obtain the “real” oxidation state of Pd in the PdO phase, as the oxide has been reduced. Hence, it is essential for high-resolution studies of PdO and other oxide catalyst systems to reduce the exposure of the system to the beam as much as possible.

Experimentally, imaging a particle at low magnification and acquiring a spectrum using a dwelling time

shorter than 10 sec, it is still possible to acquire an EEL spectrum characterizing Pd<sup>2+</sup>.

## CONCLUSION

In conclusion, the ability to observe the structure, characterize the composition, and map electronic structure changes at atomic resolution under various thermodynamic conditions provides an unparalleled capability to understand the effects that the interface and

**Fig. 13** (A) Z-contrast images of a PdO particle. (B) EEL series spectra acquired from the position 1 after having been irradiated for different times. (C) Oxygen K and Pd M<sub>2,3</sub> edges of the profile spectra together with Pd and PdO spectra.

surface of metallic particles impose on the overall behavior of heterogeneous catalytic systems. We have shown that atomic resolution analysis is possible with a chemical and spatial sensitivity never achieved before.

Results from Pt/SiO<sub>2</sub> show that single layer of material on surface of the metal clusters as well as at the cluster support can be studied. Furthermore, it can be seen that the surface morphology of the Pt metal clusters and the heterointerface structure depends strongly on the catalyst preparation. Although the metal support interaction in these systems is considered weak, we could detect a few monolayers of reduced support oxide at the interface, which might indicate an even stronger reduction for higher metal-support interaction systems.

The studies of the Pd/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalysts, reduced at three different temperatures, show that small metallic Pd particles are formed when reduced at lower temperatures with no detectable alteration of the interfacial support oxide. With increasing reduction temperature, the Pd particles grow in size, but a strong interaction occurs only between the larger metallic Pd clusters and the alumina support, resulting in negatively charged Pd cluster. The overall interaction between the particles and the support can be correlated

with the activity of the catalyst in CO dissociation. The microstructure of a Cu/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalyst during its heating in H<sub>2</sub>/Ar has also been studied. Based on the results presented here, at low reduction temperatures, no detectable separated copper species are formed in the catalyst. At higher reduction temperatures, larger pure metallic Cu particles are formed in addition to smaller Cu particles that are partially covered by a Cu<sub>2</sub>O shell, which ultimately grows to form CuO<sub>2</sub> shells surrounding metallic Cu clusters. This indicates that the MSI results in an oxygen transfer from the support to the catalyst particles to fully oxidize the Cu clusters. In the future, the combination of Z-contrast imaging and EELS in correlation with conventional methods such as chemisorption or X-ray diffraction has the potential to provide an exceptional tool to investigate the new effects observed in these catalytic systems and achieve the long-term goal of explaining their origin.

## ACKNOWLEDGMENTS

This research was sponsored by ExxonMobil Research and Engineering Company, and Monsanto Company.

The experimental results were obtained on the JEOL 2010F operated by the Research Resources Center at UIC and funded by NSF under grant number DMR-9601796. The authors would like to thank S. Miseo and W. C. Horn from ExxonMobil Research and Engineering, NJ, and N. Nag from Engelhard Corporation for providing the catalyst samples.

# Heterogeneous Catalytic Reactions by Mass Spectrometry

Steven M. Thornberg

Deborah E. Hunka

Sandia National Laboratories, Albuquerque, New Mexico, U.S.A.

## INTRODUCTION

One of the challenges facing chemists from a variety of disciplines (e.g., catalysis, biochemistry, materials science) is to determine the identity of unknowns, mechanisms and kinetics of reactions, and the nature and stability of intermediates. For example, understanding the mechanisms for catalytic reactions can allow for the design of custom catalysts. Powerful analytical tools (e.g., FT-IR, NMR, X-ray) are often used to study such things as surface states, adsorbed species, intermediates, and products.<sup>[1–4]</sup> Studying these reactions and chemical species in realistic chemical and physical environments representative of actual conditions is challenging.

Mass spectroscopy (MS) has been used for decades for compound identification as well as following the progress of reactions.<sup>[5–7]</sup> Commonly, mass spectral measurements are very rapid, making it ideal to provide information about intermediates while monitoring the consumption of reactants and the formation of products.

In this entry, Fourier transform ion cyclotron resonance mass spectroscopy (FT-ICR/MS) will be shown to be a powerful tool for investigating chemical reactions. FT-ICR/MS is capable of providing high-resolution mass values of molecules for compound identification. When monitoring reactions, relative abundances and mass values of reactants, intermediates, and products are recorded simultaneously as a function of time. Very good discussions on FT-ICR/MS theory are found elsewhere,<sup>[8,9]</sup> so only a brief summary will be presented here.

## FT-ICR/MS DESCRIPTION

High-resolution FT-ICR/MS provides the empirical formula of the molecule by measuring what is typically called the “exact mass.” Of course, some measurement uncertainty is associated with the measured mass but with parts-per-million resolution, very few combinations of atoms will add up to the measured mass. The number of combinations is usually further reduced

by incorporating some knowledge about the reaction to eliminate consideration of some atomic combinations when certain atoms are known to be absent in the reaction. A simple example is the identification of CO and N<sub>2</sub>. Both have a nominal mass of 28 Daltons (Da), but more precise calculations of the masses show CO to equal 27.99491 Da and nitrogen to equal 28.00615 Da (both rounded to five places past the decimal). Although the difference between the masses of CO and N<sub>2</sub> is only 0.01124 Da, the peaks are readily distinguishable at typical FT-ICR/MS resolutions.

Ions may be created in many ways including electron impact (EI) ionization, chemical ionization (CI), photoionization (PI), and others.<sup>[8,9]</sup> Each has advantages and disadvantages depending on the sample type and analysis needed. This entry will deal primarily with ionization as a result of laser ablation (discussed later).

A typical “rectangular” FT-ICR/MS trapping cell is shown in Fig. 1. In FT-ICR/MS, ions are “trapped” in a high-magnetic field between electrodes or end plates. Applying the appropriate positive or negative direct current (DC) voltage to the plate can trap either positive or negative ions. Although most FT-ICR/MS methods trap one or the other exclusively, trapping both positive and negative ions simultaneously is possible using RF trapping in a novel cell design.<sup>[10]</sup>

Trapped ions generally remain colinear with the static magnetic field and are repelled by the end electrodes. Many trap geometries have been used<sup>[10–17]</sup> including cylindrical, cylindrical with a concentric wire, segmented plates, and even an open cell using RF excitation to trap ions. Theoretical modeling of cell geometries and ion trajectories is typically performed using an ion simulation program such as SIMION.<sup>[11,15,17–26]</sup> In some instruments, two cells are connected together having a common electrode, or plate, between them. With this arrangement, ions can be trapped in either or both cells and transferred from one cell to the other. To detect the trapped ions, excitation waveforms are applied to the excitation plates causing the ions to assume orbits within the trap passing close to the detection plates (Fig. 2). As the ions pass by these plates, the oscillating potential is recorded as a function of time. The frequency of the orbit is related to

**Fig. 1** Example of an ion trap. Excitation plates (E) and detection plates (D) are shown. The right end plate is left out for clarity.

the mass-to-charge ratio of the molecular ion or fragment ion, so a Fourier transform<sup>[27]</sup> of that data set will yield data relatable to the mass-to-charge ratio.

In an FT-ICR experiment, the sequence and timing of events is programmed and executed. A sample timing diagram of an experimental sequence is shown in Fig. 3 and examples of other sequences specific to research applications are presented elsewhere.<sup>[16,28–31]</sup> Timing is very precise with submicrosecond accuracies possible with readily available data acquisition clocks. Many parameters can be varied in the experiment including event duration, timing between events, plate voltages, and excitation frequencies and magnitudes. As the parameter space is very large, learning the fundamentals of FT-ICR to understand the impact of changing the various parameters is very helpful.

**Fig. 2** Schematic view of an ion trap looking down the direction of the magnetic field. Once ions are inside the trap and axialized to the center of the trap as in (A), the RF excitation waveform is applied to two excitation plates causing the orbital radius of the ions to increase (B). When the excitation is “off,” the ions continue to orbit near the plates (C) allowing detection (D).

Utilizing an ion-modeling program can also assist in determining desired parameters for a specific experiment.

Ions may be selectively excited and/or rejected from the trap by using a SWIFT (stored waveform inverse Fourier transform) waveform.<sup>[28,32]</sup> For SWIFT excitation, a waveform is calculated that contains the resonant frequencies of the mass-to-charge ratios of interest. If a large excitation voltage is used, the selected mass-to-charge ratio will be ejected from the trap. By careful application of this technique, the ion populations within the trap(s) can be tailored for the particular reaction being studied.

A great amount of research has been performed to optimize parameters once the ions are trapped in the cell. For example, resolution suffers greatly if ions are widely dispersed, so tightly organized “packets” of ions are desirable. When using ionization methods such as laser ablation, the ions produced exhibit a wide range of kinetic energy and spatial distributions, which is undesirable for FT-ICR/MS analyses. A wide spatial distribution makes excitation difficult because some of the coherency as well as some of the ions is lost. The ions that are detected will not be in a well-organized packet, which will decrease the resolution. Additionally, transfer of ions from one trap to another, in the case of a dual-cell instrument, is not very feasible as most of the ions are not aligned with the small conductance limit orifice between the cells. The high kinetic energies of these ablated molecules have been described as the major problem for trapping and detection.<sup>[17]</sup> In order to alleviate this problem, a process called axialization is employed to collect ions in the center of the trap before excitation starts. This process results in enhancements of both resolution and ion yield. In one example, the resolution for a peak was improved from 2400 without axialization to 144,000 with axialization.<sup>[33]</sup> Common methods for axializing ions include inserting a time delay prior to excitation to allow for the decay of excess energy as the ions orbit in the trap, adding an inert buffer gas so that collisions remove the energy, and RF axialization of the ions. Simply waiting for the energy to decay is not practical because of ion loss. Buffer gases are effective and easy to implement,<sup>[31,34,35]</sup> however, ramping the trapping plate potentials down linearly to potentials normally used for excitation has been shown to be effective, even without a buffer gas.<sup>[34]</sup> In one application, an ablation chamber impedes the spreading of the neutrals after ablation so they act as the buffer gas.<sup>[31]</sup> Radio-frequency axialization involves applying pulses of excitation voltages to various plates (depending on the trap geometry) to cause the ions to align themselves axially with the trap magnetic axis near the center of the trapping cell.<sup>[13,14,16,17,20,28,36–41]</sup> Further tests have shown that a combination of a buffer gas (e.g.,  $5 \times 10^{-7}$  Torr argon) with active RF axialization

**Fig. 3** Sequence of events in a typical laser ablation FT-ICR/MS experiment.

has been shown effective.<sup>[33,42–45]</sup> Once an effective way to axialize the ions is realized, not only are better spectra obtained, but the ions can be re-excited and remeasured, provided that the ions are axialized between scans.<sup>[33]</sup>

Another way to improve peak resolution is to correct the data for the frequency drift of ions during data acquisition. By mathematically correcting the data using digital quadrature heterodyning, improvements in resolution of up to several orders of magnitude have been realized.<sup>[46,47]</sup>

Once a well-resolved peak is obtained, an accurate mass measurement is possible. Mass calibration is most accurate when known peaks exist within the spectra from which the frequency-to-mass relationship can be calculated.<sup>[48]</sup> One study compared the accuracy of two common frequency-to-mass algorithms showing calculated mass errors are very small (ppb).<sup>[49]</sup>

Accurate mass determination and ion manipulation make high-resolution FT-ICR/MS a powerful analytical tool to ascertain the empirical formula of a molecule and to study chemical reactions. In the next sections, the combination of laser ablation with FT-ICR/MS will be shown to be well suited for heterogeneous catalysis research.

## LASER ABLATION

Laser ablation is a technique commonly used to vaporize and ionize a solid sample in preparation for FT-ICR/MS analysis. A review of recent advances and applications of laser ablation shows widespread application and utility.<sup>[50]</sup> Parameters that can be varied to optimize ablation include wavelength, power density, and total energy deposited on the sample. Laser energy is focused on a sample causing the sample

to heat, bonds to be broken, and material to be ejected from the bulk via a short-lived plasma. The plume of sample vapors expands out from the surface of the solid in a shape that is proposed to be similar to a supersonic jet expansion.<sup>[51,52]</sup> Vapors produced are a combination of ions and neutrals, the distribution of which was estimated to be about 1% ions and 99% neutrals for ablated silicon carbide.<sup>[53]</sup>

Once ions have been produced, they need to get into the trap volume where they are stored for subsequent reactions and/or analyses. If the ablation occurs in<sup>[12]</sup> or close to the trap, the kinetic energies of the ions are used to transport the ions into the trap. However, if the distance to the trap is great or other barriers prevent the ions from freely entering the trap (e.g., the magnetic field), an ion guide is necessary to funnel the ions into the trap. Many schemes for ion transport have been contrived but typically potentials on electrodes are used to accelerate and decelerate ions, and RF excitation voltages are used to keep the ions traveling on a coherent path. SIMION (discussed previously) or some other ion trajectory modeling program can be used to aid in the design.<sup>[25]</sup> Theoretical and practical ion optics considerations for designing an ion guide are presented elsewhere.<sup>[54]</sup> Other developments include a ring ion guide,<sup>[55]</sup> an off-axis ion injection from a continuous ion source,<sup>[52]</sup> an RF octapole,<sup>[56]</sup> and a cylindrical ion guide with a concentric wire electrode.<sup>[21,22]</sup>

Trapping the ions is not a simple operation as ablated ions have kinetic energies ranging from less than one to hundreds of electron volts.<sup>[22,51,53,56–61]</sup> Some ablation sources are close to the trap eliminating the need for an ion guide, but that means the trap must be operated in such a mode as to effectively trap many ions. Even with ion guides to direct ions into the trap,

the timing and plate voltages must be carefully tuned. Most often, only a part of the ions ablated are ever retained in the trap because the slow, low-energy ions do not reach the trap before the trap voltages are applied, and/or the fast, high-energy ions either pass through the trap before the voltages are applied or simply cannot be trapped with the voltages used. The timing and trap voltage are set so as to maximize the number of ions of interest retained in the trap.

Varying the power density and wavelength applied to the sample can cause different fragmentation patterns. In a study using 1064-nm Nd-YAG laser excitation at powers of 200, 900, and 2000 MW/cm<sup>2</sup>, fragmentation patterns for several zeolites showed a dependence on power density.<sup>[29]</sup> These data showed that the higher energy density yielded larger fragments and clusters. By changing the wavelength of the ablating laser, the fragmenting and clustering patterns also change. Stöber silica was ablated using 193-, 248-, and 355-nm laser radiation, and the longer wavelengths generated larger fragments.<sup>[62]</sup>

Another type of laser ablation suitable for ionizing large molecules without extensive fragmentation is called matrix-assisted laser desorption ionization (MALDI).<sup>[63]</sup> In this technique, the molecules of interest are mixed with another molecule that strongly absorbs the laser energy. The strongly absorbing molecule will cause the large molecules to be ionized and released from the surface via energy transfer. This technique has been very successful in biological fields.<sup>[35,64–67]</sup>

## ZEOLITE/SILICA MASS SPECTROSCOPY RESEARCH

Mass spectroscopic studies of catalysts, in particular zeolites, commonly involve the use of gas chromatography/mass spectroscopy (GC/MS) to determine the efficiencies of various catalytic beds and reactant combinations.<sup>[68–70]</sup> In one recent application, product and reactant gases from a Parr reaction vessel were monitored in real-time using low-resolution MS.<sup>[71]</sup> However, relatively few studies of zeolites using high-resolution FT-ICR exist.<sup>[72]</sup>

Laser ablation of zeolites is difficult because the fragments ablated tend to undergo clustering and rearrangement. Clustering is not uncommon given the high-energy plasma environment during ablation and has been seen with other materials, e.g., dichlorosilane<sup>[73]</sup> and metals.<sup>[59,74,75]</sup> Several researchers have looked at the laser-ablated zeolites and silica powders and have observed SiO<sub>2</sub> clustering using time-of-flight/MS (TOF/MS)<sup>[76–79]</sup> and high-resolution FT-ICR/MS.<sup>[29,62,80]</sup> Fig. 4 shows a small portion of a typical mass spectrum showing the repeating peaks every 60 Da for laser-ablated beta zeolite. The distinctive “triplets” seen in a mass spectrum arise from the isotopic abundances of the naturally occurring isotopes of silicon<sup>[7]</sup> and provide a simple way to visually identify a silicon-containing compound.

Table 1 shows a summary of the experiments and the (SiO<sub>2</sub>)X<sup>−</sup> cluster series reported (others may have

Fig. 4 Three series seen in the mass spectrum when beta zeolite is ionized using laser ablation.

<sup>a</sup>A series (SiO<sub>2</sub>)<sub>n</sub> H<sub>x</sub>O<sub>2</sub><sup>-</sup> was identified but the experimental resolution was not adequate to identify *x*, the number of hydrogens.

been detected but not reported). The order of the atoms in the formula is not intended to imply any structural significance (e.g.,  $\text{HO}^-$  vs.  $\text{OH}^-$ ). Series that are in common include  $(\text{SiO}_2)_n \text{O}^-$  and  $(\text{SiO}_2)_n \text{HO}^-$ , regardless of the type of zeolite or silica, laser wavelength, and the power density used. As the formation of these series is independent of these variables, dissociation and recombination reactions in the ablation plasma must dominate their formation. Lafargue ejected ions such as  $[\text{SiO}_2]^-$  and  $[\text{OH}]^-$  from the trap that would act as building blocks for cluster formation in order to exclude the possibility of in-trap clustering. No changes in the spectra were found, implying clustering was complete prior to entering the trap.<sup>[62]</sup> Further confirmation of this is that the mass spectrum was the same for doped silica aerogels (carbon introduced through pyrolysis and Rhodamine-6G dopants) as with undoped silica aerogels.<sup>[79]</sup> However, if the silica aerogel was doped with fullerene or coke, the mass spectra showed peaks arising from the dopants only, and none from the host matrix (the silica aerogel). The table also shows a number of differences between the experiments. The  $[(\text{SiO}_2)_n \text{H}]^-$  series is only seen in the TOF/MS experiments and not in the FT-ICR/MS experiments. Zeolite ablation also yielded series containing the associated cation,  $\text{Na}^+$  and  $\text{K}^+$ , for the NaMOR (mordenite), KLTL (Linde Type L), and NaLTA (Linde Type A) zeolites. An aluminum-containing series,  $[\text{AlO}(\text{SiO}_2)_n \text{O}]^-$ , was also detected for some zeolites containing aluminum framework atoms. Additionally, the TOF/MS analysis of UV-ablated (308 nm) zeolites, silicalite-1 and MCM-41, showed series  $[(\text{SiO}_2)_n \text{Si}]^-$  and  $[(\text{SiO}_2)_n \text{OSi}]^-$  that were not reported for the IR-ablated (1064 nm) NaMOR, KLTL, and NaLTA zeolites analyzed by FT-ICR/MS.

Positive ion spectra of zeolites and silicas show no clustering with the primary cations identified as  $\text{Na}^+$ ,  $\text{Al}^+$ ,  $\text{K}^+$ ,  $\text{Si}^+$ ,  $\text{AlH}_2\text{O}^+$ , and  $\text{KAlO}_2^+$  for the NaMOR, KLTL, and NaLTL zeolites.<sup>[29]</sup> For Stöber silica, the primary cations detected were  $\text{Si}^+$  and  $[\text{SiOH}]^+$ .<sup>[62]</sup>

Negative ion mass spectra of ablated zeolites and silicas are typically very complex, having hundreds of peaks. Routinely, series of peaks can be addressed with a single descriptor (e.g.,  $[(\text{SiO}_2)_n]^-$ ) and an integer range that describes cluster sizes in the series (e.g.,  $n = 1-8$ ). However, when analyzing the mass spectrum peak-by-peak, a quick method for determining the identity of a peak's series is useful. One such method is to use the modulus equivalent, calculated using the repeating molecular mass as the base, for the experimentally measured mass of a peak.<sup>[81]</sup> For example, a peak occurring at mass 377 in a silica cluster series can be quickly categorized as part of the  $\text{OH}^-$  ligand series by computing the following:  $\text{Mod}_{60}(377) = 17$  (note: mass of  $\text{SiO}_2$  is 60 Da, and mass of  $\text{OH}$  is 17 Da). This works if each series is

separated from the other by at least 1 amu and if the ligands have a mass less than that of the cluster unit. This simple technique is readily applicable to other types of clusters (e.g., metal clusters) by simply changing the value for the base of the modulus calculation.

## CHEMISTRY INSIDE THE TRAP

Another powerful capability of FT-ICR/MS is the ability to perform chemical reactions within the ion trap between ions or between ions and neutrals. This ability has been used in many applications in many industries.<sup>[82]</sup> For example, the kinetics and mechanisms for reactions that formed explosive solid residues in dichlorosilane process exhaust stacks were identified for the semiconductor industry using FT-ICR/MS.<sup>[73]</sup> Knowing the details of the reaction made it possible to implement mitigation measures.

Few studies exist exploring the chemical reactions of zeolites, silicas, silicon dioxide, or clusters using FT-ICR/MS. In one study, hydrocarbons were desorbed from the surface of HMF1 zeolite ( $\text{Si}/\text{Al} = 55$ ) and characterized using FT-ICR/MS.<sup>[72]</sup> The zeolite was exposed to ethene for 30 min at different temperatures (298, 420, and 560 K). The ethene-treated zeolite samples were 1) introduced into the vacuum region of the trap causing the release of the hydrocarbons whereupon EI spectra were obtained; 2) laser ablated at 1064 nm but storing only positive ions, which favored hydrocarbons; and 3) chemically ionized using  $\text{Au}^+$ . Oligomerization of the ethene was evident for all three tests. In other FT-ICR/MS research, chemical reactions of  $\text{Si}_n^+$  clusters with ammonia<sup>[83]</sup> and ethylene<sup>[84]</sup> were studied.

In studies undertaken in our laboratory, alkenes (ethene, propene, 1-butene, and 2-butene) were reacted with silica clusters arising from laser ablation of beta zeolite.<sup>[81]</sup> As with the above examples of ablated zeolite and silica, dissociative and recombinative reactions in the ablation plasma are dominant for the beta zeolite as well. Fig. 5 shows the spectra obtained from the reaction of alkenes with silica clusters from beta zeolite. The attachment is seen primarily on the  $[(\text{SiO}_2)_n \text{HO}]^-$  series, but also seen to a lesser degree on the  $[\text{AlO}(\text{SiO}_2)_n \text{O}]^-$  series and not at all on the  $[(\text{SiO}_2)_n \text{H}_2\text{O}_3]^-$  series.

One criticism that must be addressed is the relevance of studying ion chemistry to bulk solution processes. A detailed comparison of gas phase vs. solution chemistry was published by Speranza.<sup>[85]</sup> One major difference is that solvation effects are not replicated in the gas phase work. Consequently, not all information obtained in the gas phase is directly applicable to solution chemistry. However, Speranza notes that gas phase chemistry provides “invaluable information

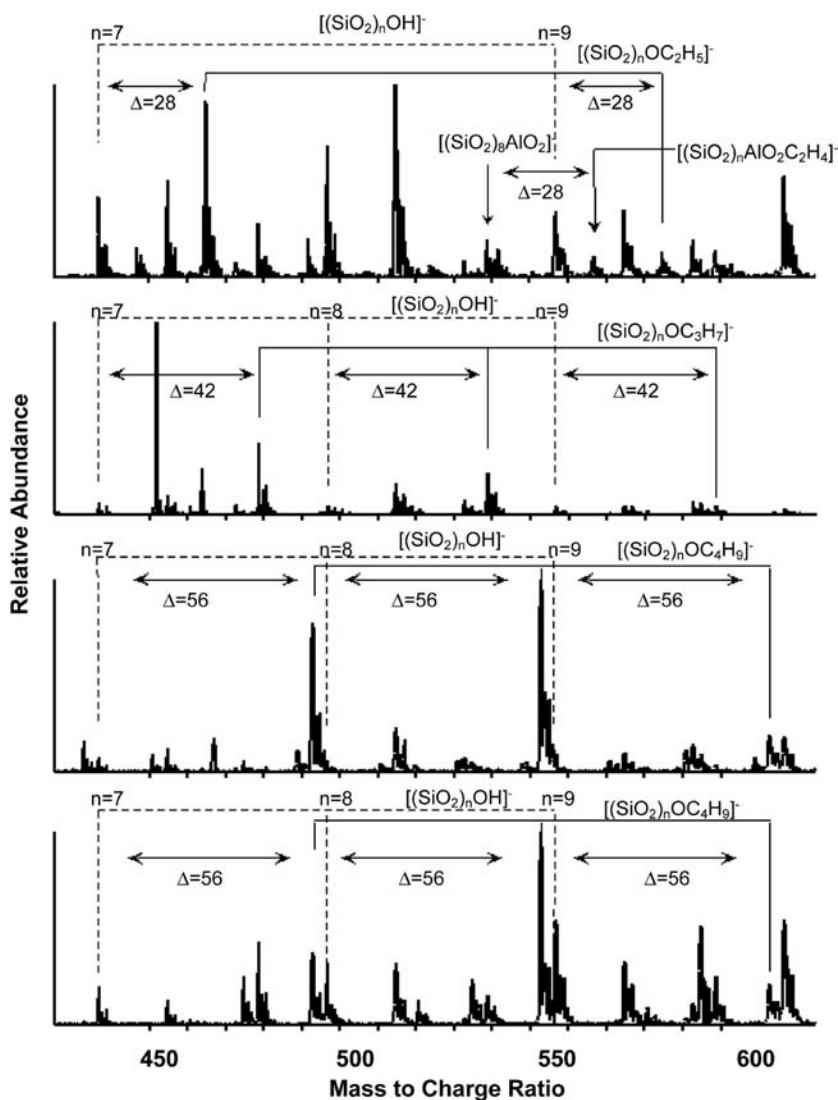

Fig. 5 Hydrocarbon attachment to zeolite fragments is shown above for (A) ethene, (B) propene, (C) 1-butene, and (D) 2-butene.

upon the nature and stability of the ionic intermediates involved in ionic reactions.” Thus FT-ICR/MS can provide very elusive information about reactions such as compound identification (reactants, intermediates, products), ion stabilities, mechanisms, etc.

## CONCLUSION

FT-ICR/MS is a powerful analytical tool capable of providing information about mechanisms, kinetics, intermediates, and compound identification in heterogeneous catalysis research. By simultaneously identifying reactants, intermediates, and products using the high-resolution mass determinations, detailed mechanisms can be determined. The ability to follow reactions as a function of time and measure all masses simultaneously provides vital information on relative abundances as reactions progress. Finally, new and

novel chemistries, e.g., cluster chemistry, can be explored easily and quickly with FT-ICR/MS.

## INTRODUCTION

Microscopically engineered surface structures allow the local control of physical properties such as adhesion, friction, and wettability. These properties are related both to molecular interactions and surface topology.<sup>[1,2]</sup> If the structure features are small enough—till nanometer scale—and well ordered, they may be applicable to electron confinement for light emission or novel electronic devices.<sup>[3]</sup> Commonly used techniques to create laterally structured surfaces are photolithography and electron beam lithography. Based on these structures, the feature size can be reduced down to 30 nm using soft lithography (microcontact printing).<sup>[4]</sup> A newly developed technique named as *Nanoimprinting* can be used to create surface features down to 5 nm over macroscopic areas.<sup>[5,6]</sup> Another way to create structured surface with nanometer-sized features is to introduce surface coating layers with defined structures, for instance, by using block copolymer lithography<sup>[7]</sup> and surface-induced patterning using polymers.<sup>[8,9]</sup>

Ultrathin organic films prepared, for example, with the *Langmuir-Blodgett* (LB) and the *self-assembly* (SA) techniques are other promising candidates for surface modification.<sup>[10]</sup> By using these techniques, organic molecules with great variability can be incorporated into organized assemblies in a well-controlled manner.<sup>[11]</sup> During the condensation procedure of molecules into densely packed states, lateral structures with adjustable shapes and arrangements may occur, which can be understood in terms of dipole-dipole interaction and line tension.<sup>[12,13]</sup> The size of structures induced in this way is usually in the range of 1–100  $\mu\text{m}$ , and many of them (especially the anisotropic structures) are randomly arranged. Less addressed are the nanoscopic structures created in these quasi two-dimensional systems, although the existence of “micelle” clusters in organic monolayers has been suggested even at the very early stage by Langmuir.<sup>[14]</sup> This was partially because of lack of high-resolution real space approach in detection methods for this size

range, until the advent of *scanning probe microscopy* (SPM) applicable on thin organic films.<sup>[15,16]</sup>

A different approach to create microscopically patterned surface is based on the wetting instability during LB transfer, as first reported by Riegler. By withdrawing a hydrophilic solid substrate (Si-wafer) through a monolayer-covered [*L*- $\alpha$ -dipalmitoyl-phosphatidylcholine (DPPC)] water surface under suitable conditions, parallel stripe patterns can be created.<sup>[17]</sup> The chemical formula of DPPC, the surface pressure/area, and the transfer position are shown in Fig. 1. The stripes are parallel to the three-phase contact line (air-substrate monolayer-covered water surface), i.e., perpendicular to the deposition direction, as shown schematically in Fig. 2. The width (several micrometers) and distance (1 to 100  $\mu\text{m}$ ) of stripes were found to be adjustable with the transfer speed, which varied from 0.5 to 4.0  $\mu\text{m sec}^{-1}$ .<sup>[18]</sup> At higher transfer speeds, the distance became smaller. Later on, Gleiche<sup>[19]</sup> observed the similar phenomena by using the same molecule but with another substrate (mica instead of Si-wafer) and at another speed range (from 83.3 to 333.3  $\mu\text{m sec}^{-1}$ ). The question of what the size (width) limitation of the stripes and the distance between them are if the monolayer is drawn further faster arises.

## REGULAR NANOCHANNEL LATTICE

To miniaturize the structure features, we first chose mica instead silicon as substrate to transfer DPPC monolayer. The freshly cleaved muscovite mica,  $\text{K}[\text{Al}_2(\text{Si}_3\text{AlO}_{10})(\text{OH})_2]$ , is negatively charged, while DPPC has a zwitterionic head group. The electrostatic interaction between DPPC and mica allows a very fast deposition of the DPPC monolayer. By increasing the transfer speed by 1–3 orders of magnitude compared with the previous works, the similar phenomenon as reported by Riegler was observed: the faster the transfer speed, the smaller the distance between the stripes. For instance, at a withdrawing speed of 33  $\mu\text{m sec}^{-1}$

**Fig. 1** Chemical structure of *L*- $\alpha$ -dipalmitoyl-phosphatidylcholine (DPPC), surface pressure/area isotherm, and the transfer position (arrow).

(2 mm  $\text{min}^{-1}$ ), the average distance between the stripes is measured to be  $14.3 \pm 1.8 \mu\text{m}$  (as shown in Fig. 3), while it became  $4.0 \pm 0.32 \mu\text{m}$  at a withdrawing speed of  $167 \mu\text{m sec}^{-1}$  (10 mm  $\text{min}^{-1}$ ) and  $2.5 \pm 0.20 \mu\text{m}$  at a withdrawing speed of  $500 \mu\text{m sec}^{-1}$  (30 mm  $\text{min}^{-1}$ ).<sup>[19]</sup>

By further increasing the withdrawing speed till  $1000 \mu\text{m sec}^{-1}$  (60 mm  $\text{min}^{-1}$ ) and under a low surface packing density ( $85 \text{\AA}^2/\text{mol}$ ,  $3 \text{mN m}^{-1}$ ) in the pure liquid expanded (LE) phase, the stripe patterns become periodic!<sup>[20]</sup> Surface topography inspections with scanning force microscopy (SFM) reveal regular hydrophilic channels of about 200 nm in width, which are separated by hydrophobic stripes of monolayer with a latitude of about 800 nm as shown in Fig. 4. The height difference between the stripe region and the channel region is about one monolayer thick. Here the “stripe” is defined as the monolayer-covered region, and “channel” is defined as the uncovered

**Fig. 2** Schematic illustration of stripe formation as a result of substrate-induced condensation during Langmuir-Blodgett transfer of amphiphilic molecules in liquid-expanded phase.

**Fig. 3** Optical micrograph of parallel stripe patterns on mica surface formed by transferring DPPC monolayer at a surface pressure of  $3.5 \text{mN m}^{-1}$  with a withdrawing speed of  $33 \mu\text{m sec}^{-1}$  (2 mm  $\text{min}^{-1}$ ). The surface was decorated with a thin silver layer to obtain optical contrast.

region. The tiniest channels obtained so far with this method exhibit a width of about 100 nm. This method is fast and reliable. For example, only 1 min is required to produce a sample of 6 cm in length fully covered with the channel lattice structure with a density of  $10,000 \text{cm}^{-1}$ . These structures can extend over the whole substrate areas, which can be easily visualized with an optical microscope by decorating the surface

**Fig. 4** Scanning force microscopy images of the structured mica surface (image size  $30 \times 30 \mu\text{m}^2$ ). Scanning force microscopy inspections reveal channels of about 200 nm in width separated by stripes (800 nm wide) of a monomolecular DPPC film (inset,  $6 \times 6 \mu\text{m}^2$ ) imaging. The monolayer prepared on pure water was rapidly transferred with a speed of  $1000 \mu\text{m sec}^{-1}$  (60 mm  $\text{min}^{-1}$ ), at a lateral surface pressure of  $3.0 \text{mN m}^{-1}$  and constant temperature of  $22.5^\circ\text{C}$ .

**Fig. 5** Optical micrograph representing the regular stripe structure over an area of  $80 \times 60 \mu\text{m}^2$ . The hydrophilic channels were filled with more silver coating (bright lines), whereas the DPPC monolayer depicted dark (less silver).

with a thin silver layer (2 nm). By thermal evaporation, silver atoms preferentially wetting the mica surface (channels) than the monolayer stripes results to an optical contrast,<sup>[21]</sup> as shown in Fig. 5.

The formation of the observed stripe structure can only take place during the molecular transfer of a low-pressure precursor film, which equals to a low surface packing density of molecules at the air/water interface. The transfer from such an isotropic liquid-expanded state (no predefined orientations) is normally not expected to build up close packed monolayers. In our experiments, the transfer ratio was approximately unity, but only 70–80% of the surface is actually covered. This corresponds well to the difference in the molecular packing density between the condensed phase on the mica surface and the expanded phase on the water surface. The mechanism of stripe formation differs from that which is responsible for striation in multilamellar liposomes at lower temperature (ripple phase)<sup>[22]</sup> or in simple granular mixtures<sup>[23]</sup> and in shrinking experiments.<sup>[24]</sup> Anisotropic domain growth at the air/water interface can also lead to stripe patterns, which can be understood in terms of a lowered line tension competing with dipole–dipole interactions.<sup>[25,26]</sup> There, however, the resulting structure has a random distribution of alignment. The transfer-induced regular structures differ remarkably from stripe phases of monolayers grown at the air/water interface because of their highly reproducible regularity and predefined orientation parallel to the three-phase contact line.

It turned out that slow monolayer deposition results in large distributions of channel distances and widths, whereas an improvement of the regularity is observed with increasing transfer velocity. The deposition speed always exhibits an upper limit where the molecular transfer ratio decreases, although the best quality of the stripe structure (i.e., homogeneous periodicity over the whole substrate) is obtained close to this critical

**Fig. 6** Defects which disturb the regularity of the stripe structure owing to A) contaminations and B) step edges on mica surface.

value at which the meniscus oscillation becomes self-synchronized. Besides the transfer speed, other experimental conditions such as temperature and molecular packing density (surface pressure) can also strongly influence the formation of the regular linear structure. With increased surface pressure (higher molecular packing density), even before the main phase transition, no stripe structure parallel to the contact line is observed.

Although the periodic structure can be found everywhere on the whole substrate, a variation in channel widths and distances must be taken into account, especially when contaminations at the air/water interface or defects on solid substrate exist, as shown in Fig. 6. To obtain long-range well-ordered structure, both DPPC solution and the LB trough have to be kept in clean conditions.

## MODELS OF WETTING INSTABILITY

Although the origin of the periodic structures by Langmuir wetting is not yet fully understood, there

**Fig. 7** Increased water meniscus height dynamic wetting ( $h_{de}$ ) compared with static wetting ( $h_{eq}$ ).

are several possible qualitative explanations falling mainly into two categories. One is the oscillation of the meniscus height induced by the substrate-mediated condensation, and the other is the local pressure oscillation induced by the transfer.

It is well known that the contact line between the water and a hydrophilic solid substrate (three-phase contact line) normally exceeds the planar water surface up to a few millimeters by surface tension, thus defining the static equilibrium meniscus height, as shown in Fig. 7. This meniscus height  $h_{eq}$  can be expressed with liquid/vapor interfacial tension  $\gamma_{LV}$  and the contact angle  $\theta$ <sup>[27]</sup> as

$$h_{eq} = \sqrt{\frac{2\gamma_{LV}}{\rho g} (1 - \sin \theta)} \quad (1)$$

Combining with the well-known Young's equation

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta \quad (2)$$

where  $\gamma_{SV}$  and  $\gamma_{SL}$  are the solid/vapor interfacial tension and solid/liquid interfacial tension, respectively, we obtain

$$h_{eq} = \sqrt{\frac{2}{\rho g} \sqrt{\gamma_{LV} - \sqrt{\gamma_{LV}^2 - (\gamma_{SV} - \gamma_{SL})^2}}} \quad (3)$$

When the water surface is covered with a monolayer of amphiphilic molecules, the molecules can condense on the substrate surface at the three-phase contact line generated as a result of the interaction between the molecules and the substrate. This is named substrate-mediated condensation (SMC).<sup>[28]</sup> Depending on experimental conditions, the condensation can either lead to a straight-line, liquid-condensed stripes and/or regular fingers. A decreased meniscus height was experimentally observed in the course of SMC. According to Eq. (3), this can be understood as a consequence of a decreased solid/vapor interfacial

tension ( $\gamma_{SV}$ ). On the other hand, the meniscus height will tend to exceed its equilibrium value by a continuous substrate motion (upstroke) building up a dynamic equilibrium height  $h_{de}$  (Fig. 4). If the water surface is covered with a monolayer, the increased meniscus height will result in an accelerated molecular adsorption on the substrate.<sup>[18]</sup> Thus the dynamic behavior of the meniscus height is governed by two counteracting processes, which lead to an oscillation of the meniscus and result in regions of transfer depletion normal to the dipping direction. It turned out in our work that the oscillation of the meniscus height may become periodic in the submicrometer size under certain controllable conditions. A similar stick-jump motion of the meniscus has been found in monolayers of dimethyldioctadecylammonium bromide, resulting in a striped surface, but on a significantly larger length scale ( $\sim 1$  mm).<sup>[29]</sup>

The second possible explanation for the generation of the periodic structures is the local surface pressure (or local surface density) oscillation instead of the meniscus oscillation. With a strong molecule–substrate interaction, molecules change their state very fast from the liquid-expanded phase to the liquid-condensed phase at the three-phase contact line. This process must result in a sudden area reduction of the molecules. Because of the viscoelasticity of monolayers, which is related to the cohesive energy of the molecules, the molecules very near the contact line will be drawn up and condensed on the substrate resulting in a low surface pressure region because of the reduced molecular density. With a very fast transfer speed, the surface pressure can even reach zero resulting in a transfer depletion. Such kind of low surface density regions were observed previously around the liquid-condensed domains, when monolayers were transferred in the two-phase coexistence region.<sup>[30]</sup> After the depletion, the surface pressure will increase because the molecules will accumulate again at the contact line by the moving barrier, thus resulting in a local surface pressure oscillation.

If the second model is correct, one should expect a temperature dependence of the periodicity because the cohesive energy of molecules depends on the temperature. At increased temperature, the cohesive energy gets reduced. Thus the periodicity should decrease with increased temperature. This is indeed observed experimentally. However, it is not possible to distinguish this mechanism from the first one solely in terms of temperature effect because the condensation will also depend on the temperature (or more precisely, the temperature gradient).

Just recently, some theoretical groups proposed models to understand such a periodic oscillation during LB deposition. One of the groups used a model for one-dimensional flow of a van der Waals fluid near

its discontinuous liquid–gas transition. They found that steady-state flow becomes unstable in the vicinity of the phase transition, and this instability can lead to complex periodic density oscillations at some suitable chosen sets of parameters.<sup>[31]</sup> It is expected that, combining theoretical and experimental works, one will be able to quantitatively understand the mechanism of the periodic pattern formation during LB transfer in the near future.

### ROBUST STRUCTURED SILICON SURFACES WITH CHEMICAL CONTRAST

Compared with other lithography methods, the Langmuir–Blodgett-based preparation for regular stripe patterns shows its advantages of low costs, fast, and an unusual ratio between the width and the length of the linear structures (the line width can be as small as 100 nm, and the length is, in principle, unlimited). However, with the combination of DPPC as the organic monolayer and mica as the substrate, the structure is not stable to be inserted into aqueous solutions and polar solvents. This restricts the application potential of such patterned surfaces as a template in many cases, especially for biological systems.

The concept was then expanded to form stable patterns on silicon surfaces based on template-directed self-assembly. First, line patterns with regular channels and stripes composed of DPPC on silicon surfaces were fabricated with the Langmuir–Blodgett technique, as previously performed on mica surfaces. By using oxygen plasma-treated silicon surface, similar periodic monolayer stripes are obtained.<sup>[32]</sup> The optimal transfer conditions of DPPC on silicon surfaces are different from that of DPPC on mica surfaces because of the different surface properties between silicon and mica. The periodicity can be as small as 410 nm, as shown in Fig. 8, and even below.

The stripe structure of DPPC on silicon is not stable when the slide is inserted into an aqueous solution as well as in the case of DPPC on mica. To obtain stable and functional structures on silicon surfaces, we used the DPPC-structured silicon surface as a mask for the pattern transfer. A general approach is based on the substitution of the stripes and channels by two different molecules (e.g., silane 1 and silane 2), which are terminated with different chemical groups, according to different purposes. Thus a robust, covalently bound, chemically active and selective patterned surface can be fabricated onto the silicon surface. Finally, a line pattern of covalently bonded molecules with selective functionality replaced the physically adsorbed DPPC structure. In Fig. 9, the basic strategy for fabricating chemically functionalized surfaces by using DPPC stripes as a template is illustrated schematically.

**Fig. 8** Scanning force microscopy image of DPPC stripe structure on silicon surface (left,  $9.2 \times 9.2 \mu\text{m}^2$ ). The periodicity can be as small as 410 nm, as indicated by the section analysis (right) which is taken from the black frame of the left image.

The second step of the general approach depicted in Fig. 9 is realized using 3-Aminopropyltrimethoxysilane to silanize in the channels selectively. After that, the DPPC stripes were washed away (step 3 depicted in Fig. 9). Fig. 10 shows a topographical image of the resulting surface obtained by SFM. The topography of the striped structure has been inverted. New stripes consisting of silane molecules formed in the original channel areas. The height of the new stripes is around 0.4 nm in the case of amino silane, which is smaller than the theoretical length of the chain. This kind of height anomaly is quite common when measuring soft organic films in tapping mode.<sup>[33]</sup> Furthermore, functional surfaces can be fabricated according to the schematic procedure depicted in Fig. 9. The original

**Fig. 9** Schematic illustration for the pattern transfer based on the self-assembly on silicon surfaces. A) Step 1: DPPC stripes on the silicon surface. B) Step 2: Silane molecule 1 silanizing the channel area of the silicon surface. C) Step 3: Silane molecule 2 on the previous stripe regions after removing the DPPC stripes. D) Step 4: Structured silicon surface with silane molecules 1 and 2. Source: From Ref.<sup>[32]</sup>.

DPPC-occupied areas were silanized with octadecyltrichlorosilane (OTS) (step 4). The resulting surface structure is shown in Fig. 10B. Because of defects in the original DPPC stripes, the conversion to an OTS layer is not complete. The holes in the stripe structure are converted to the amino silane in the first step and represent imperfections in the forming OTS layer. The images were taken in the contact mode presenting the lateral force signal (friction). The contrast in lateral force is induced by the two different functional groups ( $-\text{NH}_2$  and  $-\text{CH}_3$ ).

### ANISOTROPIC WETTING AND TEMPLATE-DIRECTED SELF-ASSEMBLY

Structured surfaces of this type introduce an anisotropic wetting behavior. Thus the shape of the liquid/solid phase boundary can be strongly influenced.<sup>[34]</sup> For example, the contact line of a droplet placed on a chemically structured surface of this type may deviate from that of an ideal circle<sup>[35]</sup> and becomes orientation-dependent. This deviation depends on the ratio of the droplet radius and the lateral size of the heterogeneity and is more prominent for comparatively small droplets. In the following wetting study, we use phenyloctane as a wetting liquid. The inset of Fig. 11 shows a droplet of phenyloctane on the structured surface (diameter of about 65  $\mu\text{m}$ ). A polygonal contact line parallel to the channels can

**Fig. 10** Scanning force microscopy images of the silanized silicon surfaces with two different silane molecules. A) SFM topographical image of 3-Aminopropyltrimethoxysilane assembled in the DPPC-free channels (image size  $10 \times 10 \mu\text{m}^2$ ). B) SFM lateral force image of 3-Aminopropyltrimethoxysilane and octadecyltrichlorosilane (OTS) assembled in the DPPC channels and stripes (image size  $5 \times 5 \mu\text{m}^2$ ).

be clearly observed. Furthermore, the drying process of this small droplet is found to be surface structure-dependent. Its phase boundary parallel to the stripe direction retracts discontinuously, jumping abruptly from channel to channel during the evaporation, whereas the contact line perpendicular to the stripe direction shows a smooth and continuous motion. Fig. 11 represents an optical micrograph of a temporal sequence gradually revealing the surface chemical structure periodicity. As a consequence, the droplet diameter perpendicular to the channel direction is determined by an even multitude of the lattice period. The dotted lines in Fig. 11 were drawn tangentially to

**Fig. 11** Time-dependent discontinuous dewetting observed with an optical microscope during the evaporation of a phenyloctane droplet. A superposition of five frames showing the retracting perimeter (from top to bottom, elapsed time in parenthesis). The contact line of the droplet parallel to the stripe direction shows a stick-jump behavior moving from channel to channel (periodicity  $\sim 1.6\ \mu\text{m}$ ). The dotted lines indicate the orientation of the underlying structure. The inset represents the initial state ( $32 \times 43\ \mu\text{m}^2$ ). Source: From Ref.<sup>[36]</sup>.

the droplet perimeter emphasizing the underlying structure. This discontinuous dewetting process is evoked by the regular change in the interfacial tension when moving across the surface. Considering a periodically striped surface with alternating chemical properties, an anisotropic wetting behavior is expected as discussed in Ref.<sup>[36]</sup>.

In recent years, template-directed selective deposition/self-assembly of nanosized materials and functional molecules received more and more scientific and technological interests. The structured mica or silicon surfaces reported here offer an easily prepared template with wetting or chemical selectivity. The different wetting behavior of the hydrophilic channels and the hydrophobic stripes can be used to deposit materials along the channels, for example, by an anisotropic surface structure-determined wetting/dewetting process<sup>[37,38]</sup> by using capillary (capillary filling)<sup>[39,40]</sup> and electrostatic forces.<sup>[41]</sup>

## Template-Directed Self-Assembly from Organic Solutions

Surface structure-dependent adsorption is obtained by applying a suitable solution carrying the material to deposit. Water-insoluble gold clusters ( $\text{Au}_{55}$ ) stabilized by an organic ligand shell<sup>[42]</sup> dissolved in 1-phenyloctane were dropped on the structured mica surface and investigated with SFM after the drop has been removed. Exposed to this solvent, the DPPC film remains absolutely stable. Channels filled with  $\text{Au}_{55}$  clusters are shown in Fig. 12. Cluster aggregates were lined up in the channels. Their height (almost 4 nm) corresponds to a single cluster diameter, but some of them exceed the monolayer height. In contrast, the DPPC monolayer is virtually not wetted and only a few cluster aggregates are located on the top of the stripe region resulting in a nearly perfect selective adsorption. With the same method, CdSe nanoclusters (5 nm) trapped by an organic ligand layer<sup>[43]</sup> were successfully selective-deposited in the channel region, as shown in Fig. 13. In the inset, an image of scanning near-field microscopy (SNOM) is shown which was taken with a home-designed setup and newly developed scanning tip<sup>[44]</sup> at the excitation wavelength of 488 nm (emission maximum of the 5-nm CdSe cluster is 532 nm). Thus we obtain the clear evidence that the channel regions are really filled with nanoclusters as wished.

**Fig. 12** Scanning force microscopy image of selective deposited  $\text{Au}_{55}$  cluster aggregates (bright spots) aligned along the channels (image size  $11 \times 11\ \mu\text{m}^2$ ) on mica surface. The spikes depicted in the three-dimensional rendered selected area (inset) indicate that the height of many cluster aggregates is about one cluster layer thick, although lateral size of the aggregates is larger than the individual clusters (image size  $5 \times 5\ \mu\text{m}^2$ ).

**Fig. 13** Scanning force microscopy image of selective deposited CdSe cluster aggregates (bright spots) aligned along the channels (image size  $10 \times 10 \mu\text{m}^2$ ) on silicon surface. The SNOM image (image size  $5 \times 5 \mu\text{m}^2$ ) shown in the inset indicates that the channels are filled evidently with CdSe nanoclusters.

### Template-Directed Self-Assembly from Aqueous Solutions

On the other hand, water-soluble  $\text{Au}_{55}$  cluster can be deposited selectively onto the robust structured silicon surfaces with chemical contrast. Here  $\text{Au}_{55}$  clusters were solved in water and dropped on the structured silicon surface. Experimental results indicate that  $\text{Au}_{55}$  clusters stay in separated form and assemble selectively on the stripes formed by the amino silane as shown in Fig. 14. The density of the cluster is higher than that assembled on the DPPC-structured mica surface and the clusters.

### Template-Directed Self-Assembly from Gas Phases

A small droplet of  $\text{FeCl}_3$  solution was brought onto the structured mica surface and evaporated slowly. The  $\text{FeCl}_3$  molecules condensing from the vapor phase were selectively adsorbed in the channels, whereas the monolayer stripes were not coated. In some places, three-dimensional crystals growing along the channel direction are observed, as shown in Fig. 15. The SFM images were taken at positions several centimeters away from the droplet of  $\text{FeCl}_3$ . Channels filled with paramagnetic  $\text{FeCl}_3$  molecules provide a contrast in magnetic force microscopy (MFM).<sup>[20]</sup>

Thermally evaporating silver in high-vacuum ( $1 \times 10^{-6}$  Torr) silver atoms will first selectively wet

**Fig. 14** Scanning force microscopy images of water-soluble  $\text{Au}_{55}$  cluster selectively deposited on the patterned silicon surface (image size  $3.5 \times 3.5 \mu\text{m}^2$ ). The inset represents the phase image (image size  $700 \times 700 \text{nm}^2$ ), where the single clusters packing along the channel region are observed. *Source: From Ref.<sup>[32]</sup>.*

the channel regions on mica surface, as discussed previously (Fig. 5). If less silver is evaporated (not more than 2 nm), only the channel regions are fully covered with silver, as shown in Fig. 16. This offers the possibility to make one-dimensional electrodes.

**Fig. 15** Scanning force microscopy image ( $4 \times 4 \mu\text{m}^2$ ) of the channel structure filled with paramagnetic  $\text{FeCl}_3$  molecules with gas deposition. In some locations, three-dimensional crystals were growing along the channels.

**Fig. 16** Evaporating silver on structured mica surface, silver atoms deposit preferably onto uncovered mica surface (channel regions), as schematically shown here (left). The SFM image (topography, image size  $16 \times 16 \mu\text{m}^2$ ) indicates that if a small amount of silver is evaporated (less than 2 nm), only the channel regions are fully covered, as shown in the inset.

## CONCLUSION

The original goal of the application of Langmuir–Blodgett technique was to achieve extended homogeneous monolayer/multiplayer of organic molecules, which should be highly ordered at the *molecular level*. It turns out in this work, however, that by adjusting the molecule–molecule interactions and molecule–substrate interactions, the LB transfer under appropriate experimental conditions can lead to long-range-ordered *nanoscopic structures* over macroscopic areas. Interestingly, the precursor LB monolayer has to be in a highly isotropic, disordered phase. Besides the nanoscopic feature size and characteristic long-range order, the structure may be heterogeneous. The potential applications of ordered heterogeneous surfaces with nanosized features as template structures for selective deposition of nanoclusters and molecules are demonstrated. The method presented above should not be restricted to a specific molecule–substrate pair and may be extended to other amphiphilic molecules and polymers.

## ACKNOWLEDGMENTS

The authors are grateful to Prof. Guenter Schmid, Dr. GAndrey Rogach for providing nanoclusters, Prof. Dr. Harald Fuchs for stimulating discussions, and the Deutsche Forschungsgemeinschaft (DFG), the state of North-Rhine Westphalia (NRW), for the financial support.

## INTRODUCTION

Hierarchical structures can be found in nature from the macroscopic level to the microscopic level. Biomaterials are selectively self-organized from molecular- to macrolength scales, with organized units of subassemblies that are generated to serve biological purposes.<sup>[1]</sup> Inspired by the complexity of biomaterials, research has been initiated to mimic biomineralization processes and chemically produce hierarchical structures.<sup>[1–10]</sup> This entry is focused on a new methodology to generate hierarchical materials as novel sorbents for separation of metal ions via hierarchical imprinting synthesis.

## Molecular Imprinting

The concept of molecular-imprinted polymers was originally introduced by Wulff and Sarhan in the early 1970s.<sup>[11]</sup> Imprinting synthesis (Fig. 1) is a polymerization method that creates selective adsorption cavities inside or on the surface of solid materials with functionalities spatially organized around templates. The templates interact with a complementary portion of a functional monomer, by either covalent<sup>[12]</sup> or non-covalent<sup>[13]</sup> interactions such as ionic, coordinative, hydrophobic, or hydrogen bonding. The functional monomers are fixed around the templates upon polymerization. After removal of templates, a set of recognition sites is retained in the polymer matrices or on the surface of the substrates. Recognition sites are employed to rebind the imprinting templates or some analogous molecule with similar physical/chemical characteristics. The imprinted cavities have “one-to-one” specific selectivity, which mimics enzyme. Accordingly, the imprinted sorbents are also called artificial enzyme or biomimic antibodies. Templates ranging from the smallest species (proton) to biomacromolecules (proteins) have been successfully imprinted.<sup>[12–21]</sup> Various applications have been

utilized in the areas of separation, catalysis, chemosensors, biomimic enzymes, drug delivery, etc.

## WHY HIERARCHICAL IMPRINTING SYNTHESIS?

Molecularly imprinted polymers are usually synthesized as bulk materials.<sup>[12]</sup> Templates are removed via extraction after grinding the bulk polymers into fine particles. Although imprinting synthesis has proven to be the most efficient method for tailoring binding sites, both site accessibility and site heterogeneity remain as problematic issues. The imprinted cavities located on the surface of the fine particles are fully accessible. However, those located inside the particles are only partially accessible or inaccessible, depending on the porosities of the corresponding hosts. Grinding of the imprinted polymers can be eliminated by casting thin films, making porous membranes, or producing small spherical particles via emulsion polymerization. Site accessibility is significantly improved through these synthesis techniques without increasing the template population. Porous membranes and surface imprinted substrates are the prototype of the imprinted sorbents with hierarchical structures. The original concept of hierarchically imprinted porous sorbents was coined based on the imprinting synthesis involving multiple templates over several discrete dimension scales.<sup>[23]</sup> This concept has been extended from its original metal-ion imprinting to various target chemical species.<sup>[60]</sup> Hierarchically imprinted porous sorbents have advantages of perfect binding-site integrity, fully accessibility of imprinted sites, excellent mass transport, and finely adjustable hydrodynamic properties.

Hierarchically imprinted structures can be assembled via two methodologies: 1) coassembly<sup>[22,23]</sup> and 2) stepwise assembly.<sup>[40,60]</sup> Imprinting synthesis through a coassembly method is based on the self-assembly of hierarchical structures through simultaneous uses of multiple templates. However, the stepwise assembly

**Fig. 1** Schematic diagram of imprinting polymerization. Source: From Ref.<sup>[23]</sup>.

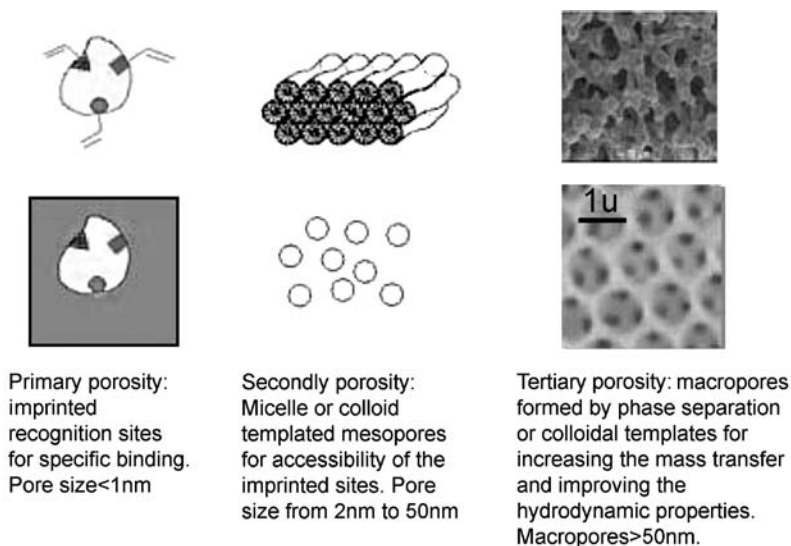

method involves sequential generation of hierarchical structures. Both methods have been successfully employed to synthesize hierarchically imprinted sorbents for metal separation. Hierarchically imprinted sorbents have more than one type of porosity, which takes different roles in applications. The primary porosity is the recognition cavities, which function as selective binding sites for template species. The secondary porosity can be mesopores. The mesopores open the accesses of solution to the binding sites. The uniformity of the mesopores offers homogeneous diffusion of the target analytes. Macropores are attributed to the tertiary porosity. Both the secondary and tertiary porosities substantially improve the mass transport properties of the hierarchically imprinted sorbents. Fig. 2 illustrates the topological structure of hierarchically imprinted sorbents. In the following, examples for the applications of these two hierarchical imprinting methodologies in developing novel sorbents are reviewed.

## COASSEMBLY SYNTHESIS APPROACH

### Mesoporous Silica Sorbents via Hierarchical Imprinting

The discovery of ordered mesoporous materials using a surfactant-templated approach has opened a new era in synthesis of ordered nanoscale materials.<sup>[23,24]</sup> This class of materials has attracted the attention of scientists from different fields because of their unique structural features. Firouzi et al.<sup>[25]</sup> have developed a model that makes use of the cooperative organization of inorganic and organic molecular species in three-dimensional arrays. They divided the global surfactant-directed ordered porous material synthetic process into three reaction steps: multidentate binding of silicate oligomers to the cationic surfactant and the silicate, preferential silicate polymerization in the interface region, and charge density matching between the surfactant and the silicate. This micelle-based template synthesis can be viewed as a mesoscale-imprinting process and ideal to generate uniform mesopores.

The combination of the above mesoscale-imprinting synthesis with metal ion-imprinting synthesis has resulted in novel hierarchical sorbents for metal separation.<sup>[22]</sup> The concept behind this multilevel imprinting is as follows. Surfactant micelles and metal ions both simultaneously act as templates in these hierarchically imprinted sorbents. An acidic ethanol solution leaches and extracts the metal ion and surfactant. The leaving of these templates results in two different yet associated imprints within the silica matrixes. Each imprint carries out a specific function individually. On the microporous level, removal of the metal ions from the corresponding complex leaves cavities (1–3 Å) that exhibit ionic recognition. These pores give the sorbents

**Fig. 2** Topological structures of hierarchically imprinted porous sorbents.

**Fig. 3** Schematic diagram showing the synthesis of a hierarchically imprinted sorbent using Cu<sup>2+</sup> and CTAB simultaneously as templates. *Source:* From Ref.<sup>[23]</sup>.

enhanced selectivity for the given ions. On the mesoporous level, removal of the surfactant micelles results in the formation of relatively large, cylindrical pores (diameters of 25–40 Å) that give the gel an overall porosity, including large surface areas and excellent metal-ion transport kinetic.<sup>[26–29]</sup> Pore sizes can be easily controlled by the chain length of the surfactant molecules.<sup>[30–35]</sup> This combination of selectivity and high capacity, coupled with fast kinetics, makes these materials ideal candidates for many separation applications.

The synthetic procedure was developed to produce hierarchically imprinted sorbents for Cu<sup>2+</sup>.<sup>[22]</sup> Briefly, the Cu<sup>2+</sup> template is coordinated with a bifunctional ligand 3-(2-aminoethylamino)propyltrimethoxysilane (aapts) via a standard literature procedure.<sup>[36]</sup> The [Cu(aapts)<sub>2</sub>]<sup>2+</sup> complex and a surfactant typically cetyltrimethylammonium bromide (CTAB) are imprinted into a silica matrix by the base-catalyzed hydrolytic condensation of tetraethylorthosilicate (TEOS). The resulting blue solid is collected by filtration. An ethanol/HCl solution effectively removes all templates. The bidental amine ligands lose the metal cations when protonated at pH 3 or below. The surfactant is extracted by the acidic ethanol. Fig. 3 gives a schematic illustration of this hierarchical imprinting methodology for the synthesis of Cu<sup>2+</sup> templated sorbents. Small-angle X-ray scatterings (Fig. 4) of the surfactant-free mesoporous sorbents show a peak around  $Q = 1.2\text{--}2.4\text{ nm}^{-1}$ . This peak indicates a long-range ordered or a wormy structure organized by the surfactant templates. Fig. 5 shows the comparison of the UV-Vis spectrum of [Cu(aapts)<sub>2</sub>]<sup>2+</sup> in a

methanol solution with the corresponding diffuse reflectance spectrum of a washed-and-dried as-synthesized mesoporous silica. The close match between the spectrum of [Cu(aapts)<sub>2</sub>]<sup>2+</sup> and that of

**Fig. 4** Small-angle scatterings of hierarchically imprinted sorbents using (A) CTAB, (B) sodium dodecyl sulfate (SDS), and (C) dideoxyadenosine DDA, where  $Q = (4\pi/\lambda)\sin(\theta/2)$ , where  $\lambda$  is the X-ray wavelength (0.154 nm) and  $\theta$  is the scattering angle. The asterisks in (A) and (B) indicate the other diffraction peaks from the hexagonally packed mesoporous materials. No additional diffraction peaks in (C) are consistent with the fact that the neutral surfactant template DDA gives rise to the worm-structured mesoporous materials. *Source:* From Ref.<sup>[23]</sup>.

**Fig. 5** UV/Vis spectra of  $[\text{Cu}(\text{aapts})_2]^{2+}$  in methanol and immobilized in a mesoporous sorbent prepared by CTAB as a structure directing reagent. Source: From Ref.<sup>[23]</sup>.

$[\text{Cu}(\text{b-aapts})_2]^{2+}$  (b-aapts = aapts ligand covalently bonded to silica) indicates that the stereochemical environments of the copper ion in the two systems are similar. Therefore the complex is covalently doped in the bulk silica matrix. The absorption position of the peak is consistent with the fact that  $\text{Cu}^{2+}$  is coordinated with four amine ligands, because both three and two amine-coordinated copper complexes have absorption peaks at much longer wavelengths.<sup>[37]</sup> Therefore the imprint of  $\text{Cu}^{2+}$  is successfully formed in the mesoscopic composite materials.

Competitive ion-binding studies were conducted with  $\text{Cu}^{2+}$  and  $\text{Zn}^{2+}$  ions to measure the selectivity of the imprinted material. The  $\text{Zn}^{2+}$  ion was chosen as the competitor species because it has the same charge and nearly identical size, and also binds well with the diamine ligand. The selectivity coefficient,  $k$ , for the binding of a specific ion in the presence of competitor species can be obtained from equilibrium binding data<sup>[38,39]</sup> according to Eqs. (1–3):

$$k = \frac{\{[\text{M}_2]_{\text{solution}}[\text{M}_1]_{\text{sorbent}}\}}{\{[\text{M}_1]_{\text{solution}}[\text{M}_2]_{\text{sorbent}}\}} = K_d(\text{Cu})/K_d(\text{Zn}) \quad (2)$$

where  $K_d$  is the distribution coefficient, expressed as:

$$K_d = \left\{ \frac{(C_i - C_f)}{C_f} \right\} \times \left\{ \frac{\text{volume solution (mL)}}{\text{mass gel (g)}} \right\} \quad (3)$$

Here  $C_i$  is the initial solution concentration and  $C_f$  is the final solution concentration. Comparison of the  $k$

values for the imprinted and control blank gels can show the effect that imprinting exerts on the metal-ion selectivity for a given material. A measure of the increase in selectivity due to molecular imprinting can be defined by the ratio of the selectivity coefficients of the imprinted and non-imprinted materials:

$$k' = k_{\text{imprinted}}/k_{\text{nonimprinted}}$$

Significant increases in  $K_d(\text{Cu})$ ,  $k$ , and  $k'$  for  $\text{Cu}^{2+}$  through hierarchical imprinting has been observed with the largest  $k \approx 33,000$  and the largest  $k' \approx 240$ . These values are, to our knowledge, the highest  $k$  and  $k'$  values currently achieved for imprinting synthesis with metal ions.<sup>[40]</sup> The hierarchical imprinting approach gives rise to a significant improvement over imprinted organic polymer sorbents in both capacity and selectivity.<sup>[38,39]</sup> The  $K_d(\text{Cu})$  and  $k$  values of the sorbents prepared without the use of surfactant templates are only 250 and 26, respectively. Both values are significantly less than those of the hierarchically imprinted sorbents, demonstrating the synergism of different scale templating synthesis.

### Mesoporous Bridged Polysilsesquioxane Sorbents Synthesized via Hierarchical Imprinting

A new approach for the hierarchical synthesis of ion-imprinted sorbents<sup>[41]</sup> is based on the newly developed mesoporous bridged polysilsesquioxane materials.<sup>[42–46]</sup> Structural similarities between bridged silsesquioxanes and organosilanes allow a good mixing of these sol-gel precursors and a uniform incorporation of the functional ligands into the mesoporous polysilsesquioxane framework. Inagaki, et al.<sup>[44]</sup> pioneered the synthesis of ordered mesoporous bridged polysilsesquioxane materials. The bridged silsesquioxane precursor that had been explored to generate hierarchically imprinted sorbents is 1,2-bis(triethoxysilyl)ethane (BTSE). In general, the copolymerization of BTSE with metal ion complexes of aapts around supramolecular assemblies of cetyltrimethylammonium chloride (CTAC) gives a nanocomposite polymer.<sup>[41]</sup> Extraction of the surfactant and metal ions results in a porous material with a high affinity for the metal ion template. Again, both the metal ions and the surfactant micelles act simultaneously as templates in this system. Removal of the surfactant leaves a network of pore channels that give these sorbents large surface area and excellent metal ion transfer kinetics. Removal of the metal ions results in the formation of tailored binding sites made of ethylenediamine functionalities. Arranged functionalities in conformations favor the rebinding to the metal ion

template. Selective sorbents have been synthesized for Cu(II), Ni(II), and Zn(II).

The batch tests indicated that the  $K_d(\text{Ni})$  of the Ni-imprinted sorbent and  $K_d(\text{Zn})$  of the Zn-imprinted sorbent over thousands have been achieved.<sup>[41]</sup> The selectivities of the nickel and zinc-imprinted sorbents were investigated by competitive sorption. All initial solutions contained equimolar amounts of Ni(II) and Zn(II) at five different concentrations from  $10^{-4}$  to  $10^{-3}$  M (with respect to both ions) and pH 6.0. Interestingly, the nickel-imprinted sorbent adsorbed more Ni(II) than Zn(II) at all concentrations. This results in higher distribution coefficients for Ni(II) than Zn(II) with the nickel-imprinted material. This sorbent removed nearly all of both metal ion species from the highly diluted Ni(II):Zn(II) mixture ( $10^{-4}$ : $10^{-4}$  M). At low concentration, the population of binding sites is larger than the total number of metal ions. The lack of competition may cause the loss of selectivity. In direct contrast to the adsorption behavior of the nickel-imprinted material, the zinc-imprinted sorbent absorbed more Zn(II) than Ni(II) at all concentrations studied. This results in higher distribution coefficients for Zn(II) than Ni(II) with the zinc-imprinted material.

### Polymer Sorbents Prepared by Emulsion Polymerization

The surface template polymerization diverges from the bulk imprinted materials by creating microspheres with imprinted external surfaces.<sup>[48,51]</sup> The original methodology was pioneered by Uezo, Goto, and Nakashio.<sup>[48]</sup> The microspheres have a hierarchical structure of spherical surfaces and imprinted cavities

scattering on the surfaces. Such a structure is formed via a coassembly synthesis approach. In this synthesis, metal ions, amphiphilic functional molecules, surfactants, and monomers play the roles of imprinting targets, selectively binding ligands, morphology-controlling agents, and polymer matrix precursors, respectively. During emulsion polymerization, each component fulfills its role, individually. The surfactants control the shape and size of the final spherical particles with certain size distribution. The complexes of the metal ions and the amphiphilic functional molecules are imbedded on the surfaces of the spherical polymer matrix to form imprinted cavities. The amphiphilic nature of the functional molecules is the key factor for this surface template polymerization. The functional molecules play two roles in this coassembly synthesis: 1) interface between hydrophobic matrixes and hydrophilic templating ions; and 2) generation of imprinted sites. Fig. 6 illustrates the methodology of the surface template polymerization. The imprinted surface has better site accessibility than the conventional molecularly imprinted polymers (MIPs). Therefore this technique overcomes the fundamental drawbacks of conventional polymer imprinting methods.<sup>[47-54]</sup>

After many years of intensive studies by several groups, surface-imprinted polymers evolved from water-in-oil (W/O) and oil-in-water (O/W) systems to more complicated water-in-oil-in-water (W/O/W) system for the better control of imprinting effect. The imprinting effect has also been improved by using rigid polymer matrixes and strong binding ligands. Trimethylolpropane trimethacrylate (TRIM) replaced divinylbenzene (DVB) in some applications by offering improved matrix rigidity. Diphenyldodecylidiphosphonic acid (DDDDPA) has been found as an efficient

**Fig. 6** Schematic diagram of ion imprinting in microspheres. Source: From Ref.<sup>[52]</sup>.

functional molecule for metal ion imprinting.<sup>[47–51]</sup> Several applications have been made for selective binding of  $\text{Zn}^{2+}$ ,  $\text{Cu}^{2+}$ , and lanthanide ions. The pH dependence of the absorption of the imprinted polymer to metal ions has been investigated. The dissociation of the metal ion/polymer complex is suppressed by the elevated pH value. Therefore the uptake of metal ions from aqueous solution is enhanced with the increase of pH. Size exclusion effect was observed when Dy(III), Ce(III), and La(III) ions were imprinted.<sup>[55]</sup> Dy(III) ion imprinted polymer excludes the accesses of the other two ions, while La(III) ion imprinted one accepts all ions. As a result of the similarity of the affinities of the lanthanoid ions to the functional molecules, the selectivity of the imprinted polymers to lanthanoids is only contributed by the size selectivity. This result is consistent with the ion radius order of Dy(III), Ce(III), and La(III), which are 1.083, 1.196, and 1.216 Å, respectively.

## STEPWISE ASSEMBLY

### Surface-Imprinted Mesoporous Sorbents

Hierarchical imprinting can also be accomplished in mesoporous materials through stepwise assembly.<sup>[40]</sup> First, ordered mesoporous materials can be fabricated via surfactant templating synthesis. Functional groups are then introduced to the pore surface of mesoporous silica through *imprint coating*. The key to this stepwise design is to coat the mesopore surface with complexes between ligands and target metal ions rather than just the free ligands. After the removal of metal ions, the ligand imprints of the template metal ions are created on the mesopore surfaces. This organization reflects both the size and stereochemical signature of the

template ion, and should ultimately lead to future ion recognition and selective rebinding of the target ion from ion mixtures. Such functionalized ordered mesoporous materials exhibit significantly greater target ion binding selectivities than sorbents prepared by conventional coating methods. The success of this new approach is built on the unique environments of ordered, hexagonally packed mesopore surfaces for conducting surface imprinting. These include: 1) circularly curved, extremely rigid pore surfaces, and optimum pore diameters (20–100 Å), which match the stereochemical requirements for surface imprinting of 4- or 6-coordinated metal ions; 2) a very uniform pore size distribution which allows the generation of the uniform imprints and limits the possible choices of coordination environments.

Fig. 7 shows a schematic diagram for making the sorbents for  $\text{Cu}^{2+}$  via the stepwise assembly. The batch uptake tests have indicated that imprinted sorbents exhibit distinctly higher effective capacities for  $\text{Cu}^{2+}$  than their respective control blanks. Fig. 8 shows samples of imprinted and non-imprinted monolith mesoporous beads after being exposed to identical solutions containing 0.001 M  $\text{Cu}^{2+}$ . The capacity enhancement due to molecular imprinting can be easily observed via the development of blue color associated with the formation of  $\text{Cu}^{2+}$ -amine complexes only in the surface-imprinted beads. Adsorption equilibria for these coated, mesoporous sorbents are generally achieved in less than 15 min, attesting to the fact that the adsorption kinetics for these materials are also significantly faster than those for analogous microporous materials. Furthermore, their capacity does not change after repeated cycles of loading and elution. These properties make them ideal for many separation applications requiring recyclable solid phases. The selectivities of these new sorbents were investigated by using

Fig. 7 Surface imprinting on mesoporous materials.

**Fig. 8** Comparison of non-imprinted (left) and imprinted (right) sorbent beads.

aqueous solutions of zinc and copper. Comparison of the  $K_d$  values for  $\text{Cu}^{2+}$  imprinted with control-blank samples for the aapts-coated sorbent system shows a sixfold increase in  $K_d$  for  $\text{Cu}^{2+}$ , while  $K_d$  for  $\text{Zn}^{2+}$  decreases by the same amount. The  $k'$  value of 40 for aapts-imprint-coated sorbent has been observed.

### Ion-Imprinted Zeolitic Sorbents

Zeolites consist of a crystal lattice having defined pores and cavities.<sup>[56]</sup> They are usually synthesized by hydrothermal methods in the presence of certain organic molecules (e.g., quarternary ammonium salts) acting as templates to control the type of lattice being formed. The harsh synthesis conditions eliminate the possibility of using the coassembly method for synthesizing hierarchically imprinted zeolitic sorbents. A “ship in bottle” imprinting technique has been developed for the assembly of cavity sites for uptakes of metal ions. The essence of this stepwise assembly method involves first introduction of metal ion via ion exchange, which is followed by a facilitated surface functionalization.

Fig. 9 shows a schematic diagram for synthesizing  $\text{Cu}^{2+}$ -imprinted zeolite-L sorbents. A comparison of the  $k$  value for the  $\text{Cu}^{2+}$ -imprinted sorbent with that

for the corresponding control sample showed an increase in  $k$  for  $\text{Cu}^{2+}$  through ion imprinting, with the  $k$  value for the imprinted zeolite near 30 and  $k'$  more than 2. For comparison, the competitive adsorption for the unfunctionalized plain zeolite has exhibited similar  $K_d$  values for both  $\text{Cu}^{2+}$  and  $\text{Zn}^{2+}$ . In this case, the mechanism of absorption is through the ion exchange reaction. This indicates that the original zeolite network has no selectivity toward a specific ion. The selectivity of the imprinted zeolite is generated through ion imprinting and surface functionalization.

### Ion-Imprinted Lamellar Sorbents

Lamellar structured silicate materials, which are composed of one or multiple negatively charged sheets of  $\text{SiO}_4$  tetrahedra with abundant silanol-terminated surfaces, provide an adjustable space with their intergaleries, whose negative charges are balanced by either  $\text{Na}^+$  or  $\text{H}^+$  in the interlayer spacing.<sup>[57]</sup> Various chemical species (charged or neutral) have been intercalated into the galleries of layered silicate such as magadiite to form the corresponding intercalation compounds for various applications. Many novel materials have been derived from layered silicate materials. For example, organic functional groups can be covalently grafted on the silanol-terminated interlayer surfaces through the use of organosilanes containing the functional ligands.<sup>[58,59]</sup> Surface imprinting synthesis of these materials as sorbents for  $\text{Cu}^{2+}$  has been successfully demonstrated via stepwise assembly. The  $^{29}\text{Si}$  cross-polarization (CP)/magic angle spinning (MAS) nuclear magnetic resonance (NMR) spectra of imprint-functionalized magadiite (A) and control blank magadiite (B) are shown in Fig. 10. The  $^{29}\text{Si}$  resonance peaks at ca.  $-103$  and  $-114$  ppm are assigned to the  $^{29}\text{Si}$  nuclei of  $\text{Q}^3$  and  $\text{Q}^4$  environments, respectively. The relative narrow peak widths indicate that the crystalline structure of the magadiite framework has been retained during the functionalization reactions. The resonance peaks at ca.  $-56.5$  and  $-67.5$  ppm arise from the  $(-\text{O})_2\text{Si}(\text{OH})\text{R}$  and  $(-\text{O})_3\text{SiR}$  species assigned

**Fig. 9** Schematic diagram of molecular imprinting in L-zeolite. *Source:* From Ref.<sup>[56]</sup>.

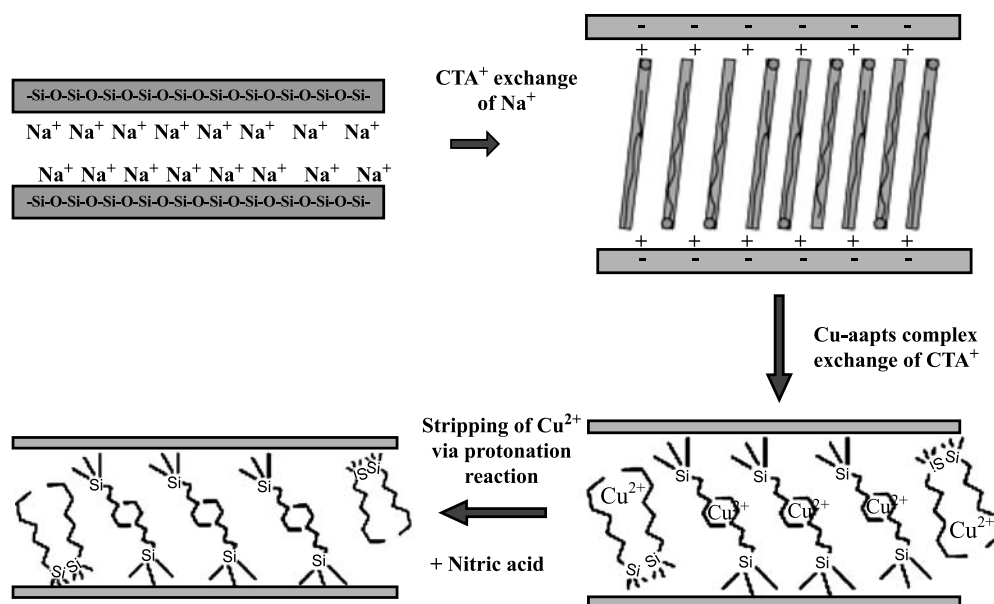

**Fig. 10**  $^{29}\text{Si}$  MAS NMR spectra of (A) imprint-functionalized magadiite and (B) control blank magadiite (inset: expansion spectrum between  $-25$  and  $-75$  ppm). *Source:* From Ref.<sup>[57]</sup>.

to T<sup>2</sup> and T<sup>3</sup>, respectively. The presence of the T<sup>2</sup> and T<sup>3</sup> bands indicates that the apts functional groups are covalently bonded to the magadiite surface. The major reactions employed in this intersurface imprinting using the magadiite host are schematically shown in Fig. 11. The enhanced uptake of Cu<sup>2+</sup> by the Cu<sup>2+</sup>-imprinted layered sorbent has been observed. The  $K_d$  value of the Cu<sup>2+</sup>-imprinted sample is threefold greater than that of the control sample. The value of the relative selectivity coefficient  $k'$  (3.24) is  $>1$ , which indicates enhanced adsorption through the ion-imprinting synthesis. The capacity did not change after several cycles of loading and stripping.

### Toward “Biomimic” and “Enzyme Mimic” Nanoporous Materials

Three-dimensional ordered nanoporous materials are widely found in nature.<sup>[60]</sup> Those materials possess hierarchically ordered structures having at least one dimension down to the nanoscale. Proteins, enzymes, and biomembranes are known as hierarchically structured materials carrying out various biological functions such as sensing, catalysis, size and shape selection, and response. The marvelous functions of biomaterials attract research interests from many fields. Material scientists simulate the bioactivity by creating artificial biomaterials through “biomimic” or “enzyme mimic.” Ion selectivity is one of the most important properties of those biomaterials. For example, the Na<sup>+</sup>/K<sup>+</sup> pump of the cell membrane maintains that the Na<sup>+</sup> concentration inside the cell is 36 times higher than that outside of the cell.

A recent report demonstrated the control of the three-dimensional architecture based on a stepwise assembly technique.<sup>[60]</sup> This approach created a novel hierarchical porous material with tunable size- and shape-selective pore structures to mimic the microchannels in biomembranes. Ordered mesoporous materials are formed by micelle templates. A monolayer of ligand is sequentially grafted to the channel surface by surface imprinting. This material consists of a rigid mesoporous oxide frame and a soft monolayer with tailored microcavities that mimics the shape and size selectivity of the biomaterials. Fig. 12 shows the scheme of the hierarchical porous materials with ordered mesoporosities and microcavities in the

long-chain molecular monolayer coatings. The triangular shape in the cavity represents the template molecules, or the idealized shape of the cavity.

## CONCLUSION

Synthesis methodologies of hierarchically structured sorbents for metal ions were reviewed. Such hierarchically structured sorbents exhibit not only fast binding kinetics and high capacities, but also molecular recognition capabilities. The simplicity of this technique should lead to a wide variety of highly selective sorbents, the properties of which can be optimized for many metal ions with the proviso that they form stable coordination complexes with suitable bifunctional ligands. Furthermore, this hierarchical imprinting methodology should not be limited to the synthesis of sorbents for the binding of metal ions. Organic molecules can be used as templates for generation of sorbents exhibiting molecular recognition of the target molecules. The general design principles illustrated by these results highlight opportunities in areas such as selective sorbents, chemical sensors, and catalysts offered by the imprinted mesoporous materials as molecular recognition devices.

# High-Strength Alloys: Nanogranular Phases

Dmitri Valentinovich Louzguine

Akihisa Inoue

*Institute for Materials Research, Tohoku University, Sendai, Japan*

## INTRODUCTION

High-strength alloys with a nanoscale-size microstructure (nanostructured alloys and composites on their base) demonstrate superior mechanical properties in a wide range obtained because of very small grain (particle) size ranging from 1 to 100 nm. Nanoscale grains (particles) can have a crystalline, quasicrystalline, or amorphous structure. These alloys often have non-equilibrium nature, although many of them exhibit remarkable stability against structural coarsening. The classical example of strong dispersion-strengthened alloys are age-hardened Al–Cu alloys, discovered in the beginning of the 20th century,<sup>[1]</sup> with nanoscale Guinier–Preston zones,  $\theta''$  and  $\theta'$  phases,<sup>[2,3]</sup> which can be considered as one of the first examples of the use of nanogranular phases in alloys for practical purposes. Because of the very small size, observation of the Guinier–Preston zones and these nanogranular phases requires application of transmission electron microscopy.

At present, alloys with nanostructured phases exhibit mechanical properties that are superior to that of conventional polycrystalline alloys. They possess high hardness, tensile, and compressive strength values, and exhibit superplastic behavior at low reduced temperature.

## FORMATION OF A NANOSTRUCTURE

Nanostructured alloys are usually produced by inert gas condensation from vapor phase,<sup>[4]</sup> sputtering,<sup>[5]</sup> rapid solidification of the melt,<sup>[6]</sup> electrodeposition,<sup>[7]</sup> or mechanical attrition<sup>[8]</sup> severe plastic deformation<sup>[9]</sup> of the solid phase as well as by devitrification of glassy alloys,<sup>[10]</sup> and other techniques.

The processing procedure can be a single-step or double/multistep one. The same material can be produced by different techniques. However, the production technique often makes significant influence of the properties of nanomaterials.

If the process involves nucleation and growth, then high nucleation rate and low growth rate of the

precipitating phase are required in order to obtain a nanostructure. Such conditions are usually obtained under primary devitrification with long-range, diffusion-controlled growth.<sup>[11]</sup> For example, Al-rich amorphous alloys with high Al concentrations above 85 at.%, in general, suffer double or multistage devitrification in which the first-stage exothermic reaction is due to the precipitation of fcc-Al, and the other exothermic peaks result from the decomposition of the residual amorphous phase to intermetallic compounds. Another way of forming a nanostructure by devitrification of the metallic glasses is spinodal decomposition.<sup>[12,13]</sup>

Al–RE–TM (RE—rare earth metals, TM—transition metal) system glassy alloys were produced in the late 1980s in Japan<sup>[14]</sup> and the United States.<sup>[15]</sup> These alloys are usually produced in a ribbon shape by the melt spinning technique<sup>[16]</sup> or in a powder one by gas atomization.<sup>[17]</sup> Al<sub>85</sub>Ni<sub>10</sub>Ce<sub>5</sub> (here and elsewhere alloy compositions are given in nominal atomic percents, at.%) bulk amorphous samples of high relative density were obtained by warm extrusion of atomized amorphous powder.<sup>[18]</sup>

Various Al–RE–TM glasses containing about 85 at.% Al show primary precipitation of Al solid solution ( $\alpha$ -Al) nanoparticles on heating<sup>[19]</sup> with extremely high nucleation rate<sup>[20]</sup> of above  $10^{20} \text{ m}^{-3} \text{ sec}^{-1}$ . fcc  $\alpha$ -Al lattice parameter measurements and atom probe ion field microscopy investigation<sup>[21]</sup> showed very low concentration of the alloying elements in nanocrystalline Al in accordance with phase diagrams<sup>[22]</sup> of Al–RE and Al–TM. Segregation of the RE metal having low trace diffusivity in Al on the  $\alpha$ -Al/amorphous phase interface is considered to be one of the most important reasons for the low growth rate of  $\alpha$ -Al. Nearly the same effects were observed during the formation of the  $\alpha$ -Fe nanocrystals.<sup>[23]</sup>

The supercooled liquid region and the regimes of heat treatment used play an important role in the devitrification behavior of the glassy alloys. Y-, Sm-, Gd-, and Dy-bearing glassy alloys of the Al<sub>85</sub>RE<sub>8</sub>-Ni<sub>5</sub>Co<sub>2</sub> composition showed a precipitation of the  $\alpha$ -Al nanoparticles after continuous heating using DSC at high enough heating rate to prevent devitrification

below  $T_g$  (0.67 K/sec and higher) or annealing at the temperature above  $T_g$ . At the same time, Y-, Gd-, and Dy-bearing metallic glasses as well as the  $\text{Al}_{85}\text{Y}_4\text{Nd}_4\text{Ni}_5\text{Co}_2$  showed simultaneous formation of the intermetallic compound(s) and  $\alpha$ -Al nanoparticles, or primary formation of the only intermetallic compound after annealing below  $T_g$ .<sup>[24]</sup> For example, the  $\text{Al}_{85}\text{Y}_8\text{Ni}_5\text{Co}_2$  alloy shows a formation of an unknown intermetallic compound conjointly with  $\alpha$ -Al nanoparticles after annealing up to the completion of the primary phase transformation. The intermetallic compound is metastable and has a multicomponent composition. The volume fraction of the intermetallic compound is higher than that of  $\alpha$ -Al and the fraction of  $\alpha$ -Al depends upon an annealing temperature below  $T_g$ .

Devitrification of the  $\text{Ti}_{50}\text{Ni}_{20}\text{Cu}_{23}\text{Sn}_7$  alloy begins from the primary precipitation of a nanoscale equiaxed, almost spherical particles of cF96  $\text{Ti}_2\text{Ni}$  solid solution (other alloying elements are partially dissolved in this phase) (Fig. 1A,B).<sup>[25]</sup> One should mention that these particles exhibit high thermal stability against coarsening and retain their nanoscale size

**Fig. 1** (A) Bright- and (B) dark-field TEM images of  $\text{Ti}_{50}\text{Ni}_{20}\text{Cu}_{23}\text{Sn}_7$  alloy after isothermal calorimetry at 725 K for 2200 sec. (C) HRTM after DSC at 0.67 K/sec up to 850 K. Source: From Ref.<sup>[25]</sup>.

**Fig. 2** Bright-field micrograph of the  $\text{Cu}_{55}\text{Zr}_{30}\text{Ti}_{10}\text{Pd}_5$  alloy annealed for 1.2 ksec at 750 K. The insert-nanobeam electron diffraction pattern of fivefold symmetry.

even after heating up to 850 K when  $\text{TiCu}$  phase starts to precipitate from the residual glassy matrix (Fig. 1C).

Formation of the nanoscale icosahedral phase was observed in  $\text{Zr-Cu-Al}$ ,  $\text{Zr-Al-Ni-Cu}$ ,<sup>[26]</sup> and  $\text{Zr-Ti-Ni-Cu-Al}$ <sup>[27]</sup> glassy alloys containing an impurity of oxygen above about 1800 mass ppm, although no icosahedral phase is formed if oxygen content is lower than 1700 mass ppm. Later, the nanoscale icosahedral phase was obtained in Zr-based alloys containing noble metals<sup>[28]</sup> as well as a result of V, Nb, or Ta addition at much lower (typically about 800 mass ppm) oxygen content. Some  $\text{Hf-NM-(Ni,Cu)-Al}$  alloys also devitrify forming nanoicosahedral phase.<sup>[29]</sup> The study of amorphous  $\rightarrow$  icosahedral phase transformation in a  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{7.5}\text{Ag}_{10}$  showed that the quasilattice constant decreases with annealing time and the zirconium and silver content in the icosahedral particles differ from those in the remaining amorphous matrix<sup>[30]</sup> as it should be in the case of primary-type reaction. Recently, nanoscale icosahedral phase with a size of less than 10 nm homogeneously dispersed in the residual glassy matrix was formed in Cu-based alloy<sup>[31]</sup> (Fig. 2).

The local atomic structures around Pt as well as Zr in the amorphous and quasicrystalline  $\text{Zr-Al-Ni-Pt}$  alloys have been determined by the anomalous X-ray scattering method.<sup>[32]</sup> The existence of chemical short-range order clusters was found in the glassy state as well. Moreover, recently it was shown that the

icosahedral order exists in the liquid phase of Ti–Zr–Ni quasicrystal-forming alloy.<sup>[33]</sup>

Two very important parameters of such composite nanomaterials are grain (particle) size and its volume fraction. Primary devitrification of highly supercooled liquid or amorphous phase often has the following unique features, i.e., high nucleation frequency, low crystal growth rate, high concentration gradient of solute element at liquid/solid interface resulting from low atomic diffusivity, formation of metastable phases by the control of redistribution of solute elements, formation of a residual amorphous phase with high solute concentration, defect-free nanocrystalline particles with low residual strain, highly dense packed structure at liquid/solid interface, nanoscale interparticular spacing, and size and shape effects of nanoscale spherical particles. Relying upon the aforementioned, new nanoscale mixed-phase alloys containing a residual amorphous phase were obtained by devitrification of glassy alloys.<sup>[34]</sup>

## STRUCTURE AND MECHANICAL PROPERTIES

### Single-Phase Nanocrystalline Alloys

In general, bulk single-phase nanostructured materials were found to exhibit low ductility at room temperature, which impedes a limit on their practical applications. For example, electrodeposited nanocrystalline Ni with a mean grain size of 10 nm showed yield strength, ultimate tensile strength, and elongation to fracture of 900 MPa, 2000 MPa, and 1%, respectively, compared to 100 MPa, 400 MPa, and 50%, respectively, for polycrystalline Ni with 10- $\mu$ m grain size<sup>[35]</sup> The major reasons for the brittleness of bulk metallic nanomaterials are connected with the difficulties of dislocation generation and movement, porosity, and other artifacts as well as instability of crack nucleation and propagation. However, recent studies on nanocrystalline pure metals showed that quite high ductility values on tensile test can be obtained at definite grain size after proper treatment.<sup>[36]</sup> For example, nanocrystalline hcp Co samples with a mean grain size of 12 nm produced by pulse electroplating on Ti substrate followed by a thermomechanical treatment showed an ultimate tensile strength of 1865 MPa, yield strength of 1000 MPa at 7% elongation, which is an example of a very good combination of strength and ductility.<sup>[37]</sup>

Mechanical yield strength of conventional polycrystalline materials obeys the well-known Hall–Petch relationship that has been extrapolated to nanomaterials as well. The Hall–Petch relation states that the yield strength  $\sigma_y$  increases monotonically with

decreasing the average grain size  $d$  as:

$$\sigma_y = \sigma_0 + kd^{-1/2} \quad (1)$$

where  $\sigma_0$  is the friction stress needed to move dislocations and  $k$  is a material-dependent constant. Considerable strengthening is achieved on reducing the grain size from the macro- to the micro- and finally to the nanoscale size. However, different types of strength variation with nanoscale grain size have been reported, ranging from respecting the Hall–Petch relationship to showing a saturation of strength or even fall of strength at the finest grain sizes.<sup>[38–40]</sup>

A number of models have been proposed to interpret the inverse Hall–Petch behavior. Some calculations<sup>[41]</sup> based on the idea that very small grains cannot sustain significant dislocation activity indicate that the Hall–Petch behavior should cease when the average grain size is below 10–20 nm. Numerous models have been proposed to explain the deformation when the grain size falls below the cut-off value for significant dislocation activity. It is frequently predicted by a mechanism based on grain boundary sliding accommodated by diffusion or by the emission of dislocations into the grains.<sup>[42]</sup> The inverse Hall–Petch relation is also explained by the size-dependent line tension where the dislocation elastic strain is assumed to be screened within the distance of the grain diameter.<sup>[43]</sup> On the basis of the composite model involving a crystalline matrix and intercrystalline layers, the yield stress of nanocrystalline materials can be expressed as the sum of the matrix contribution and the intercrystalline contribution, both of which are assumed to be linearly connected with the corresponding shear module and to be functions of the grain size.<sup>[44]</sup> The attempt was also done to explain the inverse Hall–Petch relation by the change of the deformation mechanism from a dislocation glide process to the Coble creep.

### Multiphase Nanostructured Alloys

Commercial high-strength materials usually have a multiphase microstructure. For example, a new Mg<sub>97</sub>Zn<sub>1</sub>Y<sub>2</sub> low alloy with high yield strength and ductility was produced recently by compaction and extrusion of the powder produced by high-pressure gas atomization.<sup>[45]</sup> As the extrusion temperature rises, the resulting tensile yield strength changes from 600 to 420 MPa, while the percentage elongation increases from 5% to 15%. These values are extremely high for Mg-based alloys.

Mg–Zn–Y alloys show a novel long periodic hexagonal matrix phase. Fig. 3 shows the TEM image of the Mg<sub>97</sub>Zn<sub>1</sub>Y<sub>2</sub> alloy obtained by extrusion at 573 K. The alloy consists of fine grains with grain sizes ranging

**Fig. 3** High-resolution TEM image and selected-area electron diffraction pattern of the RS/PM  $\text{Mg}_{97}\text{Zn}_1\text{Y}_2$  alloy produced at 573 K. *Source:* From Ref.<sup>[46]</sup>.

from 100 to 150 nm. In addition, each grain contains a high density of stacking fault-similar defects as well as very fine precipitates with a size of about 10 nm. In the selected-area electron diffraction pattern shown in Fig. 3,<sup>[46]</sup> one can see extra reflection spots in the direction of (0001), indicating the formation of a long-periodic structure in which the periodicity is longer than that for the ordinary hcp-Mg phase.

This long-period ordered structure has a unit cell composed of six close-packed planes of the magnesium crystal with a stacking sequence of ABCBCB', where the A and B' layers are significantly enriched in Zn and Y.<sup>[47]</sup> However, an atomic structure model of the Mg–(Zn, Y) long-period ordered structure was constructed based on a monoclinic lattice with  $\gamma = 88^\circ$ ,  $a = 0.56$ ,  $b = 0.32$ ,  $c = 1.56$  nm, by using the lattice distortion from the ideal long periodic hexagonal structure. The lattice distortion from an ideal hexagonal lattice arises from an asymmetry of the chemical order with respect to the hexagonal-type stacking order. In addition to the change in the structure of the matrix phase, homogeneous dispersion of fine precipitates of a  $\text{Mg}_{24}\text{Y}_5$  phase with cubic lattice and a size of about 7 nm was observed.

$\text{Mg}_{97}\text{Zn}_1\text{Y}_2$  alloy also exhibited high strain rate superplasticity showing tensile elongation above 700% at 623 K at a high strain rate of  $0.1 \text{ sec}^{-1}$  as well as a high strain rate sensitivity exponent of 0.4. The sample with the largest elongation at a high strain rate of  $0.1 \text{ sec}^{-1}$  was elongated through a homogeneous deformation mode. Thus the  $\text{Mg}_{97}\text{Zn}_1\text{Y}_2$  alloy has excellent mechanical properties as well as high strain rate superplasticity.

Recently, it has been shown also that a 3-mm-diameter cylindrical rod of cast  $\text{Ti}_{60}\text{Cu}_{14}\text{Ni}_{12}\text{Sn}_4\text{Nb}_{10}$  alloy consisting of a micron-size  $\beta$ -Ti dendrites and nanostructured precipitates exhibits high ultimate compressive strength of 2.4 GPa and 14.5% plastic strain.<sup>[48]</sup>

## Nanoquasicrystalline Alloys

High strength and good ductility for the icosahedral base alloys can be obtained in a nanostructured state when the icosahedral phase coexists with the fcc  $\alpha$ -Al phase and has a spherical morphology, small grain size, and homogeneous dispersion. The mixed structure consisting of icosahedral and  $\alpha$ -Al phases is formed in the Al-rich melt-spun Al–Mn–RE alloys, and the mixed phase alloys have good bending ductility and high fracture strength reaching 1320 MPa. The high-strength  $\text{Al}_{92}\text{Mn}_6\text{Ce}_2$  alloy consists of spherical icosahedral particles with a size of about 50 nm surrounded by nanoscale fcc- $\alpha$ -Al layer with a thickness of 5 to 10 nm. The similar nanoscale mixed structure is also formed in rapidly solidified Al–Cr–Ce–Co alloys<sup>[49]</sup> and the icosahedral particles with a size of 20–40 nm are homogeneously dispersed in the Al phase. For example,  $\text{Al}_{94.5}\text{Cr}_3\text{Ce}_1\text{Co}_{1.5}$  alloy exhibits high fracture strength of 1340 MPa.

The icosahedral phase-based alloys also have good cold deformability and can be cold rolled up to the significant reduction ratio in thickness above 70%.<sup>[50]</sup> The cold-rolled alloy has a much finer mixed structure consisting of an icosahedral phase with a size of 5 to 10 nm in coexistence with nanoscale fcc  $\alpha$ -Al phase.

Here it is important to point out that the high tensile strength combined with good ductility is obtained only for the mixed phase alloys prepared through the unique solidification process in which the nanoquasicrystalline phase precipitates as a primary phase, followed by the solidification of  $\alpha$ -Al from the remaining liquid. On the other hand, when the Al-based alloys have the other type of solidification processes in which an  $\alpha$ -Al solid solution is formed first, followed by the precipitation of an icosahedral phase within  $\alpha$ -Al grains and along  $\alpha$ -Al grain boundaries, the studied alloys showed low tensile strength and ductility.

In addition, the same mixed structure consisting of the nanoscale icosahedral phase surrounded by the fcc  $\alpha$ -Al phase is also formed for atomized powders in Al–Mn–RE and Al–Cr–RE–TM systems as well as in Al–Mn–TM and Al–Cr–TM systems without the RE element.<sup>[51]</sup> For the atomized powders extruded in the temperature range below 673 K, which is lower than the decomposition temperature of the icosahedral phase, one can obtain fully dense bulk icosahedral-base alloys.<sup>[52]</sup> Fig. 4 shows the relation between tensile strength and plastic elongation for the extruded bulk icosahedral base alloys in comparison with the data of conventional Al-based alloys. The bulk icosahedral-based alloys have high fracture strength values of 500 to 850 MPa combined with large elongation of 5–25%, which are much superior to those for the conventional Al-based alloys.

**Fig. 4** Relation between tensile strength and plastic elongation for the extruded bulk icosahedral base alloys. The data of conventional Al-based alloys are also shown for comparison. *Source:* From Ref.<sup>[18]</sup>.

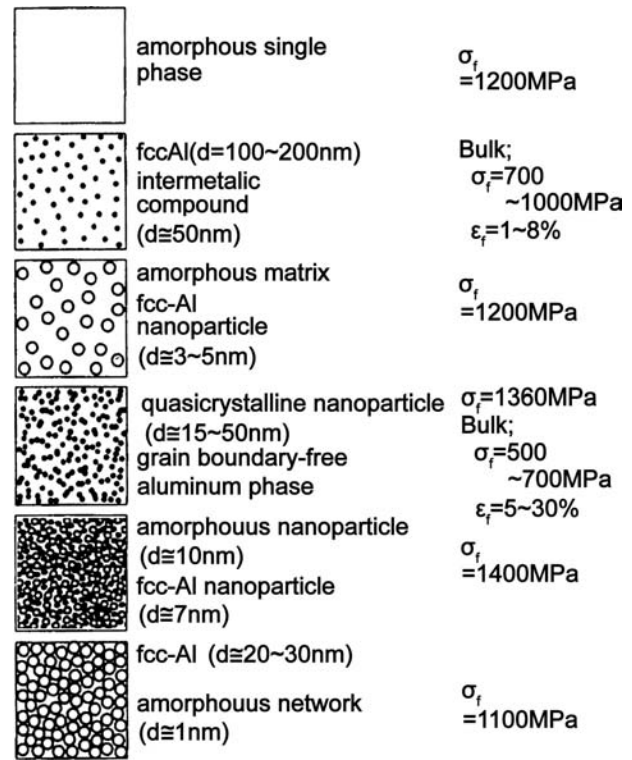

A mostly single icosahedral phase was obtained for the Al-Fe-Cr-Ti alloys.<sup>[53]</sup> The new Al-Fe-Cr-Ti alloys exhibit excellent elevated temperature strength of 400 to 460 MPa at 473 K and 350 to 360 MPa at 573 K. It has further been shown that the high elevated temperature strength level of the extruded  $Al_{93}Cr_3Fe_2Ti_2$  alloy is maintained even after annealing for 1000 hr at 573 K. The annealed alloy also keeps a fine mixed structure consisting of fine icosahedral particles and fine Al grains.

Thus the icosahedral phase-based Al alloys can be classified into three groups: 1) high-strength-type alloys in Al-Mn-RE and Al-Cr-RE-TM systems; 2) high-ductility-type alloys in Al-Mn-Cu-TM and Al-Cr-Cu-TM systems; and 3) high-elevated-temperature-strength-type alloys in Al-Fe-Cr-Ti system. The present nanoquasicrystalline Al alloys exhibit good combination for almost all properties including tensile strength, elevated temperature strength, Charpy impact fracture energy, cold workability, elongation and Young's modulus except thermal expansion. Fine-grained magnesium alloys reinforced by quasicrystalline particles were developed by thermomechanical processes for as-cast  $Mg_{96}Zn_{3.4}Y_{0.6}$  and  $Mg_{94.8}Zn_{4.3}Y_{0.7}Zr_{0.2}$  alloys.<sup>[54]</sup>

### Nanostructured Alloys with Glassy Phase

Nanocomposite materials can be produced using a single-step process, e.g., on rapid solidification by controlling the cooling rate or by using a double-step one such as devitrification of the glassy matrix.

The structure types of Al-<sup>[55]</sup> and Zr-based<sup>[56]</sup> nanostructured alloys are shown in Figs. 5 and 6 together with their typical mechanical properties.

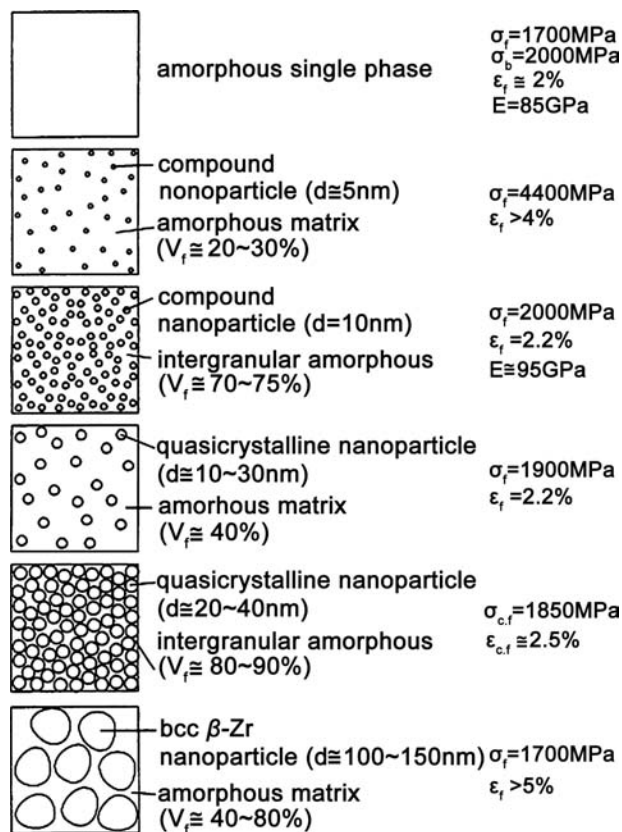

**Fig. 5** Microstructure and mechanical properties of nonequilibrium Al-based alloys. *Source:* From Ref.<sup>[55]</sup>.

One should also mention that some bulk glassy alloys contain medium-range order (MRO) zones and nanoscale particles<sup>[57,58]</sup> in as-solidified state (Fig. 7),<sup>[59]</sup> although these precipitates do not produce diffraction peaks in the XRD and selected-area electron diffraction pattern because of their low volume fraction.

Al-based amorphous alloys exhibit high tensile strength exceeding 1200 MPa.<sup>[60]</sup> It is important that amorphous alloys in the ternary Al-RE-TM system, e.g., Al-Y-Ni, in addition to their high strength, possess good bend ductility. An addition of Co partially replacing Y in the  $Al_{85}Y_{10}Ni_5$  increased the tensile fracture strength, e.g., from 920 to 1250 MPa, in the case of  $Al_{85}Y_8Ni_5Co_2$  metallic glass, without worsening of bend ductility.<sup>[61]</sup> At the same time, the addition of 2 at.% Co to  $Al_{85}Y_{10}Ni_5$  alloy also caused a drastic increment of the glass-forming ability.

Subsequently, it has been noticed that the homogeneous dispersion of nanoscale fcc  $\alpha$ -Al particles in an amorphous matrix causes a drastic increase in tensile fracture strength to 1560 MPa for the  $Al_{85}Y_8Ni_5Co_2$  without a reduction in bend ductility.<sup>[62]</sup> An optimum strength value was obtained for a crystalline phase volume fraction ranging from 5% to 25%.<sup>[63]</sup> The volume fraction of the fcc-Al phase is controlled by changing the rotation speed of the wheel and is evaluated by the change in the exothermic amount due to

**Fig. 6** Microstructure and mechanical properties of non-equilibrium Zr-based bulk alloys in Zr–Al–Ni–Cu and Zr–Al–Ni–Cu–M (M = Ag, Pd, Au, Pt or Nb) systems. *Source:* From Ref.<sup>[56]</sup>.

crystallization. The tensile fracture strength increases from about 1100 MPa at volume fraction of fcc-Al ( $V_f$ )  $V_f = 0\%$  to 1560 MPa at  $V_f = 25\%$ , accompanying an increase in Vickers hardness from 280 to 400 and Young's modulus from 63 to 71 GPa.<sup>[51]</sup> The significant decrease in tensile fracture strength by the further increase in  $V_f$  is due to the embrittlement of the remaining amorphous phase by the progress of structural relaxation and the enrichment in the solute elements.

$\text{Al}_{88}\text{Y}_2\text{Ni}_9\text{Fe}_1$  amorphous alloy containing 7% volume fraction of the fcc-Al particles with a size of about 3–7 nm (Fig. 8) has a high tensile fracture strength of 1320 and 1260 MPa with volume fraction of 24%, respectively.<sup>[64]</sup> It is notable that the values for the former alloy are higher than the highest values of Al-based amorphous single-phase alloys. The high strength is combined with good bend ductility.

Bulk  $\text{Al}_{88.5}\text{Ni}_8\text{Mm}_{3.5}$  alloy having a mixed structure consisting of amorphous and fcc-Al phases was produced by extrusion of atomized powders at an extrusion ratio of 10 and at 633 K and was found to exhibit high tensile strength of 940 MPa at room temperature, 700 MPa at 423 K and 520 MPa at 473 K.<sup>[65]</sup>

**Fig. 7** HRTEM image of rod-shaped bulk (2 mm in diameter)  $\text{Zr}_{55}\text{Co}_{20}\text{Al}_{12}\text{Cu}_5\text{Nb}_8$  glassy alloy containing MRO zones and nanoscale particles in as-solidified state. The insert represents selected-area electron diffraction pattern. *Source:* From Ref.<sup>[59]</sup>.

Similarly, the yield strength is also as high as 845 MPa at room temperature and 420 MPa at 473 K. The high values of strength remain unchanged even after annealing for 100 hr at these testing temperatures. The fatigue limit after the cycles of 10<sup>7</sup> is also as high as 330 MPa at 293 K and 220 MPa at 473 K. The fatigue limit at room temperature is also 1.2 times as high as the highest value for conventional Al-based alloys.

The deformation of amorphous materials is concentrated on the shear band of maximum shear stress, which maintains about 45° with the load (tensile or compressive) direction. The width of the shear band, e.g., in Al alloys, is about 20 nm. An  $\text{Al}_{88}\text{Ni}_{10}\text{Ce}_2$  glassy alloy primarily transforms from amorphous to amorphous plus fcc  $\alpha$ -Al state and exhibits a large elongation reaching 45% in the temperature range of 450 to 465 K. In this temperature range, primary fcc-Al particles with a size of about 12 nm precipitate homogeneously in the amorphous matrix with an interparticle spacing of about 6 nm. The appearance of the significant elongation is due to a crystallization-induced elongation phenomenon. The process occurs through inhomogeneous deformation along shear

**Fig. 8** Dark-field electron micrograph (A) and electron diffraction pattern (B) of a rapidly solidified  $\text{Al}_{88}\text{Y}_2\text{Ni}_9\text{Fe}_1$  alloy. The circle in the diffraction pattern represents the position and size of the aperture used to take the dark-field electron micrograph. Source: From Ref.<sup>[64]</sup>.

plane, followed by deformation-induced preferential precipitation of Al particles on the shear plane and then propagation of the deformation site to other site resulting from the precipitation-induced strengthening in the deformed area.<sup>[60]</sup>

The increase in strength by the dispersion of nanoscale fcc-Al particles in the amorphous matrix has been thought to result from the combination of the following three effects, i.e., 1) defect-free effect of nanoscale fcc-Al particles, as the Al particles are too fine to contain dislocations; 2) interface effect, as the amorphous/Al particle interface has a highly dense packed structure without excess vacancies owing to a low interfacial energy; and 3) nanoscale effect, as the Al particle size is smaller than the width of the inhomogeneous shear deformation region and hence the nanoscale Al particles can act as an effective barrier against the shear deformation of amorphous matrix.<sup>[34]</sup> It also explains the maintenance of a good bend ductility. At the same time, it was also suggested<sup>[66]</sup> that the hardening could be attributed mainly to solute enrichment of the residual glassy matrix due to the lowering of the Al content.

A model of the ductile–brittle transition of partially crystallized amorphous Al–Ni–Y alloys was proposed

in Ref.<sup>[67]</sup>. The maximum strength of the partially crystalline Al–Ni–Y alloys was obtained when the size of Al particles is 10 nm. However, partially crystallized Al–Ni–Y alloys become brittle when the size and the volume fraction of the Al particles exceeded the optimum values. It was assumed that the Al–Ni–Y alloys become brittle when the solute content of the interface layers reached the critical value (20%). The predictions were found to be in good agreement with the published data.

However, in some cases the formation of the primary  $\alpha$ -Al particles worsens the mechanical properties of Al-based alloy. For example, partial replacement of Ni by Cu in the  $\text{Al}_{85}\text{Y}_8\text{Ni}_5\text{Co}_2$  metallic glass caused the formation of the nanoscale  $\alpha$ -Al particles that resulted in sharp decrement in tensile strength, hardness, crystallization temperature, and disappearance of the supercooled liquid prior to crystallization.<sup>[68]</sup> Cu has a much lower absolute value of heat of mixing with Al, Y, and Co than Ni that leads to decrement of the interatomic constraint force. Thus Cu may weaken the interaction needed for the stability of the glass, thus resulting in the disappearance of  $T_g$  and precipitation of  $\alpha$ -Al nanocrystals. In addition, the volume fraction of the  $\alpha$ -Al nanocrystals in  $\text{Al}_{85}\text{Y}_8\text{Ni}_3\text{Co}_2\text{Cu}_2$ , for example, is much lower than that in the primarily devitrified  $\text{Al}_{85}\text{Y}_8\text{Ni}_5\text{Co}_2$  metallic glass.  $\alpha$ -Al interparticle distances in the  $\text{Al}_{85}\text{Y}_8\text{Ni}_3\text{Co}_2\text{Cu}_2$  metallic glass significantly exceed the particle size. Thus  $\alpha$ -Al particles cannot act as an effective barrier against the shear deformation of amorphous matrix as was supposed for the  $\text{Al}_{85}\text{Y}_8\text{Ni}_5\text{Co}_2$  metallic glass.

At the same time the existence of the MRO zones and nanoscale particles in as-cast rod-shaped bulk (2 mm in diameter)  $\text{Zr}_{55}\text{Co}_{20}\text{Al}_{12}\text{Cu}_5\text{Nb}_8$  glassy alloy (Fig. 6) enhances its ductility leading to the appearance of a plastic deformation region of about 1% deformation. Moreover, nanocrystalline bulk  $\text{Zr}_{55}\text{Al}_{10}\text{Cu}_{30}\text{Ni}_5$  alloy containing nanoscale crystals embedded uniformly in a glassy matrix also has both high tensile strength of 1.7 GPa and good ductility.

It can be shown that the cylindrical bulk sample of  $\text{Zr}_{65}\text{Al}_{7.5}\text{Cu}_{7.5}\text{Ni}_{10}\text{Pd}_{10}$  alloy, the structure of which consists of an almost single icosahedral phase with nanoscale grain sizes of 20–40 nm, shows better combination of mechanical properties than the as-cast glassy sample. The Young's modulus, 0.2% proof stress, ultimate tensile strength, total percentage elongation including elastic elongation are 85 GPa, 1640 MPa, 1750 MPa, and 2.2%, respectively, for the glassy alloy and 88 GPa, 1780 MPa, 1830 MPa, and 3.1%, respectively, for the icosahedral phase-based alloy.<sup>[69]</sup> However, it is well known that stoichiometric icosahedral phase-based alloys have high hardness and are extremely brittle. Thus it is difficult to consider that the icosahedral phase itself in the present alloys has

**Fig. 9** Schematic illustration of the deformation and fracture modes of the nanoquasicrystalline Zr–Al–Ni–Cu–Pd alloy. Source: From Ref.<sup>[56]</sup>.

plastic deformability.<sup>[70]</sup> The good mechanical properties are attributed to the existence of residual intergranular glassy phase, although the volume fraction of the glassy phase is estimated to be less than 5%. The deformation of the icosahedral-based alloy takes place in the intergranular glassy phase along the maximum shear plane. The existence of nanoscale icosahedral or crystalline particles can act as a resistant medium against shear deformation (Fig. 9). The good ductility of the glassy layer is also attributed to the localization effect of deformation. The localization generates the multi-axis stress condition as well as causes the increase in the temperature.

At the same time it is shown<sup>[71]</sup> that the nanoicosahedral phase can be obtained in Zr-based alloys with the addition of Ti instead of Pd and Al.

## CONCLUSION

Nanogranular phases of crystalline and quasicrystalline origin play a very important role in the strengthening of conventional polycrystalline as well as glassy alloys as an effective barrier for dislocation activity and shear bands propagation in the former and latter case, respectively. Moreover, nanogranular precipitates

enhance the ductility of bulk glassy alloys, which opens an area for their future application as structural materials. At the same time recent studies showed that even pure metals in nanocrystalline single-phase state after proper treatment can show high strength and good ductility values on tensile test. All the abovementioned promotes further studies on nanostructured alloys.

## INTRODUCTION

Carrier-mediated drug delivery has witnessed a sea change in the last two decades, wherein the focus on particulate carriers has shifted from lipid-based vesicles to polymeric nanoparticles. The inadequacy of the liposomal system has led researchers to focus on carriers with properties more conducive to drug loading, in vivo controlled drug release, and storage stability. The polymeric nanoparticles have evolved as an outcome of these requirements, and innumerable reports on studies in this area can be encountered in the scientific literature.<sup>[1–3]</sup> Synthetic biomaterials that are highly biocompatible and non-immunogenic have paved the way for the development and synthesis of nanoparticles from homo/copolymeric blends that can be suitably monitored according to the type of drug that requires to be delivered. In light of this interest, poly(*N*-vinylpyrrolidone) (PVP), the water-soluble homopolymer of *N*-vinyl-2-pyrrolidone (NVP), which has long been used as a blood-plasma substitute and extender, became of interest for its application in nanoparticles. Such a highly biocompatible and biologically acceptable polymer could form ideal carriers for hydrophilic drugs. The hydrogel properties of the polymer could also provide hydrophilic surface properties that would help the nanoparticles in evading the reticuloendothelial system (RES) of the body. This entry highlights various studies incorporating the preparation of PVP nanoparticles in reverse micelles and its applications.

## BACKGROUND

It is a well-documented fact that the intravascular delivery of particulate carriers—particularly those that promote opsonization—is limited due to the

recognition and scavenging by the RES. The polymeric nanoparticles being used for drug delivery investigations were prepared primarily from hydrophobic polymers, such as polyalkylcyanoacrylate, polymethylmethacrylate, polylactate, polylactate-co-glycolate, etc.<sup>[4–6]</sup> Subsequent strategies of surface modifications that would confer stealth properties to these nanoparticles had been developed so as to evade RES uptake. Several polymers with hydrophilic groups have been used for the purpose of conferring surface hydrophilicity and steric stabilization, these include PEG, PEO, the poloxamers and poloxamines, polyacrylamide, polyvinylpyrrolidone, dextran, etc.<sup>[7–12]</sup>

Besides surface hydrophilicity, the size of the nanoparticles plays an important role in ensuring access to all sites in the body without attracting RES uptake. In keeping with the architecture of normal as well as diseased tissue, nanoparticles < 100 nm in diameter are ideal candidates for access to all cell types following extravasation from the systemic circulation. To borrow an example from nature, disease-causing microorganisms, the viruses in particular, are able to aptly evade the RES and invade target cells. An important observation is that most animal viruses are considerably less than 100 nm in size. The ultralow size of these viral particles is considered to be one of the reasons for efficient evasion of the RES. Further, a virus escapes exclusion from the kidney because its size is large enough to avoid renal excretion. As a result, they are able to circulate in blood for a long time, and as the size is less than 100 nm they can extravasate to reach the target sites, where they attach and invade the host cells. The viral architecture thus provides an ideal example to emulate.

On the other hand, with the advent of recombinant DNA technology, various types of proteins and polypeptides are being used as drugs as well as vaccines.

The pace of development in the protein and peptide drug industry has altered the course of drug delivery using polymeric nanoparticles. The hydrophobic nanoparticles were not ideal candidates for entrapment of these hydrophilic drugs. Thus nanoparticles of hydrogel materials were thought to be the most suitable for overcoming these limitations. The development of hydrophilic biomedical materials or the “hydrogels” as novel pharmaceutical formulations for delivery of drugs, primarily peptides and proteins, was necessitated. The hydrogels, which are three-dimensional hydrophilic polymeric networks, are capable of imbibing large amounts of water or biological fluids, and exhibit a thermodynamic compatibility with water, which allows them to swell in aqueous media. They resemble natural living tissue more than any other class of synthetic biomaterials, because of their high water content and soft consistency. The networks may be composed of homopolymers or copolymers, which are insoluble because of the presence of cross-links (tie-points, junctions) or physical cross-links such as entanglements or crystallites. The suitability of a hydrogel as a drug delivery device, and its performance in a particular application, depends to a large extent on its bulk structure. The network structure and the thermodynamic nature of the components of these networks play a key role in the molecular mesh size changes, their diffusion behavior, and the associated molecular stability of the incorporated bioactive agents, especially in environmentally responsive hydrogels.<sup>[13]</sup> These materials do not simply release the drug, peptide, or protein at some characteristic rate, but do so in a way that the pharmaceutical scientists and molecular designers require.

Hydrogels have attracted considerable attention as excellent candidates for controlled release devices, as well as targetable carriers of therapeutic agents.<sup>[14,15]</sup> In the present context, nanoparticulate devices composed of hydrogels have greater advantages over disk- or film-shaped macrogels hitherto developed, as they would have both extensive swelling kinetics of hydrogels, as well as a wide variety of biomedical applications because of their small size. The preparation of ultralow size hydrogel nanoparticles as drug carriers for the purpose of drug targeting is a challenging area of research. Considerable effort has been devoted to the creation of nanoparticles acceptable for general systemic use and capable of carrying a drug to its target, at the tissue or cellular level. The delivery of hydrophilic drugs through targeting of nanoparticles to sites other than the RES presents an important challenge in the present context of drug delivery. Nanoparticles of hydrogel materials can be made RES evading and long circulating, without making any surface modifications. Moreover, the presence of reactive groups on the particle surface makes

attachment of appropriate ligands possible. By adjusting the chemical composition of these hydrogel materials, smart hydrogel nanoparticles encapsulating water-soluble drugs can also be prepared.

Hydrophilic polymeric nanoparticles were previously prepared by Birrenbach and Speiser<sup>[16]</sup> in 1976, using reverse micelles, but were eventually discarded due to certain inherent drawbacks. Following the basic conceptual preparative method of Birrenbach and Speiser, with the necessary modifications, nanoparticles of the hydrogel PVP have been prepared.<sup>[17]</sup> The method is suitable for any hydrophilic polymer, but the extensive biomedical usage and general acceptability of polyvinylpyrrolidone led to its use in the preparation of nanoparticles by the revised method.

### A WIDELY USED HYDROGEL— POLYVINYLPIRROLIDONE

Poly(*N*-vinylpyrrolidone), the water-soluble homopolymer of *N*-vinyl-2-pyrrolidone (NVP), was first synthesized by Professor Walter Reppe and his colleagues<sup>[18]</sup> during the 1930s, and was widely used as a blood-plasma substitute and extender during World War II. Traditionally, the synthesis of NVP and the polymerization of the homopolymer have been based on the Reppe acetylene chemistry, represented by the series of reactions shown in Fig. 1. NVP is one of the various products of the acetylene chemistry discovered by Reppe.<sup>[19]</sup> Polymerization can be carried out in bulk (including solid state), in solution, or in suspension. Radical initiation in solution is the most important method for the synthesis of linear PVP with weight-average molar masses from 2500 to 1 million. The relevant techniques are described in detail by Kern and Cherdron.<sup>[20]</sup>

PVP preparations are available in different molecular weight ranges, with means varying from a few thousand to over 1 million. Molecular weights between 2500 and  $10^6$  g/mol are described. It seems quite difficult to get a trustworthy value for the molecular weight of PVP, and it is quite common to measure its viscosity in solution and to apply the “Fikentscher *k*-value–molecular weight relationship” for its calculation.<sup>[21]</sup> Kern and Cherdron<sup>[20]</sup> have developed a relationship between  $M_w$ ,  $M_n$ , and  $k$ :  $M_w = 15k^{2.3}$ ,  $M_n = 24k^2$ . The letter  $k$  and an appropriate number related to the molecular weight are used to designate the different PVPs.  $k$ -12 has an average molecular weight of around 4000 and  $k$ -90 has an average molecular weight of around 1 million. Furthermore, PVP with a specified  $k$ -value and average molecular weight consists of a range of molecular sizes with a slightly skewed bell-shaped distribution around the average.

### PROPERTIES OF POLY(*N*-VINYLPIRROLIDONE)

A special and unusual property of polyvinylpyrrolidone is its solubility in water as well as in various organic solvents. The reason for this phenomenon is that PVP has hydrophilic as well as hydrophobic functional

groups, and therefore interactions with various solvents are possible. Only the viscosity of the resulting solution limits the extent of solubility, for all practical purposes. Aqueous solution of PVP shows that the viscosity is not affected by electrolytes. In solution, PVP probably exists as a random coil. Depending on the

molecular weight, the coil dimensions in an aqueous solution of sodium chloride have an average end-to-end distance of between 10 and 1000 Å. The size of the coil is important for applications in the medical field, in particular for the ability of the human body to excrete the polymer.<sup>[22]</sup> PVP cannot be processed in the melt because of its low decomposition temperature, and the extremely poor flow properties of the melt. Films coated from solution are very brittle, clear, and glassy. The glass transition temperature ( $T_g$ ) increases with molecular weight and reaches a plateau at about 175°C, which corresponds to a molecular weight of about 1 million. At low molecular weight  $T_g$  falls to values below 100°C. The addition of small amounts of water also leads to lower  $T_g$  values.<sup>[23]</sup>

The heat of PVP solution is  $-4.81$  kJ/mol ( $-1.15$  kcal/mol); aqueous solutions are slightly acidic, pH 4–5. Under ordinary conditions PVP is stable as a solid as well as in solution. It is also relatively inert to chemical modification. Exposure of PVP solution to light in the presence of oxidizing agents or diazo compounds can cause gelation. When aqueous solutions of PVP are heated with strong bases such as lithium carbonate, trisodium phosphate, or sodium metasilicate, a precipitate results from the opening of the pyrrolidone ring and the subsequent reaction across different chains. This precipitation mostly occurs at elevated temperatures. PVP is non-antigenic, biologically compatible, has low toxicity, film forming, and adhesive characteristics, unusual complexing ability, relatively inert behavior toward salts, and is resistant to thermal degradation in solution.

### Uses of Polyvinylpyrrolidone Homopolymer

PVP has come into prominence as a biomedical polymer, because of its primary use as a blood plasma extender or substitute, and because of its low toxicity.<sup>[24]</sup> Presently, it is no longer used as a blood plasma extender, but has found extensive application in diverse areas of pharmaceuticals, biomedical sciences, biotechnology, food and beverage, cosmetic and toiletry, as well as the photographic industries.<sup>[25–27]</sup> The major use of PVP in quantitative terms has been in the manufacture of tablets. It has been widely used medically in the manufacture of tablets and for both diagnostic and therapeutic purposes since the early 1940s. Under U.S. law PVP has a number of permitted uses in foodstuff, including use as a binder for vitamin and mineral concentrate tablets, as well as a binder for synthetic sweetener tablets. It is also used as a diluent and dispersant for food colors. PVP is permitted as a coating for fresh citrus fruit and as a component in the packaging materials, which are in contact with aqueous, fatty, and dry foods.

PVP-iodine aqueous solution, Povidone-iodine, is a form of iodine commonly used for skin cleansing, as a prophylaxis or treatment for wound infection. Present literature focuses on the importance of using such “traditional” methods of combating and preventing wound infection,<sup>[28]</sup> and as a disinfectant for cold sterilization of oral cavity prior to surgery.<sup>[29,30]</sup> PVP finds use as a protectant for the cryopreservation of microorganisms and has been used widely with satisfactory results.<sup>[31]</sup> It is also added to the protective solution used for lyophilization of human red blood cells.<sup>[32]</sup> An optimum concentration of 40% PVP in DMSO renders optimum protection to RBC. The film-forming, membrane-forming, and adhesive properties of PVP have been used to improve the adhesion properties of available water-soluble pressure-sensitive adhesives.<sup>[33–35]</sup>

Many undesirable effects of protein adsorption at solid–liquid interfaces are encountered in variable situations. Surface-induced thrombosis due to adsorption of plasma proteins, fouling of membranes used in food and beverage processing, or performance degradation in analytical protein liquid chromatography, are some of such instances. Although various factors affect protein adsorption, the surface chemistry of the substrate has been studied most intensively with the goal of affecting protein adsorption via a variety of surface modification techniques. Polymer coatings designed to reduce protein adsorption have been used to modify a variety of polymeric substrates such as polycarbonate, polysulfone, polypropylene, low-density polyethylene, polystyrene latex, as well as glass and ceramic surfaces. The nonionic polymer, PVP, has proven effective in reducing adsorption of many proteins such as lactoglobulin and bovine serum albumin onto polysulfone surfaces.<sup>[36]</sup> It has been suggested that the degree of reduction in protein adsorption is determined largely by the effect of protein exclusion from the native surface due to the polymer surface chains that provide a steric barrier.<sup>[37]</sup> PVP has also been considered for modifying ceramic surfaces to reduce fouling of ceramic membranes during protein ultrafiltration, and for producing ceramic biocompatible surfaces for biomedical applications. The potential effectiveness of PVP as a zirconia surface modifier was investigated using lysozyme. The study demonstrated that a PVP brush layer is capable of reducing lysozyme adsorption up to about 76%.<sup>[38]</sup>

### ULTRAFINE POLY(N-VINYL PYRROLIDONE) NANOPARTICLES

In order to encapsulate water-soluble drugs, it is necessary to have nanoparticles with complete hydrogel behavior. That is, both the outer shell and the inner core should be hydrophilic. Preparation of nanoparticles by

chemical polymerization or cross-linking reactions within emulsion droplets invariably produces particles with high polydispersity.<sup>[39]</sup> This problem can be overcome by carrying out polymerization reaction in reverse micelles.<sup>[40]</sup> As the size of the reverse micellar droplets is in the order of a couple of tens of nanometers in diameter, and these droplets are highly monodispersed, preparations of drug-loaded nanoparticles of diameter smaller than 100 nm in the reverse micellar droplets would be possible. These particles are expected to be fairly monodispersed. Controlling the size of the aqueous core of the reverse micellar droplets could also control the size of the nanoparticles. The water-in-oil reverse microemulsions contain pools of water enclosed in surfactant reverse micelles, surrounded by oil molecules. Each of these water droplets may be used as miniature nanoreactor to produce hydrogel nanoparticles. Chemical thermodynamics governing the reverse micellar system drives the monomer molecules added to the solution right into the water droplets. The polymerization reaction occurs inside the water droplets, triggered by the addition of an appropriate initiator substance into the micellar droplets. The microscopic polymerization process inside the tiny water droplet is similar to macroscopic polymerization. It is during this polymerization process that the polymer material takes up the hydrophilic drug molecules that are intended to be encapsulated within the nanoparticles, and the nanoparticles formed assume the spherical shape of the water droplet. The size of the resulting nanoparticles is restricted by the diameter of the water droplet, and the size of the droplet in turn depends on various parameters of the reverse micellar systems.

Most previous attempts to develop hydrophilic nanoparticles through the reverse micellar route led to an uncontrolled size distribution of the nanoparticles. By the polymerization of acrylamide and *N,N'*-methylene bisacrylamide (MBA), Birrenbach and Speiser<sup>[16]</sup> succeeded in preparing nanospheres containing several tracers or active substances, such as iodine-labeled human IgG, tetanus toxoid, and urease. The method used to prepare polyacrylamide nanospheres is a polymerization in a reverse micelles. This method requires 1) large amounts of organic solvents, e.g., hexane, toluene, or chloroform, as the external phase; 2) anionic surfactants such as sodium bis(2-ethyl hexyl) sulfosuccinate, i.e., AOT, to produce the reverse micelles; and finally, 3) an induction of the polymerization by either a physical or chemical initiator. Kopf et al.<sup>[41]</sup> succeeded in entrapping 96% of norephedrine HCl in these nanospheres. But Couvreur et al.<sup>[42]</sup> and later Labhatssewar and Dorle<sup>[43]</sup> had poor results with fluorescein, metronidazole, and primaquine. High amounts of active substances have always been included in the polymerization medium rather than adsorbed afterwards. In the previously

used preparative method, purification was always necessary to eliminate the solvents, the surfactants, and if used, the chemical initiator. Based on these initial investigations, several research groups improved and modified the original processes.<sup>[44]</sup> This included reduction in the amount of solvent and polymerization initiator in the polymerization methods. But due to several lacunae in the preparation protocols, none of these methodologies could be successfully used. Eventually, they were abandoned, and scientists reverted to nanoparticle preparation in emulsion medium.

In the earlier methods of nanoparticle preparation involving reverse micelles for pharmaceutical applications,<sup>[41–43]</sup> the most important point, i.e., the control of particle size, was always overlooked. As a matter of fact, the condition of an exact micellar phase with discrete droplets dispersed in a hydrocarbon medium was not maintained, and in most cases the polymerization took place in a separate aqueous phase in which uncontrolled particle size resulted. Other limitations of the previous reverse micelle-mediated process for preparation of drug-loaded nanoparticles were the failure of complete elimination of toxic materials, such as organic solvents, surfactants, and if used, chemical initiators, from the final product. Fine-tuning of these various aspects was necessary so as to obtain a preparative procedure that would take into account the particle size as well as the toxicity of the end product.

### Preparation of Cross-Linked Polyvinylpyrrolidone Nanoparticles

The preparation of PVP nanoparticles was optimized in our laboratory, following the original method previously developed<sup>[16]</sup> by Maitra et al. in 1997.<sup>[17]</sup> AOT was selected for the formation of reverse micelles because this surfactant aggregates in oil without the help of any cosurfactant, and the reverse micellar solution can dissolve a considerable amount of water and other hydrophilic materials. Moreover, unlike other surfactants, the removal of AOT from the aqueous system through its precipitation as calcium salt is easy, quantitative, and rapid. The reverse micelles were prepared in *n*-hexane as it is easily removable by evaporation, and for this purpose a typical system was prepared by dissolving AOT in *n*-hexane (usually 0.03 to 0.1 M of AOT solution). Because the reverse micellar droplets are highly monodispersed and the droplet size can be varied, the nanoparticles prepared using reverse micelles medium are nearly monodispersed with narrow size distribution dispersions. Moreover, controlling the size of the reverse micellar droplets can modulate their size. A typical protocol for the preparation of PVP nanoparticles is as follows.

Fig. 2 Flowchart of PVP nanoparticles.

Forty milliliters of 0.03 M AOT solution in hexane was taken and to it 280  $\mu$ L of freshly distilled NVP, 100  $\mu$ L of MBA (0.049 g/mL), 20  $\mu$ L of *N,N,N,N'*-Tetramethylethylenediamine (TEMED), and aqueous solutions of 20  $\mu$ L of ammonium persulphate (20% w/v) and 50  $\mu$ L of an active compound, such as fluorescein isothiocyanate-dextran ( $M_w = 10$  kDa) (FITC-dextran) (3.2% w/v), were added. The solution was homogeneous and optically transparent. For the entrapment of a protein solution or hydrophilic drug, FITC-dextran was replaced with 50  $\mu$ L of the required substance used. Polymerization was carried out at

37°C for 8 hr in a thermostated water bath with continuous stirring. After the completion of the reaction, the excess solvent (hexane) was evaporated off in a rotary evaporator and the dry mass was resuspended in 10 mL of water by sonication. Then 1-mL aliquots of 30% w/v calcium chloride solution were added drop by drop with continuous stirring to precipitate the AOT (surfactant) as calcium salt of di-ethyl-hexylsulfosuccinate, Ca (DEHSS)<sub>2</sub>. It was then dialysed for 2 hr. Ca (DEHSS)<sub>2</sub> was separated by centrifugation at 10,000 rpm for 10 min. The centrifuged aqueous solution contained the dye/drug-loaded

Fig. 3 Relationship of some physico-chemical parameters of polymerization, on the yield (%) of cross-linked PVP nanoparticles.

PVP nanoparticles that were homogeneous and transparent. The precipitate of Ca (DEHSS)<sub>2</sub> after centrifugation contained some dye/drug-loaded PVP nanoparticles absorbed on it. The precipitated pellet was dissolved in 15 mL of hexane and the hexane solution was washed three times with 1 mL of water. The phase-separated aqueous layer was drained out and added to the previously centrifuged supernatant solution containing the PVP nanoparticles. The total aqueous dispersion of nanoparticles was lyophilized immediately to dry powder. Lyophilized nanoparticles were easily redispersible in aqueous buffer. The flow diagram for the preparation of the nanoparticles through reverse micelles is shown in Fig. 2.

### Properties of Cross-Linked Poly(*N*-Vinylpyrrolidone) Nanoparticles

PVP nanoparticles prepared in reverse micellar droplets have a particle diameter < 100 nm with a narrow size distribution. When dispersed in aqueous buffer these particles appear to be transparent and give an optically clear solution. Lyophilized powder of these nanoparticles is redispersible in aqueous buffer, without any change in size and morphology of the particles. The yield of the nanoparticles was found to be dependent on certain physicochemical parameters, such as monomer concentration, initiator concentration, and temperature of polymerization (Fig. 3). The optimum monomer concentration is 280 mg/mL, beyond which no further increase in yield is obtained. The optimum quantity of polymer is produced at a monomer concentration of 20 mg/mL and reaction temperature of 37°C. From gel permeation chromatography data, the approximate molecular weight of the polymeric nanoparticles was found to be about 3500 kDa. The entrapment efficiency of FITC-dextran by these nanoparticles is high (> 70%), and this also depends on the amount of cross-linking agent present in the polymeric material. The release of the entrapped molecules from these nanoparticles depends on the degree of polymer cross-linking, particle size, pH of the medium, extent of loading, as well as the temperature of the aqueous phase. Extensive study and detailed characterization of the cross-linked nanoparticles was reported by Bharali et al.<sup>[45]</sup>

Characterization was done on the basis of the data obtained from FT-IR, <sup>1</sup>H NMR, dynamic light scattering (DLS) measurements of particle size, and transmission electron microscopic (TEM) pictures, to establish particle morphology. As the cross-linked PVP nanoparticles were prepared by the vinyl polymerization of the monomer, vinylpyrrolidone, in the presence of cross-linking agent methylene bisacrylamide (MBA), using the initiator ammonium

persulphate (APS), the spectra of the starting material as well as the polymer were obtained for comparative assessment. According to the FT-IR spectra (Fig. 4), the strong peak at 850 cm<sup>-1</sup> corresponding to the =CH<sub>2</sub> wagging of the vinyl double bond, and the peaks at 1630 and 1426 cm<sup>-1</sup> for -C=C- and vinyl scissoring vibration present in the monomer are absent in the spectrum corresponding to the polymer spectrum. This confirms the formation of the polymer. The C-H stretching vibration of the polymer backbone is manifested through a strong peak at 2928 cm<sup>-1</sup> corresponding to >C=O stretching from pyrrolidone units. From the <sup>1</sup>H NMR (Fig. 5) analysis polymerization is

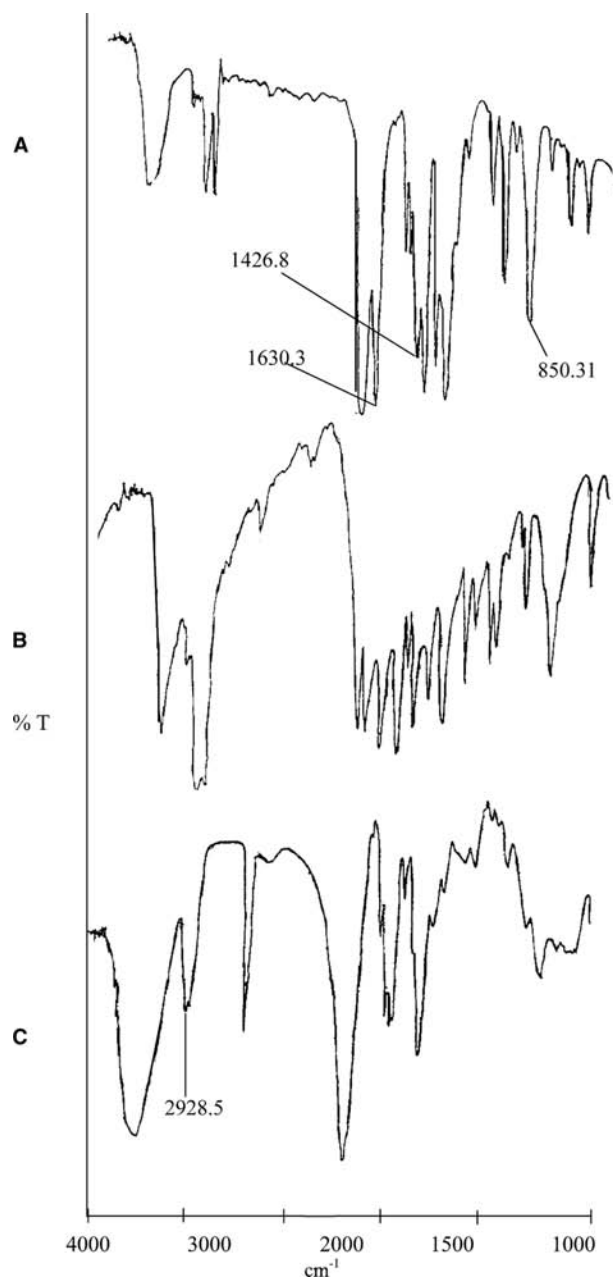

Fig. 4 FT-IR spectra of cross-linked PVP. Source: From Ref.<sup>[45]</sup>.

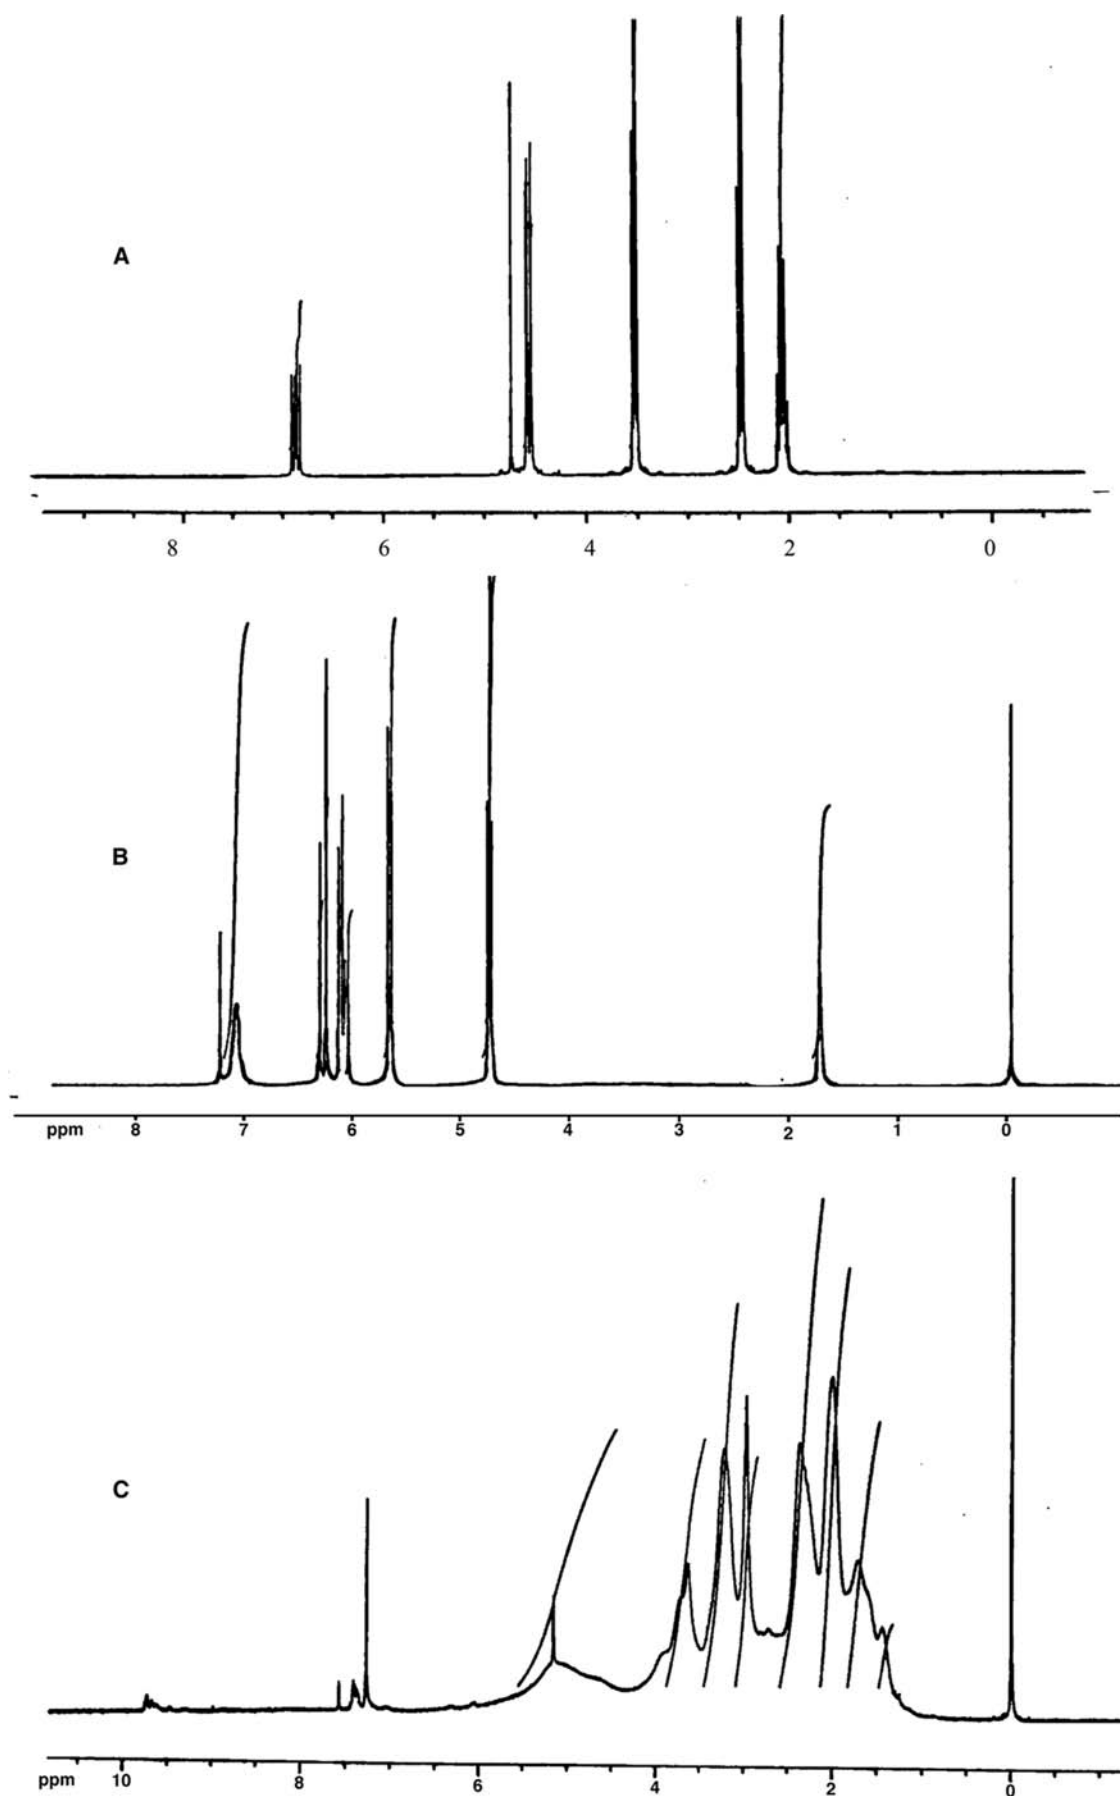

Fig. 5 NMR spectra of cross-linked PVP. Source: From Ref.<sup>[45]</sup>.

**Fig. 6** Size distribution spectra of 0.6% cross-linked PVP nanoparticles.

indicated by the absence of a double doublet for two protons at  $\delta = 4.4$  for  $\text{CH}=\text{CH}_2$  in *N*-vinylpyrrolidone, due to coupling with the neighboring proton. The absence of downfield protons in the starting compound MBA in the range  $\delta = 6.3$ – $5.7$  for unsaturation confirms cross-linking during polymerization.

The PVP nanoparticles loaded with a marker molecule, FITC-dextran, having 0.6% w/w cross-linking prepared in AOT reverse micelles of  $w_o = 15$  were found, as measured by DLS, to be around 50 nm (Fig. 6). The same particles exhibit a diameter of about

**Fig. 7** (A) TEM picture of PVP nanoparticles (cross-linking agent 0.6%). (B) TEM picture of PVP nanoparticles (cross-linking agent 1.2%).

30–35 nm in the TEM picture (Fig. 7A), while a 1.2% w/w of MBA in the polymer composition results in an increase in particle size from 35 to 80 nm (Fig. 7B). The possible difference in particle size observed for 0.6% cross-linked particles by DLS and TEM measurements could be due to the hydration and swelling of the particles in aqueous buffer. The cross-linking ratio is one of the most important factors that affect the swelling of hydrogels. It is defined as the ratio of moles of cross-linking agent to the moles of polymer repeating units. In the case of bulk gels, highly cross-linked hydrogels have a tighter structure and swell less compared to the same hydrogels with lower cross-linking ratios. Cross-linking hinders the mobility of the polymer chain, hence lowering the swelling ratio.<sup>[46]</sup> But, contrary to the observations in the bulk phase, the increase in particle size on increasing the cross-linking agent can be explained on the basis of higher interlinking of the primary polymeric particles, during interdroplet interaction in the reverse micellar phase. A detailed analysis of particle growth in reverse microemulsion may be found in the previous publications of Bharali et al.<sup>[45]</sup> and Munshi, De, and Maitra<sup>[47]</sup>

### In Vivo Applications of PVP Nanoparticles

Biodistribution of the PVP nanoparticles prepared by the optimized method<sup>[17]</sup> was studied in Balb/c mice using the hydrophilic fluorescent dye, FITC-dextran. These particles show practically negligible (< 1%) uptake by the macrophages in liver and spleen (Fig. 8), and 5–10% of these particles remain in circulation even 8 hr after intravenous injection.<sup>[48]</sup> Due to the longer residence time in blood, these PVP nanoparticles have potential therapeutic applications, particularly in cancer. The water-soluble cytotoxic agents encapsulated in these particles can be targeted to tumors while minimizing the likelihood of toxicity to the RES. PVP nanoparticles containing taxol, prepared by reverse

**Fig. 8** Blood clearance of cross-linked PVP nanoparticles, surface modified with hydrophobic groups.

microemulsion method, with particle size ranging between 50 and 60 nm, show antitumor effect in B16F10 murine melanoma transplanted in C57B1/6 mice. The *in vivo* efficacy of Taxol-containing nanoparticles, as measured by reduction in tumor volume and increased survival time, is significantly greater than an equivalent concentration of free Taxol.<sup>[49]</sup> PVP nanoparticles provide a promising delivery system for proteins, as they are biocompatible, conserve the integrity and biological activity of proteins, augment antibody response, and provide a sustained antibody level with single-step immunization. The formulation may also be useful for hyposensitization therapy for various allergens.<sup>[50]</sup> Targeted delivery of PVP nanoparticles encapsulating FITC-dextran was established in human hepatoblastoma cells (HepG2). Cytosolic delivery of nanoparticles was achieved by encapsulation in F-virosomes, which are capable of membrane-mediated delivery of nanoparticles to the cell cytoplasm.<sup>[51]</sup> The hybrid vector has the potential to deliver hydrophilic drugs to liver cells *in vivo*. Plasmid DNA encapsulated in PVP nanoparticles was also used successfully for *in vitro* transfection of MCF-7 cell line. Significant *in vivo* tissue expression of pSV  $\beta$ gal, delivered in PVP nanoparticles as vectors, was observed in the lung and liver tissue of Swiss albino mice.<sup>[52]</sup>

Using the reverse micellar system, pH- and temperature-sensitive hydrogel nanoparticles of copolymers of vinylpyrrolidone and acrylic acid, cross-linked with *N,N'*-methylenebisacrylamide, were prepared, with size ranging between 35 and 60 nm. Particle size increases with increasing molar ratio of acrylic acid (AA), due to the self-adhesive behavior of AA.<sup>[53]</sup> The release of FITC-dextran from these nanoparticles was highly pH- and temperature dependent. Release rate was increased with increase in temperature and pH, and decreased at acidic pH. Such copolymeric nanoparticles can be used as ideal carriers for oral delivery of hydrophilic drugs,<sup>[54]</sup> as AA provides muco-adhesivity, while the presence of a hydrophobic entity provides surface hydrophobicity for recognition and uptake by the Peyer's patches in the GI tract. Oral delivery of insulin using such copolymeric nanoparticles gradually reduces blood glucose level in alloxan/streptozotocin-induced diabetic rats.<sup>[55]</sup>

## CONCLUSION

Nanoparticles of polyvinylpyrrolidone cross-linked with methylene bis-acrylamide can be used for entrapping vaccines, peptide drugs, other hydrophilic drugs, and DNA. The ultralow size of these nanoparticles prepared in the aqueous core of reverse micelles, and their hydrogel nature which renders them inconspicuous to the RES, makes them ideal candidates for

*in vivo* drug delivery. The longer residence time of these nanoparticles in the blood circulation makes it possible to use them for several therapeutic purposes, particularly for drug delivery to solid tumors. Attachment of specific ligands can provide tissue- or cell-targeting ability to these nanoparticles. Further investigations in this front may yield many exciting possibilities related to drug and gene delivery in the future, using PVP nanoparticles as carriers.

## ACKNOWLEDGMENTS

Several scientists from this laboratory, such as U. Gaur, T.K. De, S.K. Sahoo, and N. Munshi, whom the authors gratefully acknowledge, have contributed in the works embodied in this article. Financial assistance from the Departments of Science and Technology and Biotechnology, Government of India, is also thankfully acknowledged.

# Ice Nanotubes inside Carbon Nanotubes

Kenichiro Koga

Hideki Tanaka

Department of Chemistry, Okayama University, Okayama, Japan

## INTRODUCTION

The carbon nanotube provides a well-defined quasi one-dimensional (1-D) space where one can prepare a quasi 1-D material and explore its new properties that have not been found for the corresponding bulk material. Water is one of the substances that may actually be confined to the carbon nanotube, but its properties in the quasi 1-D space had been as little studied as, or even less studied than, those of other quasi 1-D materials despite the fact that water itself has been more studied than any other substance. However, recent theoretical studies and the following experimental studies of water confined in the carbon nanotube showed that the confined water freezes into crystalline structures that were never found in the bulk water and exhibits the phase behavior of melting and freezing that no bulk system has ever shown.<sup>[1–3]</sup> This entry is a review of these theoretical studies of the confined water. There are other theoretical or experimental studies on water in the carbon nanotube, focusing on the dynamic properties of water,<sup>[4]</sup> and more studies of confined water in general.<sup>[5]</sup>

Computer simulation studies<sup>[1]</sup> show that the structure of solid water in the zigzag ( $\ell$ , 0), single-walled, carbon nanotube (SWCN) (with  $\ell = 13, 14, \dots$ , or 17) is quite different from the bulk ice structure; it is a 1-D array of  $n$ -gonal “rings” consisting of  $n$  molecules. As in ordinary ice—in fact, as in any one of the 12 bulk ice polymorphs excluding ice X—every H<sub>2</sub>O molecule in the solid water in the carbon nanotube is hydrogen bonded to its four neighboring molecules. Because it has a hollow-tube structure and its width is of the order of 1 nm ( $=10^{-9}$  m), this quasi 1-D ice is called the ice nanotube. Simulations show that liquid water confined in carbon nanotubes freezes into a square, pentagonal, hexagonal, and heptagonal form of the ice nanotube, each corresponding to  $n = 4, 5, 6$ , and 7, respectively. Which structure is selected on freezing is dependent on the diameter of the carbon nanotube and the external conditions such as pressure and temperature. It is also found from the simulations and free-energy calculations that the phase behavior of confined water is qualitatively different from the bulk counterpart. Melting and freezing in

any bulk system occur as an infinitely sharp change of the state of matter, i.e., as the first-order phase transition; however, freezing into and melting from the ice nanotube are either continuous with no well-defined melting point or discontinuous as in any bulk system.

In 2002, it was reported<sup>[3]</sup> that the structure of water inside the carbon nanotube at low temperatures determined by X-ray diffraction is consistent with that of the ice nanotube found in the computer simulation.

## STRUCTURE OF ICE NANOTUBE

In any known crystalline ice every water molecule is hydrogen bonded to its four neighboring molecules. This is because with this condition the potential energy of the system would be significantly lower than otherwise. Thus, all the 12 different forms of bulk ice have a perfect hydrogen bond network structure. If this condition were possible in a quasi 1-D space, water would freeze into a quasi 1-D ice with a perfect hydrogen bond network. The ice nanotube is one type of such a quasi 1-D ice. It refers to a set of crystalline ice forms that extend in only one direction with a constant diameter of the order of 1 nm. The structure of the ice nanotube, which will be described in the following, was speculated and was analyzed by the classical and quantum calculations of the potential energy in vacuum at 0 K<sup>[6]</sup> before the actual demonstration by the computer simulation that liquid water freezes into the ice nanotube in the carbon nanotube.<sup>[1]</sup>

The ice nanotube is a 1-D array of  $n$ -gonal rings of water molecules. Imagine a strip of the 2-D square lattice with some finite width and infinite height (Fig. 1A). There is a water molecule at each intersection of the vertical and horizontal lines. In this way, every molecule, except those along the two edges of the strip, is connected to its four neighbors by hydrogen bonds as denoted by the solid line segments in the figure. Now if one rolls up the strip and joins the two long edges such that each molecule along one edge forms the fourth bond with a molecule along the other edge at the same height, then one would obtain a hollow-tube structure of water with a perfect hydrogen bond network (Fig. 1B), which is the basic structure of the

**Fig. 1** (A) Square lattice with finite width and infinite height; (B) The basic structure of a perfect hydrogen bond network in the ice nanotube.

ice nanotube. This is analogous to the SWCN, which may also be viewed as a rolled graphite sheet. The difference between this ice and the carbon nanotube is that, when unrolled, the carbon nanotube has a honeycomb lattice structure, whereas the ice nanotube has a square lattice structure. Also, while the carbon nanotube may take many different forms each being specified by the index  $(\ell, m)$ , the ice nanotube seems to have only a small number of different forms; only four forms, square ( $n = 4$ ), pentagonal ( $n = 5$ ), hexagonal ( $n = 6$ ), and heptagonal ( $n = 7$ ) ice nanotubes, were found in the computer simulation,<sup>[1]</sup> and even less structures were found in the experiment.<sup>[3]</sup> The diameter of the narrowest square ice nanotube is about 4 Å and that of the widest heptagonal ice nanotube is about 6 Å.

As in the ordinary ice, each oxygen atom is surrounded by four others, and between the central O and each one of its four neighboring O's is a hydrogen atom. These four H's are not at the midpoints between two O's, but two are closer to the central O (forming H<sub>2</sub>O with the central O) and two are closer to the neighboring O's. These conditions, which are referred to as the ice rule, are satisfied in most of the bulk ice forms. In the ordinary crystalline form of ice, i.e., ice Ih, every configuration satisfying the ice rule has nearly the same potential energy. The number of such configurations is  $(3/2)^N$ , with  $N$  being the number of water molecules as obtained by Pauling, so that the residual

entropy  $S$  per mole because of the degeneracy is, with  $R$  the gas constant,  $S = R \ln(3/2) = 0.81 \text{ cal}/(\text{mol K})$ , in essential agreement with experiment.

In the ice nanotube, however, not all the configurations satisfying the ice rule correspond to the ground state; only some of them would have nearly a same lowest potential energy and contribute to the residual entropy. This is because four neighboring molecules of any given molecule are lying in the directions significantly different from the ideal tetrahedral directions as in ice Ih (Fig. 2). Two neighbors are those in the same  $n$ -gonal ring, and thus the two directions from

**Fig. 2** Configuration of an O atom and its four neighboring O atoms in the ordinary ice (ice Ih) and in the ice nanotube.

the central molecule to such two neighbors form an angle  $\pi(1 - \frac{2}{n})$ ; Two other neighbors are those in the two adjacent rings, and thus the two directions to such neighbors are both along an edge of the  $n$ -gonal prism and just opposite, forming an angle  $\pi$ . In ice Ih, two OH “arms” in a H<sub>2</sub>O molecule may be in any two directions, and thus each molecule has six possible orientations. But in the ice nanotube, two OH arms of one molecule would never form hydrogen bonds with two neighbors in the two opposite directions along the edge of the  $n$ -gonal prism because the angle  $\pi$  is too large. With this constraint, if the two OH arms formed hydrogen bonds with two neighbors in the same ring, then the formation of a closed loop of the hydrogen bonds along that ring would be impossible. Therefore, one OH arm of a molecule must form a hydrogen bond with one neighbor in the same ring and the other OH arm of the molecule must form a hydrogen bond with one neighbor at the same edge of the prism. This is a condition that every molecule in the ice nanotube must satisfy in addition to the ice rule. It follows from this condition that the OH arms along each ring line up either clockwise or counterclockwise and that the OH arms along each edge of the  $n$ -gonal prism are either all up or all down. That is, there are only two ways of arranging a set of all the OH arms along each ring or along each edge. Because the number of such rings is  $N/n$  and the number of such edges is  $n$ , the total number of possible configurations of OH arms, or H atoms, in the  $n$ -gonal ice nanotube of  $N$  molecules would be  $2^{n+(N/n)}$ .

However, the numerical calculation shows that configurations of an  $n$ -gonal ice nanotube would have significantly lower potential energies if they have the smallest number of two neighboring edges both with the same direction of the OH arms (up or down); the smallest number is 0 if  $n$  is even and 1 if  $n$  is odd. This is a special condition on the configuration of H atoms in the ice nanotube. The possible number of configurations would then be  $2^{(N/n)}$  for the  $n$ -gonal ice nanotube. The numerical calculation shows that the potential energy is nearly the same for these configurations. With  $R = N_A k$ , where  $N_A$  is Avogadro's number and  $k$  is Boltzmann's constant, the degeneracy  $W$  per mole is then  $2^{(N_A/n)}$  and the residual entropy  $S$  per mole is  $S = k \ln W = (R/n) \ln 2$ ; thus for  $n = 4, 5, 6,$  and  $7$ , we have  $S = 0.70, 0.56, 0.47,$  and  $0.40$  cal/(mol K), respectively, which is smaller than that of ice Ih.

## FREEZING AND MELTING BEHAVIOR

### Necessary Conditions

The computer simulation and the free-energy calculation<sup>[1]</sup> show that the following three conditions are

essential for the formation of the ice nanotube. First, water may freeze into the ice nanotube only when it is confined to a cylindrical pore; the spontaneous formation of the ice nanotube without confinement has never been observed in experiment or in computer simulation. Second, the diameter of the cylindrical pore must be in a range between 10 and 15 Å. The  $n$ -gonal ice nanotube with large  $n$ , say 10 or 20, would fit a pore with larger diameter, but then all the hydrogen bond angles would be so different from the ideal angle that such a structure becomes energetically less favorable than other possible crystalline or amorphous forms. Third, the surface of cylindrical pore should be hydrophobic in the sense that water molecules do not form hydrogen bonds to the surface atoms. This is because the closed hydrogen bond network of water molecules, i.e., the structure of ice nanotube, would be impossible if water molecules interact with the surface more strongly than with each other. The inner space of the carbon nanotube with an appropriate diameter may satisfy all the conditions described above and thus serve truly an ideal environment for the formation of the ice nanotube.

### Freezing into the Ice Nanotube

The structure of the ice nanotube was noted as a possible form that the hydrogen bond network may extend only in one dimension with perfect connectivity, i.e., with every water molecule being hydrogen bonded to each of its four neighbors, and the stability of various forms of the ice nanotube at 0 K in vacuum was studied.<sup>[6]</sup> However, whether liquid water may really freeze into that structure in the carbon nanotube had remained to be seen until the molecular dynamics simulations<sup>[1]</sup> demonstrated the spontaneous freezing of water into the ice nanotube at various conditions.

The potential functions and their parameters were chosen to simulate water molecules confined in the zigzag  $(\ell, 0)$  SWCN. The diameter  $D$  of this form of the carbon nanotube is given by  $D = \sqrt{3}a/\sin(\pi/\ell)$  with  $a = 1.423$  Å is the distance between two neighboring carbon atoms. Freezing and melting behavior of water was examined for the systems of the (13, 0), (14, 0), (15, 0), (16, 0), (17, 0), and (18, 0) carbon nanotubes with  $D = 10.3, 11.1, 11.9, 12.6, 13.4,$  and  $14.2$  Å. Equilibrium properties of each system at a given temperature  $T$  and a given pressure  $P_z$  in the direction parallel to the axis of the carbon nanotube was achieved by the constant  $NP_zT$  ensemble molecular dynamics simulation. For each system, a series of such simulation was performed along the isobaric path or along the isothermal path. Details of the simulation methods are given elsewhere.<sup>[1]</sup>

At high enough  $T$  (e.g., 350 K or 80°C) and low or moderate  $P_z$  (e.g., around or below 50 MPa), water confined in any of these carbon nanotubes is in a liquid state; it has no long-range order in its structure and has high diffusivity. The potential energy of the system because of the intermolecular interactions between water molecules at such  $T$  and  $P_z$  is much higher than that of the bulk water at the corresponding condition. This indicates that the hydrogen bonds in the liquid water are on average not strengthened but weakened by the hydrophobic inner surface of the carbon nanotube, as opposed to the hydrophobic effect on the structure of water around a hydrophobic solute molecule.

However, such a disordered structure of water at high  $T$  turns into an ordered structure at sufficiently low  $T$  in the (13, 0), (14, 0), (15, 0), (16, 0), and (17, 0)

carbon nanotube (Fig. 3). The resulting ordered structure is identical or almost identical to the anticipated structure of the ice nanotube; the only difference, if any, is that some defects may exist in the otherwise ordered structure, and such defects may in turn cause a twisted structure (Fig. 3B). It is unclear as yet whether an ordered structure with a few defects is already in equilibrium at finite  $T$  or would be ultimately replaced by a perfect defect-free structure. In any case, water molecules in the ordered phase have extremely small or nearly zero diffusivity, which is also indicative of a solid state.

The diameter of the carbon nanotube plays a crucial role in selecting a crystalline form of the ice nanotube. When  $P_z$  is fixed at 50 MPa and  $T$  is decreased stepwise, liquid water freezes into the square ice nanotube ( $n = 4$ ) in the (13, 0) and (14, 0) carbon nanotube, whereas

**Fig. 3** (A) Square, (B) pentagonal, (C) hexagonal, (D) heptagonal ice nanotubes at 240 K (except  $d$  at 230 K) at 50 MPa in the (14, 0), (15, 0), (16, 0), (17, 0) carbon nanotubes, and (E)–(H) the corresponding liquid phases at 320 K (except  $h$  at 300 K) at 50 MPa. Shown here for clarity are the structures at the local minima of the potential-energy surface; any instantaneous displacement from these structures because of the thermal vibrations is absent.

it freezes into the pentagonal, hexagonal, and heptagonal ice nanotubes ( $n = 5, 6,$  and  $7$ ) in the  $(15, 0)$ ,  $(16, 0)$ , and  $(17, 0)$  carbon nanotubes, respectively.

In the  $(18, 0)$  carbon nanotube, however, crystallization was not observed, at least within the timescale of simulation. As remarked earlier, the structure of the ice nanotube becomes increasingly unstable as  $n$  goes up from 6. Thus, there must be an upper limit for  $n$  for the possible forms of the ice nanotube. Then there must also be a corresponding upper limit for the index  $\ell$  or the diameter  $D$  of the carbon nanotube in which water may freeze into the ice nanotube. The results of the simulation suggest  $n = 7$  (i.e., the heptagonal ice nanotube) to be the upper limit, although it does not exclude the possibility of  $n = 8$  (i.e., the octagonal ice nanotube). However, formation of the ice nanotube with  $n > 8$  from pure water confined to a wider carbon nanotube seems unlikely.

In any ordered structure found at low  $T$  in the simulation, the orientation of water molecules indeed satisfies the special condition described in the previous section, as seen in Fig. 3; that is, the configuration of H atoms lying along the  $n$  edges parallel to the axis of the  $n$ -gonal prism is uniquely determined, and the only disorder is that in the arrangement of the

clockwise and counterclockwise configurations of H atoms along each  $n$ -gonal ring.

### Sharp and Continuous Freezing

Melting and freezing in general always occur as a discontinuous change of the state of matter, which is called the first-order transition. This is not necessarily true in a 1-D or quasi 1-D system. The simulation of water in the carbon nanotube indicates that both continuous and discontinuous freezing may occur depending on the diameter of the carbon nanotube and on the path followed in the thermodynamic  $P_z$ - $T$  plane.

Fig. 4 shows plots of the potential energy of water confined in the  $(\ell, 0)$  carbon nanotube ( $\ell = 13, \dots, 18$ ) as a function of temperature. When  $\ell = 13, 14,$  and  $15$  at  $P_z = 50$  MPa, the potential energy decreases continuously with decreasing  $T$  while when  $\ell = 16$  and  $17$  at the same pressure it makes an abrupt decrease at a certain point on cooling and exhibits a large hysteresis on heating. The molar volume of water also exhibits discontinuity or continuity just as the potential energy does. The discontinuity or continuity in the macroscopic properties of water is associated with

Fig. 3 (Continued).

Fig. 3 (Continued).

the discontinuous or continuous change from a disordered structure (of liquid water) to an ordered structure (of the ice nanotube) or vice versa. In the (18, 0) carbon nanotube, the potential energy decreases nearly linearly with decreasing  $T$  and the disordered liquidlike structure at high  $T$  remains even at the lowest  $T$ .

Whether freezing occurs continuously or discontinuously depends not only on the index  $\ell$  or the diameter  $D$  of the carbon nanotube but also on the pressure  $P_z$ . Under a very high pressure (500 MPa), water in the (15, 0) carbon nanotube freezes *discontinuously* to the *hexagonal* form of ice nanotube; remember that it freezes *continuously* to the *pentagonal* form at 50 MPa (Fig. 4C). More complex behavior is found in the (14, 0) carbon nanotube (Fig. 4B). On cooling at 50 MPa water freezes *continuously* into the square ice nanotube; at 200 MPa, it freezes *discontinuously* into the pentagonal ice nanotube; and finally at 500 MPa it freezes *continuously* into the pentagonal ice nanotube.

A set of isotherms in the  $P_z$ - $V$  plane allows us to understand such complex phase behavior and can be a basic source to construct a phase diagram. Each isotherm is a plot of the system's volume against  $P_z$  at fixed  $T$ , which is readily obtained from the  $NP_zT$ -constant molecular dynamics simulation. Fig. 5 shows the set of isotherms for the (14, 0) carbon nanotube system. When  $T$  is fixed at 280 K,  $V$  makes a sudden drop at 200 MPa on compressing and a sudden jump at 170 MPa on decompressing; that is, the isotherm shows discontinuity and a hysteresis. The low-density phase (before the sudden drop or after the sudden jump in  $V$  is observed) has a liquidlike disordered structure, whereas the high-density phase (after the sudden drop or before the sudden jump in  $V$  is observed) is basically a pentagonal ice nanotube. The diffusion constants of the low-density phase (at 190 MPa) and the high density phase (at 200 MPa), both during compression at 280 K, are  $1 \times 10^{-6}$  and  $1 \times 10^{-10}$  cm<sup>2</sup>sec<sup>-1</sup>, respectively, which reinforces

Fig. 3 (Continued).

that the low-density phase is liquidlike, whereas the high-density phase is solidlike. When  $T$  is fixed at 300 K, however,  $V$  shows a marked decline between 250 and 330 MPa but with no discontinuity, although the same liquidlike and solidlike phases are found at low and high pressures, respectively. This means the liquid–solid transformation at this temperature is *continuous*. When  $T$  is fixed at 330 K, the isotherm is much less steep, and at 350 K it slopes down even more gently. Thus, the isotherms for the (14, 0) carbon nanotube system are similar to typical isotherms around the critical point of fluids.

For the (15, 0) carbon nanotube system, all the isotherms obtained at  $T = 280, 300, 320$  K show discontinuity, and the low-density phase is always liquidlike at these temperatures whereas the high-density phase is the hexagonal ice nanotube (even at 320 K!).

## PHASE DIAGRAM

A phase diagram of water confined in the carbon nanotube is inferred from the results of the computer simulation and free-energy calculation. Before

presenting the phase diagram, however, we note that it is not obvious whether or not a quasi 1-D system would show any phase transition or phase separation, even if the corresponding bulk system does. This is because when the dimension  $d$  is less than 2, much of the theoretical models in studies of the phase transition no longer exhibit any phase transition at any finite  $T$ . We should also note that the computer simulation itself cannot prove or disprove the existence of the phase transition because it cannot treat a macroscopic number  $N \sim 10^{23}$  of molecules corresponding only to a thermodynamic limit in which the phase transition occurs. Nevertheless, the computer simulation can demonstrate discontinuous changes in microscopic and macroscopic properties of a system with changes in the temperature, pressure, or other thermodynamic field variable, and such discontinuous changes in a finite system do correspond to some abrupt, if not discontinuous, change of the state of the macroscopic system. Thus, in this sense we now use the terms “phase transition” and “phase boundary” for quasi 1-D water.

Fig. 6 shows a schematic phase diagram in the  $T$ – $P_z$  plane for the (14, 0) carbon nanotube system. The phase boundary separates the high- and low-density

**Fig. 4** The potential energy vs. temperature for water confined to the  $(\ell, 0)$  carbon nanotube with  $\ell = 13$ –18 (A–F). The axial pressure is fixed at  $P_z = 50$  MPa ( $\bullet$  and  $\circ$  in A–F), 200 MPa ( $\blacksquare$  and  $\square$  in B), and 500 MPa ( $\blacktriangle$  and  $\triangle$  in B and C). Filled and open symbols indicate the cooling and heating process, respectively. The potential energy is the energy associated with the intermolecular interactions between water molecules.

phases, which are now referred to as pentagonal and square phases for convenience. At low temperatures (e.g., 200 K) both phases are solidlike; at higher temperatures (e.g., 270 K) the high-density phase is still solidlike, whereas the low-density phase is liquidlike. Because the phase change becomes continuous above 280 K, the phase boundary should terminate at some

point around that temperature. The point is referred to as a “critical point” in the same restricted sense as remarked above. This phase diagram explains the complex phase behavior of the  $(14, 0)$  carbon nanotube system (Fig. 4B): the isobaric path at 50 MPa does not cross the phase boundary, and thus the phase change between the liquid and the square ice

**Fig. 5** Isotherms in the  $P_z$ – $V^*$  plane for confined water in the  $(14, 0)$  carbon nanotube at temperatures 280 K ( $\bullet$  and  $\circ$ ), 300 K ( $\blacksquare$ ), 330 K ( $\blacktriangle$ ), and 360 K ( $\blacklozenge$ ).  $V^* = V/(N\pi r^2 \text{ \AA}^2)$ . Filled and open symbols indicate the compressing and decompressing process, respectively.

**Fig. 6** A schematic  $T$ – $P_z$  phase diagram of water confined to the  $(14, 0)$  carbon nanotube. The phase boundary (solid line) divides the low-density (square) and high-density (pentagonal) phases. The phase boundary terminates at a critical point ( $\bullet$ ) around 280 K.

nanotube phase is continuous; the isobaric path at 200 MPa, however, crosses the phase boundary, and thus the change is between the liquidlike square phase and the solid pentagonal phase and it is discontinuous; and finally, the isobaric path at 500 MPa does not cross the boundary because it is above the critical pressure, and thus the change between the square and pentagonal phases is continuous.

For the (15, 0) carbon nanotube system, the phase boundary separates the low- and high-density phases, which may be referred to as pentagonal and hexagonal phases, respectively, because at low temperatures they are the pentagonal and hexagonal ice nanotubes. Unlike in the (14, 0) carbon nanotube system, no continuous path from one phase to another has been found in the  $T$ - $P_z$  plane examined by the simulation. That is, the phase boundary may not terminate at any critical point, just as in any bulk liquid–solid phase equilibrium.

Similarly, for the (16, 0) carbon nanotube system, low-density and high-density phases are separated by a phase boundary that does not terminate at any critical point. The low-density phase is in a liquid state, whereas the high-density phase is a solid hexagonal ice nanotube.

For the (17, 0) carbon nanotube systems—the widest nanotube that allowed formation of the ice nanotube in the simulation—again the two phases, which we now call simply the solid and liquid phases, are separated by a phase boundary with no critical point. The solid phase is identified as the heptagonal ice nanotube. In this system, unlike in other systems, liquid water expands as it freezes into the ice nanotube at 50 MPa. That is, the density of the heptagonal ice nanotube is smaller than that of the liquid at the phase boundary at 50 MPa. At higher  $P_z$  this would hold even more strongly because the density of liquid increases more rapidly than that of the solid with increasing  $P_z$ . Thus, for the (17, 0) carbon nanotube system, the slope of the phase boundary in the  $T$ - $P_z$  plane should always be negative:  $dP_z/dT < 0$ .

As we have seen above in the phase diagrams, the phase behavior of water confined in the different carbon nanotubes is qualitatively different even if the index  $\ell$  of the carbon nanotube differs only by 1. However, if  $\ell$  (or  $D$ ) is taken to be continuous, rather than discrete, and is introduced as another axis in the original phase diagram, the resulting global phase diagram in the 3-D  $TP_z\ell$  (or  $TP_zD$ ) space would account for how these apparently independent phase diagrams at discrete  $\ell$  (or  $D$ ) are related to each other.<sup>[2]</sup> From the thermodynamic relations analogous to the Clapeyron equation and the simulations for several systems with noninteger values of  $\ell$ , e.g., a hypothetical (14.2, 0) carbon nanotube system, we find the following picture of the global phase diagram. First, there are at least five

phase boundaries, which are now surfaces in the  $TP_z\ell$  space and have very steep slopes with respect to the  $\ell$  axis. Two of them, a surface separating the square and pentagonal phases and a surface separating the liquid and square phases, seem to terminate at a “critical line.” The other three are the surfaces separating the pentagonal and liquid (hexagonal) phases, the hexagonal and liquid (heptagonal) phases, and the heptagonal and liquid phases, and they seem not to terminate at any critical line.

## RELATED SIMULATIONS AND EXPERIMENTS

Some computer simulations have been performed to examine the structure of an alkali halide, KI, inside the SWCNs and the mechanism of encapsulation of the molten salt into the hollow space of the carbon nanotubes.<sup>[7]</sup> The results of the simulations suggest that the salt is crystallized rather easily in the carbon nanotubes even at temperatures at which the bulk counterpart is a melt. Coulombic interaction facilitates the formation of the crystalline structures of KI inside the SWCNs. In this sense, the salt in the confined space exhibits a phase behavior similar to that of water; however, water shows the more facile transition because of its characteristic intermolecular interaction, i.e., the hydrogen bond. Those structures of the salt are either fragments of the bulk KI crystal or a twisted one, the latter of which has nothing to do with the bulk crystalline structure. Further investigation is required to discern which structure is the real entity in the SWCNs. Among other interesting topics are the structure and phase behavior of aqueous electrolyte solutions in SWCNs, which are expected to be greatly different from those of pure water in SWCNs. The hydration structure around ions and the ion-pair formation could be influenced by the quasi 1-D confinement, and they may become distinct from the bulk counterparts.<sup>[7]</sup>

Formation of the heptagonal ice nanotube in the SWCN has recently been observed experimentally,<sup>[3]</sup> which reinforces the theoretical prediction by the molecular dynamics and free energy calculations. Also observed in the experiment is that the melting point increases with decreasing the diameter of the carbon nanotube (Y. Maniwa, private communication).

# In-Situ Electron Microscopy

Charles W. Allen

Materials Science Division, Argonne National Laboratory,  
Argonne, Illinois, U.S.A.

## INTRODUCTION

For decades, electron microscopies, transmission electron microscopy especially, have been employed as an important tool in materials research studies in nanoscience and developments in nanotechnology, for their powerful analytical techniques at spatial resolution and also as a kind of microlaboratory in which dynamic studies have been conducted “in situ.” Such in situ or real-time studies have included those involving phase transformations, mechanical deformation and failure, irradiation-related phenomena, and a host of others involving changes in physical, chemical, magnetic, and electrical structure, microstructure, and properties. This entry will present a number of examples from in situ studies to illustrate how such electron microscopy-based studies may contribute, often in unique ways, to the understanding of the behavior of material systems of relevance to modern nanoscience and nanotechnology. We will also review briefly a number of analytical techniques that have been developed over the years and applied to electron microscopies and finally comment on potential impact ongoing developments, particularly the correction of electron optical aberrations, will have on in situ studies.

## OVERVIEW

The initial demonstration of an in situ experiment with photographic record is often ascribed to an English-born photographer, Eadweard Muybridge. In the 1870s and 1880s, in part under the auspices of Leland Stanford, then Governor of California, Muybridge employed a series of photographic cameras triggered sequentially as a horse trotted by. The resulting sequence of photographs clearly demonstrated that the depiction of horses in motion in paintings and in the common belief of the time had been anatomically incorrect; that, rather than the horse’s gait being side to side with one pair of legs at a time, all four legs come

off the ground at once as a horse trots or gallops (For example, see Ref.<sup>[1]</sup>).

An in situ experiment is somewhat like watching an entire football match, rather than trying to imagine what happened by checking the score occasionally. For systems of almost any complexity or with events occurring rapidly as in the trotting horse example, it is not always possible to correctly deduce the evolution of changes simply by observing the end results in relation to the initial and final or sometimes even selected intermediate conditions. Furthermore, a well-designed in situ experiment may be an extremely efficient way to perform a scientific or technological study.

For many years in situ experiments have been performed involving a host of different analytical tools including X-ray diffractometers and synchrotron radiation sources, optical microscopes, and electron microscopes and have involved techniques of observation and measurement in real time or near real time such as microscopies (i.e., imaging of events), diffraction, elemental microanalysis, and changes in various physical properties. This entry focuses mainly on the application of transmission and scanning transmission electron microscopies (TEM and STEM), and to a lesser extent on scanning electron microscopy, for in situ experiments with particular emphasis on applications related to nanoscience and nanotechnology. The topic of related instrumentation such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM) is presented elsewhere in this volume.

In situ techniques are often very powerful in yielding insight into the mechanisms of real-time behavior, such as when two or more phenomena compete in producing changes or when highly localized short-term changes are superimposed on long-term trends. A further situation in which in situ observation is essential is when elevated or cryogenic temperatures, loads, or fields are employed in a materials study, and further changes in the experimental object would occur as a consequence of returning the material to room temperature, zero load, or zero field for subsequent observation and analysis. The same may be said for all types of in situ studies, X-ray, neutron, and electron.

**Table 1** Comparison of selected (approximate) characteristics of state-of-the-art neutron, x-ray, and electron sources employed for materials research

Type of radiation	Source brightness (particles/cm <sup>2</sup> /sr/eV)	Elastic mean-free path (nm)	Absorption length (nm)	Minimum probe size (nm)	Spatial resolution (nm)

SNS, spallation neutron source at Oak Ridge National Laboratory; APS, advanced photon source at Argonne National Laboratory.

In situ electron microscopy studies should be regarded as complementary to similar synchrotron studies and, for very slowly varying phenomena, neutron scattering studies. The latter present a view of time-dependent phenomena, generally averaged over much larger volumes of observation. It is, however, sometimes difficult to convince people who have extensive experience with X-ray or neutron scattering studies of the value-added aspect of complimentary analyses by some form(s) of electron microscopy, including the application of in situ techniques. This complementarity of techniques is emphasized in Table 1 in terms of selected characteristics for each of these types of radiation sources.

The elastic mean free paths for neutrons and X-rays are large compared to that for electrons, which means that elastic scattering, for example, is relatively inefficient in the former requiring very high intensities or long data acquisition times to achieve reasonable spatial resolutions. On the other hand, small absorption lengths for electrons require very thin specimens, but because electrons are readily focused by electromagnetic and electrostatic lenses, very fine, intense probes may be formed which, coupled with the thin specimen, result in excellent spatial resolution. The bottom line is simply that these related techniques can and should be more often understood as complementary rather than competitive.

## EXAMPLES OF IN SITU ELECTRON MICROSCOPY STUDIES

It may be easier to grasp the value of applying in situ techniques in electron microscopy by considering a variety of representative examples. By no means will these form an exhaustive compilation of such studies. The examples presented are brief excerpts from in situ TEM or STEM studies. However, some of these same ideas may be adapted or have been adapted for in situ SEM studies. Furthermore, variable pressure or environmental SEMs offer other altogether unique aspects for in situ experiments.

## Magnetic Studies

The techniques for imaging and analysis of magnetic structures in TEM have been developed over many decades. These include Fresnel, Foucault, electron holographic, and differential phase contrast imaging. The Fresnel technique is an off-focus technique which, for example, images magnetic domain walls as bright or dark lines due to an excess or deficiency of local image brightness. Foucault imaging is a dark field technique (i.e., employing scattered rather than transmitted electrons) in which the objective aperture selects a segment of a split deflected beam, which is due to different local magnetization directions within the imaged area. Electron holography is a field-imaging technique which results from the interaction of bright field specimen waves with a reference wave usually from an adjacent open area of specimen. Differential phase contrast imaging is a STEM technique employing position-sensitive detection.

For an in situ TEM investigation of the effect size of elliptical disk-shaped particles of a Permalloy (Ni + 19 at.% Fe), arrays of such particles 8 nm thick were prepared employing electron beam lithography and a 30-nm Si<sub>3</sub>N<sub>4</sub> support film. Four such particles are shown in Fig. 1, whose aspect ratios (major axis dimension/minor axis dimension) are 2:1 and whose major axes vary from 3.4 to 5.0 μm. This system of particles has been magnetically saturated in the direction indicated by the large arrow and then is subjected to an increasing applied field in the opposite sense (smaller arrows) as the specimen is imaged using the Fresnel technique (also known as Lorentz microscopy), the resulting contrast of which is sensitive to local variations of a particle's magnetic induction and its gradients in the horizontal plane. The interaction of such variations with the incident electrons produces complementary image contrast when the objective lens is under- or overfocused. The series of images in Fig. 1 shows the dependence and sequential details of the reverse magnetization processes in the four particles. Image defocus is constant. While the geometrical demagnetization factor is the same for the four disks (constant aspect ratio), the observed

**Fig. 1** Magnetization reversal in elliptical disks 30 nm thick and major axes ranging from 3.4 to 5.0  $\mu\text{m}$ ; Ni + 19 at.% Fe and constant aspect ratios 2:1. Following saturation in one easy direction (large arrow), magnetization reversal process under oppositely directed applied field (small arrows) depends on size, the larger disks reversing at smaller fields. Lorentz TEM. (Joseph Zweck, private communication, 2003.)

differences for a given applied field are due, in part, to the role of the resulting demagnetizing fields associated with the different intrinsic distributions of magnetic moment within each particle due to size (the total energy of individual particles must be minimized). In this experiment a commercially available Lorentz objective lens is employed in which the usual field of the objective may be switched off and a pair of mini-lenses is employed in its place, whose fields can be set to cancel at the specimen position; a special specimen holder incorporates a set of miniature coils to produce the required variable magnetic field in the plane of the specimen.<sup>[2]</sup> In such a situation, image resolution is limited to several nanometers (Josef Zweck, personal communication, 2003).

**Fig. 2** Reversal of the magnetic domain state of a row of sputter-deposited Co rings on silicon nitride. In-plane field component normal to row increases from (A) to (D), reversing magnetic state. Lorentz STEM. (Zaluzec, N.; Metlushko, V., private communication, 2003.)

There are a number of useful although sometimes less quantitative examples of in situ magnetic studies in which magnetic structure changes of a specimen are achieved by tilting the specimen in the objective lens field, which results in an increasing component of applied field in the plane of the specimen. An example of this is the following study of magnetization reversal in a series of patterned interconnected rings as shown in Fig. 2. Again the imaging technique involves a form of Lorentz microscopy but this time in a scanning transmission electron microscope (STEM). The material is sputter-deposited Co on a thin silicon nitride substrate. In the actual experiment the specimen was tilted in  $1^\circ$  increments about an axis parallel to the ring array. Fig. 2 shows Lorentz images at four stages in the magnetization reversal process. Many essential features of this process may be deduced unambiguously from the series of images; for example, the white and dark lines at the ring intersections in Figs. 2A and D are  $90^\circ$  domain walls (Nestor Zaluzec and Natali Metlushko, personal communication, 2003).

### Electrical Property Studies

Studies analogous to those for magnetic materials may also be performed in situ for ferro- and ferrielectric material systems, which are in some ways more straightforward because the applied fields are electric rather than magnetic fields. The magnetic field of the objective lens has little effect on electric polarization processes.

Another type of electrical property study with simultaneous TEM is a quantized conductance study of gold wires of nanometer and subnanometer cross section (quantum point contacts). In this instance a miniaturized STM was incorporated as part of the specimen holder of an ultrahigh vacuum high-resolution TEM. By means of the shear-type piezoelectric positioner, a sharpened gold tip was brought into contact with a gold island and slowly withdrawn at constant speed under computer control. Structural changes were observed continuously and video recorded as indicated in Fig. 3A–F, and electrical conductance was measured simultaneously as shown in Fig. 3G. In the same work a single row of four gold atoms (the ultimate wire) parallel to [100] was formed whose conductance was  $\sim 13 \text{ k}\Omega^{-1}$  corresponding to

$2e^2/h$ , the quantized conduction unit. In addition the conductance of a double row was twice this value, showing that equipartition holds for electron transport in these quantum systems. The high-resolution microscopy was clearly essential to the analysis of the conductance data.<sup>[3]</sup>

### Mechanical Property Studies

The deformation and fracture behavior of metals and alloys represents one of the most common applications for in situ microscopy studies since the 1960s, often having been performed in high-voltage TEM because of greater thickness for observation afforded by the higher energy electrons. In our context, the goal of

**Fig. 3** Quantum conductance of [110] rows of gold atoms. (A)–(E) Gold tip is withdrawn from gold sample, causing continuous reduction in the number of vertical gold atom rows to fracture at (F), with simultaneous conductance measurement. Note dislocation in (A). At (E) conductance is  $\sim 2 \times (13 \text{ k}\Omega)^{-1}$ , two times unit conductance (unit conductance =  $2e^2/h$ ). (G) Quantized conductance measured during withdrawal of the gold tip [as in (D)–(F)]. *Source:* From Ref.<sup>[3]</sup>.

**Fig. 4** Schematic drawing and SEM micrograph of tensile testing chip. *Source:* From Ref.<sup>[4]</sup>.

such studies is to determine the fundamental mechanisms controlling the mechanical response of nanostructured systems and to correlate it with the observed mechanical behavior. For example, to achieve this goal a novel MEMS microtensile test device has been developed which allows measurement of the applied load and sample displacement with concurrent observation of the deformation mechanisms. The device is such that it can be used in a wide range of instruments, although it has been used primarily in SEM and TEM studies. The device consists of a thin dogbone-shaped test specimen that is patterned and cofabricated with microforce and displacement sensors and supports made of silicon using standard photolithographic and deep reactive ion etching techniques. The support beams ensure true uniaxial loading. Fig. 4 describes the fabricated device. The specimen is freestanding between the beams, allowing its inherent response to loading to be determined, including details of the deformation and fracture mechanisms. Because the specimen is integrally fabricated with the loading device structure, issues of attaching it to the test frame and aligning it to ensure uniaxial loading are mitigated.<sup>[4]</sup> Fig. 5 is a series of TEM micrographs showing the glide of a dislocation from the interior of a 200-nm-thick grain to a grain boundary into which it is absorbed, leaving no trace. This demonstrates in a very elementary way the need for such dynamic in situ studies (Ian Robertson, private communication, 2003).

**Fig. 5** Dislocation motion and incorporation into a grain boundary in an Al crystal under increasing tension in device described in Fig. 4. (Ian Robertson, private communication, 2003.)

An example, quite different from the first, of the determination of elastic properties of carbon nanotubes by in situ TEM is represented in Fig. 6.<sup>[5]</sup> In this case the long carbon nanotube shown is excited to mechanical resonance by a high-frequency electric field imposed between it and a nearby positionable counter-electrode. The first and second harmonics are induced by tuning the frequency. The shape of the nanotube at resonance corresponds closely to that expected for a cantilevered uniform beam, which allows its bending modulus to be determined from the dimensions of the nanotube and the driving frequency at resonance. For nanotubes produced by arc-discharge, it is found that this modulus varies from about 1.2 TPa (like the value for diamond) for nanotubes smaller than 8 nm to as little as 0.2 TPa for those with diameters larger than 30 nm. Static electric fields which induce bending of carbon nanotubes in situ may also be employed for elastic modulus determination.<sup>[6]</sup>

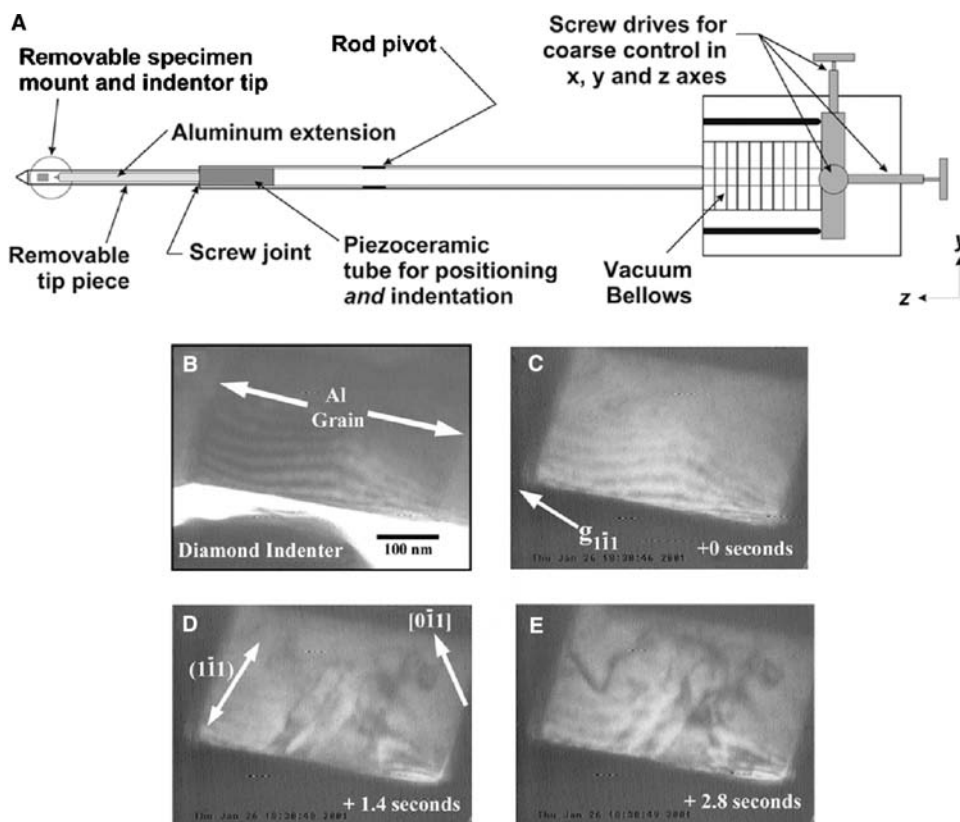

Finally, Fig. 7A describes a TEM/STEM specimen holder for nanoindentation of a thin foil or film, which, like that employed in the vibrating carbon nanotube example and the earlier quantum contact example, involves piezoelectric positioning of a part of the experimental apparatus (the indenter, the counterelectrode, or the gold tip). Fig. 7B–E shows TEM micrographs of dislocation activity during the indentation process.<sup>[7,8]</sup>

### Catalysis and Other Reaction Studies

Catalysis is responsible for the commercial production of countless organic substances, the catalytic particles responsible by necessity being in the nanosize regime. One of the aspects of this topic relevant to in situ

**Fig. 6** Electric-field-induced mechanical resonance in a carbon nanotube. (A) The nanotube is quasi-stationary (thermal vibration only). (B) The first and (C) second harmonic resonance is induced by high-frequency electric fields (MHz range). Source: From Ref.<sup>[5]</sup>.

microscopy studies, for example, involves ensuring that a catalyst remains in the nanosize regime under conditions simulated in the microscope for those to be encountered in production of a particular product. There have been two quite different approaches to allow such studies to be conducted in situ in TEM or STEM, one involving the design of environmental specimen holders which contain the entire experiment, environment and all, used in conjunction with an unmodified microscope, and the other, the design of a dedicated environmental microscope into which the desired chemical environment is introduced in the presence of a specimen holder which may provide independent capabilities such as heating. In the case of the environmental holder concept, windows with adequate electron transparency must be employed to isolate the experimental environment from the vacuum of the microscope, which may severely limit the pressures employed as well as instrumental spatial resolution. In an environmental microscope, as in older environmental cells that were inserted between the objective poles, usually of high-voltage electron microscopes (HVEMs), a pair of apertures, one pair before and the other after the specimen holder, serve this

isolation function, there being differential pumping within each aperture pair. Alignment of the apertures is critical. The success of the dedicated in situ microscope concept, especially since about 1995, attests to its experimental versatility and economic advantage for catalysis research in both industry and university.

The first of two short examples of its application is from a study of the stability of Ru particles in  $\text{TiO}_2$  during the hydrogenation of adiponitrile during the production of Nylon 6,6. Fig. 8 shows the catalyst (the 2–3-nm Ru particles) in hydrogen at 20°C and at 280°C after 2 hr, demonstrating no obvious reaction between the Ru particles and  $\text{TiO}_2$  support. Such reaction associated with reduction by hydrogen is known for this important commercial system above 500°C. This type of in situ finding has important implications for the utility and performance of such catalysts in the selective hydrogenation reaction.

The second example illustrates the in situ observation of catalyst-promoted polymerization and involves the same environmental TEM/STEM as the first example and a heating holder incorporating a windowless wet cell (the microscope provides the atmosphere and the wet cell, a microliter or so of fluid in

**Fig. 8** In situ real-time EHREM dynamic observations of Ru on titania xerogel catalyst in hydrogen environment recorded (A) at room temperature and subsequently during reaction at about 280°C for 2 hr. *Source:* From Ref.<sup>[9]</sup>.

contact with catalyst). In the case shown in Fig. 9 the catalyst/support particle (m), composed of a Ru–Co alloy on TiO<sub>2</sub>, is immersed in a solution of hexamethylene diamine and adipic acid, at ~188°C. The polymerization reaction to the polyamide is observed to occur at the interface with the particle seen in Fig. 9B. The observations demonstrate a stable catalyst and the formation of an essentially clean polymer structure. In this example a specialized specimen holder was employed. An example of a cell designed for studies of electrochemical reactions such as electroplating is shown in Fig. 10. The cell simply inserts in a holder for insertion in TEM or STEM (Frances Ross, private communication, 2003).

### Irradiation Effects Studies

Generally, in situ studies of irradiation effects require somewhat specialized electron microscopes. Because displacement thresholds by electrons, in terms of

**Fig. 9** Wet-ETEM of in situ polymerization. (A) Co–Ru on titania catalyst system particle at m (supported on sample grid G) with reactant solution from which (B) polymerization over the catalyst occurs at about 188°C. *Source:* From Ref.<sup>[10]</sup>.

incident electron energies, vary from 0.1 MeV or less for oxygen in some oxides to more than 1.5 MeV for large atomic number elements, HVEM have routinely been used for such studies since their introduction in the 1960s. For electrons in this range of energies, damage consists largely of single Frenkel pairs (vacancy–interstitial pairs). Since 1961 when the first observations of unintentional in situ ion damage were reported in Au in an 80-kV TEM, due to negative ions desorbed from the microscope’s electron source, in situ TEM studies of ion irradiation effects have become well established for both fundamental and applied irradiation effects research. While the field is often associated with nuclear science and technology, it is relevant to other areas as well such as degradation of microelectronic components in radiation environments, and

**Fig. 10** Schematic drawing of a closed system electrochemical cell for insertion in a TEM/STEM specimen holder. (Frances Ross, private communication, 2003.)

doping and creation of buried layers by ion implantation in semiconductors. Ion implantation and its associated damage consists of implanted atoms and cascades of point defect clusters which may collapse to form voids or other 3-D defects or partial dislocations which may have profound effects on physical properties. In situ ion beam-related studies require the integration of the microscope and one or more ion sources or ion accelerators, more than a dozen of which have been constructed, mostly in Japan with one in France and two in the United States, involving ion sources ranging from a focused ion beam (FIB) source to a 2-MV tandem accelerator. Two of the Japanese HVEMs employ two ion accelerators each

for simultaneous dual ion experiments. In order to do quantitative work in this area, electron and/or ion beam dosimetry, employing miniaturized Faraday cups and effectively performed at or near the specimen position, is a standard requirement.<sup>[11,12]</sup>

A simple example of a study involving high-energy electrons as the stimulus is shown in Fig. 11. The initial specimen was prepared by implantation of Xe in Al at room temperature. The Xe is very insoluble in the Al matrix and precipitates as nanocrystals, provided they are less than about 10 nm in diameter (at larger sizes the Xe precipitates are fluid). Two such Xe crystals are shown at high resolution in Fig. 11 under 1-MeV electron irradiation in an HVEM, the series of images

**Fig. 11** Migration and coalescence of two isolated crystalline Xe precipitates during continuous 1-MeV electron irradiation. Measured from the first image, the elapsed times at which video frames were recorded are (A) 0, (B) 101, (C) 418, (D) 549, (E) 550, (F) 551, (G) 561, (H) 584, and (I) 727 sec. Source: From Ref.<sup>[13]</sup>; © 1999 by the American Physical Society.

having been grabbed from videotape. In the sequence, the precipitates experience significant shape changes that lead to their migration. Immediately prior to their coalescence, the precipitates remain with a single plane of Al atoms separating them for several tens of seconds, indicating an absence of elastic interaction of the precipitates. Following coalescence, the resultant precipitate tends to spheroidize as one would expect. Such precipitates of gases in metals appear to grow only by migration and coalescence, as opposed to Ostwald ripening characteristic of purely metallic systems, an important fact which was not heretofore factored into simulations of life expectancies of nuclear reactor materials. In related experiments with the Xe-Al system, the absolute values of  $\{100\}$  and  $\{111\}$  Xe/Al interface tensions were determined and ordering at fluid Xe/solid Al interfaces demonstrated.<sup>[13-15]</sup>

Fig. 12 shows two TEM images from an ion irradiation-induced crystalline study of  $\text{CoSi}_2$ , a material studied extensively as a buried layer in Si. In this study Co and Si were coevaporated onto a thin silicon nitride substrate to produce non-crystalline  $\text{CoSi}_2$ , which was then heated in the TEM to partially crystallize it (the large “spheres” in Fig. 12). It was then subjected to 1.5-MeV Kr irradiation in situ at room temperature, causing additional fine nucleation and growth of crystals (the tiny spheres) during formation and recovery of the cascades of point defects produced by the ions. Fig. 12 shows the ion-stimulated crystallization process at two stages during continuous irradiation. From such in situ experiments one may determine the ion-induced nucleation and growth rates for the particular irradiation conditions and explore the dependence of these kinetic processes on ion mass and energy which result in different cascade structures.<sup>[16]</sup>

**Fig. 12** Ion-irradiation-assisted crystallization of  $\text{CoSi}_2$  thin film at 300 K (fine dispersion of crystals), following in situ partial thermal crystallization (massive crystals; the medium-sized sphere near the middle is 500 nm in diameter). Specimen has been irradiated with 1.5 MeV Kr to (A)  $3.4 \times 10^{18}$  and (B)  $8.5 \times 10^{18} \text{ m}^{-2}$  at 300 K in an HVEM. *Source:* From Ref.<sup>[16]</sup>.

## Quantum Dot and Thin Film Growth Studies

The first example is that of growth of quantum dots of Ge on Si. During lattice mismatched epitaxy a range of interesting structures can form spontaneously in order to minimize the total strain and surface energies. In many semiconductor systems having moderate lattice mismatch, greater than about 2%, a common growth mode is the formation of individual, coherently strained 3-D islands. The material at the top of the islands is partially elastically relaxed, reducing the total energy although the surface area of the system increases. For a lattice mismatch of several percent the islands formed have dimensions in the nanoscale regime (up to several tens of nanometers) and this restricted size can lead to interesting optical and electronic properties. This makes such self-assembled islands, or quantum dots, interesting for a range of applications from solid-state lasers to quantum cellular automata.

To understand the growth process, island self-assembly in Ge on Si was examined in real time in the TEM. Ge was grown in situ by CVD onto Si (001) at a specimen temperature of 650°C using digermene gas ( $\text{Ge}_2\text{H}_6$ ). A weak beam (dark field) imaging condition was chosen which revealed the strain field around each island. This allowed island positions and sizes to be determined, although the images do not show well the shapes of individual islands. The in situ observations reveal a rich evolutionary process as shown in Fig. 13. After nucleation, a bimodal distribution of sizes consisting of domes and pyramids is visible; later the smaller (pyramid) peak almost disappears.

A simple model was developed based on the existence of the two island shapes. During growth, islands can exchange Ge atoms by surface diffusion. If one

**Fig. 13** The evolution of Ge islands growing on a thin Si(001) substrate by in situ CVD at 650°C in a TEM. By 3 sec, nucleation of islands is evident, which coarsens with time; after 16 sec a transition occurs in which steep-walled domes form at the expense of shrinking shallow pyramids. *Source:* Frances Ross, private communication, 2003.

island, due to its shape or size, has a lower energy per atom than another island, Ge atoms will preferentially detach from higher energy islands and attach to the lower energy island. Islands thus shrink or grow depending on their energy per atom in comparison to other islands in the neighborhood. If all islands were the same shape, larger islands would always have a lower energy per atom than smaller ones by virtue of their lower surface energy/volume ratio. Larger islands would grow at the expense of smaller ones (Ostwald ripening). However, if two different island shapes are allowed, the process becomes much more complex and interesting. In the model, islands reaching a critical volume make the transition from pyramids to domes and rapidly grow at the expense of smaller pyramids. These real-time TEM observations, therefore, have led to a kinetic model for island growth that predicts how best to control island size and shape given the kinetic nature of the process so that uniformly sized island arrays may be grown. Island positioning now remains the greatest challenge to the use of self-assembled islands in novel devices, and in situ TEM can also be used to investigate the effects on island nucleation of chemical and topographic patterning of the substrate (Frances Ross, private communication, 2003).

By way of introduction to the second example, the relaxation of strain in semiconductor heterostructures is frequently accomplished by the deposition of misfit dislocation segments at the interface between the heteroepitaxial layer and the growth substrate when the film is sufficiently highly strained. These dislocations must first nucleate and then propagate to the interface. However, as the dislocations move through the film, they will likely interact with other, preexisting interfacial misfit dislocation segments. If the level of strain in the heterolayer is high, these interactions will not block the motion of the moving “threading” portion of the dislocations. However, when the epitaxial strain is lower, the preexisting interfacial misfit segments may block the threading dislocations. This limits the ability of the film to relax; these threading segments deleteriously affect the electronic performance of heterostructure devices.

In situ TEM techniques were used to investigate how individual dislocations interact during growth and annealing in strained layer heterostructures. SiGe films of varying composition and thickness were deposited onto clean Si substrates in situ in the modified ultrahigh vacuum TEM of the previous example. This allows the real-time observation of the nucleation, propagation, and interaction of dislocations during strain relaxation, an example of which is shown in Fig. 14. The experimental observations indicated that at very low levels of heteroepitaxial strain, all dislocations become blocked as a result of interactions,

**Fig. 14** Dark field TEM micrograph from an in situ study of dislocation interactions during recovery in a strained 70-nm-thick  $\text{Si}_{80}\text{Ge}_{20}/\text{Si}$  (001) heterostructure. Dislocation pairs of identical Burgers character are indicated by an asterisk if the reaction results in blocking and by an arrow for cases in which interaction does not produce blocking. Source: From Ref.<sup>[17]</sup>.

whereas for a regime at higher levels of strain, only dislocations with parallel Burgers vectors may become blocked during interactions, as illustrated in Fig. 14 (at the arrows). Computational simulations indicated that dislocation reactions that occur between dislocations with parallel Burgers vectors result in a stable configuration, and that the stability of this configuration is a function not only of the Burgers vector combination, but also of the direction of approach of the dislocations.<sup>[17,18]</sup>

### A Comment on Specialized Apparatus for In Situ Studies

While the most common in situ studies may involve only heating or cooling of the specimen, several pieces of more specialized apparatus have already been mentioned in conjunction with the specific studies cited above. These include specimen holders which 1) allow application of a magnetic field of known strength and direction, 2) incorporate piezoelectric positioning of some component of an experiment (technology borrowed from scanning probe microscope technology), and 3) incorporate MEMS-type devices for mechanical testing of thin films, nanowires, and the like. At the other extreme of size and investment are microscopes largely dedicated to in situ studies in ultrahigh vacuum or in other environments and to studies involving irradiation effects. The latter may involve connection of an ion accelerator or other radiation source to a microscope with devices for irradiation dosimetry near the position of the specimen.<sup>[12]</sup> What sets these types of studies apart from their ex situ counterparts is the

value-added advantage afforded by the simultaneous availability of a variety of imaging, electron scattering, and chemical and elemental analytical techniques while the specimen is being stimulated in appropriate ways. The possibilities for designing and performing in situ studies are limited largely by the imagination of the investigator.

### ANALYTICAL TECHNIQUES SUITABLE FOR IN SITU STUDIES

The extent to which a particular analytical technique or material property measurement method is useful for in situ applications depends largely on the time resolution required per meaningful observation. As a simple example, imagine that one wishes to study Brownian motion of 5-nm Au particles on (0001) graphite in an SEM with field emission gun (FEG). At video scan rates the spatial resolution may be worse than the size of the objects to be observed, and at slow high-resolution rates perhaps the particles move 10 nm on average over the course of a 30-sec exposure scan, for which the effective frame rate is reduced by a factor of nearly 900. Perhaps some intermediate conditions would be suitable, of course. On the other hand, in a conventional TEM it is likely that such observations would be possible at video frame rates at a resolution of 1 nm or better. In TEM the image of the entire area of view is formed at once. Unfortunately, even in this case the recording is not instantaneous though. This example points out the first two factors that are important in conducting in situ studies: the basic instrument

in which the experiment is to be conducted and the space/time capabilities of instrumentation for recording the relevant experimental information. The third important factor is the specimen itself. In the case of the SEM experiment the single-crystal graphite substrate could be relatively thick, several micrometers for example, whereas in the TEM experiment the substrate would have to be electron transparent, several tens of nanometers, for example; the thinner the better from a resolution point of view. Finally, in general, if the experimental observations involve imaging, it is important to remember that TEM images are formed in parallel (i.e., all pixels of a given image develop at the same time as mentioned above) whereas in both SEM and STEM, images are formed serially as the area of observation is repetitively scanned. This is not to say that SEM and STEM are categorically inappropriate instruments in which to conduct in situ studies; the choice of instrument largely depends on the nature of the study and the time resolution required in relation to the spatial resolution required.

While it is common and not improper to call SEMs, TEMs, and STEMs microscopies, their several image forming modes of operation are by no means their only modes of operation. For simplicity the other modes may be lumped into two categories, namely, electron scattering and other analytical modes corresponding to various signals from a material specimen resulting from interactions of the incident electron beam with the specimen. These signals may include secondary and Auger electrons, back scattered electrons, visible light and characteristic X-rays as useful signals in the case of SEM, and transmitted electrons, elastically

<sup>a</sup>Specific modes that may be more suitable for in situ studies are shown in bold.

and inelastically scattered electrons, Auger electrons, visible light, and characteristic and diffuse X-rays in the cases of TEM and STEM. A host of specific analytical techniques using these signals have been developed over the past decades as the sophistication of instrumentation has evolved. A number of these are summarized in Table 2, which is not all inclusive. Acronyms for techniques that lend themselves to at least some real-time studies are emphasized in bold. Few of these have been extensively exploited for in situ studies, however.

As indicated in Table 2, in TEM and STEM the addition of (electron) energy filtering capability, in column or post column, further enhances the quantitative and aesthetic value for nearly all those analytical techniques involving electrons directly, i.e., bright and dark field imaging, electron scattering, and electron energy loss mapping and spectroscopy.

### IMPACT OF ABERRATION CORRECTION OF ELECTRON OPTICS ON IN SITU MICROSCOPIES

With the exception of electron guns and stigmators, which incorporate electrostatic elements, all electron optical lenses in commercial electron microscopes have been electromagnetic (magnetic fields) with cylindrical symmetry (“round lenses”) which unavoidably suffer from positive spherical aberration<sup>[19]</sup> as well as the other resolution-limiting aberrations familiar in light optics.<sup>[20]</sup> However, whereas in conventional light optics spatial resolution for imaging (minimum separation of two objects which are distinguishable) is diffraction or wavelength-limited to a few hundred nanometers, in electron optics for which wavelengths are very short (for 100 kV electrons, 3.7 pm) ultimate spatial resolutions are aberration-limited, usually to a few tenths of nanometers for 100 kV, for example.

For some years, several electron optical aberrations—1) defocus, 2) twofold astigmatism, and 3) axial coma—have been routinely correctable by varying 1) the objective lens current (imaging modes in TEM, STEM, and SEM) or diffraction lens current (diffraction modes in TEM); 2) a biasing field of a weak magnetic octopole within the objective lens (imaging modes in TEM, STEM, and SEM) or diffraction lens (diffraction modes in TEM) which corrects astigmatism introduced by the specimen and objective aperture as well as that of the lens; and 3) accurate correction of beam tilt with respect to the optic axis of the objective lens (especially high-resolution imaging modes in TEM or STEM).

In the past for high-resolution TEM (HREM), the effects of (third-order axial) spherical aberration

(described by the coefficient of spherical aberration  $C_s$  or  $C_3$ ) have been partially mitigated to achieve improved spatial resolution by choosing defocus of the objective to optimize phase contrast, known as Scherzer defocus,<sup>[21]</sup> or to minimize the disk of least confusion, known as focus of least confusion.<sup>[22]</sup> Successful demonstration in the 1990s of hardware correctors for  $C_s$  has spurred commercial development of a number of aberration correction systems for electron microscopes based on combinations of electrostatic and magnetostatic hexapole and octupole elements of variable strength. While the concept was introduced 40 years earlier, its realization depended on more recent development of high-speed computer capability and of CCD cameras for execution of the necessary involved, iterative alignment procedures for the corrector elements with respect to one another and with respect to the round lenses of the instrument. The other critical element is the development of current and high-voltage power supplies of significantly improved stability. By 2003, point-to-point resolution for imaging in TEM at Scherzer defocus was improved from 0.24 to  $\sim 0.13$  nm at 200 kV. The correction of  $C_s$  in TEM, STEM, and SEM is achieved with assemblies of multipole electrostatic elements, rendering  $C_s$  a free parameter of the instrument (like defocus) rather than a fixed property of the objective lens. In addition, for high-resolution imaging in a  $C_s$ -corrected TEM, it is possible to partially mitigate the next higher order spherical aberration coefficient for the instrument ( $C_5$ ) by choosing a slightly negative value for  $C_s$  for the corrected objective lens.

These continuing developments of aberration correction systems impact ultimate instrumental resolution both for imaging and microanalysis (or more appropriately nanoanalysis) and for in situ applications.<sup>[23]</sup> In the case of in situ TEM, correction of  $C_s$  allows more space around the specimen, into which experimental devices may be incorporated. Previously, increased space was achieved by employing instruments with shorter wavelength electron sources, namely, HVEM, spatial resolution being proportional to  $C_s \lambda^{4/3}$ . However, in the cases of conventional HVEM and  $C_s$ -corrected TEM, spatial resolution remains a sensitive function of the objective lens focal length (gap size in a side-entry objective) due to chromatic aberration associated with high voltage and lens current instabilities (characterized by  $C_c$ ). For example, in an uncorrected TEM, spatial resolution for imaging of magnetic structures (Lorentz microscopy) is about 2 nm. With both  $C_s$  and  $C_c$  correction, it should be possible to improve this by an order of magnitude in an experimental space several centimeters in every dimension (Bernd Kabius, private communication, 2003). Furthermore,  $C_c$  correction regains some of the advantage of greater penetrating power associated

with higher voltage TEM for thicker specimens. Inelastic scattering for thicker specimens diminishes the information limit; this can be compensated by correcting  $C_c$ . The development of correction not only for spherical but for chromatic aberration as well should provide, therefore, a strong stimulus for both superb imaging and other analytical functions and for much improved in situ capabilities, in TEM, STEM, and SEM.

## CONCLUSION

Over the past several decades, in situ techniques applied to various electron microscopies have contributed extensively to our current understanding of dynamic processes in the areas of materials science and engineering and materials physics. This trend should thrive in the environment of nanoscience and nanotechnology in the future as well, as new and improved instrumentation and experimental techniques, as well as existing analytical techniques which have not been extensively exploited yet, are conceived and brought to bear on the many materials and material systems problems ahead. Performing studies in situ can be a very efficient way to get the job done and, in addition, oftentimes provide an entirely new insight and understanding to physical processes and mechanisms. The possibilities for designing and performing such in situ studies are limited largely by our imaginations.

## ACKNOWLEDGMENTS

Special thanks are due to Joseph Zweck, Frances Ross, Kunio Takayanagi, Eric Stach, Zhong Lin Wang, Pratibha Gai, Robert Birtcher, Nestor Zaluzec, and Ian Robertson for providing the various examples of in situ TEM and STEM studies and designs of specialized experimental holders; to Bernd Kabius for many discussions and suggestions relating to aberration correction; to Robert Birtcher and Nestor Zaluzec for help with the preparation of figures, and last, but not least, to the editors of the *Encyclopedia of Nanoscience and Nanotechnology* for patiently watching my deadlines pass. The author is grateful to the Office of Science, U.S. Department of Energy, under Contract No. W-31-109-Eng-38 for support of this work.

## INTRODUCTION

Realization of nanometer-scale semiconductor quantum dot structures has become an important area of research focus in recent years primarily because of the potential of nanometer-scale systems in future device applications.<sup>[1–5]</sup> With the conventional silicon technology rapidly moving toward saturation in terms of scalability and complexity of fabrication, semiconductor quantum dot structures hold promise as future electronic devices beyond silicon electronics. Furthermore, developing nanometer-scale quantum dot devices on Si and GaAs substrates offers the possibility of advancing their mature device technologies. As a consequence, InAs/GaAs<sup>[6–8]</sup> and Ge/Si<sup>[9–11]</sup> heterostructures are currently being investigated extensively to develop nanometer-scale quantum devices. While these structures have been extensively investigated because of the availability of advanced GaAs and Si device technologies and the relative ease of growing self-assembled III–V and Si–Ge nanostructures, the InAs/Si heterostructure offers the possibility of growing direct gap InAs on indirect gap Si and holds considerable promise as a candidate for silicon-based optoelectronics as the incorporation of direct band InAs in silicon could significantly improve the radiation recombination efficiency.<sup>[12]</sup> Although there is more than 11% lattice mismatch between InAs (6.0583 Å) and silicon (5.4310 Å) making InAs/Si a highly strained system, their closely matched thermal expansion coefficients (InAs:  $4.70 \times 10^{-6} \text{ K}^{-1}$ ; Si:  $4.68 \times 10^{-6} \text{ K}^{-1}$ ) make InAs/Si a promising heterostructure to grow nanometer-scaled InAs islands. Also, this large lattice mismatch can, in fact, be exploited to grow a high density of InAs islands on silicon surface under optimized growth conditions. Laser structures emitting at 1.013 μm have already been fabricated on silicon substrates using quantum dots of compositional InGaAs alloys as active layers.<sup>[13]</sup>

## OVERVIEW

The initial stages of semiconductor heteroepitaxial growth are governed by three possible growth modes,

viz., the Frank–van der Merve mode involving layer-by-layer growth, the Volmer–Weber (VW) mode involving island growth, and the Stranski–Krastanow (SK) mode involving layer-by-layer growth followed by island growth.<sup>[14]</sup> Of these, the SK growth mode has been predominantly used to achieve nanometer island formation in lattice mismatched semiconductor heterostructures including InAs/Si. While the large lattice mismatch may seem to indicate island growth in the SK mode, VW mode has also been observed in the InAs/Si system under certain growth conditions in the growth temperature range of 300–400°C.<sup>[15,16]</sup> Although conditions favoring specific growth modes have not been extensively studied, considerable research efforts continue to focus on the dependence of InAs island morphology on the growth parameters involved. Furthermore, solid source molecular beam epitaxy (MBE) remains the growth method of choice to produce nanoscale InAs islands on Si. Mano et al.<sup>[17]</sup> first established the possibility of growing high-quality InAs nanocrystals on hydrogen-terminated Si (100) by using MBE growth technique and used cross-section transmission electron microscopy (XTEM) and field emission scanning electron microscopy (FESEM) to characterize the crystalline quality. Their evaluation of InAs/Si interface band discontinuity indicates that both holes and electrons can be confined in InAs nanocrystals. Growth conditions favorable for yielding a high density of uniform InAs islands on silicon were studied in detail by Hansen, Bensing, and Waag<sup>[18,19]</sup> by using in situ surface analytical techniques such as reflection high energy electron diffraction (RHEED) and X-ray photoelectron spectroscopy (XPS). They have also studied the growth of InAs on Si (001) and Si (111) substrates. In addition to conventional SK growth mode, they have used a dewetting method to grow InAs islands on Si (001). This method involves devolution of continuous two-dimensional (2-D) InAs film into small three-dimensional (3-D) InAs islands by cooling the substrate temperature from the growth temperature (~370°C) down to approximately 320–300°C soon after the growth of about 1 monolayer (ML) of InAs. The InAs islands thus grown, however, have been found to be dislocated as also the InAs islands grown on arsenic (As)-terminated

Si (111).<sup>[20]</sup> While their observations suggest this dewetting transition in InAs/Si (001) to be irreversible, a similar dewetting transition used recently to grow InAs islands on GaAs (100) at high substrate temperatures ( $\sim 540^\circ\text{C}$ ) has been found to be reversible.<sup>[21]</sup> Uragami et al.<sup>[22,23]</sup> investigated the structural properties of InAs quantum dots on Si (100) by comparing data obtained from generalized grazing incidence X-ray diffraction (G-GIXD) technique with the finite element method (FEM) calculations of the structural factors. G-GIXD technique enables the observation of fine changes in lattice constant both in lateral and normal directions of island growth over the substrate surface. They found that the InAs dots were dilated in the normal direction and compressed in the lateral direction because of the strain from the lattice mismatch and conclude that the introduction of misfit dislocations beneath InAs dots alone is not sufficient to relieve the strain and that shape change of dots is also a contributing factor in releasing the lateral strain. Combining Rutherford backscattering spectroscopy (RBS) and secondary-ion mass spectroscopy, Karl et al.<sup>[24]</sup> have studied the stoichiometry of MBE-grown InAs nanocrystals buried in a silicon matrix and found significant diffusion of indium (In) and As into the Si matrix and the presence of excess As on the surface in addition to a layer of stoichiometric InAs nanocrystals. Based on these observations, the authors recommend low growth temperatures and small As/In flux ratios to successfully grow InAs nanocrystals on Si (100). Although MBE remains the most convenient growth technique to study InAs/Si nanostructures, there also have been successful attempts to form InAs nanocrystals in a silicon matrix by sequential ion implantation of In and As ion species in Si (100).<sup>[25,26]</sup> Using RBS, TEM, and X-ray diffraction (XRD/XD), the authors of this study establish that it is possible to produce InAs nanocrystals in Si (100) by ion implantation at  $500^\circ\text{C}$  followed by a  $900^\circ\text{C}$  thermal annealing cycle. Their ion implantation studies further reveal that morphological changes can be effected by reversing the order of implantation between As and In as implanting either In or As first produces distinctly different morphologies. Nanocrystals of diameter 20–70 nm imbedded in silicon were produced by this method. Si-exposed GaAs substrates have also been used recently to grow self-assembled InAs quantum dots.<sup>[27]</sup> These studies indicate that the exposure of GaAs substrates to a Si-molecular beam flux prior to InAs deposition aids in achieving higher uniformity in InAs dot lateral dimensions possibly because Si atoms on GaAs surface act as nucleation centers and create preferential growth regions for InAs.

The chief motivation for the study of nanometer-scale InAs islands on Si is to exploit the interesting optical properties that arise out of integrating InAs

into well-established silicon technology. By growing InAs nanocrystals of desired dimensions, it is possible to bring about changes in the optoelectronic properties of InAs/Si system. Cirilin et al. have conducted photoluminescence (PL) studies on InAs nanocrystals grown in both SK and VW modes in a Si matrix<sup>[15,16]</sup> and also on samples deposited with various InAs ML coverages and 30–60 nm silicon cap layers.<sup>[28–30]</sup> They found a luminescence band exhibited by these samples around 1.3- $\mu\text{m}$  region that showed a shift toward higher energies with increasing excitation density. The authors determined that the origin of this luminescence band was indeed from InAs nanocrystals by eliminating the influence of silicon substrate and the cap layer on the PL signal. They also found that samples with very small InAs coverages showed no noticeable luminescence as very small InAs inclusions ( $<5\text{ nm}$ ) would produce no charge localization. Their experiments on the temperature dependence of PL showed a monotonic shift from 1.3  $\mu\text{m}$  at 10 K up to 1.6  $\mu\text{m}$  at 290 K.

We describe below our studies on the formation of nanometer-scale InAs islands on silicon including the experimental procedures, the dependence of island morphology on critical growth parameters such as the monolayer coverage, the flux ratios, and the growth temperature. Our observations and results are also compared with the results available in the published literature of other research groups working on the InAs/Si heterostructure for nanometer InAs island growth.

## EXPERIMENTAL DETAILS

Samples used for our studies were grown on (100)-oriented epitaxially silicon wafers in a solid source-integrated molecular beam epitaxy system (Perkin-Elmer) equipped with in situ reflection high energy electron diffraction (RHEED), residual gas analysis (RGA), k-space data acquisition (KSA), and pre-growth heating systems. Effusion cells of elemental Ga, In, Al, and As and dopants C and Si are typically loaded in the system. Prior to introduction into the load-lock module, the samples were cleaned using Shiraki procedure<sup>[31]</sup> and then hydrogen-terminated in dilute HF solution. While the evolution of the growth front was monitored by RHEED, a combination of pyrometer and thermocouple was used to sense and measure the substrate temperature. The samples were heated for outgassing prior to their introduction into the growth chamber and heated up to  $600\text{--}650^\circ\text{C}$  in the growth chamber to facilitate hydrogen desorption. The surface morphology of the samples was studied by atomic force microscopy (AFM) (Park Scientific Instruments) scans. Using line scan analysis of AFM, the dimensions of several individual

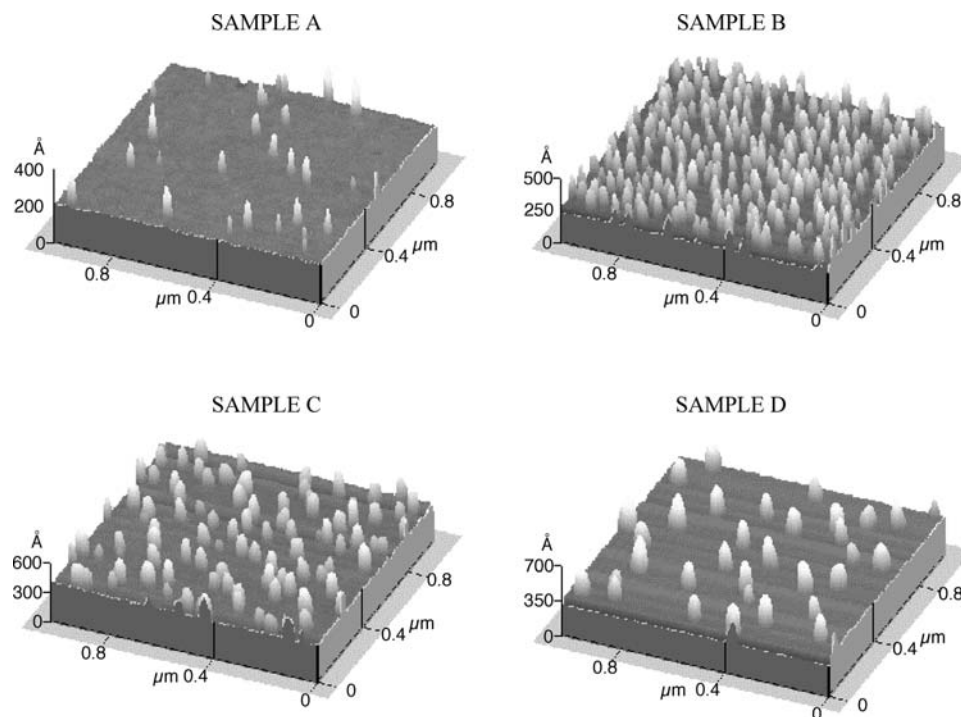

islands were directly measured and the image analysis was carried out by using ImagePro, an image analysis software to collect the statistical data on island distributions. The growth rate of InAs was calibrated by RHEED specular spot intensity oscillations using InAs homoepitaxy. The arsenic source in the system is coupled to a valved cracker to produce  $\text{As}_2$  which aids in better crystalline quality of the grown layers as  $\text{As}_2$  incorporates more efficiently than  $\text{As}_4$  on the growth surfaces.<sup>[32]</sup> The cracker mechanism also helps in economizing the consumption of arsenic material.

## RESULTS AND DISCUSSION

To study the evolution of growth front morphology with increasing InAs thickness, we have grown samples by depositing InAs of varying thicknesses on Si (100) using growth conditions optimized for producing InAs islands in SK mode. As mentioned earlier, InAs grows either in SK mode or VW mode depending on the growth conditions. In SK mode, 3-D islands begin to grow over an initial 2-D wetting layer when a critical thickness ( $t_c$ ) is reached. This critical thickness at which the growth transition takes place is dependent on important growth parameters such as the growth (substrate) temperature ( $T_s$ ), the flux ratios of reacting species In and As, the substrate orientation, and even the substrate cleaning method prior to growth. As a

consequence, there is considerable variation in the critical thickness reported by different groups. Using a growth temperature of  $450^\circ\text{C}$ , we have grown samples with nanometer-scale InAs islands by depositing 3.8 to 5 ML of InAs on Si (100).<sup>[33]</sup> The AFM images of four such samples are shown in Fig. 1A–D. Within a short range of approximately 1.5 ML InAs coverage, we observed the rapid formation of 3-D InAs islands on a 2-D wetting layer, right from the appearance of sparsely distributed small islands (Fig. 1A) through a dense formation of uniform islands (Fig. 1B) to the merging of several small islands to form larger islands (Fig. 1D). While InAs coverages below 3.8 ML showed no significant island formation, deposition of InAs material beyond  $\sim 6$  ML resulted in the formation of very large relaxed InAs islands with greatly reduced densities. Thus depending on As/In flux ratios, it is possible to obtain coherently strained InAs islands on silicon with a monolayer coverage of up to 6 ML by using moderate growth temperatures ( $<475^\circ\text{C}$ ). The dense formation of islands was found to be uniformly spread all across the substrate with no significant differences in island densities between any two regions on the sample surface. The mean dimensions of the islands obtained through direct AFM measurements on the samples in Fig. 1 are plotted against the InAs monolayer coverage in Fig. 2. It can be suggested from this figure that InAs coverage of about 4 ML may be optimum for obtaining closely related

**Fig. 1** Atomic force microscopy images ( $1 \times 1 \mu\text{m}$ ) of Si (100) samples with nominal InAs coverages of (A) 3.8 ML, (B) 4.1 ML, (C) 4.6 ML, and (D) 5.0 ML. All the samples are grown at  $450^\circ\text{C}$ . Source: From Ref.<sup>[33]</sup>.

**Fig. 2** Average island dimensions for different InAs coverages of samples grown at 450°C. InAs thicknesses of 4 to 4.5 ML yield uniform island dimensions with narrow distributions. *Source:* From Ref.<sup>[33]</sup>.

island dimensions with high densities under the growth conditions used to grow these samples. Also, a monolayer coverage in the range of 3–6 ML of InAs has, in general, been found to yield uniform nanometer-scale islands on Si.<sup>[12,17,33]</sup> The statistical data collected from large ensembles of InAs islands using image analysis of AFM images for different monolayer coverages are presented in Table 1. The retention of uniform dimensions and small standard deviations even at larger island sizes (>40 nm) averaged over large ensembles is evident from this table. The initial rapid increase in island density with monolayer coverage followed by a decrease as seen in Fig. 2 is consistent with the evolution mechanism of InAs islands on Si. In InAs/Si heteroepitaxy, strain as a result of initial overlayers is relieved by the energetically favorable formation of large ensembles of 3-D islands elastically strained to the substrate (Fig. 1B). Strain as a result of further InAs deposition leads to changes in the geometry of islands as they tend to attain irregular shapes and

eventually become faceted. Fig. 1C represents such a scenario of faceted InAs islands. Strain upon further InAs growth is accommodated by the introduction of dislocations beneath large islands formed by the coalescing of several smaller InAs islands. Fig. 1D shows such large dislocated InAs islands under coalescence. The formation of such large islands is a consequence of Ostwald ripening which is characterized by the re-evaporation of material from nearby smaller islands to larger islands. Uragami et al.'s investigations also provide physical evidence<sup>[22,23]</sup> to our explanation of strain-relieving mechanisms in effect during the evolution of InAs island morphology on silicon. The very high InAs island densities observed in our experiments are essentially a result of the high strain arising out of large lattice mismatch between InAs and Si as it becomes energetically favorable to form a proportionally large number of 3-D islands all across the substrate surface. The inter-island distances in our images showed a random spatial distribution with the Fourier transform images of island spreads for various InAs coverages showing no order. Table 2 summarizes the InAs island data obtained by various groups using different growth temperatures and growth methods. It can be seen from this table that there is a close match among InAs island sizes obtained under wide-ranging growth conditions. Coherent islands with lateral dimensions in the range of 10–40 nm may find useful applications as it is possible to achieve charge localization within these islands.<sup>[12]</sup>

Another important growth parameter found to have significant influence on the island morphology and composition is the flux ratio of reacting species In and As. Attempts made to deposit InAs islands on Si using As/In ratios from 2 to 12 revealed that while very high growth temperatures produced no islanding independent of As/In flux ratios, very high flux ratios (>7) resulted in the reduction of an order of magnitude in island density.<sup>[15,16,18]</sup> Our experiments to grow InAs islands at 450°C using very low As/In flux ratios resulted in the formation of In-rich clusters all across the sample surface as shown in Fig. 3. To explain this observation, it can be argued that the depleted As levels at low flux ratios result in stoichiometric

**Table 1** Atomic force microscopy statistical data of InAs islands grown on Si (100) surface for different InAs monolayer thicknesses obtained through direct measurements on individual InAs islands

<sup>a</sup>GaAs (100) substrate exposed to silicon flux.

deviations as several As atoms tend to adsorb to Si and several others diffuse into the Si substrate, thereby reducing the probability of 1:1 chemical bonding between In and As atoms at high growth temperatures. Thus as a trade-off between low island density at high flux ratios and In clustering at low flux ratios, a 3–6 flux ratio of As/In maybe suitable for growing stoichiometric InAs nanoislands on Si. The crystalline orientation of substrate is also of considerable importance in the growth of InAs islands. Table 3 summarizes the InAs island sizes on Si substrates of different orientations reported in literature. We used Si (100) substrates because silicon complementary metal oxide semiconductor (CMOS) manufacturing technology is based on this surface. However, hydrogen-terminated Si (111) is also being used to develop silicon-based optoelectronic devices such as the green and blue light-emitting diodes (LEDs). As can be seen from Table 3, the island dimensions of InAs grown on Si (100) by various groups are very close to those grown

on Si (111) by Hansen et al.<sup>[20]</sup> Likewise, the island densities achieved by various groups on silicon surfaces of different orientations are uniformly high in the range of  $5 \times 10^{10}$  to  $6 \times 10^{11} \text{ cm}^{-2}$ . It is interesting to note that unlike GaAs,<sup>[35]</sup> silicon of different surface orientations is amenable to the growth of InAs nanometer islands.<sup>[20]</sup> The nature of surface termination of Si has also an effect on the morphology of InAs islands grown clearly because surface preparation influences the nature of chemical bonding between reacting In and As species impinging on silicon surface. Our choice of hydrogen termination of silicon is to saturate the dangling bonds at the surface with hydrogen to try and minimize dangling Si bonds that act as adsorption sites. Empirically, InAs growth on Si (100):H seems to result in the formation of dislocation-free islands even for higher monolayer coverages and growth temperatures<sup>[17,33]</sup> as opposed to growth on Si (001):As surfaces.<sup>[20]</sup> Likewise, surface preparation by desorption of oxide layer on silicon by a high-temperature treatment step prior to growth appears to hasten the process of defect introduction at the Si–InAs interface for smaller InAs coverages.

**Fig. 3** Atomic force microscopy image ( $1 \times 1 \mu\text{m}$ ) of InAs/Si (100) sample grown using a low As/In flux ratio of 2:1. The patchy spread of matter seen in this image is clustered indium.

<sup>a</sup>Island size is generally the average value of a few base diameters of individual islands. Island size given here is the average value of the size ranges.

**Fig. 4** InAs island dimensions vs. growth temperature. Data on standard deviations are also presented to signify the uniformity of InAs islands, particularly those grown using temperatures in 400–425°C range. *Source:* From Ref.<sup>[34]</sup>.

We have also investigated the effects of growth temperature ( $T_s$ ) on the formation and morphology of InAs islands on Si (100). Choosing a temperature range of 350–530°C, we have obtained samples grown at the intervals of  $\sim 25^\circ\text{C}$  using optimized growth conditions and InAs monolayer coverages. Within this range of temperatures, we have observed drastic changes in the formation and morphology of islands. We notice that the island density increases with decreasing growth temperatures from near-zero island formation at a temperature of 530°C to an extremely dense ( $>5 \times 10^{11} \text{ cm}^{-2}$ ) formation of islands at a temperature of 350°C. Furthermore, we find the complete absence of 3-D SK island formation for temperatures higher than 530°C as evidenced both by in situ RHEED patterns and by postgrowth AFM observations. For higher growth temperatures ( $>530^\circ\text{C}$ ), the RHEED patterns remain streaky indicative of only 2-D InAs layer-by-layer growth. On the other hand, at low growth temperatures, the island formation is too dense to render any accurate measurements difficult. However, we find that a narrower growth temperature range of 400–425°C yields dense InAs 3-D islands of uniform dimensions with narrow distributions and small standard deviations. These observations, in general, are consistent with the observations of other groups.<sup>[15–18]</sup> The temperature dependence of island dimensions is shown in Fig. 4. It can be seen from this figure that the island dimensions exhibit an increase up to a growth temperature of around 450°C and then a decrease to nearly half their values around 500°C before 3-D island formation finally ceases at 530°C. This trend in island formation is possibly a result of the availability of greater thermal energy for strain relaxation at higher growth temperatures which limits island formation as a dominant mechanism to accommodate interfacial strain. The RHEED patterns of islands grown particularly in the 400–450°C range

showed prominent chevrons indicative of curved facets on InAs islands.

## CONCLUSION

Investigations on InAs/Si heterostructure as a candidate for nanometer-scale optoelectronic and quantum-optic devices show considerable promise as it is possible to realize coherent nanometer islands of direct gap InAs on indirect gap Si. We have investigated the dependence of InAs island morphology on various growth parameters such as growth temperature, As/In flux ratios, substrate orientation, and surface termination. Our experimental results establish the possibility of growing elastically strained InAs islands of uniform dimensions on Si surface using MBE under optimized growth conditions involving low flux ratios, low InAs coverages, and low growth temperatures. While photoluminescence studies by Cirlin et al. pave the way for device applications, the InAs island formation through a dewetting transition observed by Hansen et al. might lead to better insights into InAs island formation for smaller coverages well into the submonolayer regime. However, it is essential to address the issues of defect formation, reproducibility of morphologies, effects of capping layers, and luminescence properties in future through systematic characterization. Vertical stacking of island layers separated by spacer layers is another future research direction toward realizing InAs/Si nanodevices.

## INTRODUCTION

Cell membranes have many important biological functions such as controlling signal transduction and molecular transport between the inside and outside of cells.<sup>a</sup> A greater understanding of the structures and functions of the cell membrane components involved in signal transduction and/or molecular transport could be used to improve the delivery and specificity of pharmaceuticals.

Cell membranes are complex and dynamic structures generally described in terms of the “fluid mosaic” model.<sup>[1]</sup> Like any theory, the “fluid mosaic” theory is still being refined.<sup>[2]</sup> One way refinements are being tested is using nanotechnology to assemble biological and/or biomimetic components into membrane mimics to help clarify our understanding of cell membrane processes.

This entry describes measurements characterizing a particular mimetic called a hybrid bilayer membrane (HBM). HBMs are surface-supported bilayers composed of a monolayer of alkanethiol, which is tightly bound to the surface through a strong association between sulfur and gold, and a second non-covalently bound monolayer of phospholipid (Fig. 1).<sup>[3,4]</sup> The nanometer-size scale of the membrane components makes the construction and characterization of these mimetic membranes dependant on sophisticated measurement technologies. Hybrid bilayers are analytically addressable by a wide range of surface analytical techniques such as surface plasmon resonance, impedance analysis, electrochemistry, infrared spectroscopy, atomic force microscopy, ellipsometry, and neutron reflectivity.<sup>[5,6]</sup> While information from the spontaneously formed hybrid bilayers can be cross-referenced between different independent experiments, it is often desirable to obtain as much information as possible from a single technique. This article reviews the different types of information that can be obtained by using infrared

spectroscopy to study the interfacial structures of hybrid bilayer membranes.

## BIOMOLECULAR STRUCTURE AT INTERFACES

Interfaces are important in both nanotechnology and biology. Nanoscale entities, ranging in size from approximately 1 to 10,000 nm, have large surface-area-to-volume ratios. Molecules occupying an interfacial region are strongly linked to system properties. An example of this is a protein in/on a cell membrane dictating the membrane’s transport and signal transduction properties. The importance of membrane transport and signal transduction in medical science drives efforts to understand and control the composition and conformation of molecules in the interfacial regions of cells.

Biological membranes are complex and dynamic structures and their biological functions involve a number of different molecular species. Consequently, the details of the “fluid mosaic” model of freely diffusing proteins and lipids in a two-dimensional fluid<sup>[1]</sup> are still emerging.<sup>[2]</sup> To continue to clarify the complex nature of this model, better measurements, which determine the composition and/or the conformation of these moieties (proteins, lipids, etc.), are needed.

Direct attempts to determine structure at the atomic level of both lipid and protein components of membranes by crystallization and X-ray diffraction are difficult, and only a few membrane protein structures have been determined.<sup>[7–9]</sup> While it is assumed that a protein’s crystal structure is similar to that of the active protein in its native membrane environment, the surrounding dynamic lipid matrix may also influence it. Because the functions of membrane proteins often depend on conformational changes, for example, during transport across the lipid barrier, or during intracellular kinase activation after extracellular ligand binding, the motions of both the lipid and the protein must be taken into account, which limits the applicability of X-ray diffraction studies.

Without atomic-level structure, model membrane systems have allowed the study of isolated features of these otherwise highly complicated biological

<sup>a</sup>The specification of commercial products in this article is for clarity only and does not constitute endorsement by the National Institute of Standards and Technology.

**Fig. 1** An illustration of a hybrid bilayer consisting of *N*-PDP-phosphatidylethanolamine, 1,2-diacyl-*sn*-glycero-3-phosphocholine and melittin.

nanostructures, and have been essential to the development of our understanding. Lipid vesicles or liposomes,<sup>[10]</sup> black lipid membranes,<sup>[11]</sup> multilayers of lipid for diffraction studies,<sup>[12]</sup> planar lipid bilayers on solid supports,<sup>[13,14]</sup> and more recently, bicelles<sup>[15]</sup> are all forms of model systems having advantages and disadvantages as models of membranes. The liposome or proteoliposome (incorporating membrane proteins) is probably the most popular model membrane, and has contributed greatly to our understanding of biological membranes. A related type of model membrane, supported lipid bilayers are a model membrane system on a planar support and have also been employed in many important biophysical studies.<sup>[16–20]</sup>

Recently, supported bilayer systems have been extended to include metal-tethered membranes called hybrid bilayer membranes (HBMs).<sup>[3–6]</sup> HBMs are composed of a monolayer of alkanethiol, which is tightly bound to the surface through a strong association between the thiol and the gold surface, and a second monolayer of phospholipid (Fig. 1). Hybrid bilayers on metal supports are analytically addressable by a wide range of surface analytical techniques such as infrared spectroscopy, atomic force microscopy, ellipsometry, neutron reflectivity of single bilayer membranes, and nonlinear optical spectroscopy, surface plasmon enhanced fluorescence, surface plasmon resonance, impedance analysis, and electrochemistry.<sup>[5,21,22]</sup> These techniques can be used to probe the kinetics of bilayer formation, study the kinetics of ligand binding, and provide structural information.

Surface-supported bilayers generally need to be characterized by a number of analytical techniques, or by a single technique capable of describing several cross-validating features of the layer. This is important because the use of crosscutting information can reduce ambiguity and prevent erroneous conclusions. For

example, the simultaneous use of surface plasmon resonance (SPR) and impedance analysis to measure the kinetics of bilayer formation showed differences in the density of lipid layers that added to different thiol-tethered monolayers,<sup>[23]</sup> demonstrated the hydration of a cholera toxin layer bound to an HBM containing  $G_{M1}$  ganglioside,<sup>[24]</sup> and permitted discrimination between specific and nonspecific binding of ligands to the supported membrane surface.<sup>[25]</sup>

The focus of this article will be a review of the methods to obtain crosscutting information from infrared spectroscopy about hybrid bilayer membranes. However, it is important to remember that other groups of cross-validating experiments may be more appropriate in other circumstances for the study of supported bilayer membranes.

## INFRARED SPECTROSCOPY OF HYBRID BILAYER MEMBRANES

Infrared spectroscopy has long been used to characterize the molecular structure, conformation, and orientation of lipid monolayers, bilayers and their biological additives, proteins and carbohydrates.<sup>[20,26,27]</sup> Infrared spectral signatures are used to characterize the normal modes of vibrations caused by displacements of the permanent bond dipole moments in the contributing bonds. These displacements are sensitive to differences in the configuration and conformations of the chemical bonds. Thus infrared spectroscopy can be used to characterize the number (or mass), composition, structure, and conformation of the molecules comprising an HBM. For example, in a supported bilayer system, the protein of interest, the inner, and the outer leaflets of the bilayer can be simultaneously observed, allowing their complex interactions to be characterized.

As more data analysis methods are developed, this wide variety of information serves as a method to cross-check the sample preparation and structures of the various bilayer components. Other advantages of infrared spectroscopy are: 1) it is nondestructive; 2) it operates on a short time scale ( $\sim 10^{-12}$  sec), which prevents the time averaging of molecular motions; and 3) it does not require invasive and possibly perturbing molecular tags.

## External Reflection Infrared Spectroscopy of Dry HBMs

HBMs were first characterized via infrared spectroscopy using the external reflection geometry.<sup>[28,29]</sup> The external reflection technique uses a high angle of incidence reflection ( $\sim 80^\circ$  from the sample normal)

from a sample supported on an approximately 150-nm-thick gold film. In this configuration, reflected light polarized perpendicular to the plane of incidence and parallel to the substrate undergoes a nearly 180°-phase change. With this phase change, the incident and reflected light destructively interfere with each other and leave very little of the light polarized parallel to the surface to interact with the HBM. This phenomenon increases the field strength of the perpendicular polarized light and provides a sensitive technique to observe the composition, molecular conformation, and orientation of HBMs.

When the structure of the HBM was first being characterized, external reflection data showed bands from the alkane chains and the choline head groups of the phospholipids in HBMs, and confirms the presence of the phospholipid layer.<sup>[28]</sup> A variety of HBMs with different alkanethiol (hexanethiol, decanethiol, and octadecanethiol) and phospholipid (1,2-dimyristoyl-*sn*-glycero-3-phosphocoline (DMPC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphocoline (DPPC), 1,2-distearoyl-*sn*-glycero-3-phosphocoline (DSPC)) chain lengths were characterized. The study also characterized the effect the addition of phospholipid had on the structure of the underlying alkanethiol by using surface-enhanced Raman spectroscopy and external reflection spectra of alkanethiols in the presence and absence of an added layer of deuterated phospholipid. From this work, it is apparent that the addition of phospholipid generally causes small structural changes that are consistent with an ordering of the alkanethiol chains.

In another external reflection infrared study, the spectra revealed a series of CH<sub>2</sub> wagging progression bands in the 1000–1500 cm<sup>-1</sup> region for HBMs formed with hydrogenated phospholipids.<sup>[29]</sup> As wagging progressions are too weak to be observed in alkanethiol monolayers,<sup>[30]</sup> it was concluded that these progression bands were from the lipid layer. Furthermore, the progression bands suggested that the phospholipid portions of the HBMs had a high degree of intramolecular order.<sup>[29,31]</sup>

To evaluate the separation of the wagging progressions, a spectrum of DPPC-*d*<sub>62</sub> in an HBM was subtracted from the spectrum of DPPC in an HBM. After subtraction, only features due to the hydrogenated alkane chains of DPPC remain in the spectrum and support the idea that the wagging progressions are from the lipid layer. Separations between these wagging progression bands,  $\Delta\nu$ , were related to the number of *trans* bonds contributing to the wag-twist modes, *m*, by:<sup>[29,30]</sup>

$$\Delta\nu = 326/(m + 1)$$

Table 1 reports *m* values for a variety of acyl chain lengths and compares these values to those expected

**Table 1** Analysis of the wagging progression modes and the number of *trans* bonds as a function of lipid chain length

Lipid	Number of bonds	Frequency shift (cm <sup>-1</sup> )	% <i>trans</i> bonds
DSPC	17	19.8 ± 0.7	91 ± 4
DPPC	15	21.6 ± 0.9	95 ± 4
DMPC	13	26.0 ± 1.9	87 ± 6

from all *trans* chains. These values indicate that HBMs in air consist of chains averaging one gauche bond per chain. This would be expected for DPPC and DSPC with gel-to-liquid crystalline transition temperatures of 41 and 55°C, respectively. However, the gel-to-liquid crystalline transition temperature of DMPC is 23°C. Thus DMPC would be expected to be more disordered. The highly ordered structures of the lipids in the HBMs were assumed to come from either the stability of the octadecane thiol leaflet of the HBM or a lower degree of lipid hydration that could have effectively raised the transition temperatures of the HBM lipids.

### Infrared External Reflection Spectroscopy for Molecular Orientation in HBMs

Molecular orientation can be characterized using external reflection by matching experimental spectra with spectra simulated using the electromagnetic wave theory. The theory uses knowledge of the isotropic optical constants of the layer of interest and an assumed molecular conformation to scale the relative intensities of the different molecular functional groups as a function of the molecular orientation. This technique allows the degree of molecular tilt, twist, and azimuthal rotation to be determined. In addition, descriptions of the relative orientations of the constituent functional groups can be used to characterize, for example, the average *trans/gauche* conformation of the terminal methyl group of the lipid alkane chains.

There are a number of different implementations of the electromagnetic wave theory that have been developed. An early isotropic version by Hansen<sup>[32]</sup> uses a series of 2 × 2 matrices to describe an *N*-phase layer model. Hasegawa et al.<sup>[33]</sup> extended Hansen's calculations to describe uniaxially oriented layers of cadmium stearate on a GaAs substrate using a three-phase model. Parikh and Allara<sup>[34]</sup> developed a 4 × 4 matrix model for the quantitative treatment of biaxially oriented *N*-phase layered samples. More importantly, they also describe how to obtain optical constants from transmission measurements of bulk isotropic samples of the layer materials. These techniques use the entire set of information from the infrared

spectrum to determine cross-validated information about monolayer and bilayer structure.

To illustrate this technique, infrared external reflection spectroscopy was used to study the classical example of an octadecanethiol monolayer. The optical constants of isotropic octadecanethiol for the external reflection spectra calculations were modeled by using the transmission spectra calculations developed by Parikh and Allara.<sup>[34]</sup> A spectrum of isotropic octadecanethiol was obtained and decomposed into its constituent vibrational bands. For each vibration, a matrix was then constructed to determine the direction of the dynamic dipole for a chain with its carbon backbone perpendicular to the gold surface. The tilt, twist, and azimuthal orientations of the molecule were then selected relative to the surface. A rotation matrix was applied to transform the initial matrix to that of the newly oriented molecule to describe the imaginary part of the refractive index. The intensity of IR absorption is given by the square of the projection of the calculated vibration onto the  $z$  axis of the oriented molecule. Using the computed value as the imaginary part of the refractive index, a Kramers–Kronig transformation was used to determine the real part of the refractive index of the monolayer.

A three-layer model of air, octadecanethiol, and gold was then constructed by using Parikh and Allara's<sup>[34]</sup>  $4 \times 4$  matrix version of electromagnetic wave theory. At first, theory and experiment did not match well because the relative orientations of the methyl groups to the alkane chains are not the same in the monolayers as in the isotropic polycrystalline reference samples. The inclusion of gauche conformers in the structural model substantially improved the fit, especially in the region close to the symmetric and asymmetric  $\text{CH}_3$  stretching band near  $2960\text{ cm}^{-1}$ . Fig. 2 shows the juxtaposition of the external reflection experimental and calculated spectra. The spectra match with small deviations attributed to differences in conformation, and therefore band widths, between the polycrystalline transmission samples and the monolayers. The modeling procedure reveals that 21% of the methyl groups are in a gauche conformation, the acyl chains are tilted  $26^\circ$  to the surface normal, twisted by  $56^\circ$  around the chains' long axis, and that the spectra are insensitive to changes in azimuthal angle (Fig. 3). These values match well with values determined previously using similar methods.<sup>[34,35]</sup>

This method was previously used to compare the infrared external reflection spectra of HBMs with spectra calculated for different molecular orientations using electromagnetic wave theory.<sup>[29]</sup> As indicated above, the infrared spectrum of an HBM shows a well-packed lipid layer similar to the packing of a gel phase lipid bilayer. This means that the assumption of a nearly all *trans* chain conformation similar to

**Fig. 2** Experimental and theoretical external reflection infrared spectra at an  $80^\circ$  angle of incidence.

the alkanethiol case is appropriate for the lipid layer. Simulations of the CH stretching region of the external reflection spectra of DPPC layers reveal that the tilt and twist of the acyl chains are  $34^\circ$  and  $-38^\circ$ , respectively.<sup>[29]</sup> In fitting the simulated spectra to the measured spectra, several details are clarified. The lipid layers can be described as uniaxial with the azimuthal angle having little effect on the simulated spectra. The alignment of the methyl groups compared to the rest of the acyl chains is different than the alignment of the methyl groups in the polycrystalline reference spectra from which the optical constants for the calculation are derived. This difference can be attributed to  $26 \pm 16\%$  gauche terminal methyl conformations.<sup>[29,34]</sup>

**Fig. 3** Schematic diagram of the  $z$ -axis normal to the gold surface, the monolayer thickness, the tilt ( $\theta$ ), twist ( $\psi$ ), and azimuthal ( $\phi$ ) angles describing the orientation of the molecules in the monolayer.

## Infrared Spectroscopic Ellipsometry

Using infrared spectroscopic ellipsometry (IRSE), the powerful method of fitting optical models to experimental data to extract information about the molecular structure of monolayers/bilayers can be extended to obtain the optical thickness of the layer. Self-assembled monolayers were used as reference materials to demonstrate the sensitivity of this approach.<sup>[36]</sup> Film properties such as molecular orientation and thickness were used to predict the spectra of the real and imaginary components of the complex optical density,  $D$ . The calculated  $D$  spectra are compared to the measured spectra and the model revised. This iterative process continues until changes in the model produce the best fit to the experimental results.

The graph in Fig. 4 shows a comparison of experimental data (solid line) with an electromagnetic wave theory calculations (dashed line) for a hexadecanethiol monolayer. Fig. 3 illustrates the description of the molecular orientation and thickness information determined from the ellipsometric measurements. For example, the shift in the baseline of the simulated  $\text{Im}(D)$  matches the measured  $\text{Im}(D)$  shift, which suggests a film thickness of 2.0 nm. The peak intensities

**Fig. 4** Two infrared ellipsometric spectra describing the imaginary part of the complex optical density function,  $D$ , for a hexadecanethiol monolayer. The solid line depicts experimentally measured data and the dashed line depicts data simulated using electromagnetic wave theory as described in the text.

in the simulation of  $\text{Re}(D)$  (not shown, but similar to Fig. 2) also match that of the hexadecane in the electromagnetic model. In this case, the hexadecane chain is tilted at an angle of  $26^\circ$  to the surface normal and twisted by  $48^\circ$  around its long axis, similar to the octadecanethiol monolayer.<sup>[36]</sup>

Two sources of error were analyzed: analyzer repositioning and angle of incidence changes between reference and sample measurements. Results indicated that the error resulting from the analyzer position is smaller than the error arising from differences in the angles of incidence. If a simulated  $\text{Im}(D)$  is matched to two consecutive  $\text{Im}(D)$  measurements, a difference in the thickness of only 0.05 nm is revealed. A series of four measurements of the thickness of a heptanethiol monolayer were performed to evaluate the error caused by differences in the angle of incidence between the sample and the reference. Analysis revealed a thickness of  $1.0 \pm 0.2$  nm, which is similar to the value and standard deviations previously measured using visible spectroscopic ellipsometry. However, they did not require the inclusion of an extra unknown layer to describe the interface between the gold and the alkanethiol, as required in visible ellipsometry models.<sup>[36]</sup> The error in the reproducibility of these measurements,  $\pm 0.2$  nm, is equivalent to  $\pm 0.0005$   $\text{Im}(D)$  units. This study also illustrates that IRSE can be utilized to discriminate between the hexanethiol, dodecanethiol, and hexadecanethiol self-assembled monolayers on gold on the basis of thickness, and the simulations revealed values of 0.8, 1.5, and 2.0 nm, respectively.<sup>[36]</sup>

These examples illustrate the variety of structural information that can be obtained from infrared data. Optical modeling provides a method to cross-validate the identity, amount, conformation, and molecular orientation of a supported bilayer sample. The extension of these powerful techniques to more biologically relevant samples under aqueous solution is described below.

### HBMs Characterized under Aqueous Solution Using External Reflection

Polarization-modulation infrared reflection adsorption spectroscopy has been utilized to characterize HBMs under aqueous solution.<sup>[37]</sup> HBMs consisting of DMPC and hexadecanethiol with and without gramicidin D were characterized. The data clearly show the difference between the hexadecanethiol monolayer, the hexadecanethiol/DMPC HBM and the HBM containing the gramicidin. Changes in the absorbances in the CH stretching region,  $2800\text{--}3000\text{ cm}^{-1}$ , for the spectra of the self-assembled monolayer (SAM) and the HBM, are consistent with the formation of a complete bilayer. For the HBM, the frequency of the

$\text{CH}_2$  asymmetric stretching band,  $2917\text{ cm}^{-1}$ , indicates that the lipid layer acyl chains are quite ordered compared to a frequency of  $2924\text{ cm}^{-1}$  for disordered chains. Amide A, I and II bands characteristic of proteins and peptides are observed in HBMs containing gramicidin D. Shifts in these bands to lower frequencies compared to spectra in aqueous bulk solution suggest that the environment or conformation of Gramicidin is altered by incorporation into the HBM.

### HBMs under Aqueous Solution Characterized by Multiple Internal Reflection

In contrast to external reflection, internal reflection involves coating a thin ( $< 20\text{ nm}$ ) gold layer on an internal reflection element. The light impinges on the from the back, or supporting side through the thin gold layer. Similar techniques have been described for electrochemical measurements (e.g., see Neff et al.<sup>[38]</sup> and references therein). Generally, these methods are difficult and no standard methods exist.<sup>[39]</sup> Understandably, reproducibly coating a continuous thin layer of metal on an internal reflection element can be difficult. It is also difficult to determine if the gold layer is continuous because commercially available internal reflection elements are polished to optical tolerances using polishing grit (generally  $0.1\text{--}1\text{ }\mu\text{m}$  in diameter). With this type of surface finish, it is difficult to observe roughness on the order of the thickness of the gold layers.

Recently, there have been several reports of surface-enhanced infrared spectroscopy have taken advantage of the higher plasmon density at the surface of discontinuous gold layers to increase the IR signal.<sup>[40]</sup> These discontinuous gold layers present a dilemma in terms of determining the structure of the HBM. Because the thiols only adsorb to the gold-coated portion of the surface, it is unclear whether the HBM consists of a proximal alkanethiol and a distal phospholipid, or if the proximal layer is a mixture of alkanethiol and phospholipid. In addition, the plasmon density, and therefore optical field strength of these discontinuous layers, is not uniform. The non-uniformity of the field strength makes it difficult to relate the observed spectral intensities to the molecular properties of the HBMs.

For example, Sevin-Landais et al.<sup>[41]</sup> and Liley et al.,<sup>[42]</sup> using the same type of gold coating, estimated that as much as 15–20% of the crystal surface was not coated with gold. Another example is the study by Cheng et al.,<sup>[43]</sup> which describes a 14-reflection crystal coated with 20 nm of gold leaving a total path length of at least 140 nm through gold. Because the decay length for the intensity of the light is given by  $4\pi k/\lambda = \sim 13\text{ nm}$  for the CH stretching region, a path of 140 nm would essentially leave no light. However, if the gold layer is discontinuous, the path through the

gold could be substantially less and the signal proportionally greater. The Cheng et al.<sup>[43]</sup> study used infrared spectroscopy to characterize lipid bilayers formed by vesicle fusion to surfaces containing different concentrations of immobilized cholesterol. Phospholipid adsorption from vesicles was only detected for surfaces at least 24% covered with cholesterol. Because of the signal attenuation of the gold, they report field amplitudes to be small,  $\sim 0.1$  and  $0.01$  for p and s polarizations, respectively. When these values are used to determine the orientation of the lipid acyl chains, they suggest a tilt of  $12^\circ$  compared to  $26^\circ$  for a 30 mol% cholesterol layer in bulk DMPC by nuclear magnetic resonance (NMR).<sup>[43]</sup> They suggest this discrepancy is caused by a more “rigid” bilayer on the surface. However, Huber and Mantsch<sup>[44]</sup> report a  $26^\circ$  tilt for DMPC in the gel phase on an attenuated total reflection (ATR) crystal. It is more likely that the difference can be explained by a low signal-to-noise ratio caused by low field strengths.

### HBMs under Aqueous Solution Characterized by a Single Internal Reflection

Recently, Elliott et al.<sup>[5]</sup> minimized the problem of signal attenuation by the thin gold layer in the multiple internal reflection geometry by using a single internal reflection accessory. The integrity of the gold layer was improved by using a silicon crystal, like the majority of the gold supporting substrates in monolayer work. This layer has a root-mean-square (RMS) roughness on the order of 0.3 nm, and therefore only minimally perturbs the HBMs. Fig. 5 shows the electric field strengths at the gold surface for different gold film thickness. These values are calculated by

**Fig. 5** Three-layer model (silicon/gold/water) description of the field strengths in the  $x$ ,  $y$ , and  $z$  directions at the gold/water interface as a function of gold thickness.

**Fig. 6** s- and p-polarized infrared internal reflection data in the C–D stretching region of a deuterated DMPC layer in a HBM measured under aqueous buffer solution.

using the method of Hansen<sup>[32]</sup> as implemented by Citra and Axelsen.<sup>[45]</sup> From these data, the effect of multiple reflections through the gold on the field strength can be approximated by the field strengths at multiples of the gold thickness values.

As an example of the information available from this type of experiment, Fig. 6 shows parallel- and perpendicularly polarized spectra of a deuterated DMPC HBM. Using this data and the three-layer model of Citra and Axelsen,<sup>[45]</sup> the average orientation of the lipid acyl chains with respect to the membrane surface normal was calculated to be  $\sim 25^\circ$ . This value is comparable with the NMR value reported by Cheng et al.,<sup>[43]</sup> and with the  $26^\circ$  tilt angle for DMPC in the gel phase on an ATR crystal reported by Huber and Mantsch.<sup>[44]</sup> Similar techniques can also be used to describe the orientation of proteins incorporated in HBMs.

## CONCLUSION

Supported bilayer membranes embody a nanotechnology that developed to determine the structure and function of cell membranes and to clarify issues in the details of the “fluid mosaic” model in the fields of biology and medicine. The current challenge for the characterization of supported bilayer membranes is to obtain information that can be cross-validated either between different measurement techniques, or by methods measuring independent information from the same technique. This article described how infrared spectroscopy is used to obtain information from bilayer membranes supported on metal surfaces. While some methods have been developed for the characterization of lipid/protein layers at the surfaces of internal reflection crystals, complications and

enhancements associated with the addition of the gold layer still need to be addressed. For example, improved models of molecular orientation may allow more about the distribution of the molecular orientation and/or the distance a functional group is from the surface. Another area in which the analysis of infrared spectroscopy of supported bilayer membranes can be improved lies in techniques to exploit improvements in isotopic editing of proteins.<sup>[46]</sup>

## ACKNOWLEDGMENT

The author like to thank J. T. Elliott for help collecting the infrared data in Figure 6.

# Inorganic Nanotubes

Reshef Tenne

Materials and Interfaces Department, Weizmann Institute of Science,  
Rehovot, Israel

## INTRODUCTION

Nanoparticles of inorganic layered compounds, such as  $WS_2$ , were shown to be unstable in the planar form and, in analogy to carbon nanoparticles, they form closed-cage structures with polyhedral or nanotubular shapes. These findings extend the paradigm of carbon fullerenes and nanotubes to the field of inorganic chemistry, where numerous examples for its validity have been documented in recent years. Templated growth of nanotubes from isotropic (3-D) compounds such as metal oxides and chalcogenides was reported as well, but these nanotubes are generally not perfectly crystalline. Various issues in the structure, synthesis, and properties of such inorganic nanotubular and fullerene-like structures are reviewed, together with some possible applications.

## CARBON FULLERENES AND NANOTUBES

When the first generation of high-resolution transmission electron microscopes (TEM) became available during the late 1960s, nanoparticles of fired soot with unique character were revealed. These multilayer polyhedra (“onions”) were essentially closed graphitic sheets with an empty core, which were thought to consist of pieces of small graphitic platelets “stitched” together by an unknown “glue.” In 1980, Iijima proposed that such structures were in fact made of graphitic sheets “glued” together by pentagonal rings. He suggested that according to the Euler rule each polyhedron in the onion consists of 12 carbon pentagons and a large number of hexagons. Each pentagon forces the flat hexagonal network of graphitic sheets to distort from the planar structure, and disposing such 12 pentagons leads to closure of the entire plane into a hollow caged structure.

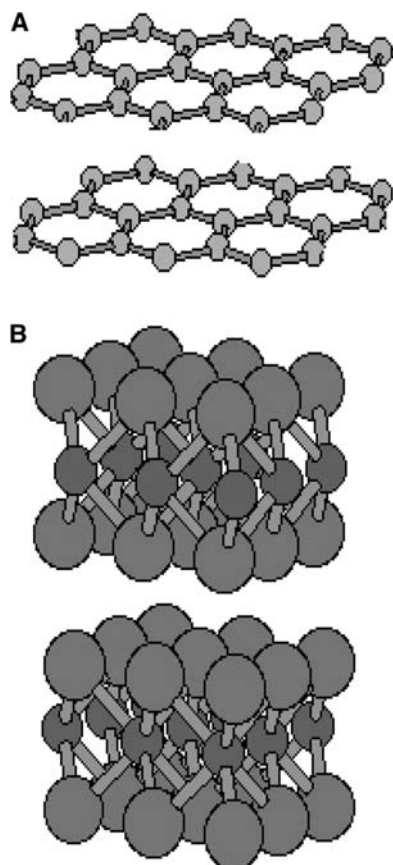

The stunning discovery of the  $C_{60}$  molecule by Kroto, Smalley, and Curl<sup>[1]</sup> led to a new era in the science of nanomaterials. This molecule was shown to consist of 20 hexagons and 12 symmetrically disposed pentagons. Following this discovery, many other fullerenes and related forms of carbon were identified,

in particular multiwall and single-wall nanotubes, discovered by Iijima.<sup>[2]</sup> Carbon nanotubes are made of rolled graphene sheets capped with half a fullerene molecule of the same diameter at each of the two ends. Therefore, these structures can be viewed as an elongated form of a fullerene. Both fullerenes and nanotubes are seamless structures having threefold bonded carbon atoms only. The absence of dangling bonds renders these structures energetically very stable. Nonetheless, the deviation from planarity induces a non-negligible amount of stress into the fullerenes, which explains many of their chemical and physical properties.

## CAN THE PARADIGM OF FULLERENES AND NANOTUBES BE EXTENDED BEYOND CARBON?

The driving force for the formation of carbon fullerenes and nanotubes stems from the abundant reactive atoms on the periphery of the quasi 2-D graphitic nanostructure. These rim atoms are only twofold bonded rather than being threefold ( $sp^2$ ) bonded as in the bulk (Fig. 1). It was concluded, therefore, that in spite of the elastic strain of the folded nanoparticles, the planar topology of graphitic nanoparticles is unstable with respect to folding into the seamless fullerenes. Using similar reasoning, it has been proposed<sup>[3,4]</sup> that the formation of fullerenes is not unique to carbon and in fact is a genuine property of 2-D (layered) compounds. Inorganic layered compounds are abundant, in particular among the transition-metal chalcogenides (sulfides, selenides, and tellurides), halides (chlorides, bromides, and iodides), oxides, and numerous ternary (quaternary) compounds. However, in contrast to graphite, each molecular sheet consists of multiple layers of different atoms chemically bonded to each other.

If one considers  $MoS_2$  as an example (Fig. 1), each molecular sheet is made of a layer of molybdenum atoms sandwiched between two outer sulfur layers. The Mo atoms are sixfold bonded to sulfur atoms, forming a trigonal bipyramid. In analogy to graphite, the S–Mo–S layers are stacked together through weak van der Waals forces. Like graphite, such compounds

**Fig. 1** Schematic drawings of graphite (A) and MoS<sub>2</sub> (B) nanoclusters. Note that in both cases, the surface energy, which destabilizes the planar topology of the nanocluster, is concentrated in the rim atoms, which are situated on the prismatic edges parallel to the *c*-axis.

are highly anisotropic with respect to many of their physical and chemical properties. The (00.1) surfaces (van der Waals surfaces) of the crystal, which are perpendicular to the *c*-axis, consist of threefold bonded sulfur atoms, which are chemically not reactive. In contrast to the fully bonded bulk atoms, the sulfur and molybdenum atoms on the rim of the nanocluster, i.e., on the prismatic (10.0) faces (parallel to the *c*-axis), are not fully bonded and are therefore chemically very reactive. Indeed, each molybdenum atom in the (10.0) prismatic edge is bonded to only two sulfur atoms of the upper plane and two sulfur atoms of the lower plane. Therefore, each Mo atom has two dangling bonds per atom on the (10.0) face and is consequently chemically reactive. On the opposite face ( $-10.0$ ) of the MoS<sub>2</sub> nanosheet, sulfur atoms are only twofold bonded and they possess one dangling bond per atom. Therefore, the Mo atoms of the (10.0) face would tend to recombine with the S atoms of the opposite side of the platelet. Because the ratio between peripheral (partially bonded) and bulk (fully bonded) molybdenum (sulfur) atoms increases with shrinking size of the

platelet (sheet), nanoparticles of MoS<sub>2</sub> are not stable in the planar form and they fold into closed-cage nanostructures. This hypothesis has been invariably confirmed by both experiment and theory. Extensive experimental data available now tend to substantiate this initially intuitive hypothesis and show that this new curved and hollow phase of layered compounds, designated as inorganic fullerene-like (IF) material, is the thermodynamically stable form, given the constraint that the particles cannot grow beyond, say 0.2  $\mu\text{m}$ . Initially, however, energy must be provided to overcome the activation barrier ensuing from the elastic energy of bending of the otherwise planar sheet. In most cases, heating (thermal energy) was provided for this purpose, but other energy sources, such as irradiation, microwave, sonochemical, and electrical energy were found to activate the nanoparticles' folding process.

Fig. 2 shows a TEM image of typical MoS<sub>2</sub> hollow nanoparticles (onions) consisting of more than 10 molecular MoS<sub>2</sub> layers arranged in a concentric seam-less form. A few kilograms of nested (fullerene-like)

**Fig. 2** TEM image of typical MoS<sub>2</sub> nanoparticles with fullerene-like structure. Each dark line represents an atomic layer of the basal plane (00.1). The distance between each two layers is 6.18  $\text{\AA}$ . The *c*-axis is always normal to the surface of the nested fullerene-like structure.

WS<sub>2</sub> structures were synthesized by the Weizmann Institute laboratory over the last year and efforts to scale up this production are well under way. Fig. 3 shows typical TEM images of multiwall WS<sub>2</sub> nanotubes. Nanotubes of this kind are currently produced by the grams, albeit not as a pure phase, yet.

Theoretical considerations show that the bending energy of isotropic (3-D) materials such as silicon or TiO<sub>2</sub> is exceedingly higher than that of 2-D compounds. This energy cannot be fully compensated for by remediation of the dangling bonds,<sup>[5]</sup> which makes their folding into crystalline nanotubes unlikely. Furthermore, for such nanostructures to become stable, their surface must be passivated, or else they will react with the surrounding and form new entities with a different chemical composition. Therefore, isotropic (3-D) materials are not likely to form stable IF nanostructures. Recently, however, nanotubes of various 3-D (quasi-isotropic) compounds such as GaN with highly faceted (hexagonal) cross-section were reported. Synthesis of semicrystalline nanotubes from such isotropic compounds has been devised, mostly through templated growth (see, e.g. Ref.<sup>[6]</sup>). In spite of this fact, or perhaps because their surface atoms are not fully bonded, semicrystalline nanotubes can be very useful. Their large surface area, combined with their nanometer-scale pore sizes and reactive chemical moieties, may lead to the development of highly reactive and selective catalysts, sensors, and a host of other applications.

**Fig. 3** TEM micrographs of three very long WS<sub>2</sub> nanotubes.

Therefore, from the chemical perspective a question of great importance concerns the borderline between those materials that can form fully crystalline, IF nanostructures and isotropic materials that cannot afford fully crystalline, evenly folded nanostructures, or can result only in semicrystalline nanotubes. Stated differently, it is possible to ask whether IF structures are generic to all 2-D layered compounds, a group of a few thousands materials, or else only to a subset of this large canon. One way to address this issue is to try to synthesize IF nanostructures from layered compounds of completely different chemical nature. For instance, by synthesizing NiCl<sub>2</sub> nanotubes<sup>[7]</sup> it became apparent that even 2-D compounds of highly ionic character, which are very hygroscopic and are quite unstable in the ambient, are able to form stable IF nanostructures. Incidentally, the kinetics of water uptake by the seamless IF NiCl<sub>2</sub> nanostructures is appreciably slower than the water uptake by nanoplatelets of the same compound, making the former much less hygroscopic and amenable to detection by electron microscopy.

## SYNTHESIS OF INORGANIC NANOTUBES

To produce pure IF phases, and nanotubes in particular, it is imperative to prevent the nanocrystallites from growing beyond a certain size during the process (arrested growth). Numerous methods have been devised for this purpose. A few grams of IF WS<sub>2</sub> were initially synthesized from the respective oxide phase.<sup>[8]</sup> However, lately a few kilograms of this phase were synthesized using the fluidized bed reactor.<sup>[9]</sup> In the first step of this reaction, which lasts about a second, heated WO<sub>3</sub> nanoparticles react with H<sub>2</sub>S gas at 840°C and are sulfidized at the surface. This fast reaction produces one closed layer of WS<sub>2</sub>, enfolding the entire WO<sub>3</sub> nanoparticle. The sulfide-encapsulated oxide nanoparticles become surface passivated and they cannot grow further in size. Once this protective layer has been completed, a slow diffusion-controlled process leads to the conversion of the oxide core into a metal disulfide in a highly uniform and regular fashion. Notably, although the inward diffusion of the (H<sub>2</sub>S) gas is isotropic, the growth of the WS<sub>2</sub> layers occurs along one growth front only, which explains the almost perfect crystallinity of the IF nanoparticles.

In early reports, only minor amounts of WS<sub>2</sub>,<sup>[3]</sup> MoS<sub>2</sub>,<sup>[10]</sup> and BN<sup>[11]</sup> nanotubes could be produced. However, recently, different strategies were successfully developed for the synthesis of various nanotubes. Thus, using the same fluidized bed reactor that is used for the synthesis of fullerene-like WS<sub>2</sub> nanoparticles, under slightly modified operating conditions, a few grams of very long and slender WS<sub>2</sub> nanotubes are being synthesized.<sup>[12]</sup> In another study, a two-step

growth process, in which an oxide nanowhisker phase is first obtained and is subsequently converted into WS<sub>2</sub> nanotubes phase in H<sub>2</sub>S atmosphere, was demonstrated.<sup>[13]</sup> Uniform WS<sub>2</sub> nanotubes were obtained also by the chemical vapor transport (CVT) technique,<sup>[14]</sup> in which the WS<sub>2</sub> powder is transported from the hot to the cold zones of a quartz ampoule using a transporting agent, such as iodine. Extremely uniform and very long single-wall MoS<sub>2</sub> nanotubes with diameter of less than 1 nm were synthesized.<sup>[15]</sup> These nanotubes all come in the armchair (3,3) configuration. Their perfectness can be also gauged by the fact that they self-assemble into a hierarchy of higher-order structures, from the single-nanotube level to macroscopic crystallites. Interestingly, these nanotubes were obtained via a CVT process using C<sub>60</sub> as a catalyst. Nanotubes of the disulfides (and some diselenides) of the transition metals W, Mo, Nb, Ta, Zr, Hf, and Ti were synthesized by high-temperature annealing of the respective metal trisulfides (see, e.g., Ref.<sup>[16]</sup>). This effort was recently summarized in a comprehensive review entry.<sup>[17]</sup> Double-wall boron nitride (BN) nanotubes of high uniformity were produced via the arc-discharge method.<sup>[18]</sup> V<sub>2</sub>O<sub>5</sub> nanotubes were synthesized using organic amines as templating molecules in a sol-gel process followed by hydrothermal treatment.<sup>[19]</sup> Whereas some of the nanotubes are open-ended and have scroll-like shape, others were made of concentric layers and with a closed tip. The inorganic-organic superstructure, obtained from the rather ionic oxide and the aliphatic amine, leads to softening of the layers making them more amenable to folding. The use of “chimie douce” processes for the preparation of new kinds of nanotubes from a number of oxide compounds has recently gained appreciable attention. Thus, scroll-like nanotubules have been obtained from potassium hexaniobate, K<sub>4</sub>Nb<sub>6</sub>O<sub>17</sub>, by acid exchange and careful exfoliation in basic solution.<sup>[20]</sup> The exfoliation process results in monomolecular layers, which are unstable against folding even at room temperature, and consequently form the more stable scroll-like structures. Moreover, although the binary oxides of these transition metals do not possess the lamellar structure, and consequently they cannot form crystalline nanotubular structures, the reduced oxides of these phases can. A typical example belonging to this category is the compound H<sub>2</sub>Ti<sub>3</sub>O<sub>7</sub>, which is a member of the class of lamellar H<sub>2</sub>Ti<sub>n</sub>O<sub>2n+1</sub> phases. This nanotubular phase was prepared by the usual sol-gel process and subsequent treatment with a concentrated NaOH solution at 130°C.<sup>[21]</sup> Numerous other strategies were employed for the synthesis of these and other inorganic nanotubes in recent years. These works demonstrate the richness of the chemical apparatus in the context of inorganic nanotubes and fullerene-like nanostructures.

Hydrothermal synthesis has recently been used extensively for the synthesis of various nanotubes. Thus, bismuth nanotubes were obtained by hydrothermal treatment of a basic bismuth nitrate solution and hydrazine at 120°C.<sup>[22]</sup> Tellurium nanotubes were obtained by hydrothermal reduction of Na<sub>2</sub>TeO<sub>3</sub> in ammonia solution at 180°C.<sup>[23]</sup> The chiral motif of the nanotubes can be attributed to the spiral structure of the trigonal unit cell of tellurium. InS nanotubes were obtained by refluxing *tert*-butyl indium with H<sub>2</sub>S gas at 203°C.<sup>[24]</sup> Interestingly, the layered form of this compound was not known before. Obviously, therefore, the seamless nanotubular structure endows extra kinetic stability to the lamellar phase. Numerous other nanotubular and fullerene-like structures have been reported in the literature over the last few years.

### STRUCTURE OF INORGANIC FULLERENE-LIKE NANOPARTICLES

C<sub>60</sub> is made of hexagons and pentagons only, exhibiting icosahedral symmetry. Neither graphite nor MoS<sub>2</sub> have pentagonal elements within their native structure. However, the trigonal network of MoS<sub>2</sub> possesses triangles and rectangles (rhombi) as genuine elements of lower symmetry. It was therefore proposed<sup>[4]</sup> and later on experimentally verified<sup>[25]</sup> that MoS<sub>2</sub> octahedra (bucky octahedra) made of six symmetrically disposed rectangular (rhombohedral) corners can be obtained. Similarly, in one case a MoS<sub>2</sub> “bucky tetrahedron,” made of symmetrically disposed four triangles in its corners, was observed. These structures are likely to be the most stable form of IF MoS<sub>2</sub> nanoparticles, i.e., the analog of C<sub>60</sub> in MoS<sub>2</sub>. Presently, the synthesis of bucky octahedra from MoS<sub>2</sub> and other compounds remains a most challenging task. Recently, rather small IF MoS<sub>2</sub> nanoparticles have been prepared by discharging graphite and MoS<sub>2</sub> electrodes embedded in deionized water.<sup>[26]</sup> Most of the nanoparticles were found to have rectangular (rhombi)-shaped corners, alluding to the great stability of such nanoparticles.

Boron nitride nanotubes and fullerene-like nanoparticles were among the early noncarbon systems to be studied. Boron is situated to the left of carbon in the periodic table while nitrogen is to its right. In analogy to carbon, BN exists in two main phases: hexagonal (graphitelike) and cubic (diamond-like). Moreover, the stable form of BN at room temperature is the graphitic (hexagonal) polytype. Therefore, nanoparticles of this phase are expected to be unstable in the planar form and afford a fullerene-like structure. Because B–B or N–N pairs are not favorable nearest neighbors, pentagonal rings cannot form. Instead, the folding can be obtained by introducing six squares into the hexagonal network. The smallest stable fullerene-like structure

was calculated to be the  $B_{12}N_{12}$  octaheder,<sup>[27]</sup> consisting of six hexagonal rings and six squares. Indeed, BN nanooctahedra with symmetrically disposed six squares<sup>[28]</sup> and nanotubes with flat tops having three squares<sup>[29]</sup> were indeed synthesized by various methods.

Using an elastic continuum model, the topology of  $WS_2$  ( $MoS_2$ ) cage structures was studied.<sup>[5]</sup> A first-order phase transition from an evenly curved (quasi-spherical) structure into a polyhedral cage was predicted for nanoparticles with shell thickness larger than about 1/10. The same model foresaw a similar transition for nanoparticles two layers thick and with radius of curvature smaller than 10 nm. A transition of this kind was observed during the synthesis of IF  $WS_2$  particles from 50-nm  $WO_3$  nanoparticles.<sup>[8]</sup> The conversion of  $WO_3$  nanoparticles to IF  $WS_2$  proceeds from the surface of the nanoparticles inward.<sup>[8]</sup> When the number of  $WS_2$  layers is three or less, the nanoparticles appear to be evenly folded and therefore have quasi-spherical shape. However, when the conversion process continues and the thickness of the sulfide shell in the nanoparticles exceeds a few nanometers, i.e., four layers and more, the nanoparticles are transformed into a faceted structure. Further agreement with the above model was obtained in a number of other experimental studies. Fullerene-like  $MoS_2$  nanoparticles 3–4 nm in diameter and two to three layers thick, prepared by laser ablation, were found to adopt a highly faceted octahedral shape.<sup>[25]</sup> Moreover, in accordance with this theory,  $NbS_2$  nanoparticles, which have larger Young's modulus than their  $WS_2$  counterparts, are found to be appreciably more faceted.<sup>[7]</sup> In contrast to the caged fullerene-like nanoparticles,  $WS_2$  nanotubes with 20-nm diameters are rarely faceted. Obviously, the elastic strain involved in folding along one axis (nanotubes) is appreciably smaller than that of nanoparticles folded along two axes (fullerene-like nanoparticles). This idea is further vindicated by comparing the stability of phosphorous nanotubes and fullerene-like structures as predicted from ab initio density functional theory tight-binding calculations. While the 1-D nanostructures are found to be perfectly stable,<sup>[30]</sup> the phosphorous fullerenes are unstable and they decompose into  $P_4$  clusters.<sup>[31]</sup>

The ionic character of layered metal chlorides, such as  $NiCl_2$  or  $CdCl_2$ , is appreciably higher than that of the layered metal dichalcogenides. Consequently, the bending modulus of the former compounds is about twice as large as that of the latter compounds. Furthermore, the free slippage of the molecular layers on top of each other is crucial in maintaining low elastic strain during folding of the nanoparticles. However, the shearing energy in the ionic  $NiCl_2$  is sixfold larger than for  $MoS_2$ .<sup>[32]</sup> Not surprisingly therefore, whereas one-layer-thick fullerene-like nanoparticles of metal dihalides afford either quasi-spherical or faceted

polyhedral structure,<sup>[7,32,33]</sup> three-layer-thick polyhedra are invariably highly faceted. The most common motif for fullerene-like nanoparticles of this family is a hexagonal polyhedron. On the other hand,  $NiCl_2$  nanotubes are generally cylindrical.<sup>[7,32]</sup>

The topology of polyhedra made of one layer has been investigated virtually for hundreds of years. Contrarily, the mathematics of polyhedra made of a number of interconnected layers with fixed lattice points in each layer, which is commonplace in IF structures, has been barely studied. This challenging issue is clearly demonstrated in the case of IF  $CdCl_2$ , where only partial information regarding the structure of the hexagonally shaped polyhedron is available. Furthermore, realistic models of IF structures, like  $MoS_2$  octahedra consisting of some 1800 atoms, require highly developed ab initio calculations, which makes this task presently quite intractable. Some progress in this direction was discussed in Ref.<sup>[34]</sup> Future developments in handling these mammoth calculations is likely to have tremendous impact on our ability to decipher the structural details and the physical properties of IF structures. In conclusion, the synthesis and elucidation of the structure of IF nanoparticles remains a most challenging task for years to come.

## PROPERTIES

Early theoretical work was concerned with BN,  $BC_2N$ , and  $BC_3$  nanotubes.<sup>[35]</sup> More recently, nanotubes of other compounds, such as phosphorous,<sup>[30]</sup>  $GaSe$ ,<sup>[36]</sup>  $WS_2$ ,<sup>[37]</sup>  $MoS_2$ ,<sup>[34]</sup> and others, were studied. It follows that nanotubes of semiconducting compounds remain so also after folding. However, the bandgap was found to shrink with decreasing diameter of the nanotubes. Therefore, the bandgap of semiconducting nanotubes can be tuned all the way from the UV spectrum (ca. 3 eV) down to the infrared (ca. 0.2 eV) by varying the diameter of the nanotubes. This behavior stands in sharp contrast with the generic behavior of semiconductor quantum dots, where the bandgap expands with decreasing diameter of the nanoparticles because of the quantum size effect.

This opposite shift was experimentally confirmed by measuring the absorption spectrum of IF  $MoS_2$  and IF  $WS_2$  of different sizes and numbers of shells.<sup>[38]</sup> More recently, however,  $I$ - $V$  curves for single  $WS_2$  nanotube was recorded using scanning tunneling microscopy, and consequently the bandgap of the nanotubes could be determined.<sup>[39]</sup> Fig. 4 shows variation of the normalized bandgap as a function of the nanotube diameter as determined in this study. As expected, shrinkage of the energy gap with the nanotube diameter was observed. This observation was confirmed

**Fig. 4** Comparison between theoretically calculated and STM measured normalized bandgap ( $g/g_0$ ) of  $WS_2$  nanotubes with varying diameters.  $g_0$  is the energy gap of the bulk materials (1.2 eV). Notwithstanding the scattering in the experimental data, the dependence of the bandgap on the nanotube diameter is clearly demonstrated. *Source:* From Ref.<sup>[33]</sup>.

by first-principle theoretical calculations.<sup>[39]</sup> The same theory shows<sup>[34,37]</sup> that armchair nanotubes possess an indirect bandgap for the lowest electronic transition, whereas zigzag nanotubes exhibit a direct transition. This surprising observation suggests that zigzag  $WS_2$  ( $MoS_2$ ) nanotubes could show strong optical absorption and luminescence, or even stimulated emission (laser action). First-principle theory also shows that independent of their diameter and chirality,  $NbS_2$  nanotubes are metallic,<sup>[40]</sup> which suggests that they will be very good field emitters. Indeed, the superconducting behavior of  $NbS_2$  and  $NbSe_2$  nanotubes was recently confirmed.<sup>[17,41]</sup>

## APPLICATIONS

2H- $MoS_2$  (2H- $WS_2$ ) are used as additives to heavy-duty tribological fluids, as tribological coatings, or as lubricating powders in ultra-high-vacuum instrumentation. The spherical shape of the fullerene-like  $WS_2$  nanoparticles and their inert sulfur-terminated surfaces offer enhanced tribological behavior for solid lubricant nanoparticles of this kind. The usefulness of IF powder as a superior solid lubricant has been worked out through a long series of experiments in the laboratory of Rapoport.<sup>[42]</sup> Further experiments show that IF  $WS_2$  and IF  $MoS_2$  powders exhibit superior tribological applications in different modalities,<sup>[43,44]</sup> suggesting almost countless number of possible applications. Fig. 5 shows the results of a

tribological test in which bronze-graphite partly prepared by powder metallurgy and impregnated with 5% IF  $WS_2$  outperforms the non-impregnated part. This work has stimulated substantial commercial interest recently.

Recently, substantial interest has been paid to metal and hydrogen intercalation in inorganic nanotubes of various kinds. Thus, Li intercalation and deintercalation in  $V_2O_5$  and  $Mn_xV_2O_{5+x}$  nanotubes were studied. Potassium and sodium intercalation in  $MoS_2$  ( $WS_2$ ) fullerene-like nanoparticles was also investigated. Reversible hydrogen<sup>[45]</sup> and lithium<sup>[46]</sup> intercalation in  $MoS_2$  nanotubes was demonstrated. The charge/discharge cycles were found to be reversible and relatively facile, which can be attributed to the high surface area and the open tips of the nanotubes. The reversibility of these systems can be attributed to the perfect crystallinity of the nanotubes, allowing one to accomplish numerous charge/discharge cycles of the rechargeable electrode without losing its loading capacity. Catalytic conversion of  $CO+H_2$  into methane and water using  $MoS_2$  nanotubes as catalyst was recently demonstrated.<sup>[47]</sup> The mechanism of the catalytic action of the nanotubes is quite a puzzle, because the fully bonded sulfur atoms in the van der Waals surfaces and in the galleries between the  $MoS_2$  layers (van der Waals gap) of the nanotubes are not expected to be chemically very reactive. This surprising result is nevertheless promising to incite a new research effort into the catalytic properties of inorganic nanotubes.

**Fig. 5** Friction coefficient as a function of load (in newtons) for a heavy-duty grease. 2H is the curve for a grease mixed with 2H-MoS<sub>2</sub> platelets, while IF is the curve for the same grease mixed with 5% fullerene-like WS<sub>2</sub> nanoparticles.

## CONCLUSION

The advent of nanotubes and fullerene-like particles from inorganic layered compounds has opened new avenues in the solid-state chemistry of inorganic compounds and new opportunities for application of such nanostructures in the emerging field of nanotechnology as well as in numerous other areas. Fundamental questions remain to be solved to permit a more judicious approach to the synthesis and study of the properties of these new nanophase materials. The elucidation of the detailed structure of IF nanoparticles, which is a most demanding and important issue in this field, is progressing by combining theory and experiment.

## ACKNOWLEDGMENTS

I am grateful to Dr. Y. Feldman, Dr. A. Zak, A. Margolin, Dr. R. Rosentsveig, Dr. Y. Rosenfeld Hacothen, and Dr. R. Popovitz-Biro, all from the Weizmann Institute of Science; Prof. L. Rapoport (Holon Academic Institute of Technology); and Prof. G. Seifert (TU Dresden). Support of the Israeli Ministry of Science (Tashtiot), Israeli Academy of Sciences (First), the Israel Science Foundation, and Minerva Foundation (Munich) are greatly acknowledged.

# Inorganic Nanotubes: Synthesis by Chemical Transport Reaction

Maja Remskar

Jozef Stefan Institute, Ljubljana, Slovenia

## INTRODUCTION

Nanotubes of transition metal dichalcogenides have raised much scientific attention since the first report on the synthesis and structure of MoS<sub>2</sub> and WS<sub>2</sub> nanotubes in 1992.<sup>[1]</sup> The two most efficient methods producing tenths of grams of nanotubes consist in annealing the oxidized transition metal films or particles in a stream of H<sub>2</sub>S gas<sup>[2]</sup> or in thermal decomposition of (NH<sub>4</sub>)<sub>2</sub>MoS<sub>4</sub> or MoS<sub>3</sub> in hydrogen.<sup>[3]</sup> Other growth techniques with lower efficiencies make use of electron beam irradiation in transmission electron microscope<sup>[4]</sup> and in scanning tunneling microscope,<sup>[5]</sup> sonoelectrochemical bath reaction,<sup>[6]</sup> and electrochemical deposition from ethylene glycol solution.<sup>[7]</sup>

The nanotubes of other transition metal dichalcogenides (NbS<sub>2</sub>, TaS<sub>2</sub>) have been recently synthesized. The reduction of NbS<sub>3</sub> and TaS<sub>3</sub> powder in a stream of H<sub>2</sub> at 1000°C for 30–60 min led to the growth of thick-walled NbS<sub>2</sub> and TaS<sub>2</sub> nanotubes with inside diameters ranging from 4 to 15 nm.<sup>[8]</sup> The silver alloyed NbS<sub>2</sub> nanotubes have been grown by partial decomposition of the Ag-(NbS<sub>4</sub>)<sub>x</sub>I ( $x \approx 4$ ) precursor crystals using electron beam irradiation or microwave irradiation. They represent the first case of nanotubes grown by self-assembly of nanocrystallites.<sup>[9]</sup>

The MoS<sub>2</sub> and WS<sub>2</sub> nanotubes were also synthesized by the chemical transport reaction, which is the standard method for the growth of transition metal dichalcogenide-layered crystals.<sup>[10]</sup> In the present report, the overview of growth mechanisms, their structural properties, and self-assembly at different range scales are presented. Besides pure MoS<sub>2</sub> and WS<sub>2</sub> nanotubes, the alloyed nanotubes with silver and gold are shown, evidencing the geometrical stabilization of new compounds, which are not known in the usual plane geometry. The subnanometer-diameter MoS<sub>2-x</sub> nanotubes, which self-organize to the first case of molecular crystals composed of inorganic nanotubes, represent the extreme case of inorganic nanotubes. Because of their metallic

conductivity, we can rank them to the promising family of molecular wires.

## THE MoS<sub>2</sub> AND WS<sub>2</sub> MULTIWALL NANOTUBES

The chemical transport method enables growth of inorganic nanotubes with very slow rate from the vapor phase. The transport agent, iodine in our case, reacts with the transition metal at high temperature, forming the volatile product that decomposes at lower temperature, where transition metal reacts again with sulfur to solid transition metal disulfide. The silica ampoules containing MoS<sub>2</sub> or WS<sub>2</sub> powder and iodine in amount of 5 mg/cm<sup>3</sup> were evacuated and sealed at a pressure of 10<sup>-5</sup> Pa. The transport reaction using iodine as a transport agent ran at 1060 K with a temperature gradient of 5.6 K/cm in two-zone furnace. After 3 weeks of growth, the silica ampoules were slowly cooled to room temperature with a controlled cooling rate of 15°C/hr. Approximately a few percent of the starting material was transported by the reaction to form nanotubes, while the rest of the transported material grows as strongly undulated thin plate-like crystals. The lasting nearly equilibrium growth conditions enable the synthesis of nanotubes of different diameters, length, and wall thickness, but with extremely low density of structural defects. They grow up to several millimeters in length. The diameters in multiwall nanotubes range from several micrometers to less than 10 nm. While microtubes usually grow as single tubes, the nanotubes frequently combine ropes formed by self-assembly and syntactic coalescence of primary nanotubes (Fig. 1).

## Crystal Structure of MoS<sub>2</sub> and WS<sub>2</sub> Plate-Like Crystals

MoS<sub>2</sub> and WS<sub>2</sub> compounds belong to Group VI family of transition metal dichalcogenides.<sup>[11]</sup> They are

**Fig. 1** (A) The high-resolution electron micrograph of a  $\text{MoS}_2$  nanotube, 15 nm in diameter, reveals the tube walls built of seven molecular layers. The distance between the layers is expanded by 3% with respect to the corresponding parameter of the plate-like crystal. (B) A  $\text{WS}_2$  single nanotube, 12 nm in diameter, and ropes grown in coaxial or side-by-side type of self-assembly.

extremely unisotropic solids with layer-type structure. The interaction holding the layers is in great part of van der Waals (VdW) type. The molecular layer S–Mo–S or S–W–S shows a trigonal symmetry. The transition metal atom is coordinated by six sulfur atoms situated at corners of a trigonal prism.

**Fig. 2** Two possible stacking of adjacent  $\text{MoS}_2$  and  $\text{WS}_2$  molecular layers: (A) three-dimensional model of the stable 2Hb stacking; (B and C) the  $[11\bar{2}0]$  sections of 2H and 3R stacking, respectively.

**Fig. 3** Electron diffraction pattern of  $\text{MoS}_2$  nanotube as a superposition of electron scattered by both nanotube walls revealing the chiral growth mode.

The molecular layers can be stacked in two ways (Fig. 2), as a hexagonal polytype 2Hb with two molecular layers (P63/mmc) and as rhombohedral polytype 3R with three molecular layers per unit cell (R3m). Filled  $d_{z^2}$  orbitals promoting to the space between the molecular layers prevent a stacking of molecular layers in such a manner that the positions of transition metal atoms would be one above the other perpendicular to the layers.

$\text{MoS}_2$  and  $\text{WS}_2$  plate-like crystals usually grow in the hexagonal 2H polytype, while the rhombohedral 3R polytype is metastable at room conditions. It was found that the 3R polytype of  $\text{MoS}_2$  is stable—it grows above  $1000^\circ\text{C}$  and at high pressures (40 kbar), but it transforms back to the 2H polytype when the pressure is decreased.<sup>[11]</sup> Lattice parameters of 3R polytypes, with respect to the 2H polytype, are slightly larger in basal plane (1% for  $\text{MoS}_2$  and 2% for  $\text{WS}_2$ ), while perpendicular to the layers, the c-parameters are shortened for  $\approx 0.2\%$  in both compounds<sup>[11]</sup> (Fig. 3).

### Nucleation and Lattice Structure of $\text{MoS}_2$ and $\text{WS}_2$ Microtubes and Nanotubes

The  $\text{MoS}_2$  and  $\text{WS}_2$  tubes grow by helical winding of molecular layers with the basal plane perpendicular

**Table 1** Unit cell parameters of  $\text{MoS}_2$  and  $\text{WS}_2$  plate-like crystals

Unit cell	2Hb- $\text{MoS}_2$	3R- $\text{MoS}_2$	2Hb- $\text{WS}_2$	3R- $\text{WS}_2$
a [nm]	0.316	0.3164	0.3154	0.3162
c [nm]	1.229	1.839	1.2362	1.85

Source: From Ref.<sup>[11]</sup>.

to the tube cross section. They typically exhibit the relative ratio of expansion of the distance between molecular layers of 1–3% with respect to plate-like crystals (Table 1). Nonalloyed tubes are always found in the helical forms.<sup>[10,12–14]</sup> They grow by a single molecular layer, which continuously winds around the tube. Projection of a tube axis onto the basal [0001] plane of the wall is rotated with respect to the  $\langle 10\bar{1}0 \rangle$  lattice directions for an angle of chirality  $\alpha$ .

Two growth mechanisms have been observed.<sup>[10]</sup> Thin folded flakes can directly roll up and adopt the cylindrical shape. The folds of strongly undulated layered crystals at a microlevel size can also serve as an origin of turbulent gas flow of transported molecules, which promotes a tube-like growth mode. Instability of weakly bonded molecular layers at plate-like crystal edges and at surface growth steps against bending causes the growth of very narrow nanotubes (Fig. 4). The nanotube nucleation stops the growth of the crystal flake in the basal plane.

**Fig. 4** (A) The nucleation of the nanotube at the layered-crystal edge. The area of extrication of the multiwall nanotube, 78 nm in diameter, from the nucleation envelope is marked by arrow. (B) The bonds between the top tube layers and the envelope are broken deeply to the inside of the nucleation channel. The envelope wall is composed of seven molecular layers.

**Fig. 5** The  $\text{WS}_2$  nanorope composed of two mutually rolled-up nanotubes with diameters of 15 nm and a spiral period of 110 nm. The pair of nanotubes nucleated at the inner surface step of the nanotube, 1.2  $\mu\text{m}$  in diameter.

The nanotube extricates from the nucleation envelope at the crystal edge and continues to grow. The area of extrication of the multiwall nanotube, 78 nm in diameter, from the nucleation envelope is marked by arrow. The bonds between the top tube layers and the envelope are deeply broken to the inside of the nucleation channel. The envelope wall is composed of seven molecular layers.<sup>[15]</sup>

Several tubes can nucleate by such a way at the same crystal edge, where they combine and continue in growth like a rope. The nanotube in a rope still grows in longitudinal direction, up to a few millimeters in length, while its radius is limited by cogrown nanotubes. The second kind of the nanotube nucleation sites are the helical extremities of external and inner spirally rolled-up molecular layer building the already growing tube.<sup>[14]</sup> They are subject of bending like surface steps or edges of flat crystals. The nanotubes in so created ropes are usually rolled around or inside the central tube. They present a special case of growth by syntactic coalescence, where the wound tubes follow the crystal structure of the supporting tube. In a case where several nanotubes nucleate at the same inner extremity, they are mutually rolled up (Fig. 5).<sup>[13]</sup>

### Explanation of the Instability of Thin Crystal Flakes against Bending

The cause of the folding of thin crystal flakes or inner or outer helical extremities of supporting nanotubes is

ABCABCABCABCABCABCABCABC

**Fig. 6** Schematically presented transition between 3R (AbA BcB CaC) and 2Hb (AcA CaC) stacking shown in the [1120] section. *Source:* From Ref.<sup>[14]</sup>.

still not known. The atomic force microscopy of the top surface of a MoS<sub>2</sub> microtube revealed superstructures that are explained as nucleation stages of rhombohedral and hexagonal stacking.<sup>[16]</sup> The subsequent nucleation of both polytypes is associated by an appearance of grain boundaries. The mismatch between both polytypes results in creation of vacancies (Fig. 6).<sup>[14]</sup> Their non-symmetrical distribution at 3R–2Hb transitions induces shearing stresses along the basal planes. The bending with shrinkage/extension effects decreases the stress caused by lattice mismatch. The perpendicular component of the strain

**Fig. 7** The nucleation of nanotube in microfold of undulated layered crystal.<sup>[10]</sup> The arrow marks a perforation of crystal flake caused by preferential growth of nanotube with respect to the layered crystal.

tensor is caused by slightly different unit cell parameters of both polytypes (Table 1).

When the tube nucleates, the cylindrical growth mode is dominant with respect to the plate-like geometry. For example, the 3.3- $\mu\text{m}$ -diameter tube shown in Fig. 7 nucleated in microfold of thin, undulated layered crystal. At the point where the tube was in contact with the crystal flake (marked by arrow), the perforation of the flake appeared. The tube has obviously grown on account of already grown layered crystal. This kind of recrystallization contributes to the very rigid growth mode of nanotubes. When an obstacle in the form of a plate-like crystal is met during growth, the perforation of crystal flakes, as a result of recrystallization, enables the straightforward growth of the tubes.

### Stacking-Order Dependence on a Tube Diameter

It was found that the variety of polytypic stackings does not only influence the instability of thin crystal flakes against bending, but also controls the diameter of nanotubes and wall thickness. Both known polytypes (2H and 3R) simultaneously nucleate on the surface of a nanotube, but one of them prevails during the process of growth. Besides the strain caused by different stacking, an enlarged circumference and bending of molecular layers increase the elastic energy by extension and/or contraction of the layers. Considering the transition metal layer as a reference layer without deformations due to bending, the external sulfur layer of the corresponding molecular layer is stretched, whereas the internal sulfur layer, which is closer to the tube axis, is compressed. The sum of elastic energy per primitive cell caused by enlarged circumference and

**Fig. 8** Transmission electron diffraction patterns taken at the tube edge presenting the [010] zones of a tube.<sup>[16]</sup> (A) 3.5  $\mu\text{m}$  in diameter; the position of side spots of (101 $l$ ) type reveal the rhombohedral 3R stacking in accordance with the rule  $(-h + k + l = 3n)$ ; (B) 190 nm in diameter; the side spots (101 $l$ ) satisfy the rule  $l = \pm(2n + 1)$ .

by bending is relatively larger in nanotubes than in microtubes, where the elastic energy is distributed over a larger number of atoms.

Actually, we have found that the stacking between molecular layers composing the walls of nanotubes with diameters up to 200 nm is different than in those tubes with diameters above few micrometers (Fig. 8).<sup>[16]</sup> The selected area diffraction on the microtube wall revealing the rhombohedral (3R) stacking, otherwise stable at elevated pressure,<sup>[11]</sup> indirectly evidences the presence of the strain incorporated into the microtube wall. The intensity of incorporated strain increase toward the tube axis, causing the contraction of interlayer distance and an instability of inner molecular layers at place where the incorporated strain is relaxed with the creation of edge dislocations or stacking faults. In nanotubes with diameters below 200 nm, the strain is relaxed, stabilizing the hexagonal (2H) stacking.

### The Dependence of Nanotube Chirality on Interlayer Distances

The contraction of interlayer distances caused by internal strain incorporated in the tube wall influences the chirality of the nanotubes. Each winding of the molecular layer of thickness  $t$ , i.e., 0.6147 nm for MoS<sub>2</sub>,<sup>[11]</sup> enlarges the tube circumference for  $\pi t$ . Because this value is not an integer multiple of lattice parameter  $a$  in the basal plane (0.316 nm), the molecular layers have to be strained and/or helical, assuming that a regular crystal lattice is formed at least in narrow strips parallel with the nanotube axis. Increasing strain intensity toward the nanotube central hole

**Fig. 9** The WS<sub>2</sub> nanotube, 76 nm in diameter, terminated in geometry of a steep crater with a small truncated cone (insert) in the central part of the tube.

**Fig. 10** The tip-shape termination of the WS<sub>2</sub> nanotube associated with the change of the chirality.

causes the coexistence of several chiralities in the same nanotube. In thick-walled nanotubes, the incorporated strain causes the reduction of the interlayer distances, in some tubes even below the value typical for plate-like crystals. In such a case, the nanotubes are stopped in longitudinal growth with the typical crater-cone terminations. For example, a thick-walled nanotube, 76 nm in diameter, terminated in geometry of a steep crater with a small truncated cone in the central part of the tube (Fig. 9). The diameter of the inner hole is less than 2 nm. At the top of the truncated cone, the hole is widened because the intensity of incorporated strain is reduced as a result of the decreasing number of rolled-up molecular layers (insert).

The abrupt change of chirality in a role of the strain relaxation can change the geometry of nanotubes and stops the longitudinal growth. For example, the WS<sub>2</sub> nanotube, 20 nm in diameter, terminates in a sharp tip shape (Fig. 10). The surface steps show the increasing of the chiral angle along the direction toward the tip termination of the nanotube. The wall thickness is decreased by 50% near the area of the transition from the cylindrical to the tip shape and by an additional 30% at the conical-shaped termination. The thickness of a nanotube wall dictates its chirality and vice versa, i.e., the chirality influences the wall thickness.

### NANOTUBES ALLOYED WITH SILVER AND GOLD

Change of the nanotube crystal structure is typical also for MoS<sub>2</sub> and WS<sub>2</sub> nanotubes alloyed with gold and silver, which are found mainly non-helical.<sup>[17,18]</sup> MoS<sub>2</sub> and WS<sub>2</sub> plate-like crystals are inert materials and only few intercalated compounds are known, mainly with alkali metals.<sup>[19]</sup> Phases composed of MoS<sub>2</sub> or WS<sub>2</sub> and noble metals have not been reported up to now in usual plane geometry. On the contrary, MoS<sub>2</sub> and WS<sub>2</sub> microtubes and nanotubes have been successfully alloyed with silver and gold. The typical tubular structure stabilizes the compounds, which are not stable in the plate-like geometry. The noble metals in proportion of 0.5 at.% were added to sulfur, molybdenum,

or tungsten for the synthesis of the starting material before the transport reaction. The transport reaction ran for 22 days at 1060 K in an evacuated silica ampoule at a pressure of  $10^{-2}$  Pa and with a temperature gradient of 5.6 K/cm.

The walls of the  $\text{MoS}_2$  and  $\text{WS}_2$  nanotubes alloyed with gold and silver are composed of molecular layers grown in the form of coaxial cylinders. Two orientation relationships of the crystal lattice with respect to the tube axis are possible: The projection of the lattice can be parallel with the  $[11\bar{2}0]$  direction (A type) or with the  $[10\bar{1}0]$  direction (B type).

The coaxial growth mode of the type A is inferred from electron diffraction patterns of Au- $\text{WS}_2$  tube, 0.1  $\mu\text{m}$  in diameter (Fig. 11). The diffraction diagram is a superposition of two specific patterns belonging to  $[001]$  and  $[010]$  zones. Electrons are scattered (1) by both tube walls with the basal planes perpendicular to the electron beam— $[001]$  zone; and (2) by the tube longitudinal edge with the basal planes parallel with the beam— $[010]$  zone. The  $(10\bar{1}0)^*$  direction, perpendicular to the  $c^*$  direction, is parallel with the tube axis. The side spots  $(10\bar{1}l)$  satisfy the rule  $l = \pm(2n + 1)$  that corresponds to the 2Hb polytype.

Both types of non-chiral growth mode (A type and B type) can coexist in the same nanotube. The diffraction diagram measured with the Au- $\text{MoS}_2$  tube (Fig. 12) is a superposition of two hexagonal patterns belonging to the  $[001]$  zone rotated by  $30^\circ$  with respect to each other. The tube axis, perpendicular to the direction of the spot elongation, is aligned along the  $[11\bar{2}0]$  direction of one of both possible orientations (A type and B type).

**Fig. 11** The transmission electron diffraction patterns of electrons scattered by both walls of the Au- $\text{WS}_2$  tube with the  $[11\bar{2}0]$  direction parallel with the tube axis revealing the suppression of the chirality. Source: From Ref.<sup>[17]</sup>.

**Fig. 12** The transmission electron diffraction patterns of electrons scattered by both walls of the Au- $\text{MoS}_2$  tube as a superposition of two orientational variants with  $[11\bar{2}0]$  or  $10\bar{1}0$  direction parallel with the tube axis. Source: From Ref.<sup>[17]</sup>.

Two types of interlayer interstices exist in the 2Hb polytype, octahedral and tetrahedral ones. In the closed-packed stacking of spherical ions, the volume of octahedral and tetrahedral interstices is smaller than 0.02 and 0.005  $\text{nm}^3$ , respectively. Comparison between atomic or ionic radius of gold (0.146 nm, 0.137 nm) and

**Fig. 13** The crater-cone shape of typical extremity of the alloyed Au- $\text{WS}_2$  nanotube in the shape of a crater and a hollow truncated cone in the central part of the tube; double layer by double layer growth mode on the crater surface and layer by layer growth of the central cone of the tube (inset). The regular distribution of the circles reveals the abrupt termination in growth of double layers. Source: From Ref.<sup>[17]</sup>.

silver (0.144 nm, 0.126 nm) with the interstice sizes shows that the noble metal atoms can occupy octahedral sites only if no shear is present. Because of the size mismatch between the octahedral interstices and noble metal atoms or ions, the van der Waals gaps have to extend in any case.

The built-in noble metal species in the tube walls increase the interaction between molecular layers and cause a double layer by double layer growth mode. Consequently, the interlayer distances are expanded, causing the change in the tube morphology. The chirality is completely or partially suppressed. The tube walls are composed of molecular layers grown in the form of coaxial cylinders (Fig. 13).

The presence of chirality in non-alloyed tubes and its suppression in the MoS<sub>2</sub> and WS<sub>2</sub> nanotubes alloyed with gold and silver are geometrically explicable. A cross section of a chiral tube perpendicular to the tube axis shows a spiral shape with  $c_0$  spacing between adjacent turns of the spiral. The difference in length of adjacent turns of the spiral is the same as the difference in circumference of two adjacent coaxial cylinders, i.e.,  $2\pi c_0$ . The length of the curve between the spiral pole and the point of the  $n$ th turn ( $L_n$ ) of the spiral is in the approximation of large angles ( $\varphi = n2\pi$ ):  $L_n = [c_0/(2\pi)][n^2(2\pi)^2/2]$ , where  $c_0$  is the spacing between adjacent turns in the radial direction. The length of the  $n$ th turn, i.e.,  $c_0\pi(2n - 1)$ , differs by  $2\pi c_0$  from the length of the previous one. This difference has to be an integer multiple ( $N$ ) of the lattice parameter in a basal [0001] plane perpendicular to the tube axis. In tubes with the tube axis parallel to one [11 $\bar{2}$ 0] direction (A type), the difference in circumferences has to be an integer multiple of the parameter  $a$ , while in the tubes with the tube axis parallel to one [10 $\bar{1}$ 0] direction (B type), it has to be an

integer multiple of  $a\sqrt{3}/2$ . In chiral tubes, the tube axis is rotated with respect to the [10 $\bar{1}$ 0] direction for the chiral angle  $\alpha$ . The tube axis is close to one [10 $\bar{1}$ 0] direction (A\* type), if  $0^\circ < \alpha < 15^\circ$ , or to one [11 $\bar{2}$ 0] direction (B\* type) for  $\alpha > 15^\circ$ . Values of the multiple number  $N$  at different extensions of lattice parameter  $c_0$  are summarized in Table 2, assuming that the lattice parameters in the basal plane are not deformed, i.e.,  $a = 0.3154$  nm (WS<sub>2</sub>) and  $a = 0.316$  nm (MoS<sub>2</sub>).<sup>[11]</sup>

The 1–3% expansion ratios in non-alloyed tubes correspond to numbers  $N$  in the intervals 12.4–12.7 (A\* type) and 14.3–14.7 (B\* type). These values do not meet the requirement that  $N$  has to be an integer. The molecular layers in such a case cannot satisfy the stacking order with respect to the previous turn without a rotation with respect to the tube axis. This geometrical matching leads to the spiral growth mode. The chiral angle  $\alpha$  can be estimated from the simple geometrical equation:

$$\alpha = 30^\circ - \arccos\left(\frac{Na\sqrt{3}}{4\pi c_0}\right)$$

The typical values of the chiral angle  $7.1$ – $2.5^\circ$  ( $N = 13$ ) and  $22.7$ – $12.1^\circ$  ( $N = 14$ ) are calculated for 0–3% expansion ratios without considering the internal strain and defects incorporated into real tube walls.

Alloyed MoS<sub>2</sub> and WS<sub>2</sub> nanotubes do not show the self-assembly in any different morphology, i.e., among microtubes, nanotubes, or ribbons-collapsed tubes, in spite of the sizes similar to those of non-alloyed tubes. The absence of the assembly in alloyed tubes evidences that the self-assembly is influenced not only by the tube dimensions but also by its chemical and/or structural properties.

**Table 2** Values of the number  $N$  calculated for the hexagonal 2H<sub>b</sub> stacking of MoS<sub>2</sub> and WS<sub>2</sub> tubes

MoS <sub>2</sub>	Plate-like crystal 2H <sub>b</sub> <sup>[11]</sup>	Non-alloyed tubes		Alloyed tubes

## SELF-ASSEMBLY OF SINGLE-WALLED $\text{MoS}_{2-x}$ NANOTUBES

The subnanometer-diameter  $\text{MoS}_{2-x}$  nanotubes were grown by a catalyzed transport method.<sup>[20]</sup> The crucial conceptual novelty in the synthesis procedure, compared to standard transport growth, is in the use of  $\text{C}_{60}$  as a growth promoter in the reaction. Thus  $\text{C}_{60}$  in proportion of 5 wt.% was added to  $\text{MoS}_2$  powder in the transport tube as a catalyst. The transport reaction was running typically for 22 days at 1010 K in an evacuated silica ampoule at a pressure of  $10^{-3}$  Pa with a temperature gradient of 6 K/cm. Iodine had been used as a transport agent. Approximately 15 wt.% of the source material was transported by the reaction to form nanotubes, with the rest remaining at the initial side in the form of layer crystals. The transported material was subsequently thoroughly washed with toluene to remove  $\text{C}_{60}$ .

The transported material grows in the form of thin furry foil composed of mutually oriented needles (Fig. 14), which are themselves bundles of  $\text{MoS}_2$  nanotubes. The bundles start to grow in “hedgehog”—needles from randomly distributed nuclei on the quartz surface. The color of the dense backside of the sample shows metallic luster while the front side is black because of the high porosity and strong light absorption. When adjacent structures touch, growth perpendicular to the quartz substrate appears to prevail. The bundles usually terminate in a sharp tip forming remarkably clean and sharp needles. Each bundle contains more than 500,000 ordered nanotubes. The secondary nucleation of the bundles on the rough top surface of the foil leads to the formation of microscopic geometrical shapes, such as spheres or rectangular forms.<sup>[20]</sup>

**Fig. 14** Self-arrangement of the  $\text{MoS}_{2-x}\text{I}_y$  bundles at different range scales. *Source:* Image taken by Dr. E. Klein, Weizmann Institute of Science, Rehovot.

**Fig. 15** The high-resolution transmission electron images of (A) the bundle of subnanometer  $\text{MoS}_{2-x}$  nanotubes along the [001] direction, revealing the regular hexagonal close package of the nanotubes; (B) the side view of the bundle along [101] direction, evidencing the ordered stacking of the nanotubes along the bundle axis.

A high-resolution transmission electron microscopy (HRTEM) investigation of the bundles along their longitudinal direction revealed a hexagonal close package of identical nanotubes (Fig. 15), where the center-to-center distance between two tubes is 0.96(1) nm. High-resolution TEM approximately perpendicular to the nanotube axis resolved the ordered structure of individual nanotube as well as their regular stacking in the bundle (insert).

Based on transmission electron diffraction and X-ray diffraction, the proposed unit cell of the hexagonal close-packed nanotubes within a bundle is 0.40(1) nm along the bundle axis and 0.96 nm perpendicular to the bundle axis. High-resolution simulations using the symmetry operations of Group  $P6_3$ -No. 173 was

**Fig. 16** Transmission electron diffraction pattern of  $\text{MoS}_{2-x}\text{I}_z$  bundle indexed in accordance with the model structure. *Source:* From Ref.<sup>[20]</sup>.

**Fig. 17** The model structure of a single-wall  $\text{MoS}_2$  nanotube in the top and the side view.<sup>[15]</sup> Considering covalent radii in the model, the diameter of the inner sulfur cylinder is 0.32 nm, the diameter of the molybdenum cylinder is 0.58 nm, and that of the outer sulfur cylinder is 0.75 nm.

found in agreement with the observed high-resolution images. The stoichiometry is still not exactly determined, especially in the case of the molybdenum–sulfur ratio. The reason is a strong overlap of the X-ray characteristic peaks, which prevents the accurate quantitative chemical analysis. Moreover, the X-ray and electron diffraction spectra are dominated by heavy molybdenum atoms, which make the determination of crystal structure difficult (Fig. 16).

The proposed model structure of a subnanometer-diameter  $\text{MoS}_2$  nanotube<sup>[20]</sup> consists of sulfur–molybdenum–sulfur cylinders (Fig. 17). Following the usual nomenclature,<sup>[21]</sup> the structure corresponds to a (3, 3) armchair nanotube. van der Waals interaction is proposed as a force that keeps the nanotubes together. The closest sulfur atoms on adjacent nanotubes in a bundle are separated by 0.35(1) nm, which approximately corresponds to their van der Waals bond length. Iodine atoms are inserted in interstitial trigonal voids between the nanotubes creating one-dimensional rows along the bundle axis. Iodine could also serve as a charge exchange reservoir between the  $\text{Mo}_3\text{S}_{6-x}$  units. It would contribute to the bonding. The periodicity of possible sites for iodine position along the bundle is 0.40 nm, which is slightly less than the van der Waals distance for iodine (0.43 nm). Iodine was only partially removed by ultrasound bathing in ethanol, which was used to decompose the bundles. The energy dispersive X-ray

analysis (EDX) evidenced the lowered concentration of iodine after the decomposition. Scanning tunneling microscopy (STM) studies show that iodine is removed from the surface of a bundle, but it might stay inserted in between the associated nanotubes. It is suggested that iodine with high density of electrons increases the stability of nanobundles on the substrate, while single nanotubes are strongly affected by the scanning STM tip.

The strong self-assembly of the single-wall nanotubes into the bundles suggests the role of  $\text{C}_{60}$  as template during the synthesis. The presence of  $\text{C}_{60}$  in the growth process was found essential, and the single-walled  $\text{MoS}_2$  nanotubes do not grow in its absence. The detailed growth mechanism is not clear at present. We remark on the fact that the (1,1,1) plane of  $\text{C}_{60}$  crystals shows a hexagonal pattern with the in-plane lattice parameter of 1.004 nm,<sup>[22]</sup> which nearly matches the nanotube crystal lattice shown in Fig. 15. In addition, it is conceivable that the mismatch between the lattice parameter of  $\text{C}_{60}$  (1.004 nm) and  $\text{MoS}_2$  nanotubes (0.96 nm) plays an active role in promoting the growth of the bundle in the typical tip shape.  $\text{C}_{60}$  is most probably situated at the extremities of the nanotubes during the growth.

## ASPECTS OF POSSIBLE APPLICATIONS OF INORGANIC NANOTUBES

As a result of their cylindrical geometry, these novel advanced nanomaterials have a low mass density, a high porosity, and an extremely large surface to weight ratio. Their potential applications range from high porous catalytic and ultralight anticorrosive materials, atomic probes, and electron field emitters to non-toxic strengthening fibers. This may lead to a more efficient use and an increase in durability of materials. Doping of these semiconducting nanostructured materials may also allow further miniaturization of electronic systems and may lead to new optoelectronic materials. The helical structure of undoped tubes with semiconductor behavior and their optical activity enable possible applications in non-linear optics and in solar cell technology. By functionalizing the nanotubes, e.g., using specific Mo containing enzymes, novel functional biomaterials could be made.

Among others,  $\text{MoS}_2$  and  $\text{WS}_2$  are also applicable for construction of photovoltaic cells in which electron-hole pairs are photoexcited and do not recombine but migrate to the edge of the crystal. Most research in this area has been concentrated on growth of large and pure layered crystals, which has been technologically very expensive and complicated. However, similar effects need to be investigated in nanotubes and

other nanostructures of the same materials, whereby acceptor molecules can be included in between the layers that will inhibit recombination and allow more efficient use in photovoltaic applications.

The  $\text{MoS}_{2-x}\text{I}_y$  subnanometer-diameter nanotubes with observed self-assembly at different scales are due to the tip geometry and the porous structure, promising candidates for applications as reversible lithium batteries,<sup>[23]</sup> in advanced electronics as molecular wires in nanodevices,<sup>[24]</sup> and as electron field emitters.<sup>[25]</sup>

## CONCLUSION

In conclusion, the chemical transport reaction enables synthesis of different transition metal dichalcogenide nanotubes. The advantage of lasting transport reaction is that the so grown nanotubes contain extremely low density of structural defects. The tubes grow up to several millimeter lengths with diameters ranging from several micrometers to less than 10 nm. The  $\text{MoS}_2$  and  $\text{WS}_2$  nanotubes have been successfully alloyed with gold and silver. The chirality, otherwise typical for the pure  $\text{MoS}_2$  and  $\text{WS}_2$  nanotubes, was partially or completely removed in the alloyed nanotubes and the electrical properties were changed. The existence of noble metal– $\text{MoS}_2$  ternary compounds gives evidence that the cylindrical geometry of crystals can stabilize new compounds otherwise unknown in a plane geometry.

The subnanometer  $\text{MoS}_{2-x}\text{I}_y$  nanotubes have been synthesized using  $\text{C}_{60}$  as a growth promoter. The nanotubes display a self-assembly on different length scales. They group to the first case of molecular crystals composed of inorganic nanotubes. Scanning tunneling microscopy investigations of individual nanotubes and nanotube bundles reveal metallic behavior in two dimensions, along the tubes and along its circumference, while the conductivity among nanotubes is hindered revealing the semiconductivity. As a result of the metallic behavior, these smallest known inorganic nanotubes belong to the family of promising molecular wires.

## ACKNOWLEDGMENTS

The author thanks Dr. Ales Mrzel, JSI, and Prof. Francis Levy, EPFL, for their cooperation, Mrs. Zora Skraba, JSI, for the technical assistance in crystal growth, and Prof. Pierre Stadelmann, EPFL, for supporting the access to the electron microscopes. The work was in main part financed by the Ministry for Education, Science, and Sports of Slovenia.

## Abstract

The combination of nanometric (the diameter) and micrometric (the length) scales make nanotubes a unique and attractive object of research, including the study of mechanical properties and fracture in particular. However, it is precisely this small size that makes the study of the mechanical properties of nanotubes difficult. Atomic force microscopy (AFM) and high-resolution scanning electron microscopy (HRSEM) are very efficient techniques to overcome this challenge.

WS<sub>2</sub> and MoS<sub>2</sub> form nanotubes with a similar crystalline structure, hence they are quite likely to show comparable mechanical behavior. Also, these materials are expected to have superior mechanical properties when compared with the bulk material, which was shown earlier for carbon nanotubes.

The investigation of the mechanical properties of WS<sub>2</sub> and MoS<sub>2</sub> nanotubes included both an experimental and a theoretical part. Young's modulus was studied by various techniques, including atomic force microscope (AFM) and scanning electron microscope (SEM); it was also calculated by using the density-functional-based tight-binding (DFTB) method. Tensile tests of individual WS<sub>2</sub> nanotubes and bending tests of MoS<sub>2</sub> nanotubes were performed as well.

Young's modulus of WS<sub>2</sub> nanotubes was found to be in the range of 150–170 GPa, which is in good agreement with DFTB calculations. As for MoS<sub>2</sub> nanotubes, Young's modulus of 120 GPa was measured while the calculated value was 238 GPa. WS<sub>2</sub> nanotubes also showed tensile strength as high as 16 GPa and fracture strain of 14%. These results indicate the high quality of these nanotubes, which reach their theoretical strength. The maximal strain of MoS<sub>2</sub> nanotubes according to molecular dynamics simulations was found to be 17–19%. Bending tests of WS<sub>2</sub> nanotubes resulted in interlayer shear modulus of 2 GPa, while similar tests of MoS<sub>2</sub> ropes of nanotubes resulted in modulus of 160 MP.

## INTRODUCTION

The mechanical properties of nanomaterials are of great interest both from theoretical and application point of view. Among the nanomaterials, the nanotubes are a very important group since it has almost perfect crystalline shape. Over the last few years, numerous theoretical and experimental studies were dedicated to the mechanical properties of carbon nanotubes.<sup>[1–6]</sup> These works revealed the unique properties of carbon nanotubes, which are high strength materials and deform elastically both in tension and under compression. The superior mechanical properties of carbon nanotubes can be attributed to their layered structure, which can be made almost defect-free. Since other layered materials like WS<sub>2</sub>, MoS<sub>2</sub>, BN, etc. can also form nanotubes, they are expected to have unique mechanical properties as well.

Studying the mechanical properties of the nanotubes is challenged by their small size. Atomic force microscopy (AFM) and high-resolution scanning electron microscopy (HRSEM) are efficient techniques to overcome this challenge. AFM is used to measure forces in the nano-Newton range and the scanning electron microscope (SEM) is used for imaging and controlled movement of nano-objects (by using an in situ nanomanipulator). The mechanical properties of individual nanotubes can be directly measured using AFM by attaching a nanotube to a silicon cantilever.<sup>[7,8]</sup> The cantilever is functioning as a force sensor (like a spring). When force is applied on the nanotube, the silicon cantilever deflects in response. The deflection can be tracked either by AFM (the deflection is tracked by a laser signal from the cantilever to the photodiode) or by SEM (the cantilever's movement is imaged).

## BACKGROUND

Significant progress has been made in the area of nanoscale science and technology in the past decade. Since the discovery of inorganic fullerene-like nanostructures and nanotubes (IF) of WS<sub>2</sub> in 1992,<sup>[9]</sup> many more IF nanoparticles were reported, including MoS<sub>2</sub>,<sup>[10]</sup> BN,<sup>[11]</sup> VO<sub>x</sub>,<sup>[12]</sup> NiCl<sub>2</sub>,<sup>[13]</sup> and CdS.<sup>[14]</sup> The nanotubes (especially carbon) have received significant attention in terms of fundamental property measurements and potential applications. This is largely due to the impressive physical behavior as revealed from both theoretical and experimental studies. It was realized that this brand of new nanomaterials possesses a wide range of electrical and optical properties, which can be tuned with the diameter of the nanotubes.<sup>[15]</sup> Furthermore, the electrical properties of nanotubes may be tuned by mechanical deformation as well.<sup>[16–19]</sup> Such properties are of great interest for applications such as sensors or smart materials. The utility of nanotubes as the strongest or stiffest elements in nanoscale devices or composite materials remains a powerful motivation for the research in this area.

The combination of nanometric (the diameter) and micrometric (the length) scales make nanotubes a unique and attractive object of research, including the study of mechanical properties and fracture in particular. However, it is precisely this small size that makes the study of the mechanical properties of nanotubes difficult. Atomic force microscopy HRSEM are very efficient techniques to overcome this challenge. Atomic force microscopy is used to measure forces in the nano-Newton range and the SEM is used to manipulate and image nano-objects. The mechanical properties of individual nanotubes can be directly measured using AFM by attaching a nanotube to a silicon cantilever.<sup>[1,7,20]</sup> The cantilever is functioning as a force sensor (like a spring). When force is applied on a nanotube, the silicon cantilever deflects and this deflection can be tracked either by AFM (the deflection is tracked by a laser signal from the cantilever to the photodiode) or by SEM (the cantilever's movement is imaged).

## WS<sub>2</sub> NANOTUBES

The mechanical properties of WS<sub>2</sub> nanotubes including Young's modulus, tensile strength, elongation, shock wave resistance, and their mechanical behavior under different conditions were studied lately. The synthesis of WS<sub>2</sub> IF nanoparticles and nanotubes was first reported in 1992.<sup>[9]</sup> A number of methods have been developed for synthesis of WS<sub>2</sub> multiwall nanotubes, for instance sulfidization of the metal oxide<sup>[9,21]</sup> or direct synthesis from vapor phase by chemical transport reaction.<sup>[22]</sup> At present, WS<sub>2</sub> nanoparticles with fullerene-like

structure enriched by 5% chiral multiwall nanotubes can be obtained<sup>[21]</sup> by using the fluidized bed reactor (FBR) with somewhat modified conditions. The length of these nanotubes varied from several hundred nanometers to several micrometers. Along with these, much longer (up to 0.3 mm) nanotubes were also observed. The nanotubes are quite uniform in shape and open-ended. Their outer diameter varies from 10 to 30 nm, with the main size distribution centered between 15 and 20 nm. The typical number of layers in a nanotube is between 5 and 8. Thus, the hollow core of such nanotubes occupies up to 70% of their total volume. According to transmission electron microscopy (TEM) analysis, the nanotubes were found to be quite perfectly crystalline and almost defect-free. These nanotubes exhibit an average chirality angle of 7–12°. First-principles calculations confirmed that such nanotubes are indeed energetically stable.<sup>[23]</sup>

## YOUNG'S MODULUS

Young's modulus of the nanotubes is of great interest for many applications. Several techniques, including axial compression and tension, were applied to measure Young's modulus of WS<sub>2</sub> nanotubes.

An axial compression force can be applied on a nanotube until Euler's buckling point and beyond. It is possible to calculate Young's modulus either from Euler's buckling equation<sup>[24]</sup> or by using the Elastica theory.<sup>[25]</sup> An individual WS<sub>2</sub> nanotube can be attached to the AFM cantilever, and axial compression force can then be applied either by using an AFM or in a SEM chamber, as desired. Young's modulus is calculated according to Euler's buckling equation from the force vs. displacement trace for each nanotube measured by AFM<sup>[24]</sup> (Fig. 1):

$$F_{\text{Euler}} = \frac{\pi^2 EI}{L^2} \quad (1)$$

**Fig. 1** Deflection of the silicon cantilever vs. its Z position as recorded by AFM. Source: Adapted from Ref.<sup>[24]</sup>.

where  $F_{\text{Euler}}$  is Euler's buckling force (which can be seen clearly as the discontinuity point in the force trace),  $E$  is Young's modulus,  $I$  is the second (or geometrical) moment of inertia (applied here to a hollow cylinder geometry), and  $L$  is the nanotube's length. The average Young's modulus obtained from these measurements was 171 GPa. The scatter of the results is quite large, apparently because not all the nanotubes were perpendicular to the surface (it is quite difficult to control the position of the nanotube relative to the surface during AFM investigations). Notwithstanding the large scattering, the measured value of Young's modulus of WS<sub>2</sub> tubes was quite close to the theoretical value, which is 150 GPa. A similar experiment using SEM<sup>[25]</sup> was conducted and the post-buckling behavior was studied (Fig. 2). Here, using the SEM images, force vs. deflection curves were constructed in which the AFM cantilever movement and the position of the nanotube were observed. The SEM-based results were analyzed using the Elastica theory. According to this theory, the running coordinates of the (large) displacement of a very thin, flexible rod with a stiffness  $EI$  can be expressed at any point  $(x,y)$  along its length  $(s)$  as a function of an axial force  $P$  applied at the free end, see Fig. 3. Here, only the expression for the  $y$  coordinate was used:

$$y = \sqrt{\frac{EI}{4P}} \int_0^\alpha \frac{\sin \theta d\theta}{\sqrt{\sin^2 \alpha/2 - \sin^2 \theta/2}} \quad (2)$$

The Young's modulus values evaluated using the above principle varied, and were close to 150 GPa only when  $\theta$  was almost identical to  $\alpha$  (edge of the nanotube). These results suggest that the assumption that the geometrical moment of inertia  $I$  (and thus the geometry of the cross-section) is constant along the buckled nanotube is in fact incorrect. A TEM image (Fig. 4) of a highly bent nanotube shows an obvious distortion of the cross-section at the locus of maximal

**Fig. 2** The large deformation of the nanotubes in the post-buckling stage is described by the SEM image (bar 1  $\mu\text{m}$ ). *Source:* Adapted from Ref.<sup>[25]</sup>.

**Fig. 3** Scheme of the post-buckling shape of a beam, which is used for the Elastica analysis. The parameters used for the Elastica equations are presented in this scheme. *Source:* Adapted from Ref.<sup>[25]</sup>.

curvature and the local geometry, therefore, strongly deviates from the assumed cylindrical shape.

A tension force can be axially applied to a nanotube<sup>[5,6]</sup> in a way similar to macroscopic tensile tests, but with some technical differences. Indeed, here the nanotubes are attached to two silicon cantilevers with different spring constants, and the nanotube is then pulled to fracture (Fig. 5). By analyzing the SEM images, the applied force and the nanotube's length are obtained.<sup>[25]</sup> The stress is calculated as the applied force divided by the cross-sectional area (of the outer shell only, since it is generally accepted that it is the only layer that bears significant load); the strain is simply the measured elongation divided by the original nanotube length. Plotting the stress against the strain

**Fig. 4** TEM image of a naturally buckled nanotube. This image demonstrates clearly that the cross-section of the nanotube is not constant (bar 20 nm). *Source:* Adapted from Ref.<sup>[25]</sup>.

**Fig. 5** SEM images of tensile test of an individual  $\text{WS}_2$  nanotube: (A) The tensile test set-up—the nanotube (ca. 20 nm in diameter) is attached to two AFM cantilevers (amorphous carbon serves as a glue); the force is applied through the upper cantilever, which has higher force constant when compared with the lower one (bar is 20  $\mu\text{m}$ ). (B) A loaded nanotube, before fracture. (C) Two pieces of the nanotube after fracture occurred (bar is 2  $\mu\text{m}$ ). Source: Adapted from Ref. [25].

yields the nanotube Young's modulus according to Hooke's law. The average Young's modulus from such measurements is 152 GPa ( $\pm 68$ ).

Regardless of the experimental setup or model used, Young's modulus of  $\text{WS}_2$  nanotubes fell in the 150–170 GPa range. The good agreement between the results from different measurements and the theoretically expected value of 150 GPa reflects the relatively uniform and defect-free structure of  $\text{WS}_2$  nanotubes synthesized in our laboratory.

## TENSILE STRENGTH AND ELONGATION

The strength of macroscopic objects can generally be determined by either their intrinsic molecular structure or by such extrinsic factors as grain boundaries, dislocations, vacancies, and other defects.<sup>[26,27]</sup> The extrinsic factors are affected by the manufacturing processes used for the preparation of a specific specimen. Thus, the strength of macroscopic objects is generally much smaller than the theoretical value (of the order of one-tenth of Young's modulus). This apparent discrepancy highlights the fact that the strength of materials is only partially determined by their intrinsic mechanical properties,<sup>[26,27]</sup> i.e. the strength of their chemical bonds.

In contrast to macroscopic models, which deal with a statistically large number of defects within a body or a continuum of matter, nanomaterials and nanotubes, in particular, must be studied and modeled on a microscopic (atomistic) level.<sup>[28,29]</sup> Only a discrete number of atomistic defects are present in the nanotube; therefore, the effect of individual defects must be examined theoretically and, if at all possible, experimentally. By isolating and studying individual nanostructures, which contain practically no defects, one may hope to achieve strengths much larger than the macroscopic analogues. Also, below a certain size, the size (diameter) of a nanospecimen has been claimed to be irrelevant with respect to mechanical strength,<sup>[30]</sup> although this remains a deeply controversial issue. Rather, the control of the synthesis of the nanotubes determines their perfectness and consequently their strength. Indeed, long and defect-free nanotubes can be stronger than shorter nanotubes, which contain even a very small number of point defects.

The ultimate strength of the  $\text{WS}_2$  nanotubes as well as the maximal elongation under axial tension was studied as described here.<sup>[25]</sup> The maximal load and length of the nanotube was obtained from SEM images. To calculate the applied stress, it was assumed that the load was applied only to the outer layer of the nanotube since the bond to the force transducer covered only the outer surface of the nanotube. Hence, rupture of the nanotube occurred only at the outer shell, and inner

shell movement followed it in a telescopic manner. This hypothesis was confirmed by observing that the total length of the fragments was significantly larger than the initial nanotube length (see Fig. 5). The ultimate strength and the maximal elongation of the WS<sub>2</sub> nanotubes are 3.7–16.3 GPa ( $\pm 11\%$ ) and 5–14% ( $\pm 0.1\%$ ), respectively. The high tensile strength of these nanotubes seems to be very promising when compared with other known (bulk) high strength materials as presented in Table 1.<sup>[5,6,27]</sup> The combination of high tensile strength and ca. 14% elongation is a unique property of all the nanotubes measured so far.<sup>[5,6]</sup> Furthermore, the strength of the strongest nanotubes is about 11% of their Young's modulus, corresponding approximately to the theoretical value of the material's strength. This value is appreciably larger than typical high-strength engineering materials. Such findings indicate that the WS<sub>2</sub> nanotubes seem to be remarkably free of critical defects.

The stress-strain plots (Fig. 6) show that the nanotubes deformed elastically, almost until failure. Weibull statistics<sup>[31,32]</sup>, which is used to predict the probability of failure of bulk materials, was found to be valid for the WS<sub>2</sub> nanotubes. This implies that either the WS<sub>2</sub> nanotubes are defect-free or that the role of defects in the nanotubes is completely different and should be estimated using another approach. Recently, a new approach to nanomaterials fracture mechanics, quantized fracture mechanics (QFM), was proposed.<sup>[33]</sup> The QFM model attempts to predict the strength of nanotubes as a function of the number of discrete critical defects. Based on the QFM model, it was found out that some of the nanotubes appear to be defect-free, while others contain 1–21 critical defects leading to fracture.

It was demonstrated that WS<sub>2</sub> nanotubes are both ultra-strong and extensible, distinguishing them from other known materials. Furthermore, the tensile strength results were found to be in good agreement with the QFM model, suggesting that the mechanical properties

**Fig. 6** Stress-strain plot of an individual WS<sub>2</sub> nanotube. The linear behavior of the plot indicates that the nanotubes deformed elastically until failure. *Source:* Adapted from Ref.<sup>[25]</sup>.

of WS<sub>2</sub> nanotubes are dictated by a discrete number of critical defects and the intrinsic strength of the W-S chemical bond. Thus, individual nanotubes have been shown to demonstrate quasi-ideal strength, providing strong evidence for defect-free structures.

## INTERLAYER SHEAR MODULUS

The cylindrical geometry of nanotubes dictates a strong anisotropy of their physical properties. In practice, the difficulty in extracting individual components of the elastic tensor has limited the available information to only very partial and indirect experimental data. By performing bending tests, the interlayer shear (sliding) modulus ( $C_{44}$ ) of single WS<sub>2</sub> nanotubes was studied.<sup>[34]</sup>

Clamped nanotubes were loaded laterally at the center of their suspended length by means of an AFM tip, and force-deflection ( $F-d$ ) curves were recorded.<sup>[28,35]</sup> According to the  $F-d$  curves, the nanotubes exhibit a linear elastic behavior at small deflections, non-linear deflection is evident when the deflection exceeded 20 nm.

A clamped beam, which is subjected to a point load, can be described by Timoshenko's bending equation.<sup>[36]</sup> The total flexural deformation is composed of tension, compression, and shearing. Hence, the total bending is composed of the bending deflection and the shear deflection, which are linked to the bending stiffness ( $EI$ ) and to the shear stiffness ( $GA$ ), respectively. To calculate the Young's modulus from the  $F-d$  curve, the shear modulus is required and vice versa.<sup>[37,38]</sup> The bending equation is:<sup>[39]</sup>

$$\delta = \delta_b + \delta_s = \frac{FL^3}{192EI} + \frac{f_s FL}{4GA} \quad (3)$$

**Table 1** Mechanical properties of strong materials

Material	Modulus of Elasticity (GPa)	Tensile Strength (GPa)	Elongation (%)
Steel alloy 4340	207	1.76	12
Stainless alloy 440A	200	1.79	3.5
Tungsten	400	0.76	2
Diamond	700–1200	1.05	
Silicon nitride	304	0.7–1	
Zirconia	205	0.8–1.5	
Aramid fiber	60–150	3.6–4.1	2.8
Carbon fiber	200–750	4.65–7.1	1.8
E-Glass	72	3.45	4.3

where  $\delta$  is the nanotube's deflection,  $F$  is the applied lateral force,  $L$  is the suspended nanotube length,  $E$  is the Young's modulus.  $I$  is the second moment of area (for a cylinder:  $I = \pi/4(r_{\text{out}}^4 - r_{\text{in}}^4)$ ) where  $r_{\text{out}}$  and  $r_{\text{in}}$  are the outer and inner radii of the nanotube, respectively.  $f_s$  is the shape factor (10/9 for a cylinder),  $G$  is the shear modulus,  $A$  the cross-sectional area of the beam. The previously determined Young's modulus value of 150 GPa<sup>[24,25]</sup> was introduced into the equation and an average shear modulus of 2.0 GPa ( $\pm 1.1$ ) was extracted.

Different models can be used to describe the shear process. The mechanism for shear deformation of a beam in a point load-bending test can be evaluated by considering thin cross-sectional elements, which can slide relative to the adjacent ones.<sup>[39]</sup> This corresponds to "in-plane" ( $C_{12}$ ) shear forces. Furthermore, in analogy to the case of the nanotubes, bending tests of sandwich materials made of alternating layers of hard and soft matter, result in a deformation, which can be characterized by shearing of the soft layers.<sup>[40]</sup> In analogy to sandwich materials, the nanotubes can be regarded as being made of a superstructure of alternating hard (chemically bonded) WS<sub>2</sub> layers and soft interlayer spacing where weak van der Waals forces predominate. Hence, it is believed that the shear deformation of the nanotubes is obtained by slip between adjacent WS<sub>2</sub> layers.

The observed value of 2 GPa agrees well with the value of 4 GPa obtained by first principle density functional tight-binding calculations for 2H-MoS<sub>2</sub>. This value of the shear modulus represents a much higher degree of anisotropy than for carbon nanotubes, and enables assignment of the mode of shear deformation.

## SHOCK WAVE RESISTANCE

Inorganic nanotubes possess some mixed covalent-ionic nature. In fact, some like WS<sub>2</sub> and MoS<sub>2</sub> are more covalent in nature, while metal-halide nanotubes, like those of NiCl<sub>2</sub>, are much more ionic, and are expected to be chemically much more reactive. The known phase diagram of Mo-S and W-S does not contain any specific high-pressure phase and consequently these materials are not expected to yield under load.<sup>[17]</sup> Indeed, diamond anvil cell experiments showed that both materials are stable under a pressure of 21–25 GPa,<sup>[41,42]</sup> Recently, the shock wave resistance of both fullerene-like nanotubes of WS<sub>2</sub> and MoS<sub>2</sub>, respectively, was studied. Shock waves generate concurrently extremely high dynamic pressures and temperatures. Pressure propagation in samples causes very high shear stresses, thereby differing from stresses produced by static pressure. According to TEM analysis of the nanotubes (Fig. 7), some of the WS<sub>2</sub> nanotubes were strong enough to withstand a pressure of

**Fig. 7** HRTEM images of WS<sub>2</sub> nanotubes with 0.62 nm layer separation: (A) post-shock sample, layer-mismatch arrowed; (B) prior to shock waves. *Source:* Adapted from Ref.<sup>[41]</sup>.

21 GPa. Sometimes, defects like layer mismatches were present but did not lead to degradation of the mechanical properties, and structures were fairly well preserved. It was shown that the nanotubes were more resistant to shear stresses when compared with the fullerene-like nanoparticles. Nanotubes, which are folded only along one axis, are less strained and chemically more stable than the fullerene-like nanoparticles of WS<sub>2</sub>. Furthermore, nanotubes are structurally perfect when compared with the IF nanoparticles, which always has defects owing to their faceted structure. Therefore, nanotubes appear to be able to survive much higher shock-waves pressure and shear stresses. X-ray diffraction (XRD) and Raman studies of the IF nanoparticles and nanotubes show that the materials are strong enough to withstand 21 GPa shock waves. When compared with carbon nanotubes, in which going through a phase transition to diamond at this pressure, the IF nanoparticles and nanotubes seem to be significantly more stable.

## MoS<sub>2</sub> NANOTUBES

The mechanical properties of MoS<sub>2</sub> nanotubes were studied both experimentally and theoretically. The synthesis of fullerene-like MoS<sub>2</sub> nanoparticles and nanotubes was first reported in 1993,<sup>[43]</sup> and subsequently MoS<sub>2</sub> nanotubes were reported.<sup>[10,44]</sup> Several methods can be used to prepare the MoS<sub>2</sub> nanotubes and fullerene-like nanoparticles.<sup>[44]</sup> The MoS<sub>2</sub>

nanotubes, which were used for the mechanical studies, were produced by a catalyzed transport reaction involving  $C_{60}$ .<sup>[45]</sup> Single-wall nanotubes were grown by a catalyzed chemical vapor transport method using iodine as a transport agent and the reaction was run for 22 days at 1010 K in an evacuated silica ampoule at a pressure of  $10^{-3}$  Pa. The material grows in the form of bundles, consisting of individual nanotubes 0.961 nm in diameter. It should be emphasized that the dihedral angle of the single-wall  $MoS_2$  reported in this work ( $70^\circ$ ) is appreciably smaller than the one observed in the bulk material ( $94^\circ$ ), indicating that the reported nanotubes are highly strained.

The bundles containing  $> 500,000$  nanotubes usually terminated in a sharp tip. They can be disassembled into thinner ones and even individual tubes by dispersion in ethanol using ultrasonic bath. Nanotubes as long as a few hundreds of micrometers in length were obtained.

## YOUNG'S MODULUS

Young's modulus of  $MoS_2$  ropes (bundles) was studied experimentally.<sup>[35]</sup> Suspended ropes were deposited on a surface of  $Al_2O_3$  membrane with average pore size of 200 nm (Fig. 8). The ropes were elastically deflected by applying a normal force with AFM. Young's and shear moduli can be calculated from the deflection vs. force data sets by using the unit load method. Here, the total deformation is considered as the sum of  $\delta_b$ -(bending) and  $\delta_s$ -(shearing) deformations as described in Eq. (3). According to these measurements, the lowest

**Fig. 8** AFM image of  $MoS_2$  rope lying over two pores. The rope's diameter is 17 nm. *Source:* Adapted from Ref.<sup>[35]</sup>.

limit for Young's modulus was estimated to be 120 GPa.

Young's modulus of single-wall  $MoS_2$  nanotubes was calculated by using a DFTB method and periodic boundary conditions.<sup>[36]</sup> Young's modulus was calculated using the conventional definition:

$$Y = \frac{1}{V_0} \left. \frac{\partial^2 E}{\partial \epsilon^2} \right|_{\epsilon_0} \quad (4)$$

where  $V_0 = 2\pi L_0 R_0 \delta R$  is the equilibrium volume of the nanotube, with  $L_0$  and  $R_0$  the calculated unit length and the average radius of the nanotubes, respectively. As in the case of carbon nanotubes,  $\delta R$  was chosen as the interlayer separation in the corresponding layered bulk material ( $\delta R$  is equal 0.62 nm for  $MoS_2$ ). Young's modulus for a series of armchair ( $n,n$ ) and zigzag ( $n,0$ )  $MoS_2$  single-wall nanotubes that were calculated from first principles are shown as a function of the tube radius in Fig. 9. As one can see from the figure, the zigzag ( $n,0$ ) nanotubes have a considerably larger Young's modulus than armchair ( $n,n$ ) nanotubes with similar radius. Whereas Young's modulus of ( $n,0$ ) nanotubes remains essentially invariant with the tube's radius, the value of  $E$  increases with the radius for ( $n,n$ ) nanotubes. Also, the value of Young's modulus of the ( $n,0$ ) nanotubes is very close to that of bulk  $MoS_2$  (238 GPa). Extrapolating the calculated Young's modulus of the ( $n,n$ ) nanotubes to radii of approximately 10 nm will lead to values for Young's modulus around those of a bulk  $MoS_2$ , too. Young's modulus of  $MoS_2$  single-wall nanotubes is very similar to that of the bulk material; i.e., the tube formation does not alter the interaction within the single layers.

**Fig. 9** Calculated Young's modulus of ( $n,m$ )  $MoS_2$  nanotubes. *Source:* Adapted from Ref.<sup>[24]</sup>.

**Fig. 10** Simulated tensile tests of single-wall MoS<sub>2</sub> nanotubes: The rupture progress is described by DFTB-MD simulation for zigzag (22,0) and armchair (14,14) nanotubes. Elongation values are 17% and 19%, respectively, for the zigzag and armchair nanotubes. *Source:* Adapted from Ref.<sup>[25]</sup>.

The calculated Young's modulus is ca. double of the one measured for single-wall MoS<sub>2</sub>.<sup>[35]</sup> The difference can be attributed to experimental errors (ca 50%) and to the difference between bundles and individual nanotubes. As indicated above, the smaller dihedral angles observed for the nanotubes when compared with the bulk material is most likely to weaken their chemical bonds, adversely affecting their mechanical properties. Also, the experimental measurements are influenced by the presence of defects in the structure, which affect their mechanical properties.

### SHEAR MODULUS

As described above,<sup>[35]</sup> the shear and Young's moduli can be calculated from bending experiments of a nanotube or a rope. In the case of ropes (bundle), the shear modulus ( $G$ ) describes the sliding between individual tubes comprising the rope and not the shear of the layers. The shear modulus is expected to be

appreciably smaller when compared with Young's modulus due to the low friction between the MoS<sub>2</sub> nanotubes within the bundle. The shear modulus determined in this way is 160 MPa ( $\pm 30$ ). This value is quite low when compared with ropes of single-wall carbon nanotubes (1–10 GPa). This may be explained by the weak interaction of sulfur atoms on the outer surface of the nanotube.

### TENSILE STRENGTH AND ELONGATION

A combined molecular dynamics-density functional-tight-binding (MD-DFTB) simulation of the stretching process was performed for single-wall MoS<sub>2</sub> nanotubes.<sup>[25]</sup> According to these simulations, the failure of the nanotube is abrupt starting at a single atomic defect and propagating very quickly across its entire circumference. The calculated stress and strain are: 40 GPa and 18% for the zigzag (22,0) tube, 34 GPa and 17% for the armchair (14,14) tube. Fig. 10

presents the simulated rupture process. No experimental study of the tensile tests of MoS<sub>2</sub> nanotubes is available in the literature, but the strain results can be compared with those of WS<sub>2</sub> nanotubes. The values of the tensile strength obtained in the simulation compare favorably with the experimental strength (11% of their Young's modulus) and elongation (14% values) of WS<sub>2</sub> nanotubes. The small differences between theory and experimental data can be attributed to the fact that under the present experimental conditions, equilibrium may not be established. Furthermore, thermal fluctuations, which can lead to "early" failure, could not be fully accounted for in the calculations. Finally, the experimental elongation is a lower bound, since for technical reasons, the series of SEM micrographs, which are taken during the experiments and serve for the analysis, do not cover the entire process until the failure point is reached.

## SUMMARY

The mechanical properties of WS<sub>2</sub> and MoS<sub>2</sub> nanotubes were studied using various techniques, by both experimental and theoretical calculations. The multiwall WS<sub>2</sub> nanotubes were studied by a variety of techniques, and showed superior mechanical behavior and properties. These nanotubes have Young's modulus of ca. 150 GPa and tensile strength above 16 GPa. They deform elastically to a large extent both under compression and in tension. Furthermore, they seem to be almost defect-free, since they reach the theoretical strength. As for MoS<sub>2</sub> nanotubes, only a limited set of experiments were reported. Young's modulus of these nanotubes was found to be 120 GPa according to bending tests and 238 GPa according to calculations. This discrepancy was attributed to the fact that ropes (bundles) of single-wall nanotubes and not individual nanotubes were measured and they are suspected to have defects, while the calculation took into account individual single-wall nanotubes, which are free of defects. The low shear modulus of these ropes (160 MPa) is indicative of the low shear between the nanotubes in the ropes, hence pointing out the low friction between them. The theoretical simulation of tensile tests shows a similar mechanical behavior for both MoS<sub>2</sub> and WS<sub>2</sub> nanotubes.

# Integrated Methods in Quantum Chemistry

Stephan Irle  
Keiji Morokuma

Department of Chemistry, Emory University, Atlanta, Georgia, U.S.A.

## INTRODUCTION

Coinciding with the discovery of the C<sub>60</sub> buckminsterfullerene molecule,<sup>[1]</sup> nanotechnology was envisioned in the mid-1980s<sup>[2]</sup> as the art of manipulating matter at the atomic level. Since then, nanotechnology rapidly became a growing interdisciplinary research area, driven by one promise: Regardless of the rate at which nanotechnology will be implemented, it holds the potential to change *everything*. Unfortunately, it has proven to be very difficult to obtain reliable structural data on nanostructures, and their chemical reaction mechanisms are still largely unknown, making it extremely difficult to create commercially successful applications. In addition to these difficulties, the quantum effects responsible for the properties and reactivity of nanoscale chemical systems are very often qualitatively different from those of either bulk material or atoms and molecules, thereby preventing us to make use of our knowledge of their electronic structures. We find ourselves today forced to study nanoscale electronic structures from the very beginning with the focus on a size domain where quantum mechanics and classical mechanics meet to create new fascinating phenomena and structural wonders. Unfortunately, the computational cost of traditional electronic structure methods remains by far too large even today at the age of ultrafast computers to permit direct investigation of realistic models relevant to the nanoscale at the quantum chemical level. The problem is the vast number of atoms involved in these structures. For instance, when one assumes an interatomic distance of ~0.2 nm in the solid state, a 3-D system only 10 nm in size involves ~125,000 atoms. Although advances in massively parallel processing, linear scaling techniques, localized orbital methods, and sophisticated integral approximation methods have in recent years extended the applicability of ab initio molecular orbital (MO) and density functional theory (DFT) methods to larger and larger systems, calculations on the nanometer scale remains far beyond their reach. Atomic level modeling of systems of this size is only theoretically achievable by means of molecular mechanics force fields. Unfortunately, classical mechanical force field approaches are incapable of

describing fundamental chemical processes such as oxidation, reduction, electronic excitation, and bond breaking. Band gaps, relative position of conduction and valence bands, lifetimes of electron/hole pairs, magnetic response, optical response, charge transfer rates, (photo)oxidation/reduction rates, and bond breaking/formation rates are important properties of quantum character that require a rigorous quantum chemical treatment where conventional molecular mechanics force field approaches naturally fail.

Clearly, describing electronic structure at the nanoscale is a great challenge, which has been taken on by many research groups worldwide using a variety of different approaches. As a zero-order approximation, computationally inexpensive and not very accurate semiempirical or tight-binding methods have been used to compute the electronic structures of large clusters and nanostructures, and in some cases DFT methods in combination with small basis sets were employed, unwillingly accepting a low level of accuracy. In very few cases, higher-accuracy methods such as second-order Møller–Plesset perturbation theory (MP2) with reasonably sized basis sets were used to predict equilibrium geometries for highly symmetrical structures.<sup>[3,4]</sup> In general, however, chemically accurate (within ~3 kcal/mol) calculations for nanoscale systems cannot be performed using straightforward, high-accuracy quantum chemical methods. As a possible solution to this dilemma, so-called “integrated” or “hybrid” methods have recently become an attractive alternative for large-scale quantum chemistry, by combining high-accuracy calculations for small parts of the nanostructures and less accurate lower levels of theory for the entire system. In fact, if applied carefully, these methods are capable of delivering chemical accuracy in the prediction of electronic structures and reactivities in the chemistry on the nanoscale. Their recent contributions toward a deeper and more accurate understanding of nanoscale quantum chemistry are subject of this review.

At first we will introduce quantum chemical methods applicable to extended molecular systems or parts of them, describe in short the theory behind integrated methods, and in the second part discuss their applications to the most recognizable areas of

nanochemistry, namely, the chemistry of fullerenes, nanotubes, and silica-based nanosystems. Finally, we will give an outlook into the future development of integrated methods and their tremendous potential in the theoretical investigation of quantum chemistry on the nanoscale.

## QUANTUM CHEMICAL METHODS FOR EXTENDED SYSTEMS

### Semiempirical Methods

Similar to ab initio Hartree–Fock (HF) theory, semiempirical methods are based on the Roothaan–Hall equations:<sup>[5,6]</sup>

$$\mathbf{FC} = \mathbf{SCE} \quad (1)$$

Here,  $\mathbf{F}$  is the Fock matrix and  $\mathbf{S}$  is the overlap integral matrix between atomic basis functions,  $\mathbf{C}$  is the matrix of molecular orbitals in an atom-centered orbital basis following the linear combination of atomic orbitals (LCAO) approach of Hund and Mulliken,<sup>[7–9]</sup> and  $\mathbf{E}$  is diagonal and its elements are eigenvalues (orbital energies) of the Fock matrix  $\mathbf{F}$ . While ab initio HF requires that all elements of  $\mathbf{F}$  have to be calculated fully without approximation, in semiempirical calculations several simplifications to the evaluation of the elements of  $\mathbf{F}$  are made.

The main effect regarding a reduction of computer time is achieved by elimination or approximation of some of the integrals needed for the evaluation of the Fock matrix elements. Furthermore, only valence electrons are considered in semiempirical methods, all other electrons are included in the “core.” Usually, Slater type (*s*-, *p*-, and *d*-type) functions are used as atom-centered basis functions. With the noticeable exception of extended Hückel theory<sup>[10,11]</sup> most semiempirical methods make use of the zero differential overlap (ZDO) approximation, which defines the overlap integral between different basis functions as zero. The overlap matrix  $\mathbf{S}$  in the Roothaan–Hall equations thus becomes a unit matrix:

$$\mathbf{FC} = \mathbf{CE} \quad (2)$$

The various ZDO models can be grouped according to their approximations for the one- and two-electron integrals and their different approaches to parameterization:

- CNDO: complete neglect of differential overlap,<sup>[12]</sup>
- NDDO: neglect of diatomic differential overlap<sup>[13]</sup>
- INDO: intermediate neglect of differential overlap<sup>[14]</sup>
- MINDO/3: modified INDO<sup>[15]</sup>
- MNDO: modified neglect of diatomic overlap<sup>[16]</sup>
- AM1: Austin Model 1<sup>[17]</sup> analogue of MNDO

- SAM1: improved AM1,<sup>[18]</sup>
- PM3 and PM5: third (fifth) parametrization of MNDO<sup>[19,20]</sup> analogue of MNDO

Most of the integrals of these methods are estimated from experimental values. Hence outside the class of chemical compounds for which these estimations are parameterized, results may be doubtful. This is especially a problem in the case of nanotechnological systems, where experimental values for quantum chemical integrals are almost impossible to obtain.

The extended Hückel theory (also sometimes called “tight-binding” method) and its charge iterative cousins neglect the two-electron integrals altogether or retain only the most important two-center repulsion integrals.<sup>[10,11]</sup> Their simplicity and resulting tremendous computational speed make them potent candidates for a qualitative treatment of electronic effects in large, extended systems. In particular, molecular dynamics (MD) calculations for systems at finite temperature have been carried out using semiempirical methods in the context of nanometer-sized systems.<sup>[21–24]</sup>

### Linear Scaling, Resolution of Identity, and Localized MO Methods

In the quest to make conventional quantum chemical methods computationally more economical, efforts toward low-order scaling have been made in recent years by taking advantage of the fact that long-range interactions can be evaluated approximately by power series expansion or by mathematical projection techniques (resolution of identity, or RI).<sup>[25,26]</sup> For instance, in DFT, the long-range Coulomb potential has been successfully approximated using a variety of linear scaling versions of the fast multipole method (FMM), and the scaling of exchange and correlation functionals has been linearized using quadrature techniques, allowing the implementation of purely  $O(N)$  DFT. The RI method is an alternative to FMM, where four-center coulombic integrals are approximated by three-center integrals, using fitting functions for the electron density in the spirit of Baerends, Ellis, and Ros.<sup>[27]</sup> An efficient implementation of RI-DFT can be found, e.g., in the TURBOMOLE program package.<sup>[28]</sup>

More accurate methods such as MP2 are based on the evaluation of orbital–orbital interactions and are very expensive because of their large number and the delocalized nature of HF orbitals. The RI method has found its application in MP2 calculations as well,<sup>[29]</sup> and analytical gradients are available. In another approach to simplify MP2, several groups found that replacing delocalized canonical HF MOs by localized molecular orbitals (LMOs) leads to a tremendous speedup for localized MP2 (LMP2)

calculations at a small loss of accuracy.<sup>[30–32]</sup> However, LMP2 analytical gradients desperately required for geometry optimizations of large molecular systems are not generally available until now. While electron correlation methods based on LMOs are still not applicable to systems beyond the size of about 100 atoms today, they certainly will provide a way to significantly extend the range of applicability for these methods.

### Hybrid Quantum Mechanics/Molecular Mechanics Methods

Hybrid methods use different levels of theory for different parts of the molecular system under investigation. The earliest practical implementation of such a technique by Warshel and Karplus combined a semiempirical MO method with a classical molecular mechanics method,<sup>[33]</sup> a methodology commonly called the “QM/MM” method.<sup>[34,35]</sup> In most QM/MM implementations, “link atoms” are introduced to satisfy the valencies of the QM atoms that are connected to any MM atoms. The Hamiltonian describing the entire system is typically partitioned as

$$H = H^{\text{QM}} + H^{\text{MM}} + H^{\text{QM-MM}} \quad (3)$$

where  $H^{\text{QM}}$  is the QM part of the Hamiltonian,  $H^{\text{MM}}$  is the energy of the MM part, and  $H^{\text{QM-MM}}$  represents the interaction between the QM part and the MM part, treated either by molecular mechanics or by quantum mechanical calculations. More recently, ab initio or DFT QM/MM methods have gained considerable popularity (see, e.g., Refs.<sup>[36,37]</sup>, and<sup>[38]</sup>). While QM/MM methods are being successfully applied in bioorganic and bioinorganic systems such as enzymes consisting of proteins the size of hundreds of thousands of atoms with a local reactivity center, their usefulness in the context of nanoscale chemistry is somewhat limited because of the extended delocalized electronic structures encountered here. For instance, carbon nanosystems typically possess almost infinitely extended  $\pi$ -conjugated systems, and the electronic structures of metallic nanoclusters closely resemble electronic bands in dependence of the system size. Because MM is not capable of incorporating these electronic effects, their influence on the QM part is missing in a QM/MM treatment of nanochemistry systems. Nevertheless, the QM/MM approach finds its use in the theoretical investigation of nanostructures because of the ability of MM to impose structural constraints, such as, e.g., ring strain and steric repulsion.

### Integrated Methods

The ONIOM (our N-layered integrated molecular orbital and molecular mechanics) method can also be

considered as a hybrid method. It has the advantage of greater conceptual simplicity than QM/MM, is well defined, can make use of all of the methods described above, and is exact in the case when identical methods are used for different layers of the system. The author and his coworkers developed ONIOM as an onion-skin-like extrapolation method (Fig. 1) that allows the combination of a variety of QM methods and optionally an MM method in a hypothetically unlimited number of layers.<sup>[39–44]</sup> Practically, two and three layers are being used, usually denoted as ONIOM2 and ONIOM3, respectively. The system can additionally be solvated by applying a well-defined integrated solvation scheme, commonly called ONIOM-PCM.<sup>[45]</sup> The ONIOM implementation of the GAUSSIAN03 program package<sup>[46]</sup> provides the flexibility to call external QM or MM program codes for individual layers, making ONIOM independent from the methods offered by GAUSSIAN itself.

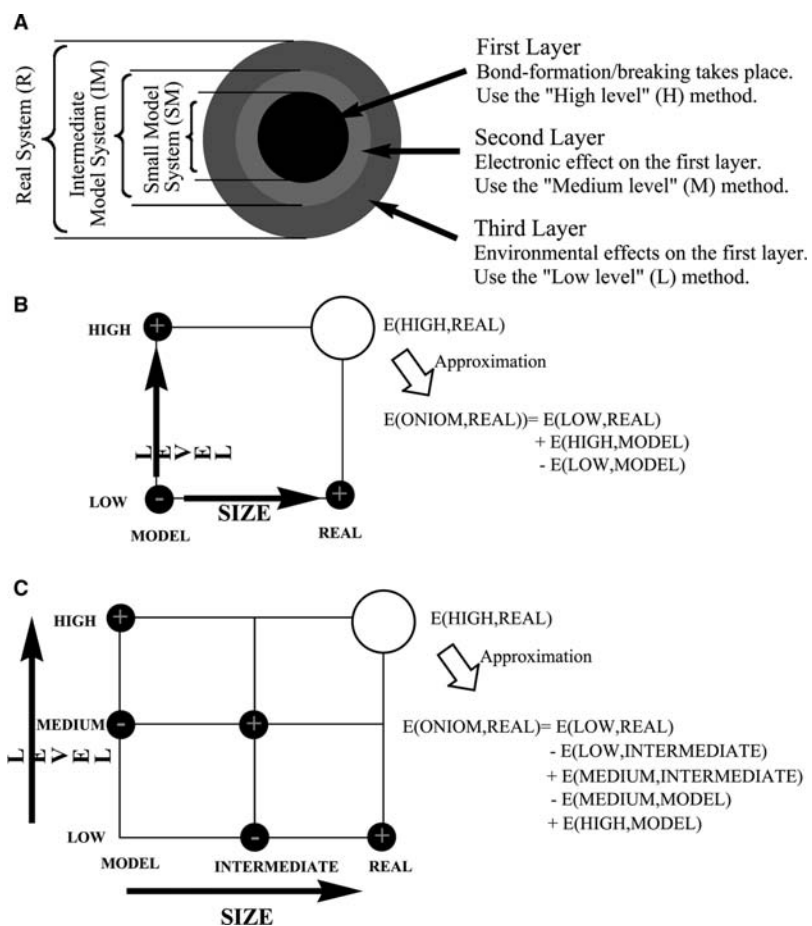

The goal of ONIOM is to describe a large *real* system at a *high* level of theory, which is usually prohibitively expensive,  $E(\text{high, real})$ . In ONIOM, this target calculation is extrapolated from a computationally more feasible, *lower*-level calculation for the *real* system,  $E(\text{low, real})$ , and an accurate *high*-level calculation for a *model* system,  $E(\text{high, model})$ , together with a “correction” term  $E(\text{low, model})$ :

$$\begin{aligned} E(\text{ONIOM, real}) &= E(\text{low, real}) \\ &+ E(\text{high, model}) \\ &- E(\text{low, model}) \quad (4) \end{aligned}$$

These are three calculations that can be carried out independently from each other, and the scheme can easily be extended to three or more layers of any theoretical method, as shown in Fig. 1. Unique to ONIOM and in contrast to the QM/MM hybrid method, it is possible to combine different theoretical levels of MO-based methods, making ONIOM more useful for extended quantum systems. Furthermore, energy gradients with respect to nuclear coordinates  $\partial E(\text{ONIOM,real})/\partial E(\mathbf{R}_{\text{real}})$  as well as various properties, such as electron densities, dipole moments, nuclear magnetic shielding, etc., are well defined and can be calculated in the same spirit as ONIOM expectation values of the corresponding operator  $o$  as

$$\begin{aligned} \langle o(\text{ONIOM, real}) \rangle &= \langle o(\text{low, real}) \rangle \\ &+ \langle o(\text{high, model}) \rangle \\ &- \langle o(\text{low, model}) \rangle \quad (5) \end{aligned}$$

Specific ONIOM combinations are uniquely denoted as ONIOM(high-level method: low-level method) with a “:” (colon) separating individual layer methods.

**Fig. 1** The ONIOM method. (A) The onion skin-like layers and models. (B) The two-layer ONIOM method. (C) Three-layer ONIOM method.

Although ONIOM(MO:MO)-type calculations include the extended electronic structure of the real system in the low layer, the user is not released from the duty of paying attention if the system under investigation can be soundly partitioned into a high-level and a low-level layer. ONIOM works well only if the "major players," i.e., the area of chemical transformation, are fairly localized in a specific region of the system, with the outer environment playing the role of "minor players" or "spectators." An arbitrary choice of partitioning scheme and method combination may not work, and therefore a systematic procedure to test the reliability of the level/method combination has been devised.<sup>[44]</sup> This test is based on the so-called

$S$ -value (substituent value), which is defined at a given level as

$$S(\text{level}) = E(\text{level, real}) - E(\text{level, model}) \quad (6)$$

and represents the influence of the environment on the model system. ONIOM becomes exact when  $S(\text{low})$  is identical to  $S(\text{high})$ . The test requires knowledge of  $S(\text{high})$ , and in practice one performs an expensive target calculation for a few compounds out of a series of related systems to which ONIOM is to be applied in order to calibrate the accuracy of ONIOM for the chosen layer/method combination. To illustrate the  $S$ -value test, Table 1 shows an example for the

**Table 1**  $S$ -values (in kcal/mol) and their differences (in parenthesis) for  $C_{sp^3}$ -H bond dissociation for *Iso*-Butane and Toluene, employing a minimal (methane) model and B3LYP/6-31G geometries

Level	<i>iso</i> -Butane		Toluene		
G2MS(R)	-7.75	(0.00)	-16.21	(0.00)	target (high) level
UHF/6-31G(d)	-7.29	(+0.46)	-26.12	(-9.91)	poor low level
RHF/6-31G(d)	-6.73	(+1.02)	-10.28	(+5.93)	poor low level
UMP2/6-31G(d)	-7.72	(+0.03)	6.93	(+23.14)	poor low level
RMP2/6-31G(d)	-8.10	(-0.35)	-15.04	(+1.17)	excellent low level

C<sub>sp3</sub>-H bond-dissociation energy of a series of hydrocarbons and derivatives. Test molecules are *iso*-butane and toluene, with a minimal CH<sub>3</sub>-H as the model system for the bond dissociation process. Here the RMP2/6-31G(d) *S*-value is very close to that of the target high-level G2MS calculation, which is itself an extrapolation method based on CCSD(T) and MP2 energetics<sup>a</sup>, making RMP2/6-31G(d) an ideal low-level method in conjunction with the high-level G2MS method in this example. Other methods in Table 1 are, however, off by as much as 20 kcal/mol, indicating that these are very poor level methods in combination with the G2MS high-level method. Tests such as these are necessary in order to assess the reliability of ONIOM calculations. Keeping this in mind, however, ONIOM is potentially a very powerful, and to date in fact the only large-scale, electronic structure method delivering high accuracy.

## APPLICATION OF HYBRID AND INTEGRATED METHODS IN NANOCHEMISTRY

### Fullerene Chemistry

Following their first appearance in mass spectra, C<sub>60</sub>, larger and smaller fullerenes, as well as their derivatives and chemical reactions, have become some of the most popular objects for research in theoretical and computational chemistry worldwide. Almost any theoretical method available to the computational chemist has been applied in the calculation of their properties and reactivities, with the only exception of expensive correlation methods based on multireference wave functions.<sup>[47–49]</sup> Here we will concentrate on the application of integrated methods that have been employed in the theoretical study of fullerene chemistry.

### Bond-breaking energies in C<sub>60</sub> fullerene

The first documented work on C<sub>60</sub> using an integrated method was published in 1999 and presented ONIOM3 results for adiabatic S<sub>0</sub> → T<sub>1</sub> and S<sub>0</sub> → Q energy splittings as models for bond-breaking processes in fullerene molecules.<sup>[50]</sup> The target method in this case was the highly accurate, single-reference G2MS level of theory, and a three-layer ONIOM3 approach was chosen to extrapolate G2MS single-point energetics for the singlet ground state and first triplet and quintet states of C<sub>60</sub> for AM1-optimized geometries. This way, single- and double-bond-breaking processes for the hexagon/hexagon C–C bond in C<sub>60</sub> were studied, using

ethylene as the high-level model and naphthalene as the intermediate-level model. For this system size with G2MS as target method, performing an *S*-value test is clearly impossible, and therefore the accuracy of different ONIOM3 energetics was determined by comparison with the experimental adiabatic S<sub>0</sub> → T<sub>1</sub> splitting of 36.1 kcal/mol. At the time this work was done, it was found that the best ONIOM3 methodology applicable to this problem was a G2MS:MP2:HF (H)igh:(I)ntermediate:(L)ow-level combination with naphthalene and ethylene as intermediate and small model, respectively, specifically the ONIOM(G2MS(R):ROMP2/6-31G(d):RHF/6-31G) methodology with a computed S<sub>0</sub> → T<sub>1</sub> splitting of 35.1 kcal/mol in almost perfect agreement with experiment. This was an indication that the G2:MP2:HF combination generally seems to work very well. In a later study it was observed that, if the target level is CCSD(T) or a G2-like method, the best choice of lower level is MP2, and that HF is a good lower-level choice for MP2.<sup>[44]</sup> No practicable single-level quantum chemical methods can even give qualitatively similar results for the bond-breaking processes of C<sub>60</sub>, as HF/6-31G for the real system lacks important dynamic electron correlation, and correlated calculations on model systems alone lack sufficient  $\pi$ -conjugation and the strain of the carbon cage.

### Insertion of a small atom or ion into the C<sub>60</sub> cage

Encouraged by the success of the previously described G2:MP2:HF ONIOM3 study, a similar ONIOM scheme was applied for the study of Li<sup>+</sup> insertion into the orifice of a chemically modified C<sub>60</sub>,<sup>[51]</sup> created by a concerted ring-opening retro [2 + 2 + 2] cycloaddition reaction as proposed by Rubin et al.<sup>[52]</sup> Precursors to the opened species are hypothetical hexahydro and hexamethyl derivatives, as well as the experimentally studied bistriazoline and bislactam derivatives. Common to these modified fullerene molecules are six substituent bonds attached to a single hexagon of C<sub>60</sub>, leading to six single C–C bonds, thereby interrupting  $\pi$ -conjugation in this region. As can be seen in Fig. 2 (which also shows the three different ONIOM layers), this hexagon can easily break open in two ways to reduce ring strain and reestablish  $\pi$ -conjugation by cutting bonds of either adjacent five-membered (5-open) or six-membered (6-open) rings. Aromatic stabilization arguments already suggest that leaving six-membered  $\pi$ -conjugated rings intact (5-open species) would be preferable, and previous AM1 and PM3 semiempirical methods already indicated this preference. The *S*-value of ONIOM is very helpful in quantifying these effects. Here particularly interesting is the *S*(I–M)-value between the (M)odel and (I)ntermediate systems, which is calculated to be about 28 kcal/mol more

<sup>a</sup>The G2MS energy is a simplified version of the G2 method and is defined as G2MS = CCSD(T)/6-31G(d) + MP2/6-311 + G(2df,2p)-MP2/6-31G(d), which extrapolates the CCSD(T)/6-311 + G(2df,2p) result.

stabilizing for 5-open species as opposed to the 6-open species. Subsequent  $\text{Li}^+$  insertion barriers were optimized using an ONIOM2 approach with MP2/6-31G(d) and RHF/3-21G for the intermediate model and the real system, respectively, and the transition states characterized by performing vibrational frequency analysis at the same level of theory. The lithium cation, as the smallest representative of a metal, experiences still a relatively high barrier for the hypothetical hexahydro and hexamethyl open derivatives between 45 and 62 kcal/mol, its value closely related to the size of the opening diameter. The bistriazoline and bislactam systems, however, exhibit slightly larger orifices, causing the barrier to drop down to 20 and 16 kcal/mol. In recent experiments, He atoms with a comparable atomic radius to  $\text{Li}^+$  have indeed been successfully inserted into the bislactam species,<sup>[53]</sup> confirming the predictions of this ONIOM3 work.

### Dynamics of endohedral fullerene complexes

Besides the formation mechanism and/or synthetic routes for endohedral and exohedral metal fullerene complexes, the dynamics of metal atoms in these systems is of great interest to theoreticians, because experimentally only very limited information can be obtained on their dynamics within or on the surface of the carbon cage. However, because strong charge transfer typically characterizes most endohedral and exohedral fullerene complexes, reasonable quantum chemical molecular dynamics simulations have to be performed for this purpose. Only recently, semiempirical QM/MM MD studies on the dynamical change of Be effective charges in  $(\text{Be} + n\text{H}_2)\text{-C}_{60}$  endohedral fullerene complexes ( $n = 0, 1, \text{ and } 2$ ) in the bulk were published by Shigeta and Saito<sup>[54]</sup> in order to elucidate the controversial question<sup>[55]</sup> as to whether the Be

atom could become negatively charged for  $n = 0$  at finite temperatures. In this study, spin-restricted AM1 dynamics are performed on singlet and triplet electronic states for a single complex, surrounded by periodic replicant MM images to simulate NVT ensembles. While MM2 parameter sets were used for MM interactions, the NDDO approximation was selected for QM/MM electrostatic interactions, with effective charges on MM atoms being replaced by the single molecule AM1 Mulliken charges. Total simulation time was 8 psec with time steps of 0.2 fsec under constant temperatures at 0, 100, 200, 300, and 400 K. In these simulations it is found that the endohedral Be atoms are indeed negatively charged in the  $n = 0$  and 1 cases, with charge fluctuation reaching  $0.1 e^-$  at higher temperatures, and that even for the  $n = 2$  case Be becomes occasionally slightly negatively charged during 10 psec of simulations at 400 K. This study revealed that dynamic charge fluctuations are potentially problematic for the design of molecular memory cells based on endohedral fullerene charge transfer complexes.

### Van der Waals interactions with fullerene

Van der Waals complexes represent a challenge for computational chemistry methods because at least the MP2 level with a polarized basis set is required for a qualitatively reasonable treatment of dispersion forces. Although fullerene molecules themselves have been treated before at the MP2 level of theory, these calculations were made possible by taking advantage of the high molecular symmetry characteristic for fullerenes.<sup>[3]</sup> Under chemical transformations, however, the high symmetry is lost, and pure MP2 calculations become beyond the reach of computational practicality. Fomine et al. investigated chemical reactions

of  $C_{60}$  with exactly these requirements, namely, complex formation with the donor molecules dimethyl ether, dimethylamine, dimethylsulfide, furan, pyrrole, and thiophene, choosing a two-layer ONIOM(MP2/6-31G(d):PM3) approach for geometry optimizations.<sup>[56]</sup> Their high-level model system included donor molecule as well as a naphthalene unit (two hexagons plus one adjacent pentagon) of the fullerene. Binding energies were then evaluated using pure LMP2 single-point energies in combination with the 6-31G(d) and 6-311G(d,p) basis sets. Tests on the reliability of the applied methods were carried out only for LMP2 benzene dimer interactions. As LMP2 analytical gradients have not yet been developed for this particular approach, ONIOM2 provided a valuable alternative for the calculation of these fullerene van der Waals complexes.

## Carbon Nanotube Chemistry

The electronic structures of carbon nanotubes (CNTs) have been studied extensively using semiempirical extended Hückel and tight-binding methods, and periodic DFT functionals have been employed as well.<sup>[57,58]</sup> In particular, band gaps and the associated electrical conducting properties for pristine nanotubes with different helical indices and diameters can be explained by using the simple Hückel theory.<sup>[59]</sup> This circumstance is particularly fortunate for theoretical investigations of carbon nanotubes using integrated MO:MO approaches, as the extended tube  $\pi$ -system can be included qualitatively at the low level using low computational cost semiempirical methods. Yet, MO:MM methods have also found application in the theoretical study of CNT chemistry, because they allow the introduction of curvature in these rolled graphitic sheets by means of a “shape restraint” at the low level.

### Functionalization of CNTs

Recent studies by Basiuk et al.<sup>[60–62]</sup> examined the suitability of either AM1 or universal force field (UFF)<sup>[63]</sup> for the lower theoretical level in ONIOM on nanotube chemistry by systematically comparing ONIOM2(B3LYP/6-31G(d):AM1) and ONIOM2(B3LYP/6-31G(d):UFF) approaches for the study of aliphatic amine interaction with carboxylated achiral, hydrogenated open SWCNTs. The model system for the carboxylated armchair or zigzag nanotubes employed in this study included just one hexagon plus two nearest neighbored carbon atoms at the opening with the  $-COOH$  group pointing outside the tube. Also included in the B3LYP/6-31G(d) layer were amines as large as nonylamine, interacting with the carboxylate via a

hydrogen bond. Reactant complexes, transition states, and hydrogen-bonded as well as separated products were computed at both levels, as well as single-level AM1 and UFF. It was found throughout their studies that armchair nanotubes are more reactive than the zigzag type, a conclusion that correlates very well with the fact that the Hückel HOMO–LUMO band gap is zero for infinite armchair nanotubes.<sup>[59]</sup> Because a target B3LYP/6-31G(d) calculation was not performed, the authors could not give a definitive answer as to which method would be more suitable for the lower level, except for the obvious advantage that UFF requires much less computer time than AM1.

Cycloaddition reactions are a natural choice for the functionalization of CNTs, and several types have been studied using integrated methods. Experimentally, the first CNT functionalization was carried out using dichlorocarbene,<sup>[64]</sup> and [2 + 1] cycloaddition reactions investigated using an ONIOM2(B3LYP/6-31G(d):AM1) scheme include dichlorocarbene, silylene, germylene, and also experimentally used oxycarbonylnitrene.<sup>[65]</sup> A pyrene-like, high-level model was chosen for a hydrogenated, open (5,5) armchair nanotube  $C_{130}H_{20}$ , and two reaction sites were investigated: the central, biphenyl-like 1,2-bond, and an adjacent 2,3-bond. The calculations revealed a strong preference for the 1,2-pair site, with thermal stabilities in the order oxycarbonylnitrene  $\gg$  dichlorocarbene  $>$  silylene  $>$  germylene, and suggest that silylene is a favorable [2 + 1] cycloaddition partner which could be employed in future CNT functionalizations.

The same group studied 1,3-dipolar cycloaddition reactions with a series of 1,3-dipolar molecules<sup>[66]</sup> as well as ozone<sup>[67]</sup> and Diels–Alder reactions with 1,3-butadiene and quinodimethane<sup>[68]</sup> on the sidewalls of differently sized armchair nanotubes, using again a pyrene-like part of the sidewall as high-level model in ONIOM2(B3LYP/6-31G(d):AM1) studies. In these studies it is found that both 1,3-dipolar cycloaddition and retro-cycloadditions are moderately dependent on the diameters of the SWCNT, implying the feasibility of making use of such addition reactions to purify and separate SWCNTs diameter specifically.

In a study by a different group, a pyrene-like, high-level model for a (5,5) armchair SWCNT was also selected in an ONIOM2(B3LYP/LANL2DZ:UFF) study on the problem of sidewall oxidation and complexation by  $NH_3$ -catalyzed, synchronized [3 + 2] cycloaddition of transition osmium tetroxide. Reactants, transition states, and cycloaddition products were investigated in the presence of  $NH_3$  and without, and the prediction of this study was that base-catalyzed osmylation should be a very feasible new way to provide a starting point to further functionalize SWCNTs.

## Binding energies of atoms and molecules with CNTs

In 2000, Bauschlicher published the first theoretical binding energies of fluorine and hydrogen atoms to the side walls of a (10,0) open-ended, hydrogen-saturated  $C_{200}H_{20}$  carbon nanotube, using the ONIOM2 (B3LYP/4-31G:UFF) approach.<sup>[69]</sup> These calculations served as an alternative for the high-level *ab initio* calculations of Jaffe on small polyaromatic hydrocarbon molecules, where curvature was artificially introduced by constraining the distance between carbon edge bonds on one hand,<sup>[70]</sup> and the semiempirical AM1 calculations of Kelly et al. on a (10,10) tube<sup>[71]</sup> on the other. Bauschlicher's high-level model was composed of six hexagons surrounding a central hexagon and included 24 carbon atoms, 12 hydrogen link atoms, as well as one hydrogen or fluorine probe atom. Attempts to use semiempirical methods for the low level reportedly failed due to SCF convergence problems that can be attributed to the high density of states near the HOMO–LUMO gap for nanotubes, and the UFF was used instead. It was found that the sum of the first two F atom binding energies of 78 kcal/mol in a 1,2-type addition is significantly larger than the  $F_2$  bond energy, which is only 34 kcal/mol at the B3LYP/4-31G level of theory, whereas calculated binding energies suggest that covalent bonding of hydrogens to the (10,0) tube would be only slightly exothermic. Most noticeably, the first addition of F as well as H yields much smaller binding energies as compared to the second addition. In the quest to investigate the addition of hydrogen to CNT side walls in more detail, ONIOM2 studies on so-called “high coverages” of hydrogen on (10,0) and (9,0) zigzag, and (5,5) armchair achiral, capped tubes have been performed.<sup>[72,73]</sup> These studies with CNT coverage rates between 24% and 100% employ also B3LYP/4-31G and B3LYP/6-31G methods in the high level and use either UFF molecular mechanics or AM1 semiempirical methods in the low level. Twenty-four carbon atoms at the center of the tubes are treated at the high level. It was found that the average C–H binding energies for similar patterns are similar for all three tubes. The 100% coverage on the outside appears to be unfavorable, while 50% hydrogen on the inside and 50% on the outside seem to be a very favorable bonding situation, thus making hydrogen storage in carbon nanotubes a strong, realistic proposition. Similar conclusions were also reached by Froudakis in ONIOM2(B3LYP/6-31G(d):UFF) studies on hydrogen-terminated, open-ended SWCNTs with smaller diameters doped with alkali metal dopants and without.<sup>[74,75]</sup>

CNTs are easy to oxidize and exhibit different electrical conductivities in their oxidized states. There are indications that oxidation might be a reversible pro-

cess, possibly allowing the manufacturing of switches in molecular wires based on oxidized CNTs. The experimental binding energies of  $O_2$  to CNTs remain unknown to date. ONIOM2(MP2:UFF) calculations were carried out both on the physisorption and on the chemisorption of  $O_2$  on the inner and outer walls of a (9,0) CNT to elucidate the binding nature between molecule and tube.<sup>[76]</sup> The basis set for geometry optimizations was 6-31 + G(d,p), whereas larger, augmented, and polarized triple zeta basis sets were used for single-point energetics. Several models were examined, ranging from four to seven fused carbon hexagons plus one  $O_2$  molecule. Similar to the case of fullerenes described above, the MP2 method was used to describe van der Waals interactions between the tube and the  $O_2$  molecule. Physisorption was found to be favorable inside and outside over a single hexagon, with a small binding energy of about 2.5 kcal/mol for triplet  $O_2$  being aligned parallel to the hexagon plane. Little charge transfer was found with Mulliken population analysis, suggesting that the band gap of the CNT would only be insignificantly modified. Chemisorption in a [2 + 2] cycloaddition reaction was computed to be favorable by 20 kcal/mol, but associated with a large barrier of 65 kcal/mol, making this process very unlikely. The nature of defects of significantly modified oxidized CNTs remains therefore unclear and subject to future studies.

Very similar in spirit, however, with a much smaller high-level model system, an ONIOM2(MP2:UFF) study was carried out for the interaction of a (9,0) capped tube with the  $N_2$  molecule, where the experimental binding energy is known to be 2 kcal/mol, suggesting physisorption in this case.<sup>[77]</sup> Similar to the previously described studies, large basis sets were used for single-point MP2 energetics, while 6-31G(d) was used for geometry optimizations. However, as high-level model, only ethylene plus  $N_2$  was considered, and no *S*-value test was performed. Their good agreement of the computed binding energy of 1.88 kcal/mol with experiment was explained to be related to error compensation. The same group published also interaction energies of N and O atoms with CNTs using ONIOM2(B3LYP/6-31G(d):UFF) and ONIOM2(B3LYP/6-31G(d):B3LYP/STO-3G) approaches.<sup>[78]</sup> Once again, ethylene was used as the high-level model part for the CNT, and both the doublet and quartet states for the N-bridged structure are found to be bound. The author says that in case of O the present ONIOM calculation fails “miserably.” As no *S*-value test was performed, it is not clear whether the poor model or the poor low-level method is responsible for this failure.

## Vibrational spectroscopy

While there have been many calculations on the vibrational spectra of various types of pristine carbon

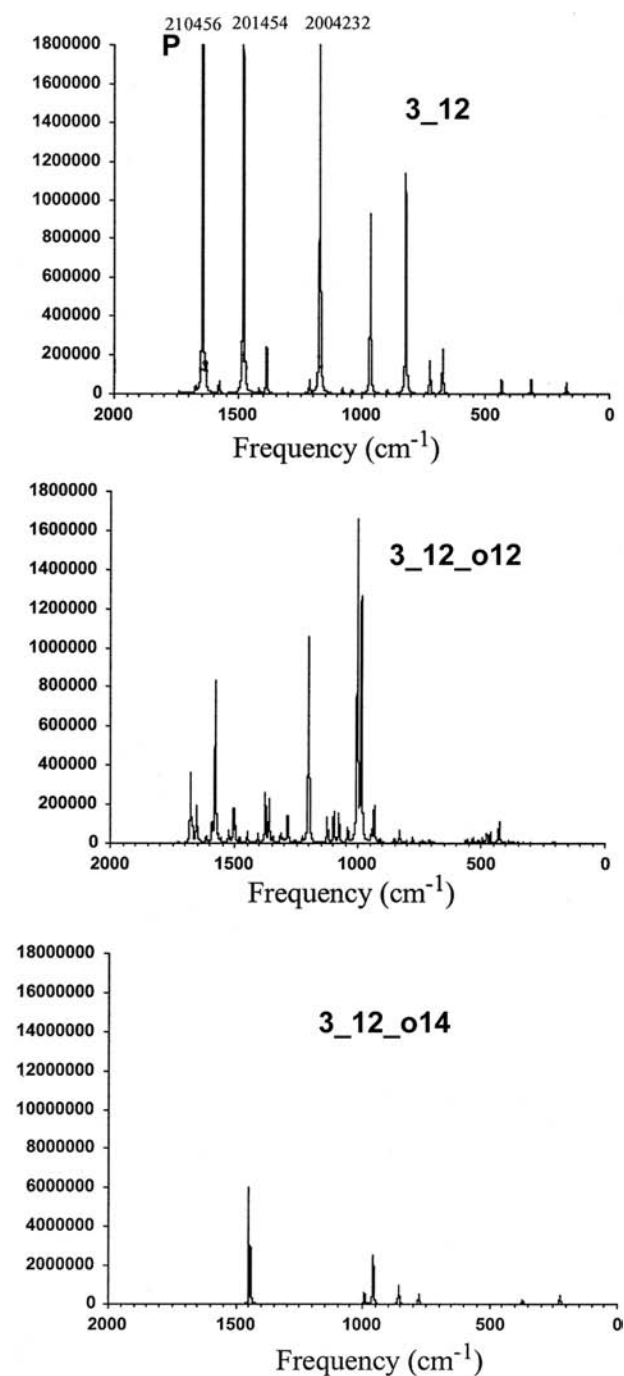

**Fig. 3** Side and top views of the ONIOM(B3LYP/6-31 G(Od):B3LYP/STO-3G)- optimized geometries of three-layered belt of [12]-cyclacene **3\_12** and its doubly oxidized 1,2-(**3\_12\_012**) and 1,4-forms (**3\_12\_014**). Bond lengths are given in angstrom. For **3\_12**, numbers in parentheses correspond to a pure B3LYP/6-31 optimization. nanotubes using periodic semiempirical extended Hückel or simple molecular mechanics calculations, only one work appeared in the literature predicting the change in Raman spectra for models of SWCNTs upon oxidation.<sup>[79]</sup> In this study, geometry optimizations and frequency calculations were performed using pure B3LYP/6-31G(Od)<sup>b</sup> density functional theory for small cyclacene rings, and the ONIOM2 (B3LYP/6-31G(Od):B3LYP/STO-3G) method for a larger

<sup>b</sup>The simple 6-31G basis set was used for carbons and *d*-polarization functions were used only on oxygen.

SWCNT model. Macrocycles consisting of 6 and 12 fused C<sub>6</sub> hexagon units, C<sub>24</sub>H<sub>12</sub> and C<sub>48</sub>H<sub>24</sub> or [6]- and [12]-cyclacene, respectively, were chosen as models for the pure B3LYP/6-31G(Od) calculations, whereas a vertically extended belt model with three fused [12]-cyclacenes, C<sub>96</sub>H<sub>24</sub>, was studied at the ONIOM level. The oxidation was modeled by 1,2- or 1,4-cycloaddition products of two oxygen atoms at the furthest ends of each macrocycle; 1,4-adducts are found to be much more stable than 1,2-adducts and are possibly the actual oxidation products. It was found for all these cases that, when oxygen atoms react, the macrocycles undergo large deformation from the totally symmetric

**Fig. 4** Calculated Raman spectra for the three-layered belt of [12]-cyclacene **3\_12** and its oxidized forms **3\_12\_012** and **3\_12\_014**. Source: From Ref.<sup>[79]</sup>.

cyclic structure toward an oval shape (Fig. 3). This is due to the introduction of  $sp^3$  centers on the ring and subsequent relaxation of the adjacent  $C_6$  hexagon units. Upon oxidation, the calculated Raman spectra show a large reduction in peak intensities (Fig. 4), which can be ascribed to the loss of cylindrical symmetry due to structural deformation. Thus this study suggested a novel explanation for the experimental

observation that the Raman spectra of individual CNTs are highly sensitive to oxidization.

### Photoluminescence of Silica-Based Nanoscale Materials

The study of silica-based nanoscale materials is an important issue because of their potential broad applications in the design of combined Si/SiO<sub>2</sub> systems such as metal-oxide-semiconductor (MOS) and nanoscale silicon optoelectronic devices and Si/SiO<sub>2</sub> superlattices.<sup>[80,81]</sup> However, the origin of the photoluminescence (PL) properties of Si/SiO<sub>2</sub> systems is still a subject of speculation and theoretically very difficult to tackle as electronically excited state calculations have to be carried out which are usually very expensive and prohibitive for nanometer-sized systems. However, Mebel et al. recently performed a combined experimental and theoretical study using a two-layer ONIOM2(B3LYP/6-31G(d):PM3) approach for geometry optimizations with subsequent time-dependent density functional theory (TDDFT) single-point calculations for excited state energies,<sup>[82]</sup> and showed that combined defects including nonbridging oxygens (NBO) and an oxygen vacancy (OV) in various positions exhibit suitable properties both for energies and oscillator strengths, which are responsible for the observed PL bands. These combined defects are proposed to occur in extremely thin (~1 nm) nonequilibrium substoichiometric silicon oxide (SiO<sub>x</sub>,  $x < 2$ ) layers. The combined ONIOM2 and TDDFT calculations clearly indicate that the PL band shift can be induced by one, two, and three OVs in the nearest vicinity of NBO, and that Si-Si bond relaxation in OVs as well as the orientation of NBOs and distances between them and OVs influences transition energies and oscillator strengths. In order to compute equilibrium geometries for these defect sites, a high-level layer containing 5 Si and 12–15 O atoms was introduced, surrounded by a low-level SiO<sub>2</sub> cluster treated with the semiempirical PM3 method. The combination of ONIOM ground state equilibrium geometry optimization with single-point TDDFT results leads to excitation energies that closely match the PL peaks observed.

### Data Storage on an Atomic Scale

Bauschlicher et al. have suggested in a series of papers<sup>[83–86]</sup> that it could be possible to store one bit of data on a surface using one atom, leading to a hypothetical data density that is about 1 million times higher than today's storage technique using magnetic disks. Their idea is based on the experiments of Avouris et al. who demonstrated that specific hydrogen

atoms can be removed from a hydrogen passivated silicon surface using an atomic force microscopy (AFM) by applying an electric field.<sup>[87]</sup> According to Bauschlicher et al., data could be stored by depositing heteroatoms X on the missing hydrogen positions and be read using a functionalized CNT. For this purpose it is extremely important that a clear difference can be found between the presence of data atoms X and hydrogen on the surface, and highly accurate calculations for the tip/H and tip/X interactions are required. Pure B3LYP/6-31G quantum chemical calculations were performed on a surface model featuring 13 Si atoms, and the AFM tip was modeled using a pyridine molecule. These calculations were applied to the study of four scenarios: the interaction of pyridine with X surrounded by six X or H atoms, or H surrounded by six X or H atoms. It was found that the choice of chlorine as data atom X is preferable over fluorine or cyanide, as the pyridine/Cl interactions were distinguishable from pyridine/H interactions by more than 1 kcal/mol in the worst-case scenario. In order to make their system more realistic, the ONIOM3-(B3LYP/6-31G:AM1:UFF) three-layer approach was employed for a Si<sub>74</sub>H<sub>61</sub>X<sub>7</sub> (X = H or Cl) two-slab model for the silicon surface, with the pyridine molecule being attached to an approximately 17-Å-long (5,5) SWCNT.<sup>[88]</sup> In order to include the effect of the CNT electronic structure, the nanotube was always treated at the AM1 semiempirical level, while the pyridine and all seven data atoms are chosen to be members of the B3LYP/6-31G high level. The silicon surface was treated using AM1 for the first slab consisting of 37 silicon atoms, allowing the electronic structure of silicon to influence the electronic charges on data atoms, while the UFF force field was applied to the second slab in order to prevent the silicon surface from deforming too much due to the different Si-Cl and Si-H interactions. Full geometry optimizations on all four scenarios were carried out, and it was found that in particular the addition of the second silicon slab improves the stability of the surface model greatly while interaction energies and N-surface distances were quite similar to those obtained with the smaller models at the pure B3LYP/6-31G(d) models. The electronic structure of the CNT did not significantly affect the interaction energies, and the conclusion of Bauschlicher et al. is that the Si (111) surface with H and Cl data atoms should be seriously considered as a possible method for data storage at the atomic level.

## CONCLUSION

Without doubt, hybrid QM/MM and even more so integrated ONIOM (MO:MO) methods have found

widespread application in a variety of nanochemical problems. They have served to accurately predict carbon-carbon bond energies in fullerene and the insertion barriers of metal atoms into their chemically modified derivatives, to study cycloaddition functionalization reactions of carbon nanotubes, to describe van der Waals complexes between adsorbent molecules and carbon nanostructures, and to predict vibrational and excitation spectra of systems with as large as 100 atoms. While these investigations mark already remarkable achievements on the way toward better understanding of the chemistry on the nanoscale, we would like to emphasize that the potential of integrated methods is actually far greater and predict that they will play an even more important role for the study of nanoscale electronic structures.

A major obstacle in their current applications is the fact that *S*-value tests cannot be performed simply in the context of nanochemistry using conventional high-level methods. Yet, linear scaling and RI-DFT methods are becoming more and more available<sup>c</sup> and popular, pushing the limits of DFT applicability to systems with up to approximately 1000 atoms. *S*-value testing thus becomes much more realistic, e.g., in an RI-DFT:AM1 approach, and knowledge obtained in these tests can be transferred to similar combinations such as B3LYP:AM1, where no *S*-value test can be performed.

Another benefit of these and LMP2 and RI-MP2 methods is that the size of the high or intermediate model systems can be increased to several hundred atoms as well, allowing calculations of systems with several thousands of atoms with semiempirical methods in the low layer. A very promising, yet never attempted low-level method is the self-charge consistent density functional tight-binding (SCC-DFTB) method, which will give more consistent results in combination with DFT high-level methods than more traditional semiempirical methods such as AM1 and PM3. Extension of DFTB in a massively parallel scheme toward the treatment of perhaps 100,000 atom systems is within current reach, expanding the size of future ONIOM calculations dramatically.

In addition, RI-MP2 analytical gradients are available and proved to be very accurate and reliable approximations for true MP2 gradients, thus allowing van der Waals complexes to be fully optimized in an ONIOM scheme with an approximated MP2 quality for the interaction region, electronically embedded in the remainder of the nanostructure-treated DFT or semiempirical methods. Three-layer ONIOM schemes,

<sup>c</sup>For instance, RI-DFT as implemented in the TURBOMOLE program package<sup>[28]</sup> can be easily facilitated in the GAUSSIAN external ONIOM scheme.<sup>[46]</sup>

although not popularly practiced yet, have impressively proven their predictive powers and should play a much more pronounced role in the future, e.g., in a G2MS:RI-MP2:HF hierarchy. For electronic excited states, computationally efficient TDDFT and RI-CC<sup>[89]</sup> methods will play an important role to extend the size of the low level in ONIOM calculations, where the model system is described using multireference wavefunction methods.

While all of the above schematics explore chemistry in a static manner, quantum chemical molecular dynamics have become an indispensable tool for the study of phenomena at the nanoscale. A spectacular success was recently presented where single-level DFTB MD has been used to elucidate the formation mechanism of fullerenes.<sup>[23,24]</sup> ONIOM MD has recently been performed on the solvation problem of simple metal cations,<sup>[90,91]</sup> and we expect even greater and more accurate insight into the dynamics of nanostructures on the atomic level using high-level quantum chemical methods.

## INTRODUCTION

Polypropylene (PP) is a versatile material whose use has significantly penetrated numerous sectors of the manufacturing, medical, and packaging industries. Polymer clay nanocomposites are multiphase organic/inorganic hybrid materials pioneered by researchers at Toyota,<sup>[1–3]</sup> which may exhibit significantly improved mechanical, flammability, and permeability properties relative to the base polymer matrix at very low clay loading. Although first demonstrated for nylon, polymer clay nanocomposites have since been prepared for a range of thermoplastic and thermoset polymers. However, the development of PP clay nanocomposites poses special challenges because of polypropylene's hydrophobicity. Nevertheless, possible commercial applications have motivated substantial research into strategies for the dispersion of clays in this technologically important polymer. This entry reviews recent progress in the synthesis, preparation, and characterization of polypropylene nanocomposites. The resulting clay intercalation structure receives particular attention because most polypropylene nanocomposites prepared to date have yielded significant structures of this kind. After reviewing the state-of-the-art in polypropylene nanocomposite synthesis, characterization of clay and polymer morphology, and measurement of rheological and mechanical properties, we identify future research challenges that should be addressed to continue improving the possibility for commercial applications of these materials.

## OVERVIEW

Mixtures of clay platelets and polymer chains compose a colloidal system. Thus in the melt state, the propensity for the clay to be stably dispersed at the level of individual disks (an exfoliated clay dispersion) is dictated by clay, polymer, stabilizer, and compatibilizer potential interactions and the entropic effects of orientational disorder and confinement. Anisometric dimensions of clay platelets also have implications for stability

because liquid crystalline phases may form. In addition, the very high melt viscosity of polypropylene and the colloidal size of clay imply slow particulate dynamics, thus equilibrium structures may be attained only very gradually. Agglomerated and networked clay structures may also lead to non-equilibrium behavior such as trapped states, aging, and glassy dynamics.

Clay structure in polymer nanocomposites can be characterized as a combination of exfoliated platelets and intercalated tactoids. Clays themselves are layered silicate minerals with charged surfaces neutralized by interlayer counterions. Unless a liquid crystalline order disorder transition occurs, the exfoliated structure is spatially and orientationally disordered and the clay is dispersed at the level of individual disks. Intercalated clay retains interlayer ordering, at least within a particular tactoid; however, intergallery spacing is increased relative to natural clay because stabilizing surfactants, compatibilizers, and/or matrix polymers are infiltrated within the clay galleries. In the extreme case of clay/polymer matrix immiscibility, intercalation spacing not much greater than the clay and its counterion indicates negligible penetration of polymeric or compatibilizing species between clay layers. Clay platelets or tactoids themselves comprise the mesoscale structure of nanocomposites. Possible structures include that of a dispersed suspension, a percolated network, or a liquid crystal with orientational order. The hierarchy of possible states is depicted in Fig. 1.

The reinforcement of polypropylene and other thermoplastics with inorganic particles such as talc and glass is a common method of material property enhancement. Polymer clay nanocomposites extend this strategy to the nanoscale. The anisometric shape and approximately 1 nm width of the clay platelets dramatically increase the amount of interfacial contact between the clay and the polymer matrix. Thus the clay surface can mediate changes in matrix polymer conformation, crystal structure, and crystal morphology through interfacial mechanisms that are absent in classical polymer composite materials.

For these reasons, it is believed that nanocomposite materials with the clay platelets dispersed as isolated,

**Fig. 1** Schematic of the hierarchy of clay structures in polypropylene nanocomposites of mixed morphology. Clay tactoids and exfoliated platelets comprise the mesoscale morphology. The internal intercalation structure of clay tactoids is determined by the compatibilizer and compounding conditions.

exfoliated platelets are optimal for end-use properties. For example, the high aspect ratio of the exfoliated disk and their nanoscale width provide the greatest potential for solid-state mechanical property enhancement. Furthermore, the probability of defects and inclusions that can compromise the impact strength of composite materials is reduced by homogeneous dispersion at the nanoscale. However, even intercalated clay nanocomposites yield valuable mechanical property enhancement and other useful end-use properties.

This entry focuses on polypropylene–clay hybrid materials. Recent general reviews of polymer clay nanocomposites and their properties are available elsewhere.<sup>[4–6]</sup>

## SYNTHESIS AND PREPARATION

Organophilic smectite clays can be introduced into a polymer matrix by methods involving in situ polymerization or melt mixing. Commonly used layered silicates of this kind include montmorillonite or synthetic sodium fluoromica. These clays typically have submicron disk radii and a width of about 1 nm. Before introducing them into the polymer host, the clays are rendered organophilic by the exchange of natural counterions for more hydrophobic species such as amine surfactants. The ion exchange treatment increases clay intergallery spacing because of the increased excluded volume of the hydrophobic surfactant. Amines with alkyl chain length in the range  $C_{12}$ – $C_{18}$  are most effective in increasing the intercalation spacing of a fluoromica clay.<sup>[7]</sup> However, for polypropylene, these steps alone are insufficient to

generate significant polypropylene intercalation or clay exfoliation.<sup>[8]</sup> The additional step of introducing a compatibilizer consisting of short-chain polypropylene with grafted maleic anhydride (PP-MA) functionality leads to enhanced intercalation and some exfoliation.<sup>[8–12]</sup> The blending has been accomplished by using a molecular diluent, such as toluene or trichlorobenzene, but this requires an additional step to remove the solvent.<sup>[13–15]</sup> Direct melt preparation by twin-screw extrusion or Braebender mixing is more consistent with potential commercial applications. Although the detailed mechanism of intercalation has yet to be elucidated, a qualitative explanation is that the polarity of the maleic anhydride yields more favorable interactions with organophilic clay. These interactions offset the entropic penalty for confinement of intercalated chains. There also exists the possibility of acid–base equilibrium reactions of the amine surfactant and maleic anhydride.

In efforts to manipulate the degree of dispersion and mechanical properties of polypropylene nanocomposites, researchers have varied clay surface treatment, compatibilizer molar mass, and compatibilizer acid content. The miscibility of the compatibilizer with neat polypropylene at melt temperatures,<sup>[10]</sup> higher compatibilizer acid content,<sup>[11]</sup> and larger compatibilizer loading<sup>[16]</sup> have been reported to be conducive to improved intercalation spacing and dispersion. However, the molar ratio of MA to PP-MA has also been proposed as an indicator of intercalation capability.<sup>[17]</sup> Kim, Kim, and Lee<sup>[18]</sup> found that maleic anhydride content above about 1.0% is undesirable because it leads to the reordering of clay layers. Other intercalation and compatibilization agents, such as diethyl maleate graft polypropylene, semifluorinated

alkyltrichlorosilane, and epoxypropyl methacrylate, have also been used to prepare polypropylene nanocomposites.<sup>[15,19,20]</sup> Recently, novel methods to promote dispersion by supercritical processing have been disclosed.<sup>[21]</sup>

The effect of melt compounding fluid dynamics on dispersion and end-use properties has, to date, received limited attention for the specific case of polypropylene nanocomposites. Lack of control of these parameters is likely a significant source of the substantial variation among literature reports of intercalation spacing and materials property characterization. A possible mechanism for the interaction of flow and clay dispersion has been provided by Fornes et al.<sup>[22]</sup> Their schematic, reproduced in Fig. 2, shows that when clay is dispersed by non-equilibrium mechanisms such as melt compounding, applied flow fields can act to rupture initially large clay aggregates, to refine tactoid dimensions, and to promote exfoliation by contacting the compatibilizer, clay, and matrix polymer.

Although melt compounding is currently the principal method of polypropylene nanocomposite preparation, metallocene catalysis yields nanocomposites with high polymer isotacticity by in situ polymerization.<sup>[23]</sup> In situ polymerization to prepare polypropylene nanocomposites is potentially attractive because of the reduced need for compatibilizer treatments that are

required in melt compounding. Although exfoliation and mechanical property enhancement are achieved by in situ polymerization, current reports indicate that the dispersion is not entirely homogeneous because micrometer-size, clay-rich particles persist after polymerization.<sup>[23]</sup>

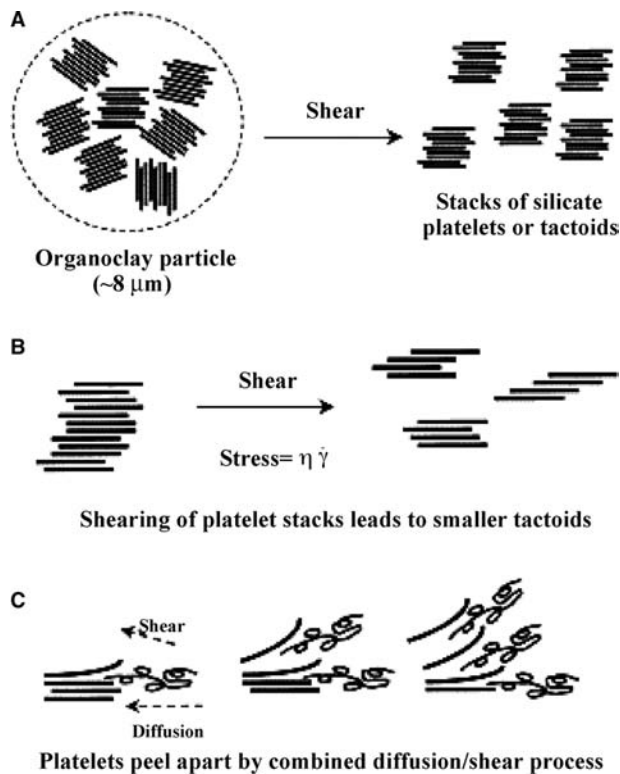

## CHARACTERIZATION OF CLAY INTERCALATION AND EXFOLIATION STRUCTURE

X-ray diffraction (XRD) and transmission electron microscopy (TEM) are principal methods for the interrogation of the intercalation structure of polymer clay nanocomposites. The ordered clay layers yield peaks in XRD intensity at scattering angles specified by the Bragg condition. For example, the spacing for naturally occurring Na-montmorillonite is about 1.1 nm. For one preparation,<sup>[24]</sup> when natural counterions were exchanged for stearylamine, the interlayer spacing increased to 2.1 nm, and melt compounding in polypropylene with a PP-MA compatibilizer further increased the intercalation spacing to 2.9 nm. In comparison, melt compounding of organophilic montmorillonite in neat polypropylene yields little increase in spacing,<sup>[10]</sup> thereby demonstrating the role of the PP-MA compatibilizer in promoting intercalation.

A major challenge in polymer nanocomposite characterization is to quantify dispersion in mixed systems comprised of both intercalated tactoids and exfoliated clay sheets, such as that depicted in Fig. 1. XRD alone offers little scope for such quantification,<sup>[25]</sup> however, quantitative analysis of sufficiently large regions of TEM micrographs is a promising way forward. Techniques for the quantification of the degree of exfoliation in polypropylene nanocomposites with mixed clay morphology have recently been discussed.<sup>[15,17]</sup> These methods should be more routinely employed to better permit the assessment of the relative performance of available synthetic and compounding strategies.

## CRYSTALLIZATION STRUCTURE AND KINETICS

The mechanical properties of semicrystalline isotactic polypropylene materials that are formed by injection molding are inferior to theoretical upper limits based on the polypropylene unit cell. Processing modifications designed to enhance the orientation of PP, such as low injection temperature or dynamic packing operation, can generate modest improvements in tensile modulus, even without the addition of conventional or nanoscopic filler. However, the traditional avenue

**Fig. 2** The mechanisms by which the fluid dynamics of compounding may affect clay dispersion in polymer/clay nanocomposites. *Source:* From Ref.<sup>[22]</sup>. ©Elsevier Science Ltd., 2001.

to manipulate polypropylene properties is to reinforce the polymer with anisometric, high-modulus inorganic particles, such as talc. Another more promising possibility is to tailor the filler so as to induce morphological changes in the crystalline structure of polypropylene itself. These morphological changes will in turn have implications for mechanical properties such as modulus, strength, and toughness. In this scenario, the nanoscopic scale of the filler becomes relevant because smaller fillers, with their larger surface area-to-volume ratio, reside in close proximity to a greater percentage of the bulk PP than conventional fillers. There are a number of ways in which nanoscopic fillers, such as exfoliated or intercalated layered silicate, may influence the crystalline morphology of PP.

First, the crystalline unit cell may change. This effect has been observed in, for example, nylon 6 nanocomposites where addition of clay induces a change from  $\alpha$  to  $\gamma$  crystalline form.<sup>[26]</sup> Three crystalline lattices for isotactic PP are known and there is evidence for preferential formation of the  $\gamma$ -phase in PP nanocomposites.<sup>[27,28]</sup>

Second, the crystalline morphology may be affected. For example, a transformation from spherulitic to oriented structure may occur. When crystallized at high shear rates, PP forms oriented structures that can hypothetically be modified by the presence of dispersed clay.<sup>[29]</sup> Fibrous crystalline morphology has also been reported in PP nanocomposites.<sup>[30]</sup>

Third, the degree of crystallization may change. As quantified by differential scanning calorimetry, it has been reported that the crystallinity of PP nanocomposites decreases modestly with increased clay content.<sup>[31]</sup>

Fourth, the characteristic size of crystalline morphology may be affected. Svoboda et al.<sup>[31]</sup> found that for nanocomposites with spherulitic structure, the average crystallite size decreases significantly with increasing clay content, possibly because of a role of clay in nucleation. Time-resolved light scattering and optical microscopy at the early stages of crystallization have also identified differences in the number of point nuclei in PP and PP nanocomposites.<sup>[32]</sup>

Fifth, the kinetics of crystallization may be modified. Time-resolved light scattering and differential scanning calorimetry studies have found that added intercalated clay can either increase or decrease characteristic crystallization times for polypropylene.<sup>[30–34]</sup> Interactions between an initially present nucleating agent, a PP-MA compatibilizer, and the dispersed clay generate complex crystallization kinetics, even in isothermal crystallization studies.<sup>[32]</sup> The data suggest that nanocomposite crystallization is dominated by the presence of a compatibilizer because nanocomposite data overlay PP/PP-MA blend measurements and crystallization times are not significantly affected by changes in clay loading.<sup>[32]</sup>

Interestingly, there have been preliminary reports of segregation of clay particles at the spherulitic boundary of maleated PP nanocomposites.<sup>[34]</sup> The possibility of polymer crystallization-induced changes in meso-scale clay morphology warrants further investigation because of the implications of such segregation for nanocomposite mechanical properties.

## RHEOLOGY

The flow properties of polypropylene nanocomposites are relevant to processing operations such as injection molding. In addition, the viscoelastic response to linear and non-linear deformation is a sensitive indicator of clay dispersion and interaction. Thus rheology can be used to evaluate the performance of various strategies for synthesizing and compounding polypropylene nanocomposites.

The compounding of organophilic clay and compatibilizer with polypropylene dramatically changes the linear viscoelastic response to shear deformation as quantified by the storage modulus  $G'$  and the loss modulus  $G''$ . Fig. 3 compares the  $G'$  and  $G''$  of polypropylene and an intercalated nanocomposite with 4.8% inorganic clay. The curves differ significantly, particularly at low frequencies. The apparent plateau in the nanocomposite data at low frequencies is consistent either with the response of a viscoelastic solid, or a viscoelastic liquid with a long relaxation time. The abrupt transition from liquidlike to solidlike linear viscoelasticity as clay loading is increased is suggestive of the generation of a gel or a network structure at a critical clay volume fraction. Because it is thought that such clay clustering is not likely to lead to optimal

**Fig. 3** The melt state linear viscoelastic moduli of 4.8 wt.% intercalated polypropylene nanocomposites. *Source:* From Ref.<sup>[24]</sup>. © 2001 American Chemical Society.

end-use properties such as modulus and toughness, measurement of melt state linear viscoelasticity is a useful tool to indirectly characterize the nanocomposite clay structure. Toward this end, qualitative effects of alkyl amine clay treatment and PP-MA compatibilizer acid content on clay structure have been assessed by rheological characterization.<sup>[17,24]</sup> Intercalation kinetics has also been estimated.<sup>[35]</sup> Koo et al.<sup>[36]</sup> generated maleated polypropylene nanocomposites with different intercalated and exfoliated clay morphologies by varying the matrix polymer molecular weight and found that the linear viscoelastic modulus  $G'$  was sensitive to morphological changes.

Non-linear rheological characterization is predictive of nanocomposite behavior in typical processing operations such as injection molding. The presence of intercalated clay even at a clay loading of less than 5.0 wt.% can increase the viscosity by many orders of magnitude at low shear rates; however, at higher shear rates, which are more characteristic of processing conditions, viscosity enhancement is much more modest. This strong shear thinning behavior may have two origins: 1) anisometric particles such as rods and disks display shear thinning even at low concentrations because flow preferentially orients the particles in the flow direction; and 2) deformation applied to a gel cluster network can induce rupture of mechanical contacts and, consequently, shear thinning.<sup>[24]</sup>

Furthermore, non-linear rheological measurements indicate that intercalated polypropylene nanocomposites possess fragile structures that are easily manipulated by flow. For example, the onset of strain dependence of the storage modulus occurs at an applied strain  $\gamma_0 \sim 0.3$  for neat polypropylene; however, the transition for a 4.8 wt.% nanocomposite occurs at  $\gamma_0 \sim 0.007$ .<sup>[24]</sup> The startup of steady shear experiments after samples were presheared and then allowed to rest quiescently demonstrates that structures deformed during flow reestablish themselves on time scales longer than hundreds of seconds.<sup>[24]</sup> Linear viscoelasticity and XRD of intercalated polypropylene nanocomposites annealed for various periods provide additional evidence that structural evolution persists even longer—at least for many hours.<sup>[37,38]</sup> This evolution in linear and non-linear rheology is likely related to strong attractive interactions, aging, and glassy dynamics in polymer nanocomposites that are not stably dispersed.<sup>[24,39,40]</sup>

Although shear rheology has been the focus of most studies to date, a report on the effect of uniaxial elongational flow on maleic anhydride-modified polypropylene nanocomposites has recently appeared.<sup>[41]</sup> Post facto TEM images indicate that at an elongational rate of  $1.0 \text{ sec}^{-1}$  and a Hencky strain of 1.3, clay platelets align perpendicular to the flow direction. Because flow in injection molding is comprised

of a significant extensional component, these results point to the possibility of direction-dependent material properties in components molded by this method.

## MECHANICAL PROPERTIES

Modulus, yield stress, toughness, and heat deflection temperature (HDT) are measures that characterize the potential for improved end-use performance of a polymer nanocomposite relative to the neat polymer or a traditional composite. Dispersed clay can affect the mechanical properties of a semicrystalline thermoplastic such as polypropylene in a number of ways. First, the high-modulus clay inclusions of anisotropic shape can reinforce the thermoplastic. This mechanism differs little from the classical picture of composite reinforcement. Thus in this view, the anisotropic shape of the discotic clay is important to mechanical property enhancement; however, the nanoscopic dimension of the clay plays no direct role. Second, inhomogeneous dispersion that results when even a small amount of micron-scale clay aggregates is present can seriously compromise the material's impact strength. Thus homogeneous dispersion at the submicron scale is desirable for successful practical application of polymer nanocomposites. Third, the nanoscale dimension of the clay filler leads to a large interfacial region at the clay surface. Thus even small amounts of clay can possibly mediate large changes in polymer matrix conformation, crystal structure, or crystal morphology. There is indirect evidence for a role of each of these conditions in mediating polypropylene nanocomposite mechanical properties.

The first reports of the successful preparation of polypropylene nanocomposites showed that the materials demonstrated only modest mechanical property enhancement relative to neat polypropylene or blends of polypropylene and PP-MA. At 7.2 wt.% inorganic clay content, 29% enhancement in tensile modulus was observed for the highest concentration of PP-MA studied.<sup>[12]</sup> Later work has generated improved tensile modulus enhancement. By varying the amine surfactant treatment and anhydride content of the compatibilizer, Reichert et al.<sup>[7]</sup> generated an increase in tensile modulus at 5 wt.% organophilic clay loading, which was as large as 74%. If nanocomposites are prepared in a matrix of pure PP-MA, the relative material property enhancement is slightly greater. For example, at approximately 5 wt.% inorganic clay content, the tensile modulus increased by 86% relative to PP-MA; however, the nanocomposite modulus is still inferior to that typical of neat polypropylene.<sup>[42]</sup> Polypropylene nanocomposites prepared by in situ polymerization

using metallocene catalysis have generated a >100% enhancement in tensile modulus at 10.5 wt.% clay loading.<sup>[23]</sup> A similar performance has been obtained for in situ polymerized PP synthesized by the Ziegler–Natta catalysis.<sup>[43]</sup> These improvements exceed results for other anisometric fillers, such as talc, which are not nanoscopic. For example, Walter et al.<sup>[44]</sup> found that more than 30 wt.% talc was required to yield modulus enhancement comparable to clay nanocomposites with less than 7 wt.% inorganic content.

Although significant progress in enhancing polypropylene nanocomposite tensile moduli has been achieved, this improvement is offset by the reduced elongation at break and impact strength of these materials. Elongation at break, which is a determinant of toughness, has been reported to fall by more than an order of magnitude relative to neat PP on melt mixing with organophilic clays and compatibilizers.<sup>[7,12]</sup> The changes have a number of possible origins: 1) the reduced toughness of PP-MA relative to PP because of its low molar mass; 2) the improved adhesion between the polymer matrix and the intercalated clay induced by the compatibilizer, which contributes to yielding a more brittle material; and 3) immiscible aggregates of clay acting as defects and stress concentrators, which contribute to failure even if they are present only at low concentrations.

A limitation to the penetration of polypropylene into various component and market categories is its low upper use temperature. One measure of this property is the HDT. At 8 wt.% clay, the HDT of polypropylene nanocomposites synthesized by in situ Ziegler–Natta catalysis is 40°C greater than for pure PP.<sup>[43]</sup>

## CONCLUSION

Recent research has generated advances in polypropylene nanocomposites that are sufficient to motivate new technological applications. For example, PP-based nanocomposites have been developed for application as exterior automotive components.<sup>[45]</sup> Cone calorimetry measurements of peak heat release rate from maleated PP nanocomposites with 4% loading are reduced by 75% relative to the pure polymer.<sup>[46]</sup> These improvements are relevant to applications requiring reduced flammability.

Yet, relative to other thermoplastic nanocomposites, such as nylon 6, the improvement in end-use properties for polypropylene nanocomposites has been modest. Thus research in the areas of synthesis and, especially, compounding, which are aimed at closing this performance gap, is necessary. Alternatively, improved fundamental understanding of the

detailed interactions and chemistry between clays, amine surfactants, and maleic anhydride compatibilizers can help elucidate the complex thermodynamics of clay dispersion. In addition, noting that many synthesized PP nanocomposites are likely to exist as non-equilibrium structures, research into the aging and rejuvenation of these mesoscale structures is warranted. Furthermore, better methods to characterize the full distribution and hierarchy of structural states present in PP nanocomposites are required because, for example, rare aggregates can seriously compromise non-linear mechanical properties such as toughness, yield stress, and elongation at break. Finally, the interaction between clay platelets and polymer crystallization requires further attention because these interactions are likely a significant determinant of the end-use properties of polypropylene nanocomposites.

Melbourne, Victoria, Australia*

## INTRODUCTION

Coalescence phenomena, emulsion stability, and the role of colloids in stabilizing liquid–liquid emulsions have been the subject of intensive study, yet there is still no satisfactory quantitative theory for the prediction of the rate of coalescence of drops at an interface or in an emulsion. Direct measurement of the forces between a liquid interface and another liquid interface or a colloid particle has been a key piece of information that has been missing. This entry describes recent advances in the theory and experimental techniques in colloid chemistry that enable the direct measurement of these forces.

This is an important step in the understanding of coalescence and emulsion stability phenomena.

## BACKGROUND OF THE MEASUREMENT OF SURFACE FORCES

The measurement of surface forces has, for many years, been the focus of much interest in the field of colloid and surface science.<sup>[1]</sup> This is principally because the long-range interactions between particles frequently control the ability of a dispersion to resist coagulation/flocculation. In addition, the rheology of dispersions can also be determined to a large degree by interparticle forces.

The interaction of solid colloidal particles with deformable liquid interfaces is of fundamental interest in many technologically important areas. Understanding the behavior of the forces acting at a liquid interface and, hence, the interactions that occur in solid/fluid particulate dispersions, is motivated by the myriad of problems encountered in many chemical engineering and processing applications within the pharmaceutical, cosmetic, and mineral processing industries, in the preparation and processing of foods, and in a vast range of biomedical technologies. For example, the interactions between solid and deformable fluid interfaces are important in determining the wetting characteristics of surfaces by liquids.<sup>[2]</sup> The

quantitative understanding of the forces acting at a liquid interface and how they are influenced by various additives is important to understanding the behavior and properties of fluid and solid particulate dispersions. The need to understand the interactions present in these systems is evident, in view of their ubiquitous presence and importance.

Interaction forces involving such interfaces have been deduced previously from measurements of related properties, such as contact angle, interfacial tension, and electrophoretic mobility. These measurements, while invaluable, provide only a qualitative assessment of long-range forces, and are unable to describe the response of a deformable interface to an approaching particle or surface.<sup>[2]</sup> Hence, the direct measurement of surface forces involving a deformable surface is important. The measurement of surface forces involving liquid interfaces is complex due to interfacial fluidity and deformability. These two features can have a great impact on hydrodynamic interactions and the resulting dynamic properties of such systems,<sup>[3–9]</sup> which are particularly important for the kinetic stability of emulsions.<sup>[3–5,10,11]</sup> With the exception of thin film measurements<sup>[12–19]</sup> (discussed later), the experimental complexities associated with direct force measurements between deformable interfaces have restricted their study. Until recently, there has not been any equilibrium study of surface forces, either experimentally or theoretically, which provides a description of the influence of surface interaction on these deformable systems. Attempts to obtain direct force measurements experimentally have been performed recently on solid–oil droplet systems and are described in the following paragraphs.

## INTERFACIAL (DLVO AND NON-DLVO) FORCES

The methodologies for the study of interactions between non-deformable surfaces are well established, and for well-characterized systems, experimental results are in good agreement with theoretical

predictions.<sup>[20–22]</sup> In the literature there is much data describing the interaction between two solid surfaces or particles dispersed in an aqueous solution. Most of these results have for their fundamental origin the mean-field theory of colloidal interaction published over 50 years ago by Derjaguin et al.<sup>[20,21]</sup> In recent years, Chan et al.<sup>[23–27]</sup> have, as a result of systematic studies covered many possible configurations of particle charge and shape, produced abundant data useful to the colloid chemist or physicist.

The stability of a colloid depends on the relative magnitude of the potential energies of attraction and repulsion with separation between a pair of particles.<sup>[28]</sup> The two most important forces acting in colloidal dispersions are the electrical double-layer (EDL) force and the van der Waals (vdW) force. The Derjaguin–Landau–Verwey–Overbeek (DLVO) theory, which includes only the combined effects of these two forces, is widely used to explain properties of colloids. The interaction free energy between two surfaces,  $V_T$ , is calculated by summing the repulsive EDL interaction energy,  $V_R$ , and attractive vdW interaction energy,  $V_A$ , thus:

$$V_T = V_A + V_R \quad (1)$$

According to DLVO theory, the stability of a lyophobic colloidal sol is determined by the shape of the total potential energy curve, which is the balance between the repulsive and attractive forces that the particles experience as they approach each other. The shape of the total potential energy curve for a sol is very important in understanding its behavior (Fig. 1).

At a fundamental level, van der Waals interactions are of importance in colloid and polymer science. The force of attraction between colloidal particles occurs between all particles in any suspension medium.<sup>[29]</sup> In many cases, these forces alone determine the stability of colloidal suspensions. A repulsive force can be introduced by adding an electrical charge to the particles. This results in an electrostatic force between the particles. Altering the magnitude of the repulsion, either by increasing the ionic strength of the solution or by changing the surface potential on the particles alters the total potential energy of interaction,  $V_T$ .

Although DLVO theory provides an excellent approximation of the interaction forces between many colloidal particles, it has become clear that it does not account for all of the phenomena observed in colloidal dispersions. There are many systems where the simple interplay between electrostatic repulsion and van der Waals attraction is neither a complete nor an accurate description of interfacial interactions. This is because beyond their simple definition as a dielectric

**Fig. 1** Total potential energy of interaction,  $V_T = V_A + V_R$  for two interacting surfaces. The broken curves show the potential energy of repulsion,  $V_R$ , due to the electrical force whereas  $V_A$  is the van der Waals attraction. The full curve,  $V_T$ , is obtained by summing  $V_R$  and  $V_A$ .

continuum containing point charges, the solvent and solutes surrounding a surface are not intrinsically considered in DLVO theory. In reality, the most “real” technological and biological interactions occur in systems where the relationship between the surface and solvent/solute mixtures is more complex. In the past few decades, other types of interparticle forces have been shown to play an important role in the stability of dispersions. These include hydrodynamic, hydration, steric, hydrophobic, and depletion interactions. In general, the net interaction energy profile resulting from all such forces governs the behavior of a suspension.<sup>[28,30]</sup>

An important non-equilibrium force when considering the forces between solid and liquid particles is the hydrodynamic force. Hydrodynamic forces include effects due to viscosity, density difference between the phases, film area, and mobility of the interfaces. The drainage of fluid from between two approaching

surfaces is not only dependent on surface forces acting between the surfaces, but also on the hydrodynamics of the system and, in particular, the speed at which the interacting surfaces approach each other. Increasing the viscosity of the intervening fluid, the film area, and the immobility of the surfaces acts to hinder film drainage and results in a decrease in the rate of fluid flow from between the plates.

An immobile surface is a surface for which the tangential components of the velocity are equal to zero. Surfaces can be rendered immobile by increasing the concentration of surfactant adsorbed to the surfaces. This is achieved by surfactant molecules adsorbed at the surfaces confining the film that are carried in the direction of fluid flow, resulting in the accumulation of surfactant molecules at the film periphery.<sup>[4,31,32]</sup> This results in the formation of interfacial tension gradients along the interfaces, which in turn induces stresses in the system and acts to restore the equilibrium distribution of adsorbed surfactant molecules. These stresses are commonly known as Marangoni stresses and act to inhibit further drainage of the film. Recent work in measuring film drainage has shown this phenomenon is important in many cases where liquid interfaces are involved.<sup>[33]</sup>

## INTERACTIONS INVOLVING DEFORMABLE INTERFACES

### Indirect Measurements of the Physicochemical Properties of Deformable Interfaces

Techniques such as electrokinetic, light scattering, and surface tension studies can be used to investigate the effect of additives on the interactions between colloids in dispersions indirectly. Measurements of isolated properties, such as contact angle, interfacial tension, and electrophoretic mobility have been used in the past to estimate the interaction forces between deformable interfaces.

#### Electrophoretic measurements

Electrophoresis is the study of the movement of particles in response to an electric field. The electrophoretic velocity of the particles can be used to calculate the  $\zeta$ -potential of the particle. Interfaces acquire surface charge in aqueous environments through the dissociation of surface groups and/or adsorption of ions from solution. Electrostatic repulsive forces resulting from the interaction between such charged surfaces are frequently responsible for the stability of colloidal suspensions or emulsions as they approach coagulation or coalescence.<sup>[34]</sup> It has long been recognized that the

$\zeta$ -potential, i.e., the electrostatic potential measured at the shear plane of isolated surfaces or particles, is a good indicator of the magnitude of the electrostatic potential present at the interface.

Many attempts have been made over the last 100 years to measure the electrical potential and charge at bubble and emulsion interfaces under different conditions using electrophoretic measurements. These involve measurements of bubble and emulsion mobility using conventional electrophoresis<sup>[2,34–46]</sup> and, more recently, electroacoustic techniques.<sup>[47–50]</sup>

It has been widely reported that negative potentials exist at the hydrocarbon–aqueous and air–aqueous interfaces in simple salt solutions or distilled water.<sup>[51–53]</sup> It has been postulated for the case of electrolytes that negative adsorption of cations occurs, giving rise to a charge separation. Preferential adsorption of  $\text{OH}^-$  ions at such interfaces has also been proposed as a mechanism for the acquisition of a net negative surface charge.<sup>[54]</sup>

A major problem with these measurements on non-rigid particles is that results are often affected by incidental contamination by surface-active materials adsorbed at the surface–aqueous solution interface.<sup>[35]</sup> Rigorously clean conditions are required for electrophoretic experiments.<sup>[2]</sup> Another problem arises in data interpretation. Classical electrophoretic mobility theories require a well defined slip boundary condition at the surface of a particle, prohibiting both the two-dimensional motion of charge at the interface and material circulation within the particle of interest, all of which cannot be assumed to be true for liquid particles. Most droplet electrophoresis studies in the literature assume solid particle hydrodynamic properties and use the theory of Smoluchowski to interpret the droplet shear surface potential, or  $\zeta$ -potential. The Smoluchowski result is reasonable in the limit of thin double layers, but for oil droplets the assumption of solid particle hydrodynamic behavior has not been justified by independent measurements.<sup>[34,41–46]</sup> The O'Brien and White theory is the accepted standard for relating measured electrophoretic mobilities to the  $\zeta$ -potentials for solid particles up to 250 mV.<sup>[55]</sup> An extension of O'Brien and White's theory was made by Ohshima, Healy, and White<sup>[42]</sup> to include the effects of internal hydrodynamic circulation in a liquid particle. Baygents and Saville<sup>[44]</sup> have also extended the Ohshima, Healy, and White theory for the analysis of bubbles and droplets. Electrophoretic studies of immiscible oil droplets therefore involve an added complexity associated with droplet hydrodynamics. Recently, using both the O'Brien and White<sup>[55]</sup> and Ohshima, Healy, and White<sup>[42]</sup> theories, an independent determination of the surface potential of the liquid interface was achieved, using a combination of light scattering and surface tension experiments, which

permitted the unambiguous determination of the  $\zeta$ -potential of liquid droplets in the presence of surfactant.<sup>[53]</sup> It was found for the system characterized that the  $\zeta$ -potentials had no obvious dependence on bulk surfactant concentrations and that the surfactant-coated oil droplets were also shown to behave like solid particles in terms of their hydrodynamic mobility for all surfactant concentrations studied.

Several other approaches including laser Doppler anemometry and the spinning cylinder technique have also been used for measuring the  $\zeta$ -potential of a gas–liquid interface.<sup>[37]</sup>

### Contact angle measurements

Contact angle measurement remains a favored methodology for assessing the interactions between liquid and solid media.<sup>[56]</sup> From the contact angle between two droplets, information about the relative depth of the interaction potential can also be obtained.

Using calculations of surface free energies derived from the Young–Dupré equation, various researchers have also attempted to develop theoretical techniques for describing the macroscopic contact angle in terms of the long-range electrostatic and van der Waals interactions implicit in DLVO theory. Klahn et al.<sup>[57]</sup> have extended this by developing analytical expressions for the nonretarded London-van der Waals potential of two identical flattened spheres and the existing force between them. The results obtained extend the applicability of the “classical” Hamaker-type equations.

Chatelier et al.<sup>[58]</sup> presented a theoretical description for the macroscopic contact angle of a solid/vapor/aqueous solution interface when the solid surface is ionizable and relatively hydrophobic. The contact angle is related to the free energy of formation of the ionizable surface in aqueous solution. Therefore, the theoretical approach takes into account the electrostatic free energy of charging the surface and the change in the free energy associated with the acid–base reactions of the surface sites.

### Scattering techniques

Colloidal particles and aggregates in a fluid can diffract light under conditions where the wavelength of the light is comparable to the size of the particles. Hence, optical techniques such as light scattering, neutron scattering, and X-ray diffraction can be used to characterize the size and structure of colloidal dispersions. Several studies have probed emulsions using static and dynamic light scattering.<sup>[59–72]</sup> Theoretical studies have also been conducted.<sup>[73–75]</sup>

## Direct Measurements of the Interactions of Liquid/Deformable Interfaces

### Thin film techniques

Thin liquid films are considered to be the basic structural elements of foam and emulsion systems. The surface forces that operate within them control the structure and stability of emulsions and foams.<sup>[76]</sup> Consequently, considerable effort has been invested in the study of thin liquid films, with a view to elucidating the interactions between the confining surfaces.<sup>[3]</sup> Thin film balance techniques have been used to measure the forces for single foam, emulsion, and solid–fluid films.<sup>[16,17,59,77–82]</sup> Investigations have focused primarily on the collapse of a drop at a flat interface or the coalescence of two drops, because results from single-drop experiments may be related to emulsion stability in a qualitative fashion. Although many theoretical and experimental investigations have been carried out to recognize the factors that affect coalescence, the phenomenon is not yet fully understood.<sup>[60,61]</sup> One of the main reasons for this is that coalescence occurs at the interfacial region, which often contains surface-active agents. Surfactants and trace impurities have been shown to have a significant effect on interfacial mobility and film flow behavior.<sup>[3–8,19,62]</sup>

The simplest thin film experiment uses an apparatus that allows a bubble or oil droplet to be manipulated near a solid surface, such as that of a plane parallel film of an aqueous solution confined between a solid and a deformable surface. The thickness of this film is monitored using an interferometric technique.<sup>[33,63]</sup> The pressure inside the bubble may be calculated from its dimensions. By controlling bubble dimensions and/or the radius of the plane parallel film, the pressure applied across the plane parallel film (which balances the disjoining pressure between the solid–liquid and air–liquid interface) is varied. In this way, a disjoining pressure–film thickness isotherm is defined.

Other refinements have been made to the thin film apparatus.<sup>[64,65]</sup> In particular, the design of the liquid surface forces apparatus (LSFA) is that of a thin capillary in which a small oil droplet in an aqueous phase can be moved in a controlled manner toward an oil–water interface.<sup>[66,67]</sup> A feature of the LSFA is that disjoining pressure isotherms may be determined for emulsion films of a few micrometers radius (i.e., of similar dimensions to the films formed by contact of two emulsion drops in a bulk emulsion).<sup>[67]</sup> Theoretical models have been produced with the aim to account for the observations of film stability and structure formation inside a liquid film containing colloidal particles.<sup>[68–71]</sup>

## DIRECT MEASUREMENT TECHNIQUES

### Surface Force Measurement Techniques

The direct measurement of surface forces between solid surfaces has been undertaken by measuring the force between macroscopic solid interfaces as a function of their separation. A large amount of data can be found in the literature that describes the interaction between two solid surfaces or particles dispersed in aqueous solution. These data have generally been obtained using devices such as the surface force apparatus (SFA) and the atomic force microscope (AFM). The AFM has one significant advantage over the SFA. It is not confined to studying optically transparent surfaces that are molecularly smooth over a large surface area. This application has enabled experimentation on systems that are not accessible using the SFA. Continuing development in atomic force microscopy has subsequently allowed progression to solid-liquid and solid-gas systems. The AFM is a useful tool for studying surface interactions because of the ease by which force-separation information may be extracted.<sup>[72]</sup> AFM force-distance curves are routinely used in several kinds of measurements for the determination of elasticity, Hamaker constants, surface charge densities, and degrees of hydrophobicity. It is also possible to extract some information about the adhesion between

the tip and the surface and the elasticity of the surface being probed. Surfaces that are not rigid can easily be deformed by the AFM tip and, consequently, the material properties of such surfaces can be studied. In Fig. 2 a schematic of the AFM is given and it demonstrates how the AFM is used to determine forces of solid surfaces.

The core of the AFM is a cantilever with a micro-fabricated tip that deflects when interacting with the sample surface. As long as the sample can be mounted on a piezoelectric scanning stage, the cantilever deflection will reproduce the sample topography. A controller regulates, collects, and processes the data and drives the piezoelectric scanner. Because the AFM measures forces between a tip and a sample surface it can be used to study interactions between the tip (or a colloidal probe attached to the tip, called the colloidal probe technique) and the sample as a function of separation. Although the colloidal probe technique of atomic force microscopy is now a routine method for exploring interfacial phenomena between two solid surfaces,<sup>[83,84]</sup> precise measurement of such forces when one or both of the particles is deformable, such as a liquid droplet, is more complex because of interfacial fluidity and deformability.

Another technique that is becoming more commonly used is total internal reflection microscopy (TIRM). TIRM monitors Brownian fluctuations in

Fig. 2 Use of the atomic force microscope on solid surfaces. Source: From Ref.<sup>[30]</sup>.

elevations as small as 1 nm by measuring the scattering created from a single sphere illuminated by an evanescent wave when the sphere is levitated by colloidal forces such as electrostatic double-layer repulsion near an interface.<sup>[85]</sup> TIRM<sup>[85,86]</sup> can measure much smaller interactions than either the SFA or the AFM. Forces as small as  $10^{-13}$  N have been measured to within a few percent of known values with TIRM,<sup>[87]</sup> compared with  $10^{-9}$  N with SFA<sup>[88]</sup> or  $10^{-11}$  N with AFM.<sup>[89]</sup> TIRM has no control over separation, unlike the SFA and AFM.

Leal-Calderon et al.<sup>[90]</sup> developed a force measurement technique that allows the determination of force vs. distance between minute colloidal droplets. This technique requires the use of monodisperse oil-in-water ferrofluid emulsions whose resultant droplets are paramagnetic.<sup>[91]</sup> This technique uses the anisotropy of the forces between magnetic dipoles, which causes particles to form linear chains. At low particle volume fraction, well-separated linear chains with a thickness of one particle and oriented parallel to the field direction are produced. The repulsive forces between droplet interfaces can be deduced once the dipolar magnetic interaction is known. Variation of the intensity of the applied magnetic field allows the full force–distance profile to be determined.<sup>[92]</sup>

### Deformable interactions

Ducker, Senden, and Dashley<sup>[83]</sup> and Butt<sup>[89]</sup> were the first to report the attachment of a colloidal probe to a cantilever for probing colloidal forces. The attachment of a colloidal probe to a cantilever has meant that virtually any colloidal particle of interest can be used with the benefit of measurements being relatively fast and easy to perform. The first direct measurements of particle–deformable interface interactions were made subsequently by Butt.<sup>[93]</sup> He measured forces between a silica particle attached to the AFM cantilever and an air bubble anchored to the piezo-driven stage in an aqueous environment. Similar experiments with air bubbles have been reported.<sup>[94–100]</sup>

Preuss and Butt<sup>[96]</sup> determined the influence of an anionic and a cationic surfactant on the force between hydrophilic and hydrophobized 5- $\mu\text{m}$ -diameter silica particles and an air bubble. It was found that the force between a hydrophobic particle and an air–water interface becomes repulsive when surfactants are added to the aqueous solution. The bubble repelled hydrophilic particles, although different behavior was observed depending on the adsorption of the surfactant to the particle surface. The measured forces were interpreted in terms of simple surface forces, which, as discussed, is clearly not the case.

The first measurements of forces between a probe particle and sessile oil drops submerged in water have

been reported by Mulvaney et al.<sup>[101]</sup> followed by Synder, Aston, and Berg<sup>[102]</sup> Hartley et al.<sup>[103]</sup> Basu and Sharma,<sup>[104]</sup> and Aston and Berg.<sup>[105,106]</sup>

Recently, however, new developments in micropositioning and displacement detection have stimulated renewed interest in the measurement of surface forces operating between deformable interfaces, and have allowed the first steps to be taken toward a comprehensive understanding of the interactions responsible for their equilibrium behavior.

### Theoretical Analysis of Deformable Surfaces

In the case of identically charged materials interacting, DLVO theory separates the total interaction into two contributions: an attractive van der Waals interaction and electrical double-layer repulsion. Importantly, the total interaction free energy can be taken as the sum of these two contributions. If the interacting surfaces have dissimilar charges, the electrical double-layer contribution can be either attractive or repulsive or can even change from one to the other through charge regulation with changes in separation. For force measurements made between a sphere and a flat plate, the Derjaguin approximation is used to relate the interaction energy per unit area between parallel plates to the force between a sphere and flat plate.

Traditionally the deformation of elastic particles has been described by the Hertz<sup>[107]</sup> and the Johnson, Kendall, and Roberts (JKR)<sup>[108]</sup> theories. The Hertz theory assumes only normal stresses and is used to predict the contact area as a function of the applied load. The JKR theory has been extended to include the effect of surface forces on contact deformation, which results in the surfaces adhering when in contact. It was predicted that the solids would separate abruptly once a critical finite tensile load (the pull-off force) was reached. Both approaches assume particles interact only when in contact and ignore the extended range of the interactions in real systems.

The Derjaguin, Muller, and Toporov (DMT)<sup>[109]</sup> model, in contrast, assumes a Hertzian pressure distribution in the contact area and that the attractive forces between the surfaces act over a finite range in a region just outside the contact zone. It was predicted that the solids would separate only when the contact area was reduced to zero and the estimated pull-off force was larger than that estimated by the JKR model.

Beyond these contact theories are the soft contact approaches,<sup>[110–112]</sup> that take into account these extended interactions, although they are also based on linear elasticity. Recently, work has been conducted on developing theoretical models.<sup>[113–118]</sup> Experiments have been performed to measure surface profiles at small separations using both the SFA and AFM and

comparing these results with the classical models<sup>[119,120]</sup> and newer, more complex models.<sup>[121]</sup> More recently, viscoelastic response interaction forces between a spherical silica probe and a cross-linked polydimethylsiloxane colloidal droplet have been performed.<sup>[122–124]</sup>

The asymmetric nature of the interaction operating between an air bubble and a particle is an added complication of a deformable surface. Miklavcic et al.<sup>[125–128]</sup> addressed the mathematical complexities associated with such systems. The development of this theory has been assisted by the work of Horn et al.<sup>[129]</sup> which involves the measurement of surface and hydrodynamic forces between a flat mica surface and a mercury drop emerging from a thin capillary. Surface forces can be detected due to very small deformations of the drop (~1 nm). By measuring the shape of the mercury drop, they were able to deduce the force between the mica surface and the drop, using a modification of the SFA, while the separation between the surface and the drop was measured using an optical interference technique. Miklavcic, Horn, and Bachmann<sup>[125]</sup> found that deformation even at a microscopic scale enhances the effective area of interaction and results in a large difference in the measured force arising from deformations.

### Force Curve Analysis of AFM Experiments

The methodologies for the study of interactions between non-deformable surfaces by AFM are well established, and for well characterized systems, experimental results are in good agreement with theoretical predictions.<sup>[20–22]</sup> Unfortunately, interpretation of AFM interparticle force experiments is not straightforward when the surfaces deform during interaction. This is because a liquid surface is much more deformable than a solid surface and can change shape dramatically in response to a surface force. Because of such deformations, the surface shapes and hence the effective interaction areas are not known a priori, but will vary with surface separation. To fully interpret the surface force measurements, knowledge of the true separation between the solid–liquid interface is required. This is a critical ingredient for developing an understanding of the apparent interplay between interfacial deformation and double-layer interactions observed in these experiments.

Until recently, the interpretation of these measurements required the additional assumption that the bubble or droplet be treated as either elastic or a non-deformable solid. For instance, the work of Ducker, Xu, and Israelachvili<sup>[94]</sup> assumed that the air bubble deforms in a linear manner in order to estimate the separation between the two interfaces in AFM force measurements. They treated the deformable

interface and cantilever as two springs in series, where the measured stiffness  $K_m$  is given by

$$\frac{1}{K_m} = \frac{1}{K_s} + \frac{1}{K_{\text{int}}} \quad (2)$$

where  $K_s$  is the spring constant of the AFM cantilever and the stiffness of the interface,  $K_{\text{int}}$  can be calculated, from the slope of the measured force in the pseudo-linear regime [Eq. (3)].  $K_{\text{int}}$  has been referred to as an effective spring constant:

$$K_{\text{int}} = K_s \left( \frac{\Delta h}{\Delta c} - 1 \right)^{-1} \quad (3)$$

The disadvantage of this method is that the bubble or droplet is treated as either an elastic or a non-deformable solid. A disadvantage with the AFM is that because of surfaces deforming during interaction, it does not provide an absolute measure of separation between the surfaces. Upon interaction of a deformable colloid with either another colloidal particle or a surface, deformation results in additional variation of the surface separation and/or the contact area, and it is inappropriate to describe the interaction behavior in the same way as for rigid colloids.<sup>[83,89,130,131]</sup>

The AFM measures force and separation, but not the absolute separation between the colloidal probe and sample. Instead, separations are calculated relative to a hard wall contact. The accurate evaluation of the data requires that a hard wall, referred to as the “constant compliance” region, be reached. In this region, it is assumed that the expansion of the piezo leads only to a corresponding deflection of the cantilever, i.e., the surfaces are in hard contact but are incompressible. However, a problem, commonly referred to as “the zero separation problem,” arises when either of the surfaces under investigation are not rigid, as is true for surfaces bearing polymers, surfactants, or biomolecules, or deformable surfaces such as air bubbles or oil droplets. Hence, an absolute separation cannot be determined with this type of analysis. Previously, the deformable system has been analyzed by defining a zero “relative separation” at the point at which a deflection of the cantilever was first observable. Hartley et al. defined zero to be when the force divided by the radius ( $F/R$ ) was equal to 0.01 mN/m.<sup>[103]</sup> Although this type of analysis allows comparison between experiments, no information about absolute separation can be obtained. A theoretical model was developed by Bhatt, Newman, and Radke.<sup>[132]</sup> Although, they developed a way of comparing experiments to theoretical predictions, they did not give a direct comparison between theory and experimental data.

The true surface separation between the solid and the deformable liquid interface needs to be determined, so that the surface forces operating at liquid–liquid interfaces can be quantitatively determined. Because this information cannot be obtained from direct measurements, a model is needed, which provides the determination of the true separation between the solid–liquid interface as well as provides an understanding of the interplay between interfacial deformation and surface forces in the system. A number of theoretical models have been recently published.<sup>[118,125–128,132,133]</sup> A theoretical model that allows the determination of the true separation between the solid–liquid interface has been developed.<sup>[118,133]</sup> Chan, Dagastine, and White<sup>[118]</sup> modeled the AFM measurement of forces between a solid colloidal particle probe and a deformable liquid sessile drop on the piezo-driven stage. Independent measurements of droplet surface potential, colloidal probe surface potential, contact angle, interfacial tension, and probe radius are needed as inputs into the interpretive theory to provide a quantitative understanding of the measured forces operating at liquid–liquid interfaces. This theory provides the possible determination of the true separation between the solid and the deformable liquid interface. It provides the link between interfacial deformation and disjoining pressure due to electrical double-layer and van der Waals interactions in contributing to the observed force in these experiments. From this theory, it is possible to deduce a quantitative picture of the deformation of the liquid interface as a function of separation.

Recent results for SDS solutions have shown an unambiguous determination of the absolute separation between the particle probe and the droplet interface was achieved if all physical parameters of the system were known. The adsorption of SDS provides the droplet interface with a surface potential of sufficiently high magnitude to stabilize the particle–droplet system against engulfment because of the ever-present attractive van der Waals interactions. Under these circumstances, deformation of the droplet interface provides a mechanism to increase the effective areas of repulsive interaction between the particle and the droplet, which stabilizes the system against engulfment even at the highest forces that can be applied in the AFM.<sup>[134]</sup> Fig. 3 shows a typical result for the force vs. separation distance between a colloid particle and a decane drop compared with the theory of Chan, Dagastine, and White.<sup>[118]</sup>

For electrolyte solutions, the surface potential of the droplet interface was not known with precision. In these cases, the model could not fully account for the interactions observed. Factors such as hydrodynamics, roughness, and Marangoni effects were considered, but did not resolve the inconsistencies seen between

**Fig. 3** Use of the atomic force microscope to measure forces between a liquid interface and a silica probe in the presence of 10 mM SDS and 1 mM NaNO<sub>3</sub>. Open circles are experimental data, the solid line is the theoretical prediction from the theory of Chan, Dagastine, and White.<sup>[118]</sup> The gray area is the estimated error in the data.

the experimental and theoretical data. A definitive resolution of this issue will require accurate determinations of the surface potentials of the decane–electrolyte interface in the absence of added surfactant.<sup>[135]</sup> This theory allows the determination of the true separation between the solid–liquid interface and provides an understanding of the interplay between interfacial deformation and surface forces in this system and known material properties needed to calculate the electrical double-layer and van der Waals interactions with retardation and salt screening effects. The picture that emerges has important implications in understanding both emulsion stability and wetting phenomena.

## CONCLUSION

Recent theoretical and experimental developments have led to the first direct force measurements between a solid colloidal particle and a deformable interface using the atomic force microscope. This development is crucial to the understanding of a range of phenomena associated with emulsion stability, coalescence of drops, etc. This entry reviews developments in this area and describes how developments in the interpretation of signals from the atomic forces microscope can be interpreted as forces and how this compares with other methods for determining these forces.

# Interfacial Phenomena: Chemical Selectivity

Vinay K. Gupta

Department of Chemical Engineering, University of Illinois at Urbana–Champaign,  
Urbana, Illinois, U.S.A.

## INTRODUCTION

The capability to control and manipulate structure and properties of chemical, biological, and physical systems at nanometer dimensions holds immense potential for technological advancement. This promise of nanotechnology has spurred increasing investment into research at the nanometer length scale in virtually every scientific discipline. One of the hallmarks of nanoscience and engineering research is the predominance of interfacial phenomena, which occurs as a natural consequence of the shrinking length scale. Examples of these phenomena include molecular interactions at interfaces within chemical or biological systems, behavior of complex fluids such as polymers confined to an interface or between surfaces, synthesis of tailored nanoparticles, and two-dimensional nanostructures built by assembling nanoscale building blocks. One of the central questions faced in the studies of interfacial phenomena at the nanoscale is the impact of the interplay between molecular structure, forces, and organization. Here we discuss how this interplay can result in an exquisite molecular selectivity at a self-assembled surface, which in turn can form the basis of innovative applications in separations, analysis, and diagnostics.

## MOLECULAR RECOGNITION AT INTERFACES

In the last few years, molecular assemblies such as self-assembled monolayers (SAMs) and Langmuir–Blodgett (LB) films have become a popular vehicle for the investigation of interfacial interactions. The phenomenon of molecular recognition and association, in particular, has been actively studied because of its relevance in immunoassays, sensing, and other applications based on selective affinity of molecules to surfaces as well as its significance to fundamental studies of supramolecular interactions in well-defined geometries.<sup>[1–10]</sup> A number of investigations have relied on SAMs of organosulfides on gold because of the ease of preparation and the flexibility in design of the chemical interface.<sup>[11,12]</sup> It has been demonstrated that

SAMs formed from alkanethiols and thiolated ligands can bind metal ions, surfactants, and volatile organic compounds.<sup>[8,13,14]</sup> Recent attention has focused on SAMs formed from complex synthetic “host” receptors such as cyclodextrins<sup>[15–17]</sup> and calix[*n*]resorcinarenes.<sup>[18–25]</sup> These hosts contain a molecular cavity for targeted recognition of “guest” molecules. A primary challenge here has been to understand the role of molecular organization, structure, and forces in the guest–host recognition process and thereby to improve the selectivity of surfaces for binding metal ions, sugars, organic vapors, steroids, and apolar molecules.

Calix[4]resorcinarenes are macrocyclic host molecules that possess a bowl-shaped molecular cavity formed by four resorcinol units (Fig. 1). These cyclic tetramers are prepared by acid-catalyzed condensation of resorcinol and aldehydes.<sup>[26,27]</sup> In pioneering work, Aoyama et al. demonstrated that calix[4]resorcinarenes could trap various guest molecules such as sugars in aqueous solutions within the bowl-shaped cavity.<sup>[28–35]</sup> The trapping was driven by either  $\pi$ -acid/base interactions or by cooperative hydrogen-bonding interactions between the guest and the host molecules.

Thoden van Velzen, Engbersen, and Reinhoudt<sup>[36]</sup> extended the strategy to self-assembled surfaces. Calix[4]resorcinarenes were modified with dialkyl sulfides that undergo physisorption on gold surfaces.<sup>[37,38]</sup> The tetrasulfide calix[4]resorcinarene host had a cavity that was made rigid by bridging the oxygen atoms of neighboring aromatic rings (Fig. 1A). One of the first studies reported selective recognition of tetrachloroethylene from the gas phase.<sup>[39]</sup> However, similar selectivity of organic vapors by amorphous polymer films demonstrated that general dispersion interactions rather than specific interactions heavily influence recognition from vapor phase.<sup>[40]</sup> In contrast, more recent studies have shown that specific recognition of steroids or other neutral molecules occurs readily from aqueous solutions on SAMs of oxygen-bridged tetrasulfide calix[4]resorcinarene.<sup>[22,41]</sup>

We and others have also reported recognition by self-assembled surfaces wherein calix[4]resorcinarenes were modified with alkylthiols (Fig. 1B) that strongly chemisorb onto gold.<sup>[18–21]</sup> Recent studies have demonstrated that self-assembled surfaces of tetrathiol

**Fig. 1** Chemical structures of calix[4]resorcinarene host molecules. (A) Tetrasulfide host where the aromatic rings are covalently bound by oxygen bridges and the dialkyl sulfide chains are similar in length; (B) tetrathiol host where the macrocyclic cavity is not oxygen-bridged.

calix[4]resorcinarene (Fig. 1B) discriminate between guest molecules that differ slightly in their molecular structure as well as between structural isomers.<sup>[18,42]</sup> These studies have established that small differences in the chemical structure of the guest molecules are important and that recognition of the guest is driven by a combination of factors such as hydrogen-bonding, hydrophobic interactions, and steric match. Furthermore, the structure of the host molecule and the organization of the self-assembled monolayer strongly influence the association of neutral molecules in aqueous solutions.<sup>[19]</sup> Results from these studies illustrate the critical relationships between molecular organization of the monolayer, the forces that drive molecular recognition, and the structure of the guest and the host molecules.

## CHEMICAL SELECTIVITY OF SURFACES: SOME REPRESENTATIVE RESULTS

### Role of Molecular Structure and Molecular Interactions

In Fig. 2, we show the experimental results from Faull and Gupta<sup>[18]</sup> that illustrate the role of molecular structure and the forces in guest–host association properties of SAMs formed from tetrathiol calix[4]resorcinarene. The three guest molecules possess slight differences in the pendant group—butyrolactone (BL), hydroxy- $\gamma$ -butyrolactone (HBL), and pantooylactone (PL) (Fig. 2A). Surface plasmon resonance (SPR) and polarization-modulation infrared reflection absorption spectroscopy (PM-IRRAS) were used to investigate

the recognition of guest molecules from aqueous solutions by the SAMs. In SPR (Fig. 2B), total internal reflection of an incident beam of light occurs. An exponentially decaying evanescent optical field probes the solid–liquid interface and resonates with the plasmon surface polariton on the metallic at the SPR angle ( $\theta_p$ ). The association at the surface was monitored by measuring the change in the SPR angle ( $\Delta\theta$ ) as the solution of the guest molecule was pumped over a gold film supporting the self-assembled monolayer.

The typical evolution of the SPR angle [ $\Delta\theta(t)$ ] when a SAM formed from the tetrathiol calix[4]resorcinarene host was placed in contact with an aqueous solution of  $\alpha$ -HBL and BL is shown in Fig. 2C. A rapid rise was observed for  $\Delta\theta$  in the case of  $\alpha$ -HBL indicating fast association with the surface, but no recognition of BL was observed. Thus the surface selectively interacts with HBL. Fig. 2C shows that for  $\alpha$ -HBL, the maximum change in  $\Delta\theta$  is reached within 1000 sec. Experiments with multiple sample surfaces reveal that typically,  $\Delta\theta_{\max}$  lies between  $0.06^\circ$  and  $0.08^\circ$ . In Fig. 2C, it is observed that upon switching the flow to pure water,  $\Delta\theta_{\max}$  dropped by approximately  $0.02^\circ$  and then stabilized, indicating that only some of the  $\alpha$ -HBL is washed away with pure water. Rinsing the surface with a few milliliters of pure ethanol, on the other hand, readily removes all of the HBL. When the rinsed surface is again placed in contact with a solution of HBL, the shift in the SPR angle is reproduced indicating that a self-assembled surface with the host receptor can be used for multiple recognition steps. Fitting of the reflectivity curve using the optical model gives a thickness of  $\sim 4 \text{ \AA}$  for the HBL layer and indicates that multilayering of the guest adsorbate is largely absent.

The SPR results in Fig. 2C show an interesting contrast with the reports on guest–host association on the more rigid, tetrasulfide calix[4]resorcinarene with O-bridged aromatic cavity (Fig. 1A). Friggeri et al.<sup>[22,41]</sup> and Schierbaum et al.<sup>[39]</sup> have reported that association of guest molecules such as benzoic acid and its derivatives occurs in a few seconds, which is significantly faster than the results on the tetrathiol calix[4]resorcinarene. Furthermore,  $\alpha$ -HBL associated with a SAM formed from the tetrathiol calix[4]resorcinarene cannot be completely rinsed using water, but the association of benzoic acid derivatives with the tetrasulfide calix[4]resorcinarene was reported to be reversed by washing with water. The absence of measurable association between BL and surfaces formed from tetrathiol calix[4]resorcinarene suggests that hydrogen-bonding interactions as a result of the hydroxyl (OH) pendant group on the  $\alpha$ -HBL play an important role in guest–host recognition at these surfaces. The importance of hydrogen bonding agrees with conclusions by Friggeri et al. based on the association of benzoic acid derivatives with various tetrasulfide

**Fig. 2** (A) Chemical structures of the guest molecules BL,  $\alpha$ -HBL and  $\beta$ -HBL, and PL. (B) Schematic of the SPR arrangement. (C) Shift in SPR angle caused by adsorption from 1 mM  $\alpha$ -HBL (circles) and BL (squares) solutions on a monolayer formed from tetrathiol calix[4]resorcinarene. Pure water flows through at  $t < 0$  and the adsorbate solution is injected at  $t = 0$ . The arrow indicates a rinse with pure water. (D) Schematic of the complex formed between  $\alpha$ -HBL and the macrocyclic cavity. For clarity, only the macrocyclic cavity is shown. Dashed lines indicate hydrogen bonds.

calix[4]resorcinarene. The association of  $\alpha$ -HBL reported here with tetrathiol calix[4]resorcinarene is plausibly enhanced by the presence of hydroxyl groups on the rim of the macrocyclic cavity.

To gain insight into the orientation of the  $\alpha$ -HBL associated with the surface, PM-IRRAS was used to characterize the surface before and after association. After 1200 sec of contact with an aqueous 1-mM solution of  $\alpha$ -HBL, a large positive peak at  $\sim 1744\text{ cm}^{-1}$  and a weaker peak at  $1125\text{ cm}^{-1}$  were observed. The peak at  $\sim 1744\text{ cm}^{-1}$  can be assigned to the carbonyl,

C=O, bond in  $\alpha$ -HBL. Comparison with a spectrum of a cast film of  $\alpha$ -HBL on gold shows that the peak at  $1125\text{ cm}^{-1}$  in the surface may be a result of the C-C(=O)-O- bond stretch in  $\alpha$ -HBL.<sup>[43]</sup> Because the frequencies corresponding to both the C=O bond and the C-C(=O)-O- bond can be discerned in the IR spectra, it can be inferred that the HBL molecule is oriented such that the transition moments of these two bonds have components along the normal to the surface. The lack of a peak in the  $1100\text{--}1300\text{ cm}^{-1}$  region, where typically the -C-O-H bend vibration

would be observed, indicates that  $-C-O-H$  absorption is either quite weak or has a large component parallel to the surface. Fig. 2D shows the associated complex that conforms with the IR results and shows the potential hydrogen bond between the OH group of  $\alpha$ -HBL and the tetrathiol calix[4]resorcinarene. A Corey-Pauling-Koltun (CPK) model of Fig. 2D shows that there is a close steric match between the guest and the host. Interestingly, this model of the association predicts that the  $\alpha$ -HBL projects out by a distance of approximately 3.5 Å, which matches quite well with the estimated thickness from SPR.

As a control experiment, a surface formed by the self-assembly of  $HO(CH_2)_{11}SH$  was used to test the interaction of  $\alpha$ -HBL with a hydrophilic surface. No measurable shift is observed in the SPR angle suggesting that the hydrophobic interactions contribute to the guest–host recognition by tetrathiol calix[4]resorcinarene. To further test the recognition capability of the SAMs formed from host surface, pantooylactone (PL) was used as a guest molecule. The guest molecule PL possesses a pendant hydroxyl (OH) group and two pendant methyl ( $CH_3$ ) groups (Fig. 2A). No measurable shift in the SPR angle was observed when an aqueous solution of PL was brought in contact with the tetrathiol calix[4]resorcinarene surface. The absence of interaction of PL with the surface formed from tetrathiol calix[4]resorcinarene surface can be interpreted in light of the schematic illustrated in Fig. 2D. Unlike  $\alpha$ -HBL, hydrogen-bonding interaction between tetrathiol calix[4]resorcinarene and the hydroxyl moiety in PL is not possible as the pendant methyl groups pose a large steric hindrance.

It has been demonstrated recently that the balance between various forces contributing to the recognition of guest molecules by SAMs formed from tetrathiol calix[4]resorcinarene can be exploited to selectively discriminate between two structural isomers.<sup>[18,42]</sup> Fig. 3 shows that in contrast to the positive  $\Delta\theta$  observed with  $\alpha$ -HBL, no shift in the SPR angle is observed when a solution of  $\beta$ -HBL is placed in contact with the surface formed from tetrathiol calix[4]resorcinarene. Like pantooylactone, hydrogen-bonding interactions between the hydroxyl group of  $\beta$ -HBL with the tetrathiol-calix are hindered, plausibly, because the oxygen atom in the  $C=O$  group precludes a steric match with the macrocyclic cavity.

Faull and Gupta<sup>[42]</sup> have also demonstrated that the chemical selectivity of SAMs of host molecules such as calix[4]resorcinarenes extends to isomers of several different guest molecules besides those discussed above. By using structural isomers of guest molecules such as bipyridine and nitrophenol that are multidentate hydrogen bond acceptors, it has been shown that geometric match between guest and host molecules is an integral aspect of the recognition phenomena.

**Fig. 3** Shift in SPR angle during adsorption of  $\alpha$ -HBL and  $\beta$ -HBL on a monolayer formed from tetrathiol calix[4]resorcinarene. The curves are offset such that pure water is flowing through the cell at  $t < 0$  and the solution of adsorbate is injected at  $t = 0$ . The arrow indicates the time at which the surface was rinsed with pure water after HBL adsorption. Sparse markers have been used for clarity (every third point is shown).

Results from SPR and PM-IRRAS experiments highlight the interplay between steric size and forces such as hydrogen-bonding and hydrophobic interactions. These experimental studies also highlight the value of molecular modeling studies of the interaction between groups such as hydroxyl (OH), nitro ( $NO_2$ ), and pyridine nitrogen of guest molecules and hydroxyl groups of host surfaces and the molecular orientations of the guest that favor these interactions. In other experiments<sup>[42]</sup> on competitive and sequential adsorption of guest molecules such as  $\alpha$ -HBL and 4,4'-bipyridine, it has been shown that the guests compete for the same binding sites on the surface and the interplay between steric size and molecular forces underlies the preferential selectivity of one guest molecule over another. Such studies promise valuable insights into the fundamentals of the interfacial recognition phenomena and tailoring of surfaces to exploit the phenomena in novel applications.

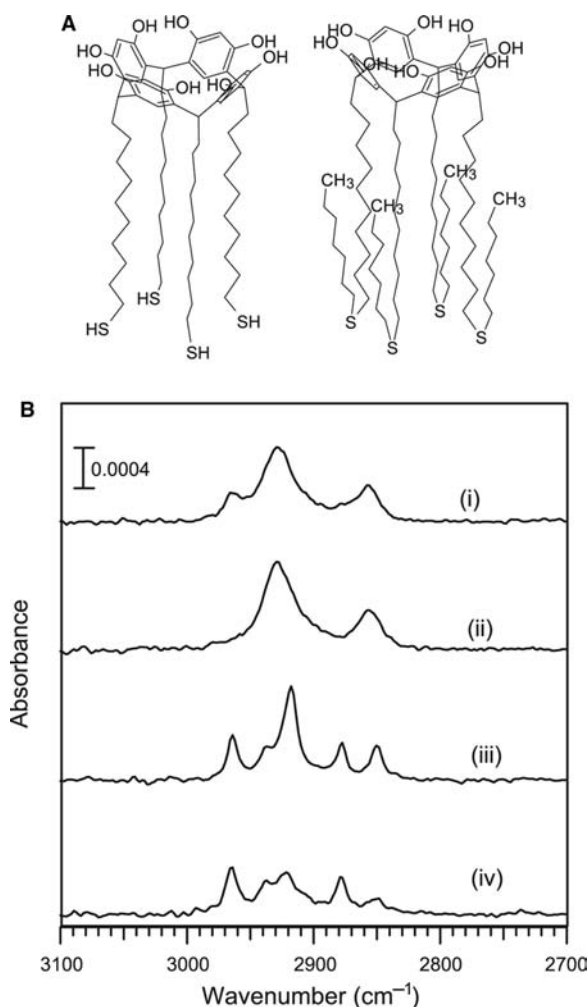

### Interplay between Molecular Organization and Molecular Interactions

While the discussion in the previous section points to the impact of guest structure and molecular forces in the interfacial recognition process at nanometer length scales, the molecular organization of a monolayer is known to be a sensitive function of the chemical and physical structure of the molecules that form the monolayers and therefore can be expected to play an important role in the molecular association. This has

been illustrated recently in studies<sup>[19]</sup> on comparative studies of guest–host recognition on SAMs formed by two different host molecules—thiol-derivatized and dialkyl-sulfide-derivatized calix[4]resorcinarene molecules that possess similar head groups (Fig. 4A).

The impact of the host structure on the monolayer structure is clearly observed in Fig. 4B, which shows PM-IRRAS spectra of self-assembled monolayers formed from the two host molecules. For comparison, SAMs formed from hexadecanethiol [ $\text{CH}_3(\text{CH}_2)_{15}\text{SH}$ ] and octanethiol [ $\text{CH}_3(\text{CH}_2)_7\text{SH}$ ] are also shown. Both tetrathiol calix[4]resorcinarene and tetrasulfide calix[4]resorcinarene show peaks corresponding to the stretching modes of methylene ( $-\text{CH}_2$ ) groups at  $\nu_{\text{as}} = 2929\text{--}2930\text{ cm}^{-1}$  and at  $\nu_{\text{s}} = 2856\text{ cm}^{-1}$ . For the tetrathiol derivative, no peaks are observed at

**Fig. 4** (A) Chemical structures of calix[4]resorcinarene host molecules modified with 4 alkylthiol or dialkyl sulfide anchors. (B) PM-IRRAS spectra of monolayers formed from (i) tetrasulfide calix[4]resorcinarene, (ii) tetrathiol calix[4]resorcinarene, (iii)  $\text{CH}_3(\text{CH}_2)_{15}\text{SH}$ , and (iv)  $\text{CH}_3(\text{CH}_2)_7\text{SH}$  on gold in the spectral region  $3100\text{--}2700\text{ cm}^{-1}$ .

frequencies corresponding to the methyl stretch (near  $2936$ ,  $2964$ , and  $2877\text{ cm}^{-1}$ ) because the molecule does not contain methyl groups (Fig. 4A). In comparison, the spectrum of tetrasulfide shows a broad shoulder at  $\nu_{\text{as}} = 2962\text{ cm}^{-1}$ , which corresponds to the asymmetric stretch of the methyl ( $-\text{CH}_3$ ) group. This is consistent with the presence of the methyl on the dialkyl sulfide tether (Fig. 4B).

Comparison of the PM-IRRAS spectra of the calix[4]resorcinarene hosts and the reference spectra of monolayer formed from  $\text{CH}_3(\text{CH}_2)_{15}\text{SH}$  highlights the differences in molecular organization of these monolayers. In the two SAMs formed from the calix[4]resorcinarene hosts, the asymmetric stretch of the  $-\text{CH}_2$  groups is observed at a higher wave number than in a monolayer of  $\text{CH}_3(\text{CH}_2)_{15}\text{SH}$  ( $2929\text{--}2930\text{ cm}^{-1}$  vs.  $2918\text{ cm}^{-1}$ ). A similar shift toward higher wave numbers is also observed in the symmetric  $-\text{CH}_2$  peak ( $2856\text{ cm}^{-1}$  vs.  $2850\text{ cm}^{-1}$ ). These shifts indicate that the alkyl chains in the SAMs formed from both macrocyclic hosts possess more gauche conformations and less order. Previous reports by Reinhoudt et al. on O-bridged, dialkyl sulfide SAMs of calix[4]resorcinarene have also shown that SAMs formed from these bulky macrocyclic hosts lack the well-ordered nature of simple, long-chain alkanethiols.

Fig. 4B shows that the peak positions for  $-\text{CH}_2$  absorption occur at comparable frequencies for the tetrathiol calix[4]resorcinarene and tetrasulfide calix[4]resorcinarene, which indicates that the degree of conformational ordering within these two types of monolayers is similar. In previous studies, Thoden van Velzen et al.<sup>[24]</sup> reported an asymmetric  $-\text{CH}_2$  peak absorption near  $2925\text{--}2927\text{ cm}^{-1}$  for monolayers formed from O-bridged, calix[4]resorcinarene molecules with dialkyl sulfide tethers (Fig. 1A). Thoden van Velzen et al. estimated the cross-sectional area of a calix[4]resorcinarene head group as  $\sim 140\text{ \AA}^2$  and speculated that because four alkylthiol chains with an area  $\sim 4 \times 20\text{ \AA}^2$  do not fill the void space beneath the macrocyclic cavity, a host with eight dialkyl sulfide is necessary to form monolayers with higher order. In later studies, Schoenherr et al.<sup>[44]</sup> used a computational model to correct the head group cross-sectional area of the host shown in Fig. 1A to  $\sim 117\text{ \AA}^2$ . Results in Fig. 4B indicate that increasing the number of alkyl tethers from tetrathiol to tetrasulfide does not necessarily enhance the order. Molecular modeling results show that the cross-sectional area of the calix[4]resorcinarene head group in Fig. 4A is  $\sim 85\text{--}95\text{ \AA}^2$ , which suggests that the four alkylthiol chains instead of the dialkyl sulfide chains provide a better fit to the head group size.<sup>[19]</sup> These simple geometric arguments alone indicate that the tetrasulfide host should occupy a larger area per molecule and will consequently have a lower density than tetrathiol derivative. The IR spectra

support the impact of host structure on the organization of the monolayers as they show comparable intensity for the asymmetric  $-\text{CH}_2$  ( $2929\text{--}2930\text{ cm}^{-1}$ ) peak in both hosts. Because the absorption as a result of  $-\text{CH}_2$  groups remains the same despite the increase in the number of methylene moieties, the spectra indicate that the density of tetrasulfide calix[4]resorcinarene within the monolayers is smaller than tetrathiol calix[4]resorcinarene. A schematic illustration of the monolayers is shown in Fig. 5A.

The changes in the monolayer structure illustrated in Fig. 5A are manifested in interfacial wettability and film thickness measurements. The thickness of the monolayer of tetrathiol calix[4]resorcinarene was found to be  $21\text{ \AA}$  ( $\pm 1\text{ \AA}$ ), while self-assembled monolayers formed from tetrasulfide calix[4]resorcinarene were determined to be  $13\text{ \AA}$  ( $\pm 1\text{ \AA}$ ) by SPR, which indicates that the dialkyl sulfide chains do not fold neatly beneath the calix[4]resorcinarene head group. The SAMs formed from tetrasulfide calix[4]resorcinarene also show a slightly greater hydrophobic nature (larger advancing contact angles) as well as a higher receding angle. This difference in hydrophobic nature can, in turn, be expected to impact the molecular forces at play in the guest–host recognition.

A typical temporal evolution of the SPR angle [ $\Delta\theta_p(t)$ ], when SAMs formed from the two hosts were placed in contact with an aqueous solution of  $\alpha$ -HBL, is shown in Fig. 5B. Both surfaces show a rapid rise in  $\Delta\theta_p$  indicating fast association of  $\alpha$ -HBL with the self-assembled surfaces. The magnitude of the maximum shift ( $\Delta\theta_{\text{max}}$ ) is  $\sim 0.1\text{--}0.12^\circ$ , which indicates the molecular dimension of the adsorbed layer ( $\sim 3\text{--}5\text{ \AA}$ ). Subsequent water rinse causes a slight decrease in  $\Delta\theta_{\text{max}}$  but does not wash out the  $\alpha$ -HBL. Interestingly, the interaction of  $\alpha$ -HBL with a SAM formed from tetrasulfide calix[4]resorcinarene shows that the time scale of the rise in  $\Delta\theta_p$  and the magnitude of the angular shift are comparable to tetrathiol calix[4]resorcinarene. The orientation of the  $\alpha$ -HBL associated with the two surfaces can be probed by using PM-IRRAS to characterize each surface before and after association. The spectra of both surfaces show a large positive peak at  $\sim 1744\text{ cm}^{-1}$  as a result of the carbonyl,  $\text{C}=\text{O}$ , bond in HBL and weaker peaks at  $1260$  and  $1125\text{ cm}^{-1}$  as a result of the  $\text{C}\text{--}\text{C}(=\text{O})\text{--}\text{O}$  bond stretch in HBL. The orientation of the HBL molecule and its association with the calix[4]resorcinarene cavity follows the schematic shown in Fig. 2D.

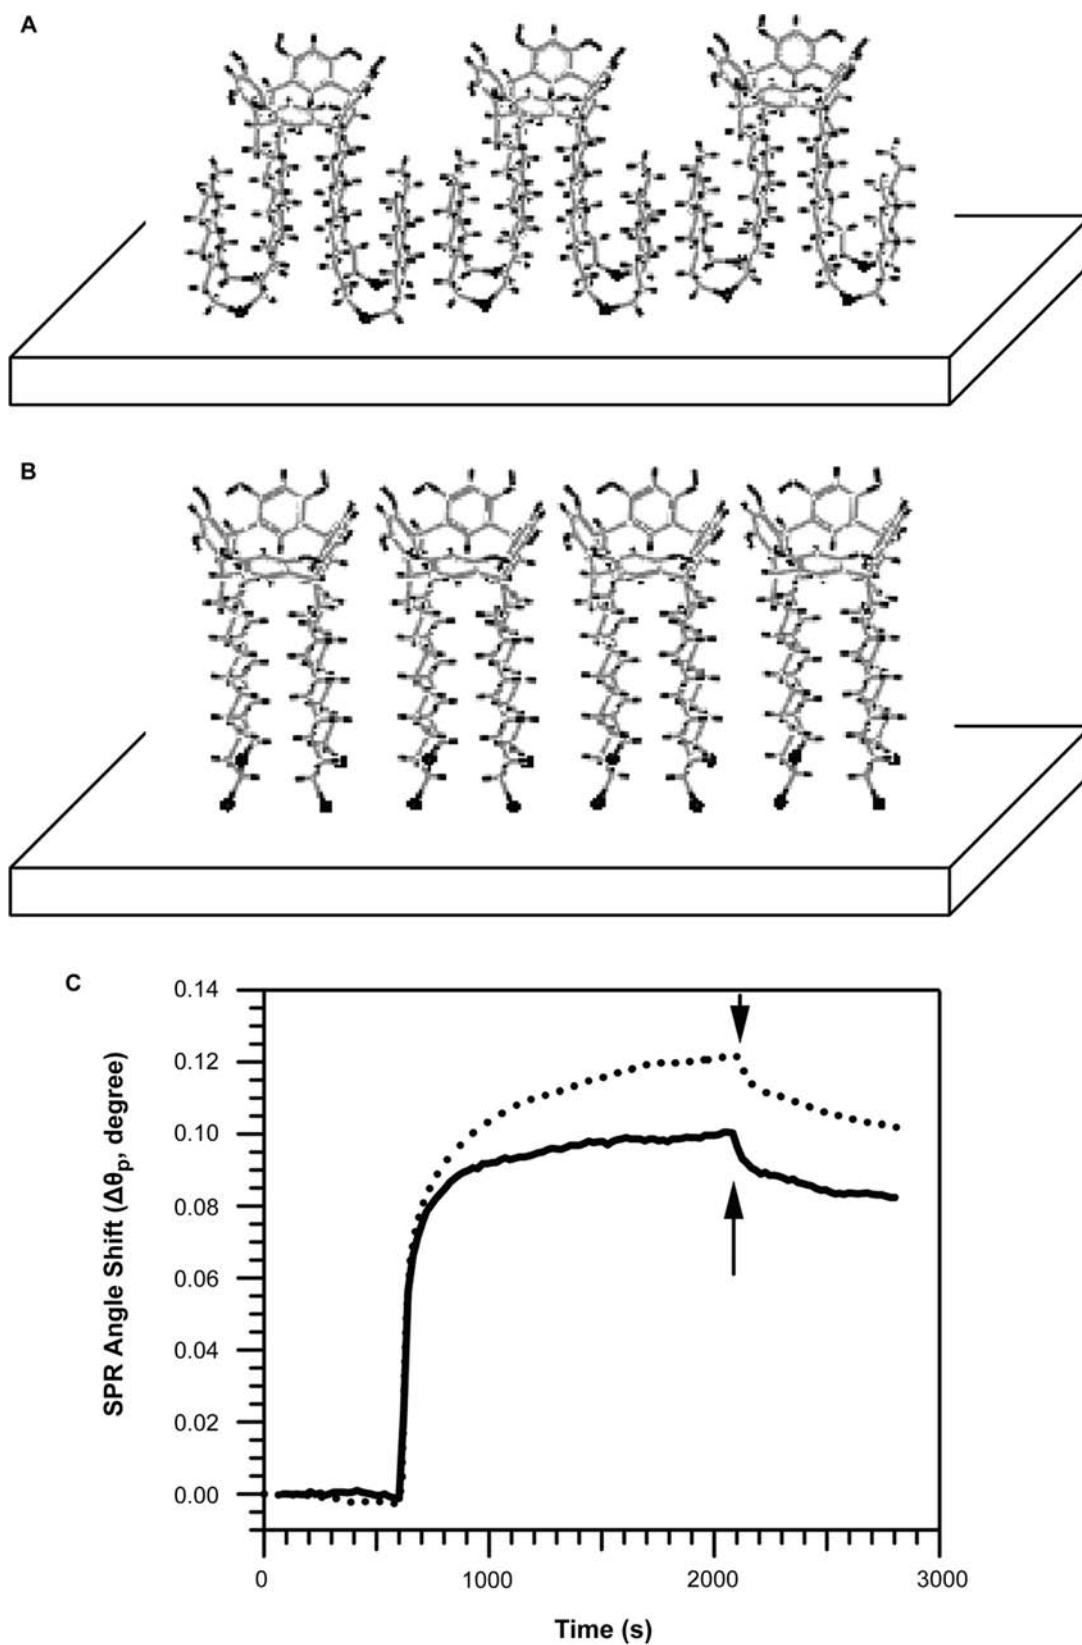

Differences in the structure and monolayer organization between the tetrasulfide and tetrathiol hosts do not show significant effects in SPR and IR measurements on the molecular association with  $\alpha$ -HBL. Because the thermodynamic affinity of  $\alpha$ -HBL to the surface is a sensitive function of the forces driving the interaction, and because the SAMs formed from

the two hosts differ in their hydrophobic nature and molecular organization, the association of  $\alpha$ -HBL was measured as a function of its bulk concentration in solution. Fig. 6 shows a plot of the shift in  $\Delta\theta_p$  observed for  $\alpha$ -HBL concentration varying between  $0.01$  and  $10\text{ mM}$ . Both surfaces show a Langmuir-type behavior with saturation of the response at high concentration. This behavior is in stark contrast to the measurements reported by Friggeri et al.<sup>[22]</sup> for SAMs formed from the O-bridged calix[4]resorcinarene host (Fig. 1A). Friggeri et al. reported that  $\Delta\theta_p$  for a guest molecule such as benzoic acid increased linearly with bulk concentration, which was interpreted to result from physisorption and formation of multilayers of the guest.

The experimental data in Fig. 6 were fit to the equation derived from a Langmuir isotherm, and regression analysis gives  $\Delta\theta_{\text{sat}} = 0.166 \pm 0.006$  and  $\Delta G^\circ_{\text{ads}} = -4.6 \pm 0.5\text{ kcal/mol}$  for the association with the tetrasulfide calix[4]resorcinarene surface and  $\Delta\theta_{\text{sat}} = 0.1 \pm 0.002$  and  $\Delta G^\circ_{\text{ads}} = -5.2 \pm 0.6\text{ kcal/mol}$  for the tetrathiol calix[4]resorcinarene surface. Comparison of this complexation energy with measurements in bulk solution will be important to understand how preorganization of host molecules on a surface and conformational mobility influence the phenomena of guest–host recognition. The estimates suggest that the difference in the energy of association is comparable to thermal energy and the saturation capacity of the surface formed from tetrasulfide calix[4]resorcinarene surface is larger than tetrathiol calix[4]resorcinarene surface.

Because the structural characterization strongly indicated that there are fewer tetrasulfide calix[4]resorcinarene surface molecules per unit area compared with tetrathiol derivative, the above result suggests that the guest  $\alpha$ -HBL molecules come in contact with binding sites other than the macrocyclic cavity on self-assembled surfaces of tetrasulfide calix[4]resorcinarene. The schematic structure shown in Fig. 5A indicates that interstitial cavities can exist within the monolayers because of the incommensurate packing of dialkyl sulfide chains below the calix[4]resorcinarene head group. The interstitial cavities are similar to the macrocyclic cavity of the calix[4]resorcinarene head group with, plausibly, some difference in the steric structure as well as the hydrophobic character. Previous studies on both self-assembled monolayers and Langmuir films have demonstrated that steric traps (similar to the interstitial cavities in SAMs of tetrasulfide calix[4]resorcinarene) can cause molecular recognition.<sup>[8,45,46]</sup> It is therefore reasonable to expect that intercalation of HBL is possible within these interstitial cavities. Faull and Gupta<sup>[19]</sup> have shown that the intercalation of guest molecules has important consequences when multiple

**Fig. 5** Schematic illustration of monolayers formed from tetrasulfide (A) and tetrathiol (B) calix[4]resorcinarene hosts. (C) Shift in SPR angle ( $\Delta\theta_p$ ) caused by adsorption from a 1-mM aqueous solution of HBL on monolayers formed from tetrasulfide calix[4]resorcinarene (dotted curve) and tetrathiol calix[4]resorcinarene (solid curve). The arrow indicates the time at which the surface was rinsed with pure water.

**Fig. 6** Magnitude of the shift in SPR angle ( $\Delta\theta_p$ ) for adsorption of HBL from aqueous solutions of different bulk concentration ( $C$ ) onto self-assembled surfaces of tetrasulfide calix[4]resorcinarene (squares) and tetrathiol calix[4]resorcinarene (circles). Dashed lines are drawn as a guide to the eye.

adsorption–desorption is performed using the self-assembled surfaces. Whereas HBL bound to the SAMs formed from tetrathiol derivative could be almost completely desorbed into an organic solvent, the binding to the tetrasulfide surface was largely irreversible. Multiple adsorption cycles revealed that the ratio of reversibly associating HBL molecules is 25–30% for SAMs formed from tetrasulfide calix[4]resorcinarene relative to over 95% for tetrathiol calix[4]resorcinarene. Thus the interstitial trapping on the SAMs of the tetrasulfide host results in complexation that is relatively strong in comparison to the host–guest complexation within the macrocyclic cavity.

## CONCLUSION

Incorporation of synthetic receptors such as calix[4]resorcinarene within molecular assemblies of Langmuir or Langmuir–Blodgett films, self-assembled monolayers, and lipid bilayers is a useful route to promote selective molecular association in a manner that is analogous to enzymatic recognition. The phenomenon of molecular recognition and association plays a critical role in immunoassays, sensing, and other applications based on selective affinity of molecules to surfaces. The results reviewed here demonstrate that the SAMs formed from hosts such as calix[4]resorcinarene provide a unique environment to study the relationships between molecular structure, organization, and forces that drive intermolecular association at the solid–liquid interface.

The experiment highlights several promising directions for future studies on the interfacial phenomenon of molecular recognition. The interplay between the

host structure and the molecular organization of the self-assembled surface and its impact on the trapping of molecules suggests that tailoring of the terminal functionality of the dialkyl sulfide derivatives can be used to manipulate the molecular forces at play in the interstitial trapping. It is also clear that the capability to prepare surfaces of these complex synthetic hosts and their use in targeted recognition of organic molecules can now be greatly expanded to systems such as chiral calix[4]resorcinarene hosts for enantioselective recognition and ionized calix[4]resorcinarene assemblies for recognition of cationic analytes. Concurrently, the experimental results indicate that more definitive insights into the molecular association process also require direct measurement of the monolayer structure and the binding of the guest molecule to the surface. Future studies that employ methods such as scanning probe microscopy (STM and AFM) for molecular imaging of the self-assembled surfaces and the guest–host interactions will be highly instructive. Finally, an inevitable consequence of the nanometer length scale of guest–host recognition at interfaces is that the experiments need to be supplemented by computational modeling and visualization to fully elucidate the complex molecular interactions.

## INTRODUCTION

The self-assembly of colloidal particles into disordered structures or highly ordered superlattices can be achieved in different ways. Hydrodynamic forces during controlled drying allow control over the deposition process<sup>[1,2]</sup> by varying the solvent vapor pressure<sup>[3]</sup> and temperature, or, more physically, by structuring the substrate.<sup>[4]</sup> Impressive results have been obtained, for example, with nanocolloidal magnetic particles.<sup>[5,6]</sup> In addition, the application of electric and magnetic fields during drying leads to modifications of the deposited structures.<sup>[7–12]</sup>

To study deposition processes without the influence of hydrodynamic interactions, colloidal superstructures need to be formed prior to evaporation of the solvent. One way to achieve this is by chemical modification of the substrate to induce a specific affinity for the colloidal particles. For a number of different particles, chemical modifications by using either polymers, amino-functionalized and thiol-functionalized monolayers, or even DNA have been described.<sup>[13–21]</sup> For example, for gold nanocrystals, there is a strong attractive electrostatic interaction between positively charged  $\text{NH}_2$  groups on the derivatized substrate and negatively charged citrate groups on the surface of the suspended gold particles.<sup>[2,13,15,19,22,23]</sup>

The high surface affinity and the resulting strong bonding of the deposited gold particles to the surface give rise to negligible surface mobility and sticking probability of one. Deposition processes governed by these characteristics can be adequately described as a

random sequential adsorption (RSA) process.<sup>[24–33]</sup> In RSA simulations, the adsorbing particles are treated as “hard” disks, which are randomly placed on a planar surface. Placement of such a disk is only successful when it does not overlap with any other previously deposited disks. The maximum particle density after an RSA event is markedly lower than that of a hexagonal close-packed monolayer of spherical particles. The saturation coverage has been determined from extensive numerical calculations and is equal to the jamming limit  $\theta_{\text{jam}} = 54.7\%$ .<sup>[24,26–30,32]</sup> However, strong repulsive interactions, for example, because of electrostatic forces, can lead to a considerably lower maximum attainable coverage,<sup>[24,25,28–32]</sup> in agreement with the Derjaguin-Landau-Verwey-Overbeek (DLVO) theory.<sup>[34,35]</sup> This will be described in more detail in “Electrostatic Interactions in Particle Deposition.”

In previous work, many investigations into the importance of electrostatic interactions in colloid deposition processes have been described based on results using large particles (diameter  $> 100$  nm). In this entry, we use scanning electron microscopy (SEM) to study *ex situ* the deposition of colloidal gold nanocrystals ( $\approx 13$  nm) on Si/SiO<sub>2</sub> substrates, derivatized with aminopropyltriethoxysilane (APTES). Spatial distributions after saturation of the deposition experiments are analyzed in terms of radial distribution functions, and indicate that the interparticle distance is tunable by varying the ionic strength. The results are shown to be in good quantitative agreement with other experiments on markedly larger particles.

## ELECTROSTATIC INTERACTIONS IN PARTICLE DEPOSITION

Electrostatic interactions play a dominant role in the field of colloid science.<sup>[35,36]</sup> One of the most prominent examples is that of charge-stabilized colloidal systems.<sup>[34]</sup> Generally, the surface charge of particles suspended in a liquid gives rise to a double layer of countercharge surrounding the particle. This is schematically illustrated in Fig. 1. Overlap of the double layers of neighboring particles is energetically unfavorable, leading to a repulsion of the suspended colloids and thus to a stable suspension. Variation of the ionic strength allows tuning of this double-layer interaction; a higher ionic strength is accompanied by a more effective screening of the surface charge and thus a thinner double layer. The spatial extent of the repulsive interaction, as described by the DLVO theory, is related to the Debye screening length  $\kappa^{-1}$ . The Debye screening parameter  $\kappa$  is given by:<sup>[34–36]</sup>

$$\kappa^2 = \frac{e^2 \sum_i n_i z_i^2}{\epsilon \epsilon_0 k T} \quad (1)$$

where  $n_i$  and  $z_i$  are the number density and valence of ions  $i$ , respectively; and  $e$ ,  $k$ ,  $T$ , and  $\epsilon \epsilon_0$  are the elementary charge, Boltzmann constant, absolute

**Fig. 1** Schematic representation of the double layer formed near the surface of a charged (colloidal) particle because of accumulation of countercharge. Assuming a constant surface potential, the spatial extent of the double layer is smaller for higher ionic strengths. This is indicated by the schematic graph of the potential  $\psi$  as a function of distance from the particle surface, for two concentrations with  $C_2 > C_1$ .

temperature, and dielectric permittivity of the electrolyte, respectively. Recently, the tunability of the repulsive interaction because of double-layer overlap, in combination with an externally applied potential, has been elegantly used to control the crystallographic structure of colloidal superstructures.<sup>[37]</sup>

The stabilization of colloidal suspensions is often governed by electrostatic repulsive interactions, whereas attractive electrostatic forces between colloids and the substrate can be employed to control the deposition of particles.<sup>[2,14,16,22,25,32,33]</sup> In this work, we investigate the adsorption of negatively charged nanocolloidal gold particles on positively charged APTES-derivatized silicon surfaces.<sup>[38]</sup> However, attractive interactions have been used in systems of a very different nature to control the deposition and the resulting morphology. Examples including proteins<sup>[30,39]</sup> and bacteria,<sup>[40]</sup> and the self-organization of charge-bidisperse mixtures of colloidal particles have been studied.<sup>[41–43]</sup> Furthermore, the adsorption of polyelectrolytes onto surfaces,<sup>[16,44–46]</sup> both in a single layer and layer-by-layer self-assembly, is also governed by electrostatic interactions arising from negatively charged polyanions and positively charged polycations. Similarly, combinations of colloidal particles and polyelectrolytes have been used to controllably grow polymer/nanoparticle multilayer films.<sup>[15,16,20,21,23]</sup> In addition, the roughness of polyelectrolyte films has been shown to depend on the ionic strength.<sup>[45]</sup> With increasing salt concentration, the polymers go through a transition from an extended conformation, because of repulsive interactions between charged groups on the chain, to a more compact form.

As mentioned in the “Introduction,” deposition processes governed by strong attractive interactions between particles and substrates are generally characterized by large sticking probability and low lateral surface mobility. These systems have been adequately described in terms of RSA,<sup>[25–33]</sup> in which the adsorbing particles are treated as “hard” disks. The maximum saturation coverage in the RSA model amounts to  $\theta_{\text{jam}} = 54.7\%$ .<sup>[24,26–30,32]</sup> Markedly different results have been obtained in experimental studies on the deposition of charge-stabilized colloidal particles. The maximum attainable coverage is considerably lower than the aforementioned jamming limit,<sup>[2,14,16,19,25–32,38]</sup> which can be understood by considering the interparticle repulsion in suspension. This is schematically illustrated in Fig. 2, where universal coverage curves are plotted as a function of the effective screening parameter  $\kappa a$ , where  $\kappa$  is the Debye screening parameter as given by Eq. (1) and  $a$  is the particle radius. On the right in Fig. 2, the coverage approaches the jamming limit  $\theta_{\text{jam}}$  at  $\kappa a \gg 1$ , which corresponds to “hard,” non-interacting spheres with a Debye screening length much smaller than the particle radius  $a$ . For low ionic strengths and/or relatively

**Fig. 2** Schematic representation of the coverage as a function of the screening parameter  $\kappa a$ . The dash-dotted line represents the jamming limit for random sequential adsorption. The solid and dashed lines show the variation of the coverage with varying double-layer thickness and surface potential.

small particles (small  $\kappa a$ ; left in Fig. 2), the interparticle repulsion in suspension dominates and the maximum coverage is well below the jamming limit. The concept of RSA is still applicable, but the colloidal particles, with their electric double layer, are best treated as spheres with an effective radius  $a_{\text{eff}}$  markedly larger than their actual size  $a$ . The maximum attainable surface coverage  $\theta_{\text{max}}$ , in relation to the jamming limit  $\theta_{\text{jam}}$ , is described by:

$$\theta_{\text{sat}} = \theta_{\text{jam}} \left( \frac{a}{a_{\text{eff}}} \right)^2 \quad (2)$$

The effective radius  $a_{\text{eff}} = a + \Delta a$  not only depends on the ionic strength, but also on the particle surface potential  $\psi_p$ . For low surface potentials, the effective enlargement  $\Delta a$  of the radius is much smaller than for high surface potentials. This results in a shift of the saturation coverage curve to larger  $\kappa a$  values, as indicated in Fig. 2. In fact, a comparison of calculations to the measured saturation coverage values allows a rough determination of the particle surface potential.

## SYNTHESIS AND IRREVERSIBLE ADSORPTION OF GOLD NANOCRYSTALS

### Synthesis of Nanocolloidal Gold Suspension

Colloidal suspensions of gold nanocrystals are prepared by standard citrate reduction.<sup>[22,47]</sup> In a

typical synthesis, 250 mL of a 1-mM  $\text{HAuCl}_4$  aqueous solution is heated to 100°C under refluxing conditions. Under vigorous stirring, 25 mL of a 38.8-mM sodium citrate solution is rapidly added. This results in color changes of the originally yellow solution to transparent, to dark blue/gray, and, finally, after approximately 2 min, to burgundy red, which marks the end of the reaction. For 15–20 min, the reaction vessel is kept at 100°C. Subsequently, it is cooled to room temperature, still stirring continuously.

Based on their size and the initial gold concentration, the nanocrystal density in the as-prepared suspension is estimated to be  $7.70 \times 10^{18} \text{ m}^{-3}$ . The ionic strength of the as-prepared colloidal solution is estimated based on the composition of the initial reactants, and by taking into account the pH ( $\approx 5$ ) of the solution. In this way, we obtain an ionic strength  $I = 0.5 \sum_i z_i^2 c_i = 15.8 \text{ mM}$ , where the summation is over all ions  $i$  in solution, with  $z_i$  and  $c_i$  as their valence and concentration, respectively. The ionic strength is varied by adding NaCl to the suspension.

All chemicals are used as-received, without any further purification. Sodium citrate ( $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7$ , 99%) and hydrogen tetrachloroaurate ( $\text{HAuCl}_4$ , 99.999%) are from Aldrich; all other chemicals are “for-analysis” grade from Merck. Aqueous solutions are prepared with water purified in a Milli-Q system (18.2 MΩ cm).

### Gold Nanocrystal Size Distribution

Several methods have been employed to characterize the size distribution of the gold nanocrystals. The diameter distribution, as determined by transmission electron microscopy (TEM) measurements, is shown in Fig. 3.

**Fig. 3** Distribution of particle sizes determined from TEM images, such as that shown in the insert. The solid line represents a Gaussian fit to the data, which yields an average radius  $a = 6.4 \text{ nm}$  and a standard deviation  $\sigma = 1.05 \text{ nm}$ .

The distribution exhibits a peak at diameters of  $2a = 12.5\text{--}13.0$  nm. In agreement with this, a Gaussian fit yields an average particle size of 12.7 nm (i.e., a radius  $a = 6.4$  nm), with a standard deviation  $\sigma = 1.05$  nm, which corresponds to a polydispersity of approximately 8%. The TEM results also show that nearly all particles are spherical; the number of particles with a measurable shape anisotropy is less than 0.5%.

Atomic force microscopy (AFM) measurements on colloidal films<sup>[38,48]</sup> also provide an indication of the particle size. From the pixel height diagram, the difference between the substrate level and the top of the particles amounts to 13.2 nm, thus an average particle radius  $a = 6.6$  nm. In addition, the coverage as obtained from counting the particles in AFM images of known size has been compared with the total amount of gold atoms determined by X-ray fluorescence (XRF) measurements.<sup>[48]</sup> A linear relationship is obtained, which yields an average total of  $7.6 \times 10^4$  gold atoms per colloidal nanocrystal. Based on TEM images, such as the insert in Fig. 3, we conclude that the particles consist of a number of crystalline domains. Therefore we use the bulk density of gold to deduce from the XRF measurements an average particle radius of 6.7 nm, slightly larger than what is found by the other two methods. In the following sections of this contribution, we use the average radius of the aforementioned values (i.e.,  $a = 6.6$  nm).

### Substrate Treatment and Particle Deposition

We use polished silicon (100) wafers, with typically a 1.5-nm native oxide layer. For reflectometry measurements, a thicker oxide of 45 nm provides higher accuracy. The wafers are cleaved into  $12 \times 12\text{-mm}^2$  pieces. The substrates are cleaned ultrasonically in methanol for at least 15 min prior to further handling. High surface affinity for the colloidal gold particles is achieved by derivatization<sup>[23]</sup> of the silicon substrates in a 10% APTES solution in methanol for 60 min, followed by thorough rinsing in methanol. After drying in nitrogen flow, the samples are immersed in water for 15 min.

Deposition of the gold particles is done by immersing the derivatized substrates in the colloidal suspension for at least 12 hr. The suspension is diluted five times, which leads to an effective particle concentration

of  $1.54 \times 10^{18} \text{ m}^{-3}$  for all experiments. Samples that have not been treated with APTES do not show any deposition of gold on the surface. All of these procedures are performed at room temperature.

### SPATIAL DISTRIBUTION AND SATURATION COVERAGES

In a recent publication, we presented a study of the tunable spatial distribution of colloidal gold nanocrystals based on AFM images.<sup>[48]</sup> Because the particles and the AFM tip have radii of the same order of magnitude, adsorbed nanocrystals appear markedly larger than they actually are. This hinders accurate determination of particle positions, especially within clusters consisting of a number of touching particles. Consequently, this limits the accuracy of the spatial distribution obtained from the analysis. Here we present similar images, but in this case, they were obtained using low-voltage SEM. The SEM measurements are performed with a LEO Gemini 1550 FEG-SEM, equipped with a field emission gun plus Thermo Noran Vantage EDX system and Thermo Noran MAXray parallel beam spectrometer. The electron acceleration voltage can be set between 200 V and 30 kV; because of the low voltage, the deposition of a thin metal (gold) film is not required to ensure electric conduction. The lateral resolution is approximately 2 nm, which enables accurate determination of particle positions.

In Fig. 4, three typical SEM images are shown for colloidal gold assemblies at maximum coverage. Saturation of the coverage is obtained after 5–6 hr, which is primarily determined by diffusion of nanocrystals to the surface. However, generally, deposition is performed overnight, ensuring that, indeed, the surface particle density has reached its maximum value. The ionic strength in Fig. 4 increases from left to right. In agreement with the DLVO theory,<sup>[34,35]</sup> the average distance between particles decreases with increasing ionic strength, leading to an increase of the overall coverage. The SEM measurements in Fig. 4 were obtained after removal of the samples from the colloidal suspension, thorough rinsing with water and, finally, drying. The adherence of the nanocrystals

**Fig. 4** Typical SEM images of colloidal gold particles irreversibly adsorbed at silicon/silicon oxide substrates, derivatized with APTES. The image size amounts to  $750 \times 750 \text{ nm}^2$ . The ionic strength was varied to tune the average interparticle distance. Coverages are obtained by manual counting and amount to 10% (left), 18% (middle), and 28% (right) for the three images.

to the substrate is good, as multiple reimmersion, rinsing, and drying steps do not lead to a measurable change in the particle distribution and/or coverage.

More quantitative information is obtained from radial distribution functions, calculated from SEM images such as those presented in Fig. 4. Positions of all particles in these images are determined using Scion Image (Beta 4.0.2; Scion Corporation). The radial distribution function (also referred to as the pair correlation function) is obtained from these positions by calculating:

$$g'_i(r) = \frac{\delta N(r)}{n2\pi r\delta r} \quad (3)$$

for every particle  $i$ , where  $\delta N(r)$  represents the number of particles within a ring of width  $\delta r$  at a distance  $r$ . The overall surface density of particles is represented by  $n$ . The total radial distribution function  $g(r) = N^{-1}\sum_i g'_i(r)$  is found by averaging over all  $N = nA$  particles, with  $A = 0.56\mu\text{m}^2$  as the surface area in the image. In Fig. 5, the radial distribution functions obtained from the images in Fig. 4 are shown. As mentioned above, we have recently shown<sup>[48]</sup> that all  $g(r)$  curves in the coverage range considered in this work scale onto a single radial distribution function  $g(r/r_0)$  when the distance  $r$  is normalized by  $r_0 = n^{-1/2}$ . This scaling behavior is also exhibited in the coverage

**Fig. 5** Three-dimensional representation of the coverage-dependent radial distribution functions  $g(r)$ , calculated from the three images in Fig. 4. The projected curves on the back panel clearly show the increase of the peak height and its shift to smaller distances for higher coverage. In the bottom plane, the coverage-dependent shift of the peak maxima for a larger number of radial distribution functions is shown; the solid line is a guide to the eye.

dependence of the peak positions in the bottom plane of Fig. 5; the solid line is given by  $r = (\pi a^2/\theta)^{-1/2}$ . Surprisingly, this scaling implies an approximately cubic distribution of nanocrystals over large ranges on the surface. For a close-packed distribution, hexagonal distribution is expected, which is not the case as can clearly be seen in Fig. 4. Nevertheless, the cubic distribution is also not evident from the SEM images.

The fact that the curves can be scaled indicates that, in the range of ionic strengths considered in this work, the spatial distribution of nanocrystals is universal. Apparently, a single mechanism dominates the nanocrystal organization on the surface, irrespective of the ionic strength. Obviously, for considerably lower coverages, at which the interparticle interactions can be neglected, this is no longer valid. In that case, the statistical distribution of nanocrystals results in a Boltzmann distribution. Careful examination of the heights of the maxima in the radial distribution functions (see back panel in Fig. 5) indeed exhibits a decrease with lower coverages (i.e., for lower ionic strengths).

The radial distributions exhibit features such as the maximum at  $r_0$ , followed by the shallow minimum near  $1.5r_0$ , which are in good agreement with results of RSA simulations assuming effectively enlarged colloidal particles<sup>[24–26,29–32]</sup> (i.e., with an electric double layer on the order of, or larger than, the particle radius). For ideally distributed highly monodisperse nanoparticles, a considerably higher and narrower peak is expected, followed by a larger number of minima at larger distances. However, polydispersity of the colloidal suspension gives rise to a lower maximum and widening of the peak; this phenomenon is even more pronounced for particles in the low-nanometer range, compared with much larger particles.<sup>[29,49]</sup> Moreover, for ideal distribution, the polydispersity must be below 5%, which is obviously not the case in our suspensions.

Unfortunately, with the citrate-stabilized nanocolloidal gold system, only a limited range of ionic strengths is available. At high ionic strength, the repulsive interaction between particles is reduced and the van der Waals attraction begins to dominate. Eventually, this leads to irreversible coagulation of the particles in suspension, which gives rise to the deposition of larger clusters on the substrates. For gold suspensions, an upper limit for the ionic strength of  $I = 24\text{mM}$  has been reported.<sup>[34]</sup> This corresponds to a maximum coverage of approximately 35%, which is also the upper limit of the data in Fig. 5. Low ionic strengths can only be achieved by dialysis or ultracentrifugation. In both cases, the citrate concentration in the solution becomes so low that citrate groups on the particles (the stabilizing mechanism) start to desorb. This then leads to instability of the colloidal suspension.

## KINETICS OF NANOCOLLOIDAL GOLD ADSORPTION

In addition to the aforementioned study of spatial distributions after saturation of the coverage, we have also investigated the ionic strength-dependent kinetics of nanocolloidal gold adsorption at APTES-derivatized surface. For this in situ study, we used single wavelength reflectometry, in combination with a radial impinging jet cell<sup>[14,24]</sup> geometry to provide a controlled supply of colloidal particles to the substrate surface. This setup is often combined with an optical microscope to visualize the adsorbed particles,<sup>[7,9,10,24,32]</sup> but as the gold nanocrystals are markedly smaller than the wavelength of the probing light (HeNe laser, 632 nm), we use a non-imaging polarized optical reflection technique. The coverage is calculated from the reflectometry signal using the thin island film theory, similar to what was described previously.<sup>[38]</sup>

In Fig. 6, typical reflectometry transients, obtained at various ionic strengths, are shown. The intrinsic ionic strength of the diluted suspension amounts to 3.6 mM. The ionic strength of the solution is varied by adding 0–15 mM NaCl, which corresponds to Debye screening lengths from 5.1 to 2.2 nm. Two distinct regimes are observed in the curves in Fig. 6. For short times, the deposition rate is constant and independent of the ionic strengths, which implies that, initially, the deposition process is limited by the supply of colloidal particles to the surface. The hydrodynamics of colloid deposition in a radial impinging jet

**Fig. 6** Three-dimensional representation of the ionic strength-dependent adsorption kinetics of gold nanocolloidal particles in stagnation point flow geometry. The coverage is obtained by polarized reflectometry. The data on the back panel indicate the evolution of the saturation coverage with increasing ionic strength for a number of reflectometry experiments; the solid line is a guide to the eye.

cell has been discussed by Dabros and Van de Ven.<sup>[50]</sup> The particle flux toward the surface is, in principle, constant and is merely determined by the cell geometry, the fluid viscosity, the diffusion constant of the particles, and the colloid density in the suspension. Assuming a sticking probability of one in the initial stage of the deposition process, a constant deposition rate  $d\theta/dt$  is expected because the particle concentration and the nanoparticle diffusion constant are constant for all reflectometry measurements. This is indeed observed in the transients for the first few minutes.

The initial linear deposition region is followed by a transition to a region where the deposition rate decreases and the adsorption saturates. A quantitative analysis of this transition range lies outside the scope of this work, and will be described in a forthcoming publication. We now turn to the saturation regime of the deposition curves in Fig. 6. With increasing ionic strengths, the maximum attainable coverage becomes larger, as it is also indicated by the solid line in the back panel. As we already discussed above, this is in agreement with the DLVO theory, considering that the double layer surrounding every particle gives rise to an enlarged effective nanocrystal radius  $a_{\text{eff}} = a + \Delta a$ , with  $\Delta a \sim 1/\kappa$ . This in turn gives rise to saturation coverages below the RSA jamming limit of 54.7%, in agreement with Eqs. (1) and (2). In “Quantitative Analysis,” the results presented in Figs. 5 and 6 will be discussed quantitatively, also in comparison to literature data.

## QUANTITATIVE ANALYSIS

The results described in “Kinetics of Nanocolloidal Gold Adsorption” can be compared with calculations using a relatively simple model for the repulsive interaction between particles. Many experiments dealing with the influence of the ionic strength on the deposition of large particles in the 100–1000 nm range have been published. Different techniques were employed, including optical microscopy, AFM, and SEM. To quantitatively compare results for varying ionic strengths and particle radii, and to obtain a universal curve, the coverage is often plotted as a function of the screening parameter  $\kappa a$ .<sup>[24–30,32,49]</sup> For deposition processes with “hard,” non-interacting spheres, with a Debye screening length considerably shorter than the particle diameter, which are governed by RSA, the saturation coverage approaches the aforementioned jamming limit  $\theta_{\text{jam}} = 54.7\%$ . For small values of the screening parameter  $\kappa a$  (i.e., for low ionic strengths and/or small particles), the repulsive interaction between particles in the solution limits the coverage to values well below the jamming limit.

In Fig. 7, the data from Figs. 5 and 6, together with our previous results using AFM,<sup>[48]</sup> are plotted as a

**Fig. 7** Experimental coverage, obtained from the data in Figs. 5 and 6, as a function of the screening parameter  $\kappa a$ , compared with the calculated curves as shown in Fig. 2. Also shown are the data for polystyrene particles with sizes in the 40–530 nm range and for silica particles with sizes in the 32–190 nm range. *Source:* From Refs.<sup>[14,31,51]</sup>

function of the screening parameter. Also shown are the results calculated from experiments on polystyrene<sup>[31]</sup> and silica<sup>[14,51]</sup> particles. The results are compared with a calculation for ionic strength-dependent coverage, represented by the solid line. Generally, the repulsive interaction between neighboring colloidal spheres, owing to the overlap of their double layers, can be obtained by solving the Poisson–Boltzmann equation. For a system of two spherical particles, the Poisson–Boltzmann equation cannot be solved analytically, and an approximation has to be used. The frequently employed low surface potential approximations<sup>[34–36]</sup> are not valid for our citrate-stabilized colloidal gold system because the particles have a surface potential on the order of 80–100 meV.<sup>[52,53]</sup> However, because of the limited available range of ionic strengths, the distance between neighboring particles is, in all cases, relatively large, which enables a description in terms of a far field effective potential. Sader<sup>[54]</sup> formulated an accurate analytical expression for the particle–particle repulsive interaction  $U_{pp}(r/a)$ , which is valid for all values of the screening parameter:

$$U_{pp}\left(\frac{r}{a}\right) = kTB_{pp} \frac{a}{r} e^{-\kappa(r-2a)} \quad (4)$$

where  $r$  is the center-to-center distance between particles. The characteristic particle–particle repulsion is given by:<sup>[30]</sup>

$$B_{pp} = \left(\frac{4\pi\epsilon\epsilon_0 kTa}{e^2}\right) \left(\frac{y_p + 4\gamma\Omega\kappa a}{1 + \Omega\kappa a}\right)^2 \quad (5)$$

where  $y_p = \psi_p(e/kT)$  is the dimensionless particle

surface potential. The quantities  $\gamma$  and  $\Omega$  are defined as:

$$\gamma = \tanh(y_p) \quad (6a)$$

$$\Omega = \frac{y_p - 4\gamma}{2\gamma^3} \quad (6b)$$

If we assume a constant surface potential  $\psi_p$ , the interparticle distance  $r_{kT}$  at which  $U_{pp}$  drops below  $kT$  can be obtained numerically as a function of the screening parameter  $\kappa a$  from Eqs. (456b). From Eq. (2), with  $a_{\text{eff}} = 0.5r_{kT}$ , the corresponding coverage is obtained. The choice of  $kT$  is, in principle, arbitrary, but it originates from the fact that the repulsive interaction is competing with the Brownian motion of the nanocrystals in suspension; the energy involved in the latter process is on the order of  $kT$ . The solid line in Fig. 7 represents a fit to our data for nanocolloidal gold particles with an average diameter of 13 nm. From the fit, we find a surface potential  $|\psi_p| = 129$  meV, which is considerably larger than the absolute value of the  $\zeta$ -potential found by Chow and Zukoski<sup>[52]</sup> and Van der Zander et al.<sup>[53]</sup> from electrokinetic measurements at comparable ionic strengths. This discrepancy is very common and is extensively described in standard colloid chemistry textbooks.<sup>[35]</sup>

When we compare our results and the corresponding fit curve in Fig. 7 to results obtained for silica and polystyrene particles,<sup>[14,31,51]</sup> qualitative agreement between the different experiments is found. In the region  $\kappa a = 1$  and  $\kappa a = 5$ , the coverage for all types of particles and sizes is comparable to what we find for gold nanocolloids. The data for polystyrene and silica particles for values of the screening parameter  $\kappa a > 5$  deviate from the fitted curve. This can be understood by considering that the far field potential approximation we employed in Eqs. (4) and (5) is only valid at relatively large particle separations. For higher coverage at larger values of the screening parameter, this approximation no longer provides an accurate description of the interparticle repulsive interaction. Furthermore, polydispersity may also give rise to deviations from ideal behavior, but in that case, a higher coverage is to be expected, compared with model calculations. Finally, the surface potential of the polystyrene and silica particles probably differs from the value of citrate-stabilized gold colloids. As indicated schematically in Fig. 7, this also gives rise to deviations from the calculated curve.

## CONCLUSION

Using SEM, we present an investigation into the influence of ionic strength on the spatial distribution of nanocolloidal gold particles irreversibly deposited at APTES-derivatized substrates. Radial distribution

functions are used to analyze the SEM images, and indicate that the deposition process is governed by RSA. This is in agreement with the large sticking probability and the low lateral mobility of gold nanocrystals on the surface after adsorption.

The radial distribution functions exhibit a maximum, which corresponds to the minimum interparticle separation of the adsorbed nanocrystals. This distance, and thus the overall surface coverage, can be tuned by varying the ionic strength, in agreement with DLVO theory. Scaling indicates an approximately cubic long-range distribution of particles. The results are in agreement with calculations, in which the repulsive particle-particle interactions are described using a far field potential approximation. Furthermore, our results for nanocolloidal gold films are in qualitative agreement with similar results deduced from literature for silica and polystyrene particles with sizes in the range of 332–530 nm.

## Abstract

Iron has a number of properties that make it particularly useful as a nanoparticle. Iron is cheap and plentiful, it is environmentally benign, and has no human toxicity except in extreme doses. Its magnetic properties are also very useful. Iron has the highest room temperature saturation magnetization of any element, and its cubic crystalline structure helps make it a soft magnetic material. The high saturation magnetization means that an iron nanoparticle can possess a very large magnetic moment, while the fact that it is a soft magnet means that a fairly large nanoparticle (with a correspondingly large moment) can still have a superparamagnetic blocking temperature at a relatively low temperature. The magnetic softness of iron nanoparticles can, however, be overcome if necessary. For magnetic storage applications, where a hard magnet is desirable, iron rods can be used. The shape anisotropy of the nanorods makes them extremely hard. In either case, the high magnetic moment of iron is a huge advantage.

Iron has one major weakness that impacts its usefulness in nanoparticle form, its reactivity. Iron is very reactive towards both water and the oxygen in air. This reactivity manifests itself slowly in large iron structures as rusting, but in nanoparticles it can occur rapidly and spectacularly. This has effectively limited the use of iron nanoparticles to inert or reducing environments unless they are pretreated to passivate them towards oxidation. This entry highlights the various methods of preparing iron nanoparticles, the existing and potential applications, and some of the fundamental properties of iron nanoparticles.

## PROPERTIES

### Magnetic Properties

Probably, the most interesting property that magnetic nanoparticles can possess is superparamagnetism. It is by no means unique to iron, but it is commonly seen in iron nanoparticles. For a particle to be superparamagnetic, it must not only be strongly magnetic (with ferromagnetic or ferrimagnetic ordering of its atoms' spins), but also consist of a single magnetic domain. This occurs when the particle is smaller than the characteristic magnetic domain in the material. For iron, the single domain size is about 20 nm, and particles below this size tend to be single domain. The result of the particle being a single domain is that we can think of it as possessing a single giant spin whose magnitude is the sum of the individual atoms' spins for a ferromagnetic material like iron.

In addition to being single domain particles, superparamagnetic particles must have enough thermal energy that the spins of the single domain particles can freely reorient. The energy required for the reorientation of a particle's spin is proportional to the volume of the particle. As a practical matter, this generally places a greater limitation on the size of particles that exhibit superparamagnetism than the requirement that they be single domain.

As an illustrative example, we can imagine beginning with a lone iron atom (or ion) and growing an

iron nanoparticle around it and see how its magnetic properties change. A lone iron atom, owing to its unpaired electrons, will exhibit paramagnetism. Once we have a small cluster of iron atoms, due to the strong magnetic exchange coupling, the spins will align and exhibit superparamagnetism. As the nanoparticle grows in size, though the spins remain fully aligned, the energy barrier to spin reorientation grows to the point that it cannot occur in a certain timeframe (by convention 100 sec), and coercivity appears. Coercivity is a measure of how difficult it is to magnetize or demagnetize a sample, where materials with low coercivity are termed soft and highly coercive materials are hard magnets. At this point, the nanoparticles are magnetically soft ferromagnets. As this particle grows, the energy barrier to spin reorientation grows with it, and the particles become a highly coercive, hard magnet. Finally, at some size above 20 nm, it becomes energetically favorable for the particle to break into multiple magnetic domains. The size where this occurs represents the tipping point between two features that increase the energy of the system. Single magnetic domains have a higher flux leakage, a term used to describe the energy stored in an external magnetic field, than multiple domain particles. Lines of flux emanate from the north pole of a magnet and return to the south pole, and having multiple poles in a single particle decreases the energy by having shorter paths from north to south poles. Breaking into multiple magnetic domains increases energy through a different

**Fig. 1** The progression of the coercivity of a magnetic nanoparticle as its size is increased. Very small nanoparticles have no coercivity and are superparamagnetic. When coercivity appears, they become superparamagnetic, and somewhere near the maximum coercivity, the particle breaks into multiple magnetic domains. From here, the particle coercivity begins an approach to bulk coercivity. *Source:* Adapted from Refs.<sup>[1,2]</sup>.

mechanism, the energy stored in the interfaces between domains. The point where the energy decrease from lowered flux leakage is greater than the energy increase from the new domain walls is where the particle becomes multidomain. At this point, the coercivity along with its other magnetic properties begin to move towards bulk values. This progression is illustrated in Fig. 1.

Now, we will discuss a superparamagnetic sample as discussed earlier, and look at its magnetic properties as a function of temperature. At very low temperatures, there is insufficient thermal energy to allow the free reorientation of magnetic spins, and the particles are ferromagnetic. If we begin with an unmagnetized sample and slowly increase the temperature under a constant field, the magnetization of the sample increases as more reorientation is allowed. If we stopped at temperatures along the way to measure hysteresis loops, we would also notice the hysteresis decreasing with increasing temperatures. At some temperature, a maximum in magnetization at a constant field is reached, and the magnetization begins to decrease as  $T^{-1}$ . The maximum in magnetization coincides with a total loss in coercivity, and is termed the blocking temperature, as below this temperature spin reorientation is blocked. Above the blocking temperature, the sample is superparamagnetic and has no hysteresis but can have a very high susceptibility. The magnetization falls off as  $T^{-1}$ , as temperature is increased above the blocking temperature. This

**Fig. 2** A typical magnetometry experiment on iron nanoparticles. The particles are cooled in the absence of a magnetic field, a weak field is applied (here 1 mT), then the particle sample is slowly heated and the moment measured as a function of temperature. This progression produces the ZFC (zero-field cooled) curve shown earlier. The ZC (field cooled) curve is produced by stopping the warming, and recooling the sample.

progression describes a ZFC (zero-field cooled) plot in magnetometry, and is shown graphically in Fig. 2. The field-cooled curve (FC) is produced after the ZFC curve by subsequent cooling in the presence of the magnetic field used in the ZFC curve. The two curves are coincident where the sample is superparamagnetic (there is no hysteresis), but separate at the blocking temperature, as the FC curve remains fully magnetized.

An interesting result of all of this is that nanoparticles can represent the lowest coercivity possible (zero for superparamagnetic particles) or very highly coercive for somewhat larger nanoparticles. These high coercivities can in fact be increased further through shape anisotropy by, for example, producing high aspect ratio particles. This has led to the use of iron nanorods in high-density magnetic recording.

Surface effects are very important in nanoparticles, and the effects of the surface are extremely important in the magnetism of iron nanoparticles. The reactivity of iron nanoparticles makes it difficult to keep the surface in its fully reduced form. Even when fully protected from oxygen and water, the surface of iron nanoparticles can be effectively oxidized by the surfactant used to stabilize them. In some cases, a detectable oxide can be formed by the action of a surfactant such as a carboxylic acid.<sup>[3]</sup> Surface oxides tend to add little or nothing to the overall magnetism of the particle, and

may even decrease the magnetic response of the underlying, unoxidized iron. The reason for the lack of magnetic response of the oxide is the pinning of the spins in the oxide. These pinned spins do not reorient with the particle spin, and contribute nothing to particle moment.<sup>[4]</sup> While in the case of larger particles, this may not be a serious issue, for particles below about 5 nm, a surface oxide can essentially destroy the magnetic properties of an iron particle.

Even in the absence of an oxide layer, a strongly interacting surfactant can disturb the electronic structure of iron enough to seriously impact the magnetic properties of the nanoparticle. This effect was well demonstrated by a series of experiments by Gedanken and coworkers.<sup>[5]</sup> Iron nanoparticles were synthesized with no stabilizing surfactant, and these particles were then coated with a series of surfactants. The surfactants decreased the saturation magnetization of the particles depending on the strength of their interactions, with surfactants such as a sulfonic acid or phosphonic acid causing a huge reduction, while much milder alcoholic surfactants had a less dramatic effect. Nearly all of the saturation magnetization of an iron nanoparticle can be maintained by selecting a sufficiently weakly interacting surfactant, such as a  $\beta$ -diketone.<sup>[6]</sup>

### Chemical Properties

Iron nanoparticles are extraordinarily reactive, most notably being pyrophoric. It is important to keep this in mind whenever handling iron nanoparticles both for safety reasons and to maintain the nanoparticles' integrity. There are a number of ways to mitigate the extreme reactivity that iron nanoparticles have towards oxidizing agents, including gently oxidizing the surface. By exposing the surface of the particles to a weak oxidizer, or a very dilute strong oxidizer, the particles can be passivated. At ambient temperatures, the oxidation of iron nanoparticles typically produces magnetite, which is a strongly adherent layer that can passivate the particles towards further oxidation. While rapid oxidation produces heat that can lead to delamination of the oxide and wholesale oxidation in a potentially spectacular reaction, the slow, gentle oxidation of the surface only can protect the core and maintain it as iron. An example of this is shown in Fig. 3. Species that have been used successfully for this passivation include: low partial pressures of oxygen,<sup>[7]</sup> carboxylic acids,<sup>[3]</sup> and alcohols.<sup>[8]</sup> This gentle passivation can be of particular use to particles destined for catalytic application as they can later be reduced back to elemental iron. Early work by Selwood<sup>[9]</sup> not only demonstrated that this conversion could be performed on nanoscale iron, but also showed that the reduction and oxidation could be followed by measuring the

**Fig. 3** Iron nanoparticles whose shells have been gently oxidized by oleic acid. These particles can be handled in dry air without further damage to their iron cores.

magnetic moment of the catalyst material. While oxidizing the surface may leave the core unchanged, it will still enormously change the properties of the nanoparticle. The chemical properties are obviously greatly altered as are magnetic properties due to the very large fraction of the volume that is contained in the outer layers of the particle. These are also issues for the other methods of preventing oxidation: coating with oxidation-resistant coatings, and alloying. Alloying will naturally make an entirely different material, such as iron platinum alloys that are still highly magnetic, but are indefinitely stable in air. Even coating particles has a surprisingly strong effect on the magnetic properties of the particles, generally greatly weakening them. This has been shown by a number of researchers to occur when gold coating iron nanoparticles.

The extreme reactivity of iron nanoparticles can be of use in catalytic applications, however. The tendency to oxidize in air does limit the application to carefully controlled systems that contain either inert atmospheres, or even reducing atmospheres. There is one important industrial application for iron nanoparticles as catalyst, and that is the Fischer–Tropsch conversion of carbon monoxide and hydrogen gas into alkanes. This process is conducted in a reducing atmosphere, so iron's tendency to oxidize is not detrimental to the reaction, and in fact the easy oxidation of iron may be a crucial part of its catalytic activity in this reaction. Iron nanocatalysts have a number of advantages in Fischer–Tropsch reactions, including the abundance and low cost of iron, the high catalytic activity,<sup>[10]</sup>

and ability to maintain its high catalytic activity in this reaction. In contrast, applications of iron nanoparticles for the liquefaction of coal have been continuously hampered by the presence of sulfur-containing species that very quickly poison iron nanoparticle-based catalysts. Iron nanoparticles have been shown to catalyze numerous other reactions including the growth of carbon nanotubes,<sup>[11]</sup> hydrogenation of naphthalene,<sup>[12]</sup> and degradation of trichloroethylene.<sup>[13]</sup>

## PREPARATION

Mechanical grinding of iron nanoparticles,<sup>[14,15]</sup> while certainly the most intuitively simple approach to nanoparticle formation, is in fact a difficult to produce and well-defined product. The product of high-energy milling tends to be irregularly shaped and polydisperse. The advantage of this process is the ease with which it can be scaled up to produce large quantities.

Iron nanoparticles can also be produced by vapor deposition onto a non-wetting surface. If an appropriate amount of iron is deposited onto the surface, the iron forms discrete nanoparticles, while if too much is applied, the iron will form a continuous film. Obviously, this process is surface area limited, making it difficult to produce appreciable quantities of nanoparticles. Several clever methods have been used to increase the yield of this type of procedure by constantly refreshing the surface. For example, by codepositing a metal and frozen solvent, Klabunde and coworkers were able to produce finely divided magnesium.<sup>[16]</sup> When applying this process to iron, they codeposited iron with other metals and inorganic compounds to form iron nanoparticles protected from oxidation by being embedded in micron-scale particles of the other chemical species (i.e., barium fluoride,<sup>[17]</sup> indium,<sup>[18]</sup> magnesium,<sup>[19]</sup> magnesium fluoride,<sup>[17,19]</sup> and neodymium<sup>[18]</sup>).

Another approach is shown in Fig. 4.<sup>[20]</sup> In this process, a drum is rotated around the evaporation source, with the bottom submerged in a viscous liquid. This viscous liquid forms a film over the drum, and the particles collect in this liquid, directly forming a ferrofluid.

By far, the most common method of forming iron nanoparticles to be found in the literature is the use of wet chemical synthesis. There are two primary methods of chemical synthesis of iron nanoparticles: decomposition of iron compounds and reduction of iron salts or oxides. I will discuss each of these methods in the following paragraphs.

The most popular chemical decomposition method is the thermal decomposition of iron pentacarbonyl. This method has long been used to make micron-scale iron particles, often called carbonyl iron. The advantage of the decomposition of this species is that its

**Fig. 4** Formation of a ferrofluid by evaporating iron into a continuously refreshed thin film of liquid. *Source:* Reproduced with permission from Ref.<sup>[20]</sup>.

decomposition yields only iron and carbon monoxide, which leaves as a gas. There are no ions or other impurities to contaminate the product (if the iron pentacarbonyl was pure). Iron pentacarbonyl is also very soluble in organic solvents, which is useful as one will not easily yield metallic iron nanoparticles in an aqueous environment. Iron pentacarbonyl also decomposes at modest temperatures, with the rate becoming appreciable around 100°C and being quite fast around 200°C (at this temperature, a typical decomposition reaction can be complete in under an hour). Precise control of particle size is rather difficult in these types of systems, owing to the extraordinarily complex kinetics of the decomposition of iron pentacarbonyl. The decomposition rate, and even the mechanism and kinetic order of the decomposition, are highly dependent on the reaction conditions. The decomposition is self-catalyzed, as well as being catalyzed by numerous other species,<sup>[21]</sup> so that as concentrations change through the course of the reaction, the reaction rate can change greatly. The first literature reports of the formation of iron nanoparticles through iron pentacarbonyl used a variety of polymers as both catalyst and surfactant.<sup>[21,22]</sup> A number of other surfactants have been used for this type of reaction, but the essence of the reaction has changed a little. The iron carbonyl, an appropriate high boiling point solvent, and the surfactant are placed in a vessel under an inert atmosphere and heated. The carbon monoxide must be allowed to vent for the reaction to continue to completion, so an oil bubbler is often used as a one-way valve.

Sonochemical decomposition of iron pentacarbonyl to form nanoscopic iron powders,<sup>[23]</sup> then well-dispersed

nanoparticles<sup>[24]</sup> was demonstrated by Suslick et al. In this approach, the decomposition of iron pentacarbonyl proceeds at a globally low temperature, with highly localized energy provided through acoustic cavitation. This method suffers from the same difficulty as the thermal decomposition, in that the reaction is kinetically complex, and precise size control is difficult.

On the whole, decomposition of iron pentacarbonyl to form iron nanoparticles has been shown to be an extremely versatile approach. A large number of surfactants with varying functionalities can be used to produce iron nanoparticles, including alcohols,<sup>[25,26]</sup> carboxylic acids,<sup>[3,24,27,28]</sup> amines,<sup>[3]</sup> amides,<sup>[3]</sup>  $\beta$ -diketones,<sup>[6]</sup> polyvinylpyrrolidone,<sup>[24]</sup> polybutadiene,<sup>[21]</sup> poly(styrene-*co*-butadiene),<sup>[21]</sup> poly(styrene-*co*-4-vinylpyridine),<sup>[21]</sup> alkanethiols,<sup>[27,29]</sup> alkyl sulfates,<sup>[30]</sup> chlorosilanes,<sup>[30]</sup> and alkyl sulfonic acids.<sup>[31]</sup>

Chemical reduction of metal salts has long been the most common method for the formation of metallic nanoparticles. This procedure is not as common in iron as in other metals, primarily due to iron's chemical reactivity. Many of the most popular methods of nanoparticle production are done in aqueous environments (either purely aqueous, or in a two-phase aqueous/organic system). The presence of water can make it very difficult to keep iron in its zero-valent state, as it has a strong tendency to re-oxidize the iron. Even some of the most popular reducing agents can contaminate iron nanoparticles, in particular the borohydrides, which are known to lead to formation of iron borides.<sup>[32,33]</sup>

There are, however, a number of reports of iron nanoparticles synthesized through the reduction of salts. The synthesis is a fairly simple one, requiring only the mixing of a reducing agent into a solution of iron salt and a surfactant to prevent wholesale agglomeration. The choice of a surfactant is a critical one, as it limits the choice of solvents and reducing agents, as well as altering the properties of the finished nanoparticles. Particular attention must be paid to the surfactant-reducing agent compatibility, because, for example, oleic acid and lithium aluminum hydride are incompatible (the acid will be reduced). To avoid incompatibilities with reducing agents, it is common to use reduction-resistant surfactants such as quaternary ammonium salt<sup>[13,33,34]</sup> or poly-ether<sup>[33]</sup> based surfactants for syntheses involving the reduction of iron salts.

The reduction of iron oxides has also been used to synthesize iron nanoparticles, but the approach is generally quite different. Iron oxides are not very soluble and their reduction to form iron nanoparticles, therefore, generally takes place in the solid state. The typical approach is heating the iron oxide particles in a reducing atmosphere, generally containing hydrogen.<sup>[8,35]</sup> The particle dimensions and shape are determined by the oxide precursor particles, and are largely

maintained during reduction.<sup>[8]</sup> Since iron oxide particles are generally easy to make, can be made in large quantities, and can be made with good control of shape and size, this is a major industrial process used to make iron needles for high-density magnetic data storage.

## APPLICATIONS AND POTENTIAL APPLICATIONS

The largest current application of iron nanoparticles is without a doubt the use of iron nanorods in magnetic recording media. This is the current state-of-the-art material for removable drive material. While this may be the only large-scale industrial application of iron nanoparticles at the moment, there are a number of other applications under investigation. The unique magnetic properties of iron nanoparticles underlie many of them. Potential applications based on the iron nanoparticles' high magnetic saturation and low hysteresis include transformer cores, motors, magnetic record heads, and other small electromagnets. The magnetic properties may also be useful in biomedical applications, including magnetic resonance imaging (MRI) contrast enhancers, and the destruction of tumors through magnetic heating of nanoparticles by oscillating magnetic fields (hyperthermia). Detailed discussions of these and other potential applications are beyond the scope of this entry, but can be found in a number of other references.<sup>[2,36,37]</sup>

## CONCLUSION

Iron nanoparticles are a fascinating material with a few current uses and a great deal of untapped potential. Their two most promising properties are their extreme reactivity, with possible applications in catalysis, and their magnetic properties, with applications in information storage, electromagnetic applications, and biomedical imaging.

The preparation of iron nanoparticles has progressed greatly in the past decade or two, and in the cases of the non-catalytic applications, the only thing standing between the use of this material is a convenient method of treating the particles to mitigate their extreme reactivity. Iron is an outstanding magnetic material and it is here where iron nanoparticles may have the greatest impact.

# Iron Oxide Nanoparticles

Mamoru Senna

Department of Applied Chemistry, Keio University, Yokohama, Japan

## INTRODUCTION

Iron oxide is one of the oldest materials used even in archeological finds, e.g., in Ajanta or in Altamira, as red pigments. Even today, its significance in the pigmental materials is not lost. Since the advent of magnetic recording systems, however, ferromagnetic iron oxides gained its importance quite rapidly. These two important application fields are coupled to gain magnetic or intelligent inks.

There are many chemical species categorized as iron oxides. While hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>), maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>), and magnetite (Fe<sub>3</sub>O<sub>4</sub>) are, by far, the most important species of pure iron oxides, many hydroxides, such as ferric hydroxide (Fe(OH)<sub>3</sub>), and oxyhydroxides, such as goethite ( $\alpha$ -Fe(O)OH), are also of industrial significance, particularly as precursors of pure or complex oxides. As for the complex iron oxides, ferrites are of particular importance as ferromagnetic materials.

Like many other nanoparticles, those of iron oxides and ferrites are prepared either via wet chemical routes such as colloid chemical or sol-gel methods or by dry processes such as vapor deposition techniques. Usually, nanoparticles are not shaped by conventional granulometrical methods. Instead, they are most frequently arranged to films, so that many preparation methods of thin films are regarded as those for nanoparticles as well. It is often desired to assemble or pattern iron oxide nanoparticles to give magnetic or optomagnetic functions.

This review summarizes the preparation, magnetic properties, and some representative examples for application of the pure and complex iron oxides.

## PREPARATION OF PARTICULATES

### Concepts

Morphological states of nanoparticles are generally divided into two, i.e., matrix-supported and self-supported. It is also important to select whether the produced primary particles should be well dispersed or aligned. While self-supported or free particles are prepared either by wet chemical or by vaporization-condensation processes, supported particles are

prepared by the methods usually used for making thin films, as mentioned in "Introduction."

### Preparation of Pure Oxides via Colloid Chemical Routes

Preparation of iron oxide ultrafine particles has been developed in view of obtaining magnetic fluids, whereby iron oxide nanoparticles are usually produced via a surface modification after the formation of magnetic nanoparticles.<sup>[1,2]</sup> A typical preparation method of magnetite nanosol is to wash magnetite precipitates by very diluted HCl and put into a soap solution, e.g., 1% aqueous solution of sodium oleate.<sup>[3]</sup> It is possible, however, to peptize a nanosol without using any organic species. The method is quite simple: A mixed aqueous solution of ferric and ferrous chlorides (e.g., 40 ml of 1 M FeCl<sub>2</sub> and 10 ml of 2 M FeCl<sub>3</sub> in 2 M HCl) was added to an ammonia solution (e.g., 500 ml 0.7 M). When the precipitate was stirred with 2 M aqueous solution of 2 M perchloric acid, peptization was achieved by merely diluting with water.<sup>[3]</sup>

On the other hand, we have wonderful models of preparing iron oxide nanoparticles in nature. Many wandering animals have inborn abilities to orient themselves by magnetic particles, mostly magnetite. They are formed generally from soluble precursors within a soft-tissue matrix.<sup>[4]</sup> The difference from common preparation methods of magnetic fluids by using soaps or similar surfactants and biological formation is the growth of the magnetite nanoparticles in the presence of polymers in the latter. It is therefore reasonable to prepare magnetic nanoparticles in some aqueous polymer dispersion. One of the examples is to precipitate magnetite particles by adding ferrous and ferric chlorides in an aqueous solution of poly(vinyl chloride) containing NaOH to set the initial pH value as high as 13.8. Well-dispersed, phase pure magnetite particles of ca. 8 nm were obtained.<sup>[5,6]</sup>

When 0.1% of OH groups of poly(vinyl alcohol) (PVA) were converted to COOH groups, a polymer layer was observed on the particles; forming a cluster, they are similar to magnetotactic bacteria, which contain chains of magnetic nanoparticles.<sup>[7]</sup>

**Fig. 1** XRD patterns of the prepared powder for various ultrasonic irradiation times; ●:  $\text{NiFe}_2\text{O}_4$ . Source: From Ref.<sup>[8]</sup>.

### Ferrites and Composites

Usually, ferrite nanocrystals are available only after heating at elevated temperatures. Immediate products from colloid chemical processing, most commonly by coprecipitation, are quite often either amorphous or poorly crystallized, so that they are regarded as precursors and subject to subsequent heating. It is therefore important to promote nucleation in the precursor and decrease the temperature needed for crystallization. Ultrasonication, for instance, was revealed to promote crystallization. Shin et al.<sup>[8]</sup> obtained fairly well crystallized Ni–Cu ferrite nanoparticles by ultrasonication. After ultrasonication for 5 hr, distinct crystalline ferrite powders were obtained, as shown in Fig. 1. By prolonged irradiation (for 25 hr), its crystallinity became higher than those heated at 500°C for 2 hr.

Reactant solutions are often confined into a micro-space to guarantee limited growth of the particles to obtain well-dispersed nanoparticles. Inverse micelle or microemulsion methods are typical examples under these concepts. Barium ferrite nanoparticles were prepared in a

microemulsion dispersed in *n*-octane by using cetyl trimethyl ammonium bromide (CTAB) as a surfactant and 1-butanol as a cosurfactant.<sup>[9]</sup> Two identical emulsions were prepared containing a mixed aqueous solution of barium and ferric nitrates in the first one and an aqueous solution of ammonium carbonate in the second. Well-dispersed precipitates of the precursor comprising particles between 3 and 8 nm were calcined at 950°C for 12 hr to obtain phase pure magnetoplumbite. Particle size did not exceed 100 nm despite fairly severe heating condition.

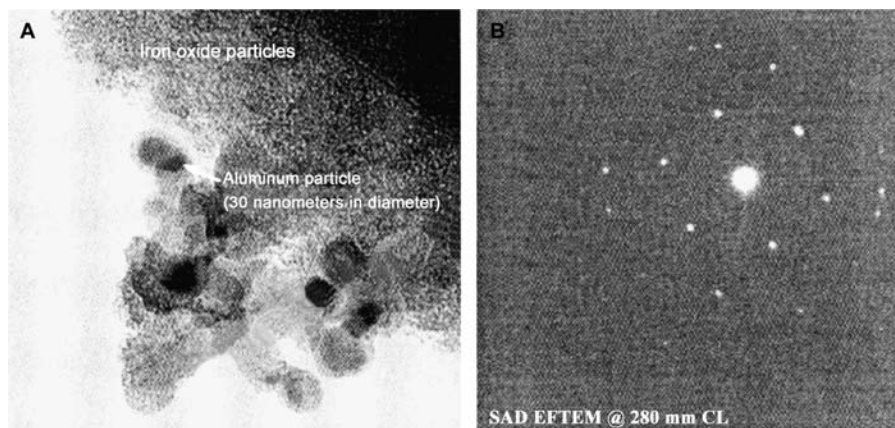

An alternative preparation of ferrite nanoparticles is autocombustion. Mg–Zn ferrites doped with Cu were prepared from a mixed solution comprising nitrates of respective metallic species and citric acid.<sup>[10]</sup> Dried gel obtained by heating the solution at 135°C under constant stirring was subsequently ignited to commence self-propagating combustion, which ended up with the formation of fairly well crystallized loose powder. Average particle size was 56 nm determined from a XRD profile by Scherrer method.<sup>[11]</sup>

Iron oxide–metal nanocomposites were obtained from ethanolic solution of ferric nitrate by slow addition of propylene oxide to occur rapid gelation.<sup>[12]</sup> When other fine-grained metal powders (e.g., Al) were added to the stirred Fe(III)/epoxide solution just before gelation, rigid composite gel was obtained. Slow evaporation or supercritical extraction with  $\text{CO}_2$  brought about xerogel. As shown in Fig. 2, the microstructure of the monolithic xerogel comprises interconnected clusters of hematite (3–10 nm) with well-dispersed Al powers of ca. 30 nm.

### ORIENTATION AND PATTERNING

#### Concepts

One of the most important properties of the ensemble of magnetic particles is their coherency or chain-like

**Fig. 2** (A) HRTEM of  $\text{Fe}_2\text{O}_3$ /ultra-fine-grained Al powers xerogel nanocomposite and (B) SAED pattern of the labeled Al particle in (A). Source: From Ref.<sup>[12]</sup>.

clustering. Anisotropic aggregation, in turn, inevitably results in the anisotropy of the magnetic properties. Patterning and two-dimensional assemblage, on the other hand, are not exclusive for magnetic particles. Many functional materials could be prepared, however, from these techniques on iron oxides as well. Some typical examples are given below.

### Thin Films with Aligned Magnetic Nanoparticles

Starting from a commercially available water-based magnetic fluid comprising  $\text{Fe}_3\text{O}_4$  particles of ca. 10 nm, PVA was added and the viscosity was adjusted by water evaporation.<sup>[13]</sup> Spin-coated films were then formed in the magnetic field up to 5 kOe. Orientation of the chain clusters with increasing the magnetic field is visible in Fig. 3. The separation of the chain cluster was estimated to be  $0.27\ \mu\text{m}$  regardless of the magnetic field.

Magnetic susceptibility was measured in the field parallel ( $\parallel$ ) and perpendicular ( $\perp$ ) to that during the film preparation. As shown in Fig. 4, their deviation becomes larger with increasing the applied field during film formation.

The film serves as an optical grating because of the angle dependence of the transmittance measured by using 628 nm linearly polarized light. Optical anisotropy was revealed to be proportional to the magnetic anisotropy. This kind of materials can serve as a

**Fig. 3** Photographs of films for three different alignment field strengths  $H_d$ : (A) 5.0 kOe; (B) 0.1 kOe; and (C) 0 kOe. Source: From Ref.<sup>[13]</sup>.

**Fig. 4** Change in the susceptibility,  $\chi$ , of films with  $H_d$ . Source: From Ref.<sup>[13]</sup>.

light-controlling device utilizing magneto-optical effects.

### Two-Dimensional Array

Not only one-dimensional assembly, as mentioned in the previous section, but also two-dimensional array of nanoparticles gives rise to many new functions. Use of self-organizing properties of organic molecules is a rational method to realize such an assemblage. Ferritin, being a popular iron-containing protein, is appropriate for such a purpose.<sup>[14]</sup> Ferritin was obtained from a horse spleen by adding  $\text{CdSO}_4$ . On the surface of dilute ferritin solution containing NaCl and phosphate buffer, poly-1-benzyl-L-histidine was spread after solubilization in chloroform. After a heat treatment, well-ordered two-dimensional array of ferritin molecules was obtained at the air-water interface. The array was easily transferred to different substrates, i.e., Si single crystals. By subsequent heat treatment up to  $700^\circ\text{C}$  in nitrogen, protein shell of the ferritin molecules was eliminated to obtain FeO nanoparticles.<sup>[14]</sup> Closer examination by FT-IR and thermogravimetry, it turned out that FeO was obtained after heating at above  $450^\circ\text{C}$ . Heating at higher temperatures tends to break assemblage, as shown in Fig. 5.

The array of iron oxide cores can be observed after heating up to  $500^\circ\text{C}$ . As SEM cannot visualize the protein shell of the ferritin molecule, AFM study in contact mode is necessary to examine the existence of the shell and subunits of the ferritin molecule.<sup>[14]</sup>

### In Situ Patterning

Microscopic patterning by iron oxides was made by using the hydrophilic self-assembled organic monolayers and subsequent microcontact printing ( $\mu\text{CP}$ ).<sup>[15]</sup> Stamps with patterned relief structure were prepared by mixing poly(dimethyl siloxane) (PDMS) with a curing agent at room temperature and

**Fig. 5** H-SEM images of arrays of the ferritin molecules (A) before and (B–D) after heat treatment under nitrogen at 300°C, 500°C, and 700°C for 1 h, respectively. *Source:* From Ref.<sup>[14]</sup>.

subsequently cured at 100°C. Chrome and gold layers were sputtered. For inking, the stamps were dipped into a dilute ethanolic solution of hexadecanethiol. After curing the inked stamps, they were conformably contacted to the gold surface to create hydrophobic self-assembled monolayers (SAMs). The samples were dipped into hydrophilic SAMs solutions to deposit dithiothreitol SAMs for the area, where hexadecanethiol was not stamped. Selective deposition of iron oxide films was then carried out from an iron nitrate aqueous solution. By annealing under different conditions, patterned  $\alpha$ - or  $\gamma$ - $\text{Fe}_2\text{O}_3$  or  $\text{Fe}_3\text{O}_4$  nanoparticles were obtained with a line width as narrow as 1  $\mu\text{m}$ .<sup>[15]</sup>

## MAGNETIC PROPERTIES

### Concepts

Downsizing of magnetic particles is accompanied by the decrease in the saturation magnetization. The mechanisms of such magnetic degradation are manifold but are somehow associated with increases in the specific surface and lattice defects. Some data with this context are given with possible strategy of preventing size-dependent degradation.

Mössbauer spectroscopy is a versatile tool for iron-containing materials. The second half of this article deals with the use of Mössbauer spectra in the analyses of iron oxide nanoparticles.

## Saturation Magnetization and Coercive Force

Ferrite particles with their average particle size smaller than 20 nm were primarily applied to magnetic fluids, so that their magnetic properties, among others, saturation magnetization, have been studied in detail. Saturation magnetization of most of those particles decreases drastically when their particle size becomes below 20–30 nm. In the case of ultrafine magnetite, for instance, saturation magnetization amounts between 30 and 60 emu/g as compared with that of bulk material, 92 emu/g.<sup>[16]</sup> Variation of the saturation magnetization is illustrated in Fig. 6 for some representative ferrites.<sup>[16]</sup>

Crystalline magnetic anisotropy constant,  $K_1$ , also plays an important role on the relative saturation magnetization. As shown in Fig. 7, the relative saturation magnetization is smaller for materials with a larger value of  $K_1$ .

It is well known that saturation magnetization decreases with the decrease of the crystallinity. However, even when the particles are well crystallized as confirmed by high-resolution electron micrographs, decrease in the magnetization is unavoidable. One of the main reasons for the decrease is then the existence of the magnetically inactive surface layer. The relationship between the crystalline magnetic anisotropy constant and the thickness of the inactive layer is displayed in Fig. 8.

**Fig. 6** Dependence of the relative saturation magnetization,  $\sigma_s/\sigma_{\text{bulk}}$ , on average particle size  $D_{311}$ . Solid line: particles by coprecipitation; broken line: grown particles by heat treatment. *Source:* From Ref.<sup>[16]</sup>.

**Fig. 7** Relationship between  $\sigma_s/\sigma_{\text{bulk}}$  and  $K_1$  at constant particle size for several different ferrites. Points of a to f indicate materials corresponding to those of Fig. 6 and the symbols with parentheses indicate estimated values. Source: From Ref.<sup>[16]</sup>.

Crystalline magnetic anisotropy is closely related with the coercive force. Many attempts were therefore made to control large  $K_1$  by varying preparation methods without great success hitherto. It is to be noted, however, that coexistence of  $\alpha\text{-Fe}_2\text{O}_3$  in  $\gamma\text{-Fe}_2\text{O}_3$  brings about substantial increase in the coercivity.<sup>[17]</sup> This kind of materials is prepared by careful annealing of conventionally precipitated hydrous oxide.<sup>[17]</sup>

## Mössbauer Spectra

Characterization of detailed structure of nanoparticles is not particularly easy. In case of iron-containing compounds, however, Mössbauer spectroscopy serves as a versatile tool for characterization. A typical Mössbauer study was made on Mn-Zn ferrite nanoparticles embedded in silica matrix.<sup>[18]</sup> The spectrum comprises two components superimposing with each other, i.e., one sextet as a result of ferromagnetic particles and a doublet as a result of superparamagnetic behavior of nanosized ferrite at the center. Quadrupole splitting of the nanoparticles is larger than that of bulk ferrite presumably because of the loss of cubic symmetry in the finer particles.

A more detailed study on the Mössbauer spectra is given on the pressed sample of 3 nm  $\alpha\text{-FeOOH}$ .<sup>[19]</sup>

When nanoparticles are compressed together, significant Mössbauer absorption is observed even at room temperature, with a quadrupole doublet typical for superparamagnetic materials as shown in Fig. 9. This is not the case on the loose power. The difference is attributed to the suppression of the particle motion, which is significant for such nanoparticles because of the loss of recoilless fraction by the particle motion, overlapped with the lattice vibration. At temperatures

**Fig. 9** Mössbauer spectra of compressed 3 nm  $\alpha\text{-FeOOH}$  at 10 K and room temperature. Source: From Ref.<sup>[19]</sup>.

**Fig. 10** Plot of  $\langle x^2 \rangle$  as a function of temperature for the as-prepared sample. Theoretical line is also plotted with  $\omega = 2 \times 10^{11}$ . Source: From Ref.<sup>[19]</sup>.

as low as 10 K, we observe well-known hyperfine structure.

By detailed analysis of the spectra, the amount of the mean-square amplitude of the vibration in the direction of  $\gamma$ -ray emission,  $\langle x^2 \rangle$ , was calculated and plotted as a function of temperature, as shown in Fig. 10.

## FUNCTIONS AND APPLICATION

### Concepts

Functions and application of iron oxide nanoparticles, mostly with their assembly, are quite diverse in nature and large in quantity, if not of industrial significance for the time being. Some interesting case studies are given below.

### Catalysis

Catalytic activity depends largely on the specific surface so that downsizing of the particles is always

favorable for catalysis. Milling products are generally considered to have drawbacks for any characteristics attractive for modern industrial application just because of lower crystallinity. Milling zinc ferrites, for instance, were, nevertheless, revealed to be very effective for adsorption of gaseous species such as  $\text{H}_2\text{S}$ .<sup>[20]</sup> Mechanical activation leads to the substantial increase of its sulfur absorption capacity. Increased mobility of cations at sulfurization temperature, connected with their thermally stimulated return from the inversion into equilibrium sites, is the main reason for the increase in the absorption capacity.

### Magnetic Inks

A product of extended traditional technology of magnetic fluids is an intelligent ink, i.e., a colored water-based magnetic fluid. This is appropriate for an ink-jet-type printer<sup>[21]</sup> and is extended to magneto-fluidgraphy.<sup>[22]</sup> By combining Mg-Zn and Mn-Zn ferrites with appropriate dyes, the concept for intelligent ink could be furnished by red and yellow azo dyes

**Fig. 11** Proposed structure of the self-assembled films consisting of the BTHA dication, anionic polyelectrolytes, and  $\text{Fe}_3\text{O}_4$  particles. Abbreviations: ATS (3-aminopropyltrimethoxysilane); PSS (sodium polystyrenesulfonate); PAH (polyallylaminehydrochloride); and BTHA [4,4'-bis(trimethyl ammonium hexyloxy) azobenzene bromide]. Source: From Ref.<sup>[24]</sup>.

or mixed with copper phthalocyanine for blue magnetic inks.<sup>[23]</sup> Viscosity of these magnetic inks ranges between 1.5 and 2.0 mPa · S, being fluid enough for practical rapid printing.

## Electromagnetic Functions

When ferromagnetic iron oxide particles are well assembled in a thin film together with photoisomerizable molecules such as azobenzene-containing layers, the magnetic properties of the film can be controlled by photoillumination at room temperature.<sup>[24]</sup> Self-assembled films were prepared by dipping a substrate, e.g., silanized quartz, into an aqueous solution of cationic and anionic polyelectrolytes alternatively. Cationic colloidal magnetite was subsequently adsorbed on the precoated substrate to obtain the final organized layer. A corresponding surface chemical structure is schematically illustrated in Fig. 11.

Photoisomerization of the film was examined by UV-vis spectra. The initial *trans* state was illuminated with 360-nm UV light to transform to the *cis* state. The latter, in turn, reversibly transformed to the *trans* state by illuminating visible light (400–700 nm). The photoisomerization was accompanied by the reversible change in the magnetization of the film to exhibit photoswitching properties at room temperature.<sup>[24]</sup>

Similar photoswitching properties were observed in conjunction with the light-induced excited spin state trapping (LIESST).<sup>[25]</sup> Some ferric coordination compounds were found to be sensitive to LIESST so that their application toward molecular devices is expected.<sup>[26]</sup>

Fine particulate ferrites prepared by self-combustion method are quite appropriate for multilayer chip ferrite inductor (MLCI).<sup>[10,11]</sup> Because of the low temperature necessary for sintering (<950°C), fineness of the grain is maintained without disturbing thermal stability.

## CONCLUSION

Preparation, properties, and application of pure and complex iron oxides were presented with special emphasis on the particularity of downsizing as well as particles organization. Intrinsic properties of nanoparticles are symbolized by the increased significance of magnetically inert near-surface region and superparamagnetism. While unsupported, unorganized nanoparticles are not particularly attractive from application viewpoints; alignment and assemblage of nanoparticles look quite promising for various functional devices. Experimental characterization, particularly its topochemical aspect, is quite insufficient just because of the resolution limit of the existing analytical tools. Simulation studies with

emphasis on the near-surface region might compliment these experimental difficulties.

# Island Nucleation: Predictions

Maria C. Bartelt

Lawrence Livermore National Laboratory, Livermore, California, U.S.A.

## INTRODUCTION

Under a range of technologically interesting conditions, films of metals, certain oxides, and semiconductors grow or etch via two-dimensional island formation. Atomic-scale control of the resulting island distribution and final morphology of these films depends on a detailed understanding of these early stages of island formation. This, in turn, requires a precise treatment of the environment dependence of adatom or ad-vacancy capture by other adatoms or ad-vacancies and by growing islands. In particular, the evolution of the densities of islands of different sizes (i.e., of the island size distribution) reflects the form of the “capture numbers” and specifically their dependence on island size, which measures the propensity for islands of different sizes (in a variety of environments) to capture diffusing ad-species.<sup>[1–3]</sup> One current challenge is the formulation of both an analytic treatment of the observed form of the “capture numbers” and new simulation strategies for analysis of the asymptotic behavior of models of island formation, in the regime of large characteristic lengths, which is still expensive to simulate with conventional algorithms.

Traditional mean-field rate-equation treatments,<sup>[4]</sup> in which the typical environment of an island is assumed independent of its shape and size, fail to reproduce the form and scaling properties of the island size distributions observed in experimental and simulation studies.<sup>[5–10]</sup> This has been a half-century-old challenge. Recent simulation studies revealed not only the well-known spatial correlation of island positions associated with depletion of the population of nearby islands (as a result of competition by islands for diffusing ad-species),<sup>[11]</sup> which has been incorporated into mean-field approaches,<sup>[4]</sup> but also a more subtle correlation between the size and separation of islands, which is still missing and is hard to fold into traditional mean-field approaches. It is the latter correlation that controls the individual island growth rates and the island size dependence of the “capture numbers” and thus the selection of the shape of the island size distribution.

## OVERVIEW

Key to quantifying and elucidating the development of this island size-spatial correlation is a precise characterization of island nucleation,<sup>[8–10]</sup> especially when nucleation is irreversible. A basic observation is that when only a few islands exist, nucleation occurs quasi-deterministically, not surprisingly near the dominant maximum in the density of the diffusing ad-species. However, once a more complex landscape of islands develops, nucleation occurs more randomly, often near secondary maxima. Very importantly, these deviations from the dominant maxima allow for stronger correlations in the growth rates of neighboring islands.<sup>[10]</sup> They have not been characterized in detail in the literature.

Some of these basic features are best illustrated for a few-island system. A system of two-dimensional vacancy islands or pits, obtained by exposure of a Si(001) terrace to molecular oxygen,<sup>[7]</sup> is chosen below for this purpose. However, only results for larger simulation systems allow a statistically relevant characterization of the island nucleation process, i.e., the typical behavior and fluctuations. In particular, one is interested in assessing the generally expected tendency for islands to nucleate near the boundaries of a suitable tessellation of the surface (into so-called “capture areas or cells”) based on the island positions. This information is essential to guide the development of simpler, geometric-like, and computationally less-expensive models of island formation.<sup>[12]</sup>

The main goal of this work is then to provide exact predictions of island nucleation obtained from kinetic Monte Carlo (KMC) simulations of a realistic model of island formation during deposition or etching. The focus is entirely on the simplest case of irreversible two-dimensional island formation, via homogeneous nucleation, mediated by isotropic diffusion of ad-species. Work on the reversible case has just begun. Several quantities describing spatial features of the nucleation process are monitored in the simulations. The results show that they are generally characterized by broad probability distributions, implying a broad spread of environments for islands of each size. This feature underlies observed scaling properties.

**Fig. 1** Dark-field LEEM images, a few seconds apart, recorded during the etching of a 10- $\mu\text{m}$ -wide terrace at 1235 K, in an oxygen pressure in the  $10^{-7}$  Torr range. Darker gray regions have lower height. The islands are labeled in the order in which they nucleated. *Source:* Courtesy of J.B. Hannon and G.L. Kellogg, Sandia National Laboratories, New Mexico.

## OUTLINE

The remainder of this work is organized as follows. The next section describes the experimental and simulation study of the system of a few islands formed irreversibly during the etching of a large Si(001) terrace at high temperatures and oxygen pressures. This example illustrates perfectly the failure of purely deterministic models of island formation to even qualitatively predict basic aspects of island nucleation, such as the sequence of nucleation events, the resulting spatial arrangement of the islands, and, ultimately, their individual growth rates. For quantitative predictions for irreversible island formation, a general model and simulations are then developed, which also serve to illustrate the unique power of simulations to address these nucleation issues. The goal is to describe in detail the exact nature of the non-equilibrium spatial correlations that develop during the nucleation process and thereby predict, using suitable measures, the expected impact of a nucleation event on the evolution of a large system of islands.

### A FIRST VIEW OF ISLAND NUCLEATION: ETCH PITS ON Si(100)

As mentioned above, a small system of islands can provide a direct view into basic aspects of the island nucleation process and motivate and guide specific studies on larger systems. In fact, the etching study described here is one of the existing few that have provided a real time, in situ view of island nucleation. The actual nucleation positions of the etch pits, recorded with low-energy electron microscopy (LEEM), were compared with predictions from solving the diffusion equation for the ad-vacancy species density, with appropriate boundary conditions, and from kinetic Monte Carlo (KMC) simulations. The solution of the diffusion equation was used to study simplified, deterministic rules of island formation, which fail to describe the exact behavior observed in the KMC simulations.

### Basic Experimental Observations

At elevated temperatures ( $>1000$  K), exposure of a clean Si(001) surface to molecular oxygen leads to

the production of volatile SiO and a net removal of Si from the surface. No oxide layer develops. On large, step-free surfaces, this active etching process begins with the nucleation of two-dimensional vacancy islands or pits, as illustrated in the sequence of LEEM images in Fig. 1. The LEEM images were formed using the (1/2,0) beam associated with one of the  $(2 \times 1)$  reconstruction domains of the Si(001) surface, resulting in contrast across adjacent terraces. Islands are the darker gray regions in Fig. 1. Under continued oxygen exposure, these islands grow, each at a rate that directly reflects the local distribution of neighboring islands.<sup>[7]</sup> Islands with large “capture areas” (like island no. 3 in Fig. 1) grow much faster than those with many close neighbors, indicative of a diffusion-mediated island formation process. The observed island growth rates have been reproduced quantitatively<sup>[7,13]</sup> in simulations of a model that assumes irreversible incorporation of ad-vacancies at the edge of near-elliptical islands and at the terrace outer step. The model has no free parameters because the ad-vacancy diffusion coefficient and (weak) anisotropy have been estimated from experimental data<sup>[14]</sup> and from first-principles calculations,<sup>[15]</sup> and an estimate of the vacancy flux was obtained from a combination of etching experiments.<sup>[7]</sup>

### Purely Deterministic vs. Stochastic Rules for Nucleation

The issue of the island nucleation positions was not addressed in the work mentioned above. Fig. 2 shows clearly that a purely deterministic rule for nucleation, by which islands nucleate at the instantaneous global maximum of the ad-vacancy species density, produces a different “time” sequence of nucleation events and a different final island spatial configuration (reflecting the near sixfold symmetry of the terrace) than experiment.<sup>[16]</sup> The maxima were obtained by solving the steady-state diffusion equation,  $D\nabla^2 n + F = 0$ , with absorbing boundary conditions ( $n = 0$ ) at the edges of previously nucleated islands and at the outer terrace step. Here  $D$  is the diffusion coefficient of the ad-vacancy species,  $n$  is the ad-vacancy species density,

**Fig. 2** Comparison between (A) the actual island nucleation positions observed with LEEM and (B) the predictions of a purely deterministic nucleation rule based on the location of the instantaneous global maximum of the ad-vacancy species density.

and  $F$  is the net flux (chosen as estimated from experiment<sup>[7]</sup>). Even if the actual positions of previously nucleated islands are assumed, deviations in the location of the next nucleation event from the instantaneous global maximum, toward a secondary maximum, are typical (Fig. 3). Kinetic Monte Carlo simulations confirm that, indeed, nucleation is a stochastic process. In Fig. 4, island nucleation positions were marked for several millions of nucleation events obtained during irreversible island formation (consistent with the model that matched the island growth rates at a lower oxygen pressure or lower flux.<sup>[7,13]</sup>) The nucleation conditions and initial island configurations are the same as for Fig. 3 (except that the steady-state condition was not assumed a priori). These simulation results show a considerable spread in the regions of significant nucleation probability, well beyond the neighborhood of the global and secondary maxima.

### Pit Positions Relative to Diffusion Cell Boundaries

Finally, it is interesting to compare the actual island nucleation positions for the Si(001) system with the

location of the boundaries of a tessellation of the terrace based on the numerical solution of the steady-state diffusion equation for the ad-vacancy species density. The net flux of diffusing ad-vacancies is zero across the boundaries of the tessellation cells (“diffusion cells” or DCs). Inside each DC associated with an island, the lines of flux converge to that island. It is thus easy to show that the free area inside a DC is exactly proportional to the rate of diffusion-mediated ad-vacancy capture by the associated island.<sup>[5,6]</sup> For this small system of islands, the nucleation positions appear all near the DC boundaries (Fig. 5). However, for larger, statistically more relevant systems of islands, the results are more complex. In fact, the probability of island nucleation is non-zero and fairly high in wide regions around the DC boundaries, extending well inside the cells. This feature is revisited below.

## GENERAL BEHAVIOR OF MODELS OF IRREVERSIBLE ISLAND FORMATION

### Basic Model Prescription

During irreversible island formation on a single-crystal surface, represented by a regular array of adsorption sites, ad-species are created randomly at rate  $F$  per adsorption site, they hop between adjacent sites at total rate  $h$ , irreversibly nucleate new islands upon meeting, and irreversibly incorporate into existing islands upon aggregation. Compact, near-equilibrium island shapes are chosen whenever island-shape restructuring upon capture of ad-species by islands is efficient on the timescale of aggregation. To describe behavior at very low coverages, when islands cover only a small fraction of the surface, one can consider simpler “point-island” models,<sup>[17]</sup> in which islands occupy a single site, but carry a label indicating their size. Point-island models are especially useful to separate correlations that develop during the island formation process from

**Fig. 3** Contours of the ad-vacancy species density from the numerical solution of the steady-state diffusion equation with absorbing boundary conditions at island and step edges, for each partial set of islands observed in the experimental sequence of Fig. 1. The position of the instantaneous global maximum is marked with a dot. Only the 1st, 2nd, and 3rd islands nucleate near the global maximum.

**Fig. 4** Simulation results for the spatial distribution of nucleation events during the etching of the Si(001) terrace of Fig. 1. Each dot marks the location of a nucleation event for the partial island configuration shown in each panel. The color of the dots is chosen according to the probability for nucleation, which increases from red to blue to green to yellow.

other subtle effects because of the island finite extent. Fig. 6 compares island configurations for point- and near-square islands. Measured two-point correlation functions for the positions of the island centers show similar results for the two models at submonolayer coverages. The basic shape of the island size distribution is also similar.

### Basic Algorithm for Simulation

To characterize the general behavior of the model, an  $L \times L$  square lattice (typically with  $L > 1000$ ) is used, with periodic boundary conditions. Ratios  $h/F$  typical for many systems are larger than  $10^7$ , requiring for efficiency that one keep a compact list of the positions of all hopping ad-species. With probabilities

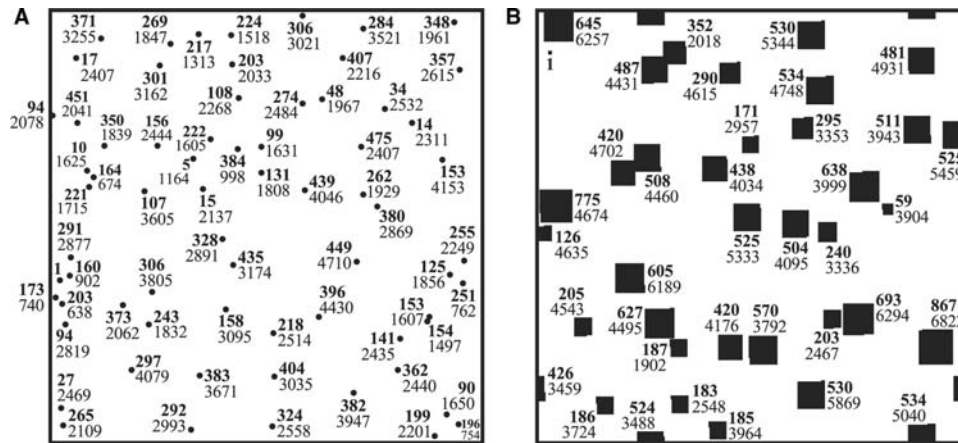

proportional to total rates, one randomly chooses between creation (total rate  $L^2F$ ) and hopping (total rate  $h$  times the number of hopping ad-species). For the former, one randomly chooses a site. For the latter, one randomly chooses an entry from the list, which is updated after each hopping, creation, or aggregation event.

### Analyses

For understanding various spatial features of island nucleation and the detailed shape of the island size distribution, a central concept already introduced above is that of “capture zones” (CZs) associated with each island. Because construction of “exact” CZs based on the solution of the diffusion equation for the ad-species density is non-trivial and computationally

**Fig. 5** Comparison between (A)–(C) the actual nucleation position of the 3rd, 4th, and 5th island and (D)–(F) the location of the DC boundaries for the configuration of islands that exist prior to nucleation. As in Fig. 3, the dot in each panel marks the location of the global maximum of the ad-vacancy species density.

**Fig. 6** Simulation snapshots ( $400 \times 400$  sites) of typical configurations of (A) point-islands ( $s_{av} = 255$ ,  $A_{av} = 2550$ ) and (B) near-square islands ( $s_{av} = 459$ ,  $A_{av} = 4590$ ), for  $h/F = 10^{10}$ ,  $\theta = 0.1$  ML. The labels are the island size (in bold, in units of atoms) and the area of the EC of the island (in units of sites), which includes the island “footprint.”

expensive, it is convenient (and often a reasonable approximation) to construct CZs based on geometric tessellations of the surface that reflect the island spatial arrangement. The simplest possibility is to use Voronoi cells (VCs), which are based on the distance between the island centers. Sites within a VC are closer to the center of the associated island than to that of any other island. A more realistic alternative for islands of finite extent is to use “edge cells” (ECs), which are based on the distance to the island edges.<sup>[6]</sup> The tessellations of VCs and ECs coincide for point-islands.

In the simulations, one can readily monitor several quantities of interest. In particular, from  $N_{s,A}$ , the density of islands of size  $s$  and CZ area  $A$  ( $s$  and  $A$  measured in lattice sites), one gets 1) the density,  $N_s = \sum_A N_{s,A}$ , of islands of size  $s$  (averaged over CZ areas), 2) the density,  $N_A = \sum_s N_{s,A}$ , of islands of CZ area  $A$ , 3) the average island density  $N_{av} = \sum_{s>1} N_s$ , 4) the average CZ area for islands of size  $s$ ,  $A_s = \sum_A A N_{s,A} / N_s$ , 5) the average CZ area for all islands (note that the partition fills the surface),  $A_{av} = \sum_{s>1} A_s N_s / N_{av} = 1 / N_{av}$ , 6) the coverage (or fraction of the surface covered by islands and diffusing ad-species),  $\theta = Ft = \sum_{s>1} s N_s$ , where  $t$  is the duration time of deposition or etching, and 7) the average island size,  $s_{av} = \sum_{s>1} s N_s / N_{av} = (\theta - N_1) / N_{av}$ . In the scaling regime of large  $s_{av} \approx \theta / N_{av}$  and  $N_1 \ll N_{av}$ , one introduces continuous scaled variables  $x = s / s_{av}$  and  $\alpha = A / A_{av}$  and defines scaling functions  $H(x, \alpha)$ ,  $f(x)$ , and  $g(\alpha)$  such that

$$\begin{aligned} N_{s,A} &\approx N_{av} (s_{av} A_{av})^{-1} H(x, \alpha), \\ N_s &\approx N_{av} (s_{av})^{-1} f(x), \text{ and} \\ N_A &\approx N_{av} (A_{av})^{-1} g(\alpha) \end{aligned} \quad (1)$$

with

$$\begin{aligned} f(x) &= \int_{0 \leq x \leq \infty} d\alpha H(x, \alpha), \\ g(\alpha) &= \int_{0 \leq x \leq \infty} dx H(x, \alpha), \text{ and } \int_{0 \leq x \leq \infty} dx \\ &\quad \times \int_{0 \leq \alpha \leq \infty} d\alpha H(x, \alpha) x^i \alpha^j = 1 \end{aligned} \quad (2)$$

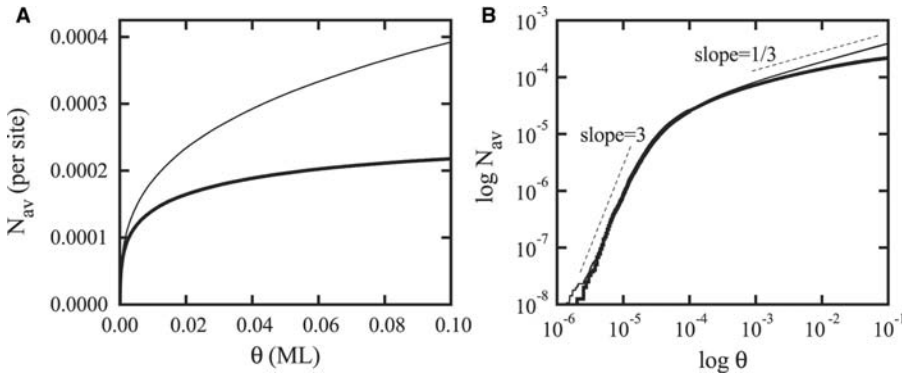

for  $i$  or  $j = 0$  or  $1$

As indicated above, the focus here is on quantities that characterize basic aspects of the island nucleation process, motivated by the realization that they influence the selection of the shape of the scaling functions  $H$ ,  $f$ , and  $g$ .<sup>[2,8–10]</sup> Such quantities include the distribution of CZ areas for just-nucleated islands, the distribution of the number of existing islands whose CZ’s are reduced by each nucleation event, the fraction of area that each contributes to the CZ of a just-nucleated island, and some measure of the tendency for nucleation to occur near the boundaries of the CZs. Whenever significant, behavior for point-islands is compared with that of near-square islands.

## CHARACTERIZATION OF THE ISLAND NUCLEATION PROCESS

### The Nucleation Rate

In the initial stages of irreversible island formation, on an initially empty substrate, one expects a transient regime where the ad-species concentration increases linearly with time, in proportion to the flux,  $F$ , followed by a steady-state regime where gain of

**Fig. 7** Simulation results for the evolution of the average island density,  $N_{av}$ , for point-islands (thin solid line) and near-square islands (thick solid line), for  $h/F = 10^{10}$ ,  $\theta \leq 0.1$  ML. Statistics were obtained for nearly 200,000 point-islands and 100,000 near-square islands.

ad-species is roughly balanced by loss as a result of aggregation with existing islands. For small  $\theta$ , one can write simple rate equations for the diffusing ad-species density,  $N_1$ , and for  $N_{av}$ , that can capture this behavior. Keeping only the dominant terms (for large  $h/F$ ), one has for isotropic diffusion

where  $\sigma_1$  and  $\sigma_{av} = \sum_{s>1} \sigma_s N_s / (\sum_{s>1} N_s)$  measure the propensity for diffusing ad-species to be captured by other diffusing ad-species or by islands, respectively. Logarithmic corrections are discussed in Ref.<sup>[17]</sup>. It follows that

$$\begin{aligned} dN_1/dt &\sim F - \sigma_{av} h N_1 N_{av} \text{ and } dN_{av}/dt \\ &\sim \sigma_1 h (N_1)^2 \end{aligned} \quad (3)$$

$$N_1 \sim \theta \text{ and } N_{av} \sim (h/F) \int d\theta \sigma_1 \theta^2 \quad (4)$$

**Fig. 8** Simulation results for the dependence of  $\sigma_1$  (solid circles) and  $\sigma_{av}$  (open circles) on  $\theta$  for (A) point-islands and (C) near-square islands, for  $h/F = 10^8$ ,  $0.001$  ML  $\leq \theta \leq 0.1$  ML. In (A), the lines are the fits  $\sigma_1 = 0.606 + 0.0272\ln(\theta)$  and  $\sigma_{av} = 0.695 + 0.0358\ln(\theta)$ . The fits in (C) are not as simple. Simulation data (symbols) for the fraction  $\sigma_1/\sigma_{av}^2$  are shown in (B) for point-islands and in (D) for near-square islands. Nearly perfect fits (lines) are obtained with  $\sigma_1/\sigma_{av}^2 = 1.11 - 0.136\ln(\theta)$  in (B) and  $\sigma_1/\sigma_{av}^2 = -0.417 - 0.259\ln(\theta)$  in (D). In (D), but not in (B), the logarithmic term dominates in the range of  $\theta$  considered.

in the transient regime, where  $\theta \ll \theta^* \sim (h/F)^{-1/2}$ ,<sup>[17]</sup> and

$$N_1 \sim F/(\sigma_{av}hN_{av}) \text{ and} \\ N_{av} \sim (h/F)^{-1/3} \left( \int d\theta \sigma_1/\sigma_{av}^2 \right)^{1/3} \quad (5)$$

in the steady-state regime ( $dN_1/dt \sim 0$ ), where  $\theta \gg \theta^*$ . Simulation data for point-islands shown in Fig. 7 are consistent with  $\sigma_1$  and  $\sigma_1/\sigma_{av}^2$  weakly dependent on  $\theta$ . In fact, simulation data shown in Fig. 8 suggest the relation  $\sigma_1/\sigma_{av}^2 \approx 0.606/0.695^2 \approx 1.25$ , for not too small  $\theta \geq 0.01$ . For sufficiently large  $h/F$  values, one also finds from the simulation data that

$$N_{av} \sim (h/F)\theta^3 \quad (6)$$

in the transient regime and

$$N_1 \sim (h/F)^{-2/3}\theta^{-1/3} \text{ and } N_{av} \sim (h/F)^{-1/3}\theta^{1/3} \quad (7)$$

in the steady-state regime, again consistent with  $\sigma_1$  and  $\sigma_1/\sigma_{av}^2$  weakly dependent on  $\theta$ . At fixed  $\theta$ , Eqs. (6) and (7) give also the  $h/F$  dependence of the densities for finite-extent, compact islands (near-square islands are used here). However, the steady-state  $\theta$  dependence (at fixed  $h/F$ ) is significantly modified from point-island

scaling, even for small  $\theta \ll 1$ . For example, for  $h/F = 10^{10}$ , the deviation between point-island and near-square island behavior, i.e., the difference in the actual values of  $N_{av}$  in Fig. 7(A) and in the scaling with  $\theta$  in Fig. 7B, is significant already for coverages on the order of  $10^{-3}$  ML. These differences reflect stronger  $\theta$  dependence (in the form of logarithmic corrections) of  $\sigma_1/\sigma_{av}^2$  for near-square than for point-islands. This is because of more efficient capture of random walkers by finite-extent islands than by point-islands. More details are shown in Fig. 8. For near-square islands, one finds  $\sigma_1/\sigma_{av}^2 \propto -\ln(\theta)$ , in the range of  $\theta$  considered here, so, from Eq. (5), one gets  $N_{av} \propto \theta^{1/3} [-\ln(\theta)]^{1/3}$ , the  $\ln(\theta)$  factor producing the observed saturation of  $N_{av}$  with  $\theta$  shown in Fig. 7. If one assumes the form  $N_{av} = \gamma(h/F)^{-\chi}$ , at each fixed  $\theta$ , then one finds for the effective exponent  $\chi$  and prefactor  $\gamma$  the values  $\chi = 0.24, 0.29, 0.30, 0.31$ , and  $0.31$  and  $\gamma = 0.022, 0.12, 0.19, 0.38$ , and  $0.49$  (consistent with the relation  $\gamma \approx 1.08\theta^{1/3}$ ; Fig. 8) for point-islands and  $\chi = 0.26, 0.31, 0.32, 0.33$ , and  $0.33$  and  $\gamma = 0.028, 0.15, 0.23, 0.42$ , and  $0.49$  for near-square islands, at fixed  $\theta = 0.001, 0.005, 0.01, 0.05$ , and  $0.1$  ML, respectively, for  $10^8 \leq h/F \leq 10^{10}$ .

**Fig. 9** Scaled area distributions ( $\alpha = A/A_{av}$ ) for (A)–(B) VCs of point-islands ( $A_{av} = 612.7$  sites) and (C)–(D) ECs of near-square islands ( $A_{av} = 979.4$  sites) of size  $s = 2$ , obtained with  $h/F = 10^8$ ,  $\theta = 0.1$  ML. In (A) and (C), data are for just-nucleated dimers only, and in (B) and (D), data are for all dimers. The average dimer areas are  $A_{\text{just-nucleated}} \approx 0.93A_{av}$  ( $0.57A_{av}$ ) and  $A_2 \approx 0.88A_{av}$  ( $0.53A_{av}$ ) for point-islands (near-square islands). The distributions are slightly skewed relative to a Gaussian (line fits).

**Table 1** Statistical properties of the area distributions for VCs of point-islands (PI) and ECs of near-square islands (NSI) of size  $s = 2$  (just-nucleated dimers and all dimers) at  $\theta = 0.1$  ml

System	$h/F$	$A_{\text{just-nucleated}}$	$A_2$	$\nu_{\text{just-nucleated}}$	$\nu_2$	$\kappa_{\text{just-nucleated}}$	$\kappa_2$
PI	$10^7$	284.7	268.3	88.6	87.7	0.40	0.45
	$10^8$	572.7	537.5	182.8	179.2	0.42	0.45
	$10^9$	1165.0	1098.1	381.3	374.2	0.42	0.45
NSI	$10^7$	268.7	251.8	93.9	94.8	0.39	0.40
	$10^8$	560.6	515.9	198.7	199.5	0.37	0.43
	$10^9$	1125.0	1076.1	455.5	427.8	0.40	0.42

The  $A$ 's denote the average area, the  $\nu$ 's denote the standard deviation, and the  $\kappa$ 's denote the skewness. Average areas for all islands are  $A_{\text{av}} = 307.0, 612.7,$  and  $1243.9$  for point-islands, and  $A_{\text{av}} = 461.9, 979.4,$  and  $2110.0$  for  $h/F = 10^7, 10^8,$  and  $10^9,$  respectively. Areas and standard deviations are in units of surface sites. The skewness is dimensionless.

Finally, for both point-islands and near-square islands, note that the island density  $N_{\text{av}} \sim (h/F)^{-1/2}$  at the onset of the steady-state regime,  $\theta \sim \theta^*$ , is well below the steady-state value of  $N_{\text{av}} \sim (h/F)^{-1/3}$ . Thus most nucleation occurs in the steady-state regime, in which the next sections focus.

### Distribution of Capture Zone Areas of Just-Nucleated Islands

Once a nucleation event occurs, the distribution of CZs (and the growth rates) of the islands neighboring the nucleation site is modified. The typical area assigned to the new island is an essential quantity in rate-equation formulations of the evolution of the CZ area distribution during island formation.<sup>[2,8,9,18]</sup> Typical distributions of CZ areas for a new island, for tessellations of ECs, are shown in Fig. 9, for a selected set of simulation parameters. It is interesting to compare these distributions with those of the CZ areas for all dimers. First, note that the average CZ area of a dimer must be strictly smaller than the average CZ area of a just-nucleated dimer (and both of these smaller than the average CZ area for all islands) because areas of just-nucleated dimers can only decrease with continued island nucleation. However, the basic statistical properties of the two distributions, including the area fluctuations, are similar

(Fig. 9 and Table 1). Second, there is a noticeable difference for point-islands and near-square islands in the average CZ areas of dimers or just-nucleated islands relative to the total average CZ area (for all islands). For near-square islands, the ratio is smaller than 0.6 (and only slightly higher, if taking the ratio to the average free area, defined as  $A_{\text{av}} - s_{\text{av}}$ , instead) compared with 0.9 for point-islands. Finally, for contrast, Fig. 10 shows the CZ area distribution for all islands. Note that the (normalized) envelope of this distribution is the function  $g(\alpha)$ .

### The Impact of Nucleation on the Capture Zones of Existing Islands

Some of the natural measures of the impact of nucleation on a configuration of islands, and in particular on its CZ area distribution, are 1) the probability that the CZ of a given island will be overlapped (and thus reduced) by the CZ of the just-nucleated island, 2) the typical number of such overlapped islands, per nucleation event, sorted by island size or CZ area, and 3) the typical fraction of the area that each overlapped island contributes to the CZ area of the just-nucleated island (see the schematic in Fig. 11). Simulation results for each of these measures are presented below.

**Fig. 10** Scaled area distributions ( $\alpha = A/A_{\text{av}}$ ) for (A) VCs of point-islands and (B) ECs of near-square islands of all sizes ( $h/F = 10^8,$   $\theta = 0.1$  ML). The lines are Gaussian fits. The standard deviation and skewness of the data are  $\nu \approx 0.33A_{\text{av}}, \kappa \approx 0.46$  for point-islands, and  $\nu \approx 0.38A_{\text{av}}, \kappa \approx 0.46$  for near-square islands. The skewness for a random Voronoi tessellation in two dimensions is significantly higher ( $\approx 0.66$ ). Source: From Ref.<sup>[19]</sup>.

**Fig. 11** Schematic showing the rearrangement of VC boundaries for a point-island distribution ( $h/F = 10^{10}$ ,  $\theta = 0.001$  ML) following a  $M_0 = 4$  nucleation event. The new island is marked with a  $\times$ , and existing islands are marked with dots. The shifted boundaries (dashed lines) enclose the CZ of the new island. Little or no rearrangement occurs for cells beyond the nearest neighbors of the new island. The four area portions contributed to the cell of the new island are highlighted with a pattern.

These three measures are not independent. If  $P_{s,A}$  denotes the probability that a nucleation event reduces the CZ of area  $A$  belonging to an island of size  $s$  and  $\langle M_0 \rangle$  denotes the average number of existing CZs overlapped by the CZ of a just-nucleated island, then one has the normalization condition

$$\sum_s \sum_A P_{s,A} = \langle M_0 \rangle \tag{8}$$

In addition, if  $A_{\text{subset}}(s,A)$  denotes the average area of the portion of the CZ of the just-nucleated island that overlaps the existing CZ of area  $A$  belonging to an

island of size  $s$  and  $\langle A_{\text{subset}} \rangle$  denotes the average area of such individual portions, then one also has the constraint

$$\begin{aligned} \sum_s \sum_A A_{\text{subset}}(s,A) P_{s,A} &= \langle A_{\text{subset}} \rangle \langle M_0 \rangle \\ &= A_{\text{just-nucleated}} \end{aligned} \tag{9}$$

where  $A_{\text{just-nucleated}}$  is the average area of a just-nucleated island (Fig. 9 and Table 1).

The probability that a nucleation event reduces the capture zone of an existing island

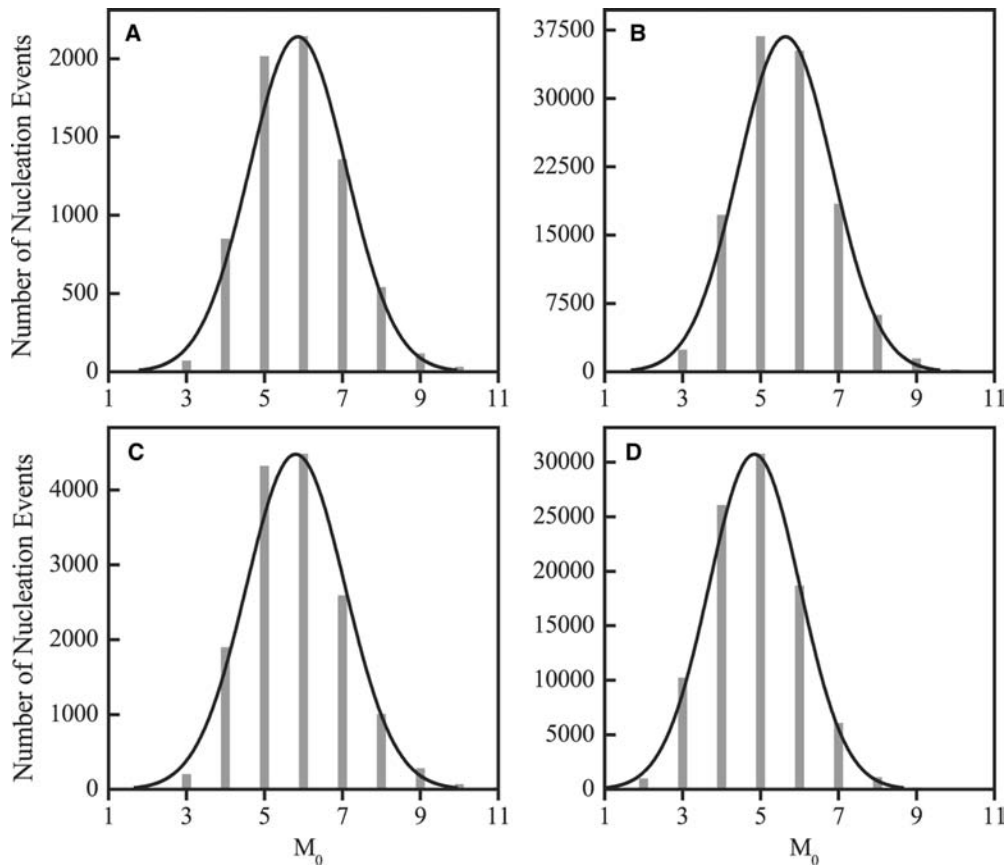

Although the probability  $P_{s,A}$  that a nucleation event impacts (i.e., reduces) a CZ of area  $A$  belonging to an island of size  $s$  includes contributions from nucleation events occurring inside that area- $A$  cell and inside neighboring cells, generally of different area, one anticipates that  $P_{s,A}$  scales directly with the fraction of islands of size  $s$  and CZ area  $A$ ,  $N_{s,A}/N_{\text{av}}$ . One can then write

$$P_{s,A} \approx (N_{s,A}/N_{\text{av}})q(s,A) \tag{10}$$

where the scaling factor  $q(s,A)$  reflects the actual propensity for overlap. The simulation data shown in Fig. 12 for the reduced probabilities  $P_s = \sum_A P_{s,A}$  that a nucleation event impacts the CZ of some island of size  $s$  and  $P_A = \sum_s P_{s,A}$  that a nucleation event reduces the CZ of some island of CZ area  $A$  indeed have a shape similar to  $N_s$  and  $N_A$ , respectively. If the above factorization holds, this behavior of the reduced probabilities implies that the factor  $q(s,A)$  is a weak function of both  $s$  and  $A$ , in the range where  $N_{s,A}$  is significant. In fact,  $q(s,A)$  is probably a stronger function of  $A$  than of  $s$  because the likelihood of overlap should depend primarily on the area  $A$ .<sup>[9]</sup>

**Fig. 12** Simulation results for (A)  $P_s$  and (B)  $P_A$ . Data are for point-islands,  $h/F = 10^7$ ,  $\theta = 0.1$  ML ( $A_{\text{av}} \approx 307$ ,  $s_{\text{av}} \approx 30.7$ ). The thinner lines are the average density of islands of size  $s$ , in (A), and the average density of islands of CZ area  $A$ , in (B). The data were normalized so that the area under all the curves is unity.

**Fig. 13** The distribution of  $M_0$  values for (A)–(B) point-islands and (C)–(D) near-square islands, for  $h/F = 10^8$ . In (A) and (C),  $\theta = 10^{-3}$  ML; in (B) and (D),  $\theta = 0.1$  ML. The lines are Gaussian fits. The average,  $\langle M_0 \rangle$ , and the standard deviation,  $\nu_{M_0}$ , are (A)  $\langle M_0 \rangle = 5.9$ ,  $\nu_{M_0} = 1.2$ , (B)  $\langle M_0 \rangle = 5.6$ ,  $\nu_{M_0} = 1.2$ , (C)  $\langle M_0 \rangle = 5.8$ ,  $\nu_{M_0} = 1.3$ , (D)  $\langle M_0 \rangle = 4.8$ ,  $\nu_{M_0} = 1.2$ . Statistics were obtained for 10,000–100,000 nucleation events.

**Fig. 14** Simulation data for  $A_{\text{subset}}$ ; in (A), scaled by the total area,  $A$ , of the overlapped CZs, in (B). Data are for 100,000 point-island nucleation events, with  $h/F = 10^7$ ,  $\theta = 0.1$  ML ( $A_{\text{av}} \approx 307$ ,  $s_{\text{av}} \approx 30.7$ ):  $\langle A_{\text{subset}} \rangle \approx 52$ ,  $\nu_{\text{subset}} \approx 51$ ,  $\kappa_{\text{subset}} \approx 1.5$ ,  $\langle A_{\text{subset}}/A \rangle \approx 0.14$ ,  $\nu_{\text{subset}/A} \approx 0.13$ ,  $\kappa_{\text{subset}/A} \approx 1.1$ . The lines are fits with an exponential distribution. The insets show  $A_{\text{subset}}(s)$ , averaged over  $A$ , in (A), and  $A_{\text{subset}}(A)$ , averaged over  $s$ , in (B). Here, statistics were obtained from nearly 500,000 nucleation events. The lines in the insets are guides to the eye only.

**Fig. 15** One thousand nucleation events (small dots) for a fixed configuration of point-islands (large dots) obtained at (A) 0.001 ML ( $s_{av} = 12.0$ ) and (B) 0.01 ML ( $s_{av} = 53.8$ ), for  $h/F = 10^{10}$ . The tessellation of VCs is also shown. The average VC area is (A) 12,100 and (B) 5375 lattice sites. Both panels are a  $380 \times 380$  site zoom of a larger simulation lattice.

### The distribution of $M_0$ values

Fig. 13 shows distributions of  $M_0$  values for two distinct coverages, one near the onset of the steady state, where point-islands and near-square islands behave similarly, and the other within the steady state. In either case, note that no nucleation events with  $M_0 = 1$  were recorded in the simulations; that is, the CZ of a just-nucleated island never overlapped just one existing CZ. Thus despite the dramatic simplification of theory that this scenario brings,<sup>[2,8]</sup> such an assumption is not well justified. Other features are interesting to note. With increasing coverage, there is a large shift in the distribution for near-square islands toward smaller  $M_0$ . For example, far fewer nucleation events with  $M_0 \geq 7$  and many more events with  $M_0 = 3$  occur at 0.1 ML than at  $10^{-3}$  ML. Such shift would be consistent with an increasing preference to nucleate closer to triple points (assuming the average number of neighboring cells of a CZ, which is about 6,<sup>[13]</sup> and other topological properties of the tessellation do not change significantly with increasing coverage).

### The portions, $A_{\text{subset}}$ , of existing capture zone areas overlapped by the capture zone of a New Island

The distribution of  $A_{\text{subset}}$  values, distinguished by size and area ( $A$ ) of the overlapped CZs, is well described by an exponential distribution, as shown in Fig. 14. (Note that for an exponential distribution, the mean and variance are equal, and the skewness is equal to 2.) It exhibits a significant population at small area portions and exponentially small populations for  $A_{\text{subset}}$  above  $A_{av}$ . In fact,  $A_{\text{subset}}$  is, on average, only  $0.14A$  and only  $0.17A_{av}$ . However, it does follow, as anticipated, that  $A_{\text{subset}}(s,A)$  is mainly determined by  $A$  (that is, it is a weaker function of  $s$ ) (see the insets in Fig. 14 and Ref.<sup>[9]</sup> for more details). Note that the relation  $A_{\text{just-nucleated}} = \langle A_{\text{subset}} \rangle \langle M_0 \rangle$  holds, e.g., for  $h/F = 10^7$ ,  $\theta = 0.1$  ML, one finds  $A_{\text{just-nucleated}} \approx 285$  (Table 1),  $\langle A_{\text{subset}} \rangle \approx 52$  (Fig. 14), and  $\langle M_0 \rangle \approx 5.5$  (Ref.<sup>[9]</sup>).

### The Island Nucleation Positions

A natural expectation is that most nucleation events that occur in the steady-state regime must occur near the boundaries of CZs where the diffusing ad-species density (and thus the nucleation rate) is relatively high. (Some caution is justified when using geometric tessellations, as these do not exactly reflect the spatial profile of the ad-species density.) Small sets of nucleation events do show such bias.<sup>[20]</sup> However, for statistically more relevant sets of nucleation events, this feature is less obvious (Figs. 4 and 15). Fig. 15 shows not only some clustering of nucleation events near boundaries and triple points, but also many nucleation events occurring inside the larger cells. This, no doubt, reflects the feature that the ad-species density does not vary sharply across the CZ boundaries, as is often assumed.

### CONCLUSION

The selection of simulation results discussed above underscores two important features of the behavior of canonical lattice-gas models of thin film epitaxy. First, the exact behavior of even simple quantities, including those describing spatial aspects of island nucleation, is highly non-intuitive, making phenomenological approximations of their behavior often unreliable. Second, most quantities are better described by broad probability distributions, reflecting strong fluctuations about the average environment of an island, and the stochastic nature of the island nucleation process. Moments of these distributions are key input to refined rate-equation formulations.<sup>[8,9]</sup>

## INTRODUCTION

Nanoisland patterned surfaces, in which functionalized nanodomains are surrounded by a matrix of secondary functionality, are scientifically and technologically important for their wide variety of applications in biomimetic materials, templated nanocrystallization, induced reactions (as surface catalysts), etc. Islands terminated with particular groups can serve as direct sites for molecular recognition and can therefore be used in separations (e.g., as chromatographic supports). Designing the matrix to be nonadsorbing reduces the fouling of the surface and enhances the island activity for molecular arraying. For example, polyethylene glycol (PEG) terminations are particularly important for their resistance to nonspecific protein adsorption and thus are valuable in bioassaying, in which the receptors are often large molecules (ranging from a few nanometers in cross section for DNA to several nanometers for proteins). Corralling of these receptors into domains is not always effective because steric interaction limits the number of targets that can bind to the receptors. In this case, it is more advantageous to individually isolate the receptors onto nanoscale island sites, where only one receptor is anchored by the terminal group in the island. In addition, by anchoring the terminal group in recessed islands (pockets), the conformation of the binding site can be arranged for optimum accessibility of the target. For example, thiol functionalization of the island self-assembled monolayer (SAM) can be used to link a protein through disulfide linkages to cysteine residues. Another important potential application of nanoislands is for nanocrystallization. Due to their small size and unique electrical, photonic, and transport properties, nanoparticles have been the focus of much research intended to

take advantage of their unique properties. The nanoparticulate form is a preferred route of delivery because of the ready passage of the particles through the circulatory system, and unimpeded transport across cell membranes. The ability to tailor the band gap structure of a semiconductor nanoparticle by controlling the particle size<sup>[1]</sup> leads to useful technological applications.<sup>[2]</sup> Recessed nanoislands can serve as vestibules for the crystallization of nanocrystals or the sequestering of nanosized particles such as liposomes. It is well recognized that chemically functionalized surfaces at the interface of a crystallizing solution can heterogeneously nucleate crystallites, sometimes with polymorph selectivity. Charged functionalizations are effective nucleators of ionic crystals as they attract oppositely charged counterions in the solution to the surface, which leads to the assembly of the incipient nucleus. Island patterned surfaces consisting of recessed nanodomains that have floors that are functionalized with active templates and that are surrounded by a matrix inert to crystallization can nucleate individual, nonagglomerating nanoparticles of controlled size. Particles covered with island cavities on their surfaces sequestering grown nanoparticles can subsequently be dispersed in an appropriate matrix (e.g., glass or polymers) to achieve a substantial collective response, avoiding the usual problems associated with nanoparticle agglomeration.

In order to fabricate nanoisland surfaces, some approaches with SAMs have been developed to chemically pattern surfaces in the nanoscale. For example, the tip of a scanning probe microscope [atomic force microscope (AFM) or scanning tunneling microscope (STM)] has been used to pattern the surface,<sup>[3,4]</sup> with the tip being used to displace molecules of an already deposited SAM either physically (AFM, nanoshaving) or electrically (STM, electrochemical etching) to create

a pattern. Alternatively, in dipped pen nanolithography, the tip is used to transfer a self-assembled surfactant onto the surface, creating the pattern. While these techniques can be used to create intricate patterns, as well as the island domains of interest here, they do suffer from certain drawbacks compared to the backfilling and mixed adsorption techniques we have developed here. First, the backfilling and mixed adsorption methods are easier to employ than the scanning probe methods, and while intricate patterns cannot be created, island patterns are all that are required in many applications. Second, the scanning probe methods allow only patterning over square micrometer-sized planar areas. While this may be acceptable for some applications (e.g., miniaturized sensors), other technologies that require a high surface area per volume may require patterning onto the curved surface of a particulate (e.g., particulate patterned with island receptors for chromatographic support, and beads patterned with recessed island templates to produce nanocrystals on a large scale). Such patterning cannot be undertaken with scanning probe lithography, but can easily be undertaken by the backfilling and mixed adsorption methods to be developed here. In this paper, we review the literature on using SAMs for the preparation of island surfaces and then explore newly developed approaches.

## BACKGROUND

The most widely used SAMs are generally classified into thiol and silane SAMs.<sup>[4–8]</sup> In the case of alkylthiols  $[X-(CH_2)_n-SH]$  adsorbed on gold (1 1 1), the  $-SH$  head group covalently bonds to the hollow sites of the hexagonally arrayed Au atoms of the (1 1 1) surface. For methyl terminated alkylthiol SAMs  $[CH_3-(CH_2)_{n-1}-SH]$  at room temperature, when  $n$  is approximately six or more, the van der Waals cohesion between the chains is large enough to drive the amphiphiles into a dense crystalline array at full coverage, whereas for smaller hydrophobic chain lengths ( $n < 6$ ), the SAM at complete coverage has a mottled appearance.<sup>[9,10]</sup> The adsorption of alkyl trifunctional silanes  $[X-(CH_2)_n-SiY_3]$ ;  $Y = Cl, OMe, \text{ or } OEt]$  to hydroxylated surfaces does not initially involve covalent linking to the surface<sup>[11–13]</sup> but involves a three step adsorption process,<sup>[14,15]</sup> in which the chloro or trifunctional silane groups are first hydrolyzed to form silanols  $[X-(CH_2)_n-Si(OH)_3]$ ; the alkylsilanols then hydrogen bond to the physisorbed water layer on the surface, and gradually siloxane crosslinking bridges form between adjacent amphiphiles and a few surface hydroxyl groups. At full coverage at room temperature, SAMs of the methyl terminated long chain octadecyltrichlorosilane [OTS:  $CH_3(CH_2)_{17}SiCl_3$ ], the

most well-studied alkylchlorosilane, form a well-ordered SAM with the hydrophobic chains trans extended canted approximately  $10^\circ$  from the normal and an area per molecule of approximately  $21 \text{ \AA}^2$ , equivalent to the alkylthiols. As the chain length decreases, gauche defects appear in the chain because of the reduced van der Waals cohesion; the chains begin to become disordered, and their tilt from the normal and the area per molecule increases. For alkylchlorosilanes with only a few methylene groups the monolayers are completely disordered.<sup>[16–18]</sup>

With regard to using the alkylthiol and alkylsilane amphiphiles to form nanoisland surfaces by backfilling, both exhibit the prerequisite clustering into nanoislands for adsorption times less than those required for full coverage. Methyl terminated alkylthiols of  $n > 6$  adsorb at room temperature on a clean gold surface at first randomly as a lattice gas, and then form the stripped lying down phase in which the head groups pair and the chains lie along the surface. Upon further adsorption, the stripped phase undergoes a series of transitional states from which emerge nanoisland domains of upright, densely packed,  $c(4 \times 2)$  ordered phase, which grow and form the complete monolayer.<sup>[19–22]</sup> The fact that the condensed islands arise from the stripped and intermediate phases makes it difficult to fill around them using a second functional phase.<sup>[23,24]</sup>

Rondelez and coworkers<sup>[25,26]</sup> studied the adsorption of the alkyltrichlorosilanes on hydrated silicon oxide surfaces. For sufficiently hydrated surfaces, they measured OTS as a function of temperature (in the range of  $5\text{--}60^\circ\text{C}$ ) and found that below a critical temperature  $T_c (= 28 \pm 4^\circ\text{C})$  the prepared monolayers exist in the condensed well-ordered state. In contrast, in those prepared above the critical temperature, the infrared (IR) peak shifted, signifying reduction of the trans conformers and the rise of gauche defect populations. Simulations of the IR adsorption data indicated that the disordered regions existed as islands rather than being uniformly mixed. This suggested, in analogy with the Langmuir monolayers, that below the critical temperature, the SAM forms by direct condensation of a gaseous phase to a condensed phase, while above  $T_c$  an intermediate liquid phase forms; the condensed phase nucleates from the liquid and complete monolayers retain some liquid domains. Atomic force microscopy studies have directly confirmed this picture and provided details of the assembly process: Height AFM images of partially complete OTS monolayers prepared at room temperature show, after a few seconds of immersion, condensed island domains with heights of the order of the fully extended chain and island sizes in the hundreds of nanometers size range.<sup>[27–29]</sup> With time, these islands grow to micrometer sizes and eventually become surrounded

by a matrix liquid phase whose height begins to grow with time and arrests the growth of the island phase. For deposition conditions below 16°C, Maboudian et al.<sup>[29]</sup> found that the micrometer-sized islands with fully extended chain heights are once again observed after a few seconds, but grow continuously, with the surrounding area remaining bare (or with a gaseous monolayer) during the growth. These low temperatures are below the critical temperature for the existence of a liquid phase, and the monolayer develops directly by condensation from the gaseous state. Whether this state is gaseous cannot be established conclusively from scanning probe topography images and it could also be a liquid phase of low density in equilibrium with the condensed phase.<sup>[28]</sup>

While the clustering of condensed domains in a sparse background for alkylsilanes is now well recognized, there have been only a few studies that have considered using backfilling to produce nanoisland topography. Mathauer and Frank<sup>[30]</sup> studied the system of OTS and a naphthalene terminated silane with an 11-carbon hydrophobic spacer, alternatively backfilling either with OTS or the naphthalene silane. Examination of the ratio of the intensities of the excimer to monomer fluorescence of the naphthalene terminal group gave no indication of macroscale phase separation because the ratio increased uniformly with increase in the amount of the naphthalene amphiphile. These observations did not provide clear insight into the existence of nanoscale separation in the monolayer. In a related effort, Knobler et al.<sup>[31]</sup> spread Langmuir monolayers of alkyl trichlorosilanes, transferred them by the Langmuir–Blodgett technique onto hydrophilic surfaces, and then heated the surface to create condensed micrometer-sized domains that were then backfilled by deposition of a second silane.

Phase separation in mixed SAMs of alkylthiols due to mixed adsorption was first studied by Whitesides et al.<sup>[32,33]</sup> in the course of their investigations on the relationship between wetting and the composition of the mixed SAMs. In order for phase separation to take place, two conditions must be met. First, preferential interactions between the amphiphiles of one component in the binary mixture must be able to counter the entropic energy gain that is realized through random mixing of the two components in the monolayer. Second, the adsorbed amphiphiles should be laterally mobile so that molecules of one kind can take advantage of the preferential interaction. Whitesides et al. studied two examples of preferential interaction in their wetting studies. The first was a significant difference in the length of the hydrocarbon spacer, and the second was hydrogen bonding interactions of the terminal group. When the hydrophobic chains of one amphiphile are much larger than those of the other, there is an increased van der Waals dispersive cohesion

that is especially important when the chains pack in the lengthwise fashion of assembled alkylthiols. Monte Carlo and molecular dynamic simulations of laterally mobile alkylthiols have shown phase separation for methyl terminated thiols when the difference between the chain lengths is larger than approximately 7–10 methylene units.<sup>[34]</sup> Laibinis, Nuzzo, and Whitesides<sup>[33]</sup> measured the contact angles of binary alkylthiol SAMs in which the thiols differed by 10 methylene units and were terminated by methyl groups. The contact angles of the pure components were almost identical, while the mixed SAMs showed a pronounced minimum in contact angle. If macroscopic islands (domains micrometers in size, which would be the only ones expected to affect the contact angles) were present, then, since the methyl groups in the islands would be ordered and well packed, the mixed monolayer should have contact angles the same as those of the pure component surfaces. However, nanoscale separation was not ruled out, and IR spectroscopy provided some evidence of islands of the longer chain thiolate.<sup>[33]</sup> Recently, a few scanning probe microscopy studies have provided definitive evidence for nanoscale separation. Tamada et al.<sup>[35]</sup> have shown nanometer scale phase separation of mixtures of the alkylthiols  $\text{CH}_3(\text{CH}_2)_3\text{SH}$  and  $\text{CH}_3(\text{CH}_2)_{11}\text{SH}$ . The second preferential interaction studied by Whitesides et al. is hydrogen bonding interactions at the terminal group of one of the components.<sup>[32]</sup> Contact angles of water on a binary SAM in which both amphiphiles have the same hydrophobic length but one is capable of hydrogen bonding [ $\text{HS}(\text{CH}_2)_{10}\text{CH}_2\text{OH}$  and  $\text{HS}(\text{CH}_2)_{10}\text{CH}_3$ ] decreased in a convex monotonic form with constant hysteresis as a function of the fraction of the polar component, indicating no microscopic separation. The nanoscale features of this system remain unclear and related studies using scanning probe microscopy are contradictory as to whether phase nanoscale separation occurs.<sup>[36]</sup> However, nanoscale phase separation has been consistently observed in the case in which the terminal groups of short chain hydrogen bonds as shown in the systems  $\text{HO}(\text{CH}_2)_4\text{SH}/\text{CH}_3(\text{CH}_2)_{16}\text{SH}$  by Allara, Liedberg, and Allara,<sup>[37]</sup>  $\text{HOOC}(\text{CH}_2)_2\text{SH}/\text{CH}_3(\text{CH}_2)_{16}\text{SH}$  by Imabayashi et al.,<sup>[36]</sup> and 4-aminothiophenyl/ $\text{CH}_3(\text{CH}_2)_{16}\text{SH}$  by Hayes et al.<sup>[38]</sup> Evidently the extra attraction between the shorter chain hydrogen bonding amphiphile insures its exclusion from the condensed domain forming from the longer chain amphiphile.

There have been several studies of two component SAMs deposited from binary alkyltrichlorosilane solutions, but not many researchers have investigated the formation of nanoislands. Mixed methyl terminated SAMs with two different alkyl chain lengths have been studied by a few authors,<sup>[39]</sup> but for the most part they have focused more on the determination of

composition in the monolayer and not on phase separation. Offord and Griffin noted from measurements of the surface energies of mixed monolayers of methyl terminated short (*n*-butyl and *tert*-butyl) and long chains (dodecyl, hexadecyl, octadecyl) that because the surface free energies of the mixed SAMs were higher than the energies of the single components, it was doubtful whether there was macroscopic phase separation, since the surface energy of the mixed SAM would be a weighted average of the two contact angles. Mixed SAMs of an aryl and methyl terminated SAMs have also been studied, but only the study of Mathauer and Frank,<sup>[40]</sup> who observed no macroscopic separation, addressed the issue of phase segregation. Silane amphiphiles with hydrophobic spacers consisting of  $-\text{CF}_2$  rather than  $-\text{CH}_2$  groups, which make the hydrophobic spacers less flexible, are plausible candidates for phase separation when mixed with amphiphiles with methylene spacers, because analogous Langmuir monolayers phase segregate. Studies of mixed monolayers of octyltrichlorosilane and  $\text{CF}_3(\text{CF}_2)_5(\text{CH}_2)_2\text{SiCl}_3$  by Chuang et al.<sup>[41,42]</sup> demonstrated preferential adsorption of the fluorosilane and showed that macroscopic phase separation was unlikely; however, no conclusions could be reached on whether the fluorosilanes altered the structure by being well mixed in the monolayer or in nano-sized islands. Finally, a few other studies focusing on the composition of mixed monolayers of methyl terminated and, among others, either carboxyl,<sup>[43]</sup> halogen, ester,<sup>[44]</sup> or cyano terminated silanes have been undertaken.

The above discussion makes it clear that alkyltrichlorosilanes are preferable to alkylthiols for use in the backfilling method. With regard to binary mixed adsorption, while it is clear from the few scanning probe microscopy studies mentioned above that alkylthiols can phase separate into nanodomains under the right conditions (e.g., if the amphiphiles differ sufficiently in chain length), none of these studies demonstrate an ability to manipulate the size of the islands. Due to the covalent linking of the thiol group to the gold, lateral diffusion is limited, and it is doubtful that the size can be easily manipulated. On the other hand, while there have been no studies identifying nanoislands in mixed alkylchlorosilanes, their lateral mobility and analogous behavior to Langmuir and Langmuir–Blodgett monolayers makes them better candidates for use in sequential adsorption, and hence we use the alkylsilanes for both the sequential and mixed adsorption studies.

## APPROACHES TO PREPARING ISLAND SURFACE

Self-assembled monolayers of trichlorosilane or trialkylsilane amphiphiles,  $\text{X-R-SiY}_3$  (where X is the terminal

group and R the hydrophobic spacer; Y is a chloro or alkyl group), have been used here to fabricate functionalized nanoisland surfaces. Since the surface property of SAMs is primarily determined by the terminal functional groups ( $-\text{X}$ ) of the assembled molecules, the functionalization of nanodomains could be simply tethering the desired functional group moiety to the hydrophobic assembled silane. But if the moiety is reactive to the silane group or has an affinity for the surface (which competes with the attachment of the silane group to the surface and compromises chain packing and ordering), an unreactive precursor has to be assembled with the SAMs first and then subsequently the desired moiety has to be derivatized. Because of space constraints, details of precursor synthesis are omitted here.

## Backfilling (Sequential Adsorption)

In the backfilling technique, the nanoisland domains are created first. They are assembled by using silanes that when adsorbed (for periods of deposition shorter than those necessary to achieve complete coverage) could phase separate into condensed islands and a background gaseous phase. To insure this phase separation, the deposition is carried out for relatively short deposition times, so that the condensed phase does not entirely cover the surface, at temperatures below room temperature, and using the longer chain silanes: OTS ( $n = 17$ ) for methyl termination, aminophenyltrimethoxysilane [APhMS:  $\text{NH}_2\text{C}_6\text{H}_4\text{-Si}(\text{OMe})_3$ ] for amine termination,  $\text{CF}_3\text{CH}_2\text{O}(\text{CO})(\text{CH}_2)_{17}\text{SiCl}_3$  for carboxylate termination, and  $\text{CH}_3(\text{CO})\text{S}(\text{CH}_2)_{17}\text{SiCl}_3$  for thiol termination (in situ reactions can change these precursor functionalities to the desired ones). Phase separation of the long chain cyano, trifluoroester, and acetothiol silanes has not been studied; however, their long chains should provide enough cohesive energy to drive the condensation phase transition despite the opposing effect of the bulkiness of the terminal groups.

Another case that we observed in our experiments is that, instead of nanoisland formation, long chain amphiphile deposition on the surface for a relatively long time (not long enough to completely cover the whole surface) led to the formation of a continuous phase with nanoscale holes (nanowells). Fig. 1 is a typical AFM image of a 2-[methoxy(polyethylenoxy) propyl]trimethoxysilane [mPEG:  $\text{CH}_3\text{O}(\text{CH}_2\text{CH}_2\text{O})_n\text{C}_3\text{H}_6\text{Si}(\text{OMe})_3$ ;  $n = 6\text{--}9$ ] nanoisland surface formed by this approach (for convenience, the term nanoisland is used for both nanoscale pillars and holes). After an mPEG nanoisland surface of desired size is obtained, the nanoisland can also be modified by a secondary chemical functionality, like amino, cyano, ester, or thioacetyl terminated silane.

**Fig. 1** (A) AFM image of partially packed mPEG surface with nanoisland defects. Cross-section analysis gives average diameter of island to be about 100–300 nm and depth approximately 2.5 nm. (B) In situ three-dimensional image.

The major issue in the backfilling technique—once self-condensation has been established in the first step—is how to control the size of the islands (“pillar” or “holes”) and their density. These features are controlled in the first step by controlling the size and density of the condensed islands, and it is clear that the deposition time, the concentration of the silane, and the amount of water in the solvent (determined by the polarity of the solvent and its state of hydration) are the parameters that control how much silane adsorbs onto the surface, and therefore the area occupied by the condensed phase. Hence, these parameters can be used to determine the rough island sizes and densities. But given a certain condensed phase area, how can the island size be fine-tuned? During the first deposition, the line tension created at the island perimeter between the silane’s methylene chain and the depositing solvent plays a central role: Large

tensions favor large and less numerous islands, and lower tensions smaller and more islands, each within the constraint of how much condensed phase has adsorbed. As the spacer is hydrophobic, the more polar the solvent the larger the tension and the coarser the island structure—for the same amount of condensed silane adsorbed. Therefore, our strategy is to first obtain a reference “rough scale” island structure for a given concentration, deposition time, and solvent, and then fine-tune the island size by changing the solvent while adjusting the concentration and deposition time to keep constant the amount of silane adsorbed. Thus, if the adsorption is from a polar solvent yielding large islands, we could fine-tune to smaller islands by reducing the polarity of the solvent. To compensate for the probable reduction in available water necessary for chlorosilane hydrolysis, the concentration of silane can be increased or the deposition

time lengthened so as to keep constant the total amount adsorbed.

### Mixed Adsorption

In the mixed adsorption technique, the silicon wafer is dipped into a solution containing the silanes that make up both the island and matrix phases, and these, upon adsorption, phase separate to form the desired pattern. The central challenge is to insure that the segregation takes place, and this requires an understanding of the factors that control the phase separation as opposed to those that promote uniform mixing. As discussed before, most of our insight into phase separation in mixed systems derives from alkylthiol studies, which showed that mixtures with disparate chain lengths (i.e.,  $n < 5$  and  $n > 16$ ) segregate due to the increased cohesion of the longer chains, which drives their mutual aggregation into condensed domains, excluding the lower chain amphiphiles, which organize themselves into a more disordered phase. Chain length induced phase separation has also been verified by computer simulations of the adsorption of two alkylthiols with differing chain length on Au (1 1 1); these demonstrate phase separation when the chain length differs by more than seven or eight methylene units. Another crucial factor that needs to be taken into account is the interactions of functionalities embedded in the hydrophobic spacer or at the terminus. In principle, if one of the amphiphiles in the binary mixture contains a terminal group (or a group embedded in the hydrocarbon spacer) that is strongly attractive to itself (as for example hydrogen bonding moieties), this extra interaction could promote phase separation. This kind of phase separation has been observed in mixed monolayers spread at the air/water interface and subsequently transferred to a hydrophilic surface by the Langmuir–Blodgett technique. For example, two amphiphiles, each with the same chain length but one containing an amide head group [ $-C(O)NH_2$ ] and the other an amide and carboxylic head group [ $-C(O)NH(CH_2)_2COOH$ ], phase separate due to the extra hydrogen bonding of the carboxylic group. Analogous experiments by Allara et al. on mixed SAM formation via the coadsorption of two thiols of approximately the same chain length with one capable of hydrogen bonding [ $CH_2O_2(CH_2)_{15}SH$ ] while the other is unable to hydrogen bond [ $CH_3(CH_2)_{16}SH$ ] show nanoisland phase separation. However, contradictory results have been obtained with similar systems by Bo and Lieberg using  $HOC(CH_2)_{10}SH/CH_3(CH_2)_{10}SH$  and Kakiuchi et al. using  $HOOC(CH_2)_{10}SH/CH_3(CH_2)_{10}SH$ , each of which showed no evidence of phase separation. If the chain length of the methyl terminated amphiphile is

much longer than the length of the amphiphile with the hydrogen bonding terminus, phase separation is observed consistently, as shown in the systems  $HO(CH_2)_4SH/CH_3(CH_2)_{16}SH$  by Allara et al.,  $HOOC(CH_2)_2SH/CH_3(CH_2)_{16}SH$  by Imabayashi, and 4-aminothiophenyl/ $CH_3(CH_2)_{16}SH$  by Hayes et al. Evidently the extra attraction between the shorter chain hydrogen bonding amphiphile insures its exclusion from the condensed domain forming from the longer chain amphiphile.

We use different chain lengths as our primary tool to insure segregation. Because of the flexibility of the ethylene oxide chain for oligomeric and polymeric PEG silanes, we take advantage of this to use PEG-grated silane to form the long chain phase. Once phase separation is assured, the amphiphile that constitutes the matrix phase and the size of the islands is governed primarily by which amphiphile adsorbs more quickly to the surface, as this is the one that usually forms the continuous matrix phase, with the slower adsorbing species forming the island phase. The factors that govern the relative rates of adsorption of the silanes are principally: 1) the composition ratio in the bulk; 2) the affinity of the terminal groups for the surface; 3) the affinity of the amphiphile for the solvent; and 4) any cooperative effects that enhance the adsorption of one amphiphile once some adsorbed molecules of that amphiphile are already down on the surface. The latter effect is particularly important for the mixed adsorption of short and long chain thiols, where the greater cohesive force of larger chains may be expected to accelerate their adsorption and leads to a surface enrichment relative to the solution phase. In the design of our systems, we begin by using the composition ratio of the bulk solution to set principally which phase is the island phase and which is the matrix, and the size and density of island. Total concentration of amphiphiles in the depositing solution and the time of deposition are adjusted to allow for full coverage. Once a rough scale for the size and density is achieved with a given composition ratio, we again use the solvent polarity to tune the island size and density on the surfaces.

### EXAMPLES

In the following, we give some examples of nanoisland surfaces prepared by the backfilling and mixed adsorption methods discussed above. Usually, we use single crystal silicon wafers (double side polished, n-type, (1 1 1)) with a native oxide layer to assemble silane monolayers. These substrates were cleaned, stored in deionized water, and dried in a stream of nitrogen prior to use; treated in this way, the substrates retain a physisorbed water layer upon immersion into the nonpolar solvent. All chemicals, including silanes and organic

solvents with different polarities (chloroform, carbon tetrachloride, toluene, etc.), were used as received without further purification. The bulk solutions of different silanes were prepared by adding OTS, 3-aminopropyltrimethoxysilane [APS:  $\text{NH}_2\text{C}_3\text{H}_6\text{Si}(\text{OMe})_3$ ], APhMS, or mPEG in the required quantities to the organic solvent. The silane amphiphiles were assembled onto the silicon oxidized substrates by adsorption from solutions of varying polarity. The cleaned silicon substrates were immersed into the bulk solution with different compositions for a certain amount of time so that the silanes could be hydrolyzed by the water present in the solution. The deposition was terminated by rinsing the substrates in organic solvent for 5 min or sonicating for 1 min if necessary. The excess solvent was blown off with a dry nitrogen beam. The substrates could also be baked on a hot plate at  $120^\circ\text{C}$  to complete the chemisorption of the silane to the hydroxylated surface by promoting siloxane bridging linkages between silanes and the surface.

We used the solvent polarity to tune the island size and density. After deposition for a prescribed time in the assembled silane solution, the wafers were rinsed (or sonicated) to remove excess silane or siloxane oligomers from the surface, and dried by nitrogen stream. In situ modifications (i.e., CN reduction to amines, ester hydrolysis to carboxylates, thioacetyl hydrolysis to thiols), if required, followed. For mixed adsorption, the process was then complete. In the case of sequential adsorption, the dried and possibly modified substrates were then redipped in a second silane solution, sonicated, dried, and (if necessary) in situ modified once again.

The primary tool to visualize the surface morphology is atomic force microscopy, which allows direct in situ scanning of the surfaces. Atomic force microscopy images were obtained by using a Nanoscope III instrument (Digital Instruments, Inc.). Silicon nitride sharpened tips with a force constant of  $0.58\text{ N/m}$  were used for height and friction images in contact mode. A normal force of approximately  $10\text{ nN}$  was used in the contact mode experiments. For every sample, at least three different locations were acquired. Height and friction data for various phases on the samples were obtained by taking cross sections at random locations. All the friction images acquired were from the same area as that from which the height images were acquired.

Long chain methyl terminated silane OTS and short chain amine terminated APS were mixed adsorbed on the surface to form a pattern in which the recessed islands with charged functionality were surrounded by a hydrophobic methyl terminated matrix. The total concentration of amphiphiles in the depositing solution and the time of deposition were adjusted to allow for full coverage. The use of the short chains of APS

relative to the long chain OTS insures phase separation, and the matrix is elevated  $1.5\text{--}2.0\text{ nm}$  relative to the islands. The significant hydrogen bond of amine strengthens the later chain interaction and thus enhances the segregation. The islands of the polar terminated silanes are formed because the composition ratio favors the methyl terminated silanes. As Fig. 2 shows, the binary OTS/APS system phase separates on the surface to form the nanoisland surface when the OTS/APS ratio in the bulk solution is 3:1 and total concentration is  $2.0\text{ mM}$  in anhydrous chloroform with  $0.02\%$  (v/v) water added. The water contact angle equals  $98^\circ$ , implying that the majority phase is hydrophobic OTS (pure OTS has a contact angle of  $110^\circ$ ). The friction image (right) with the same pattern also confirms this result, since the amino group of APS has relatively higher friction compared with the alkyl group of OTS, so that the lower islands of APS (“dark dots”) on the height image appear to be bright spots on the friction image (right). Cross-section analysis gives an island size of  $\sim 50\text{ nm}$  and a depth of  $\sim 1.5\text{ nm}$ , consistent with the former thickness prediction.

Phase separation on solid-liquid interface from a binary mixture of amphiphiles in which one component terminates in a PEG chain has not been studied, either for the thiol or the silane case. The steric repulsion between the ethoxylated head groups of the oligomeric (6–9 units) PEG terminated silanes acts to form a disordered SAM relative to the ordering we might expect from the long alkyl chain silanes. Therefore, we use amino terminated silanes (APhMS) and coadsorb these with oligomeric mPEG terminated silanes. Following the same protocol and using APhMS and long chain mPEG to replace OTS and APS, respectively, we also obtained a similar nanoisland pattern on the surface (Fig. 3). Cross-section analysis shows that the approximate size of the recessed island is about  $300\text{ nm}$  and the depth is about  $3.0\text{ nm}$  from matrix. The height image and friction image of the surface tell us that the island is APhMS and the matrix is mPEG. The depth of the island is also consistent with the height difference between the two amphiphiles.

As discussed before, the deposition conditions are essential for the phase separation behavior on the surface. For the same system and experimental conditions, when the composition of the bulk solution is changed, phase separation still occurs, but the pattern of each phase domain is totally different. Fig. 4 shows the same system of APhMS/mPEG with the same bulk composition ratio of 1:1 for an immersion time of 3 hr. Instead of APhMS holes forming, the long chain mPEG forms pillars and the APhMS forms a continuous matrix. The mPEG pillars appeared to be bright patches on the height image (left) and dark patches on the friction image (right). The size of the mPEG

**Fig. 2** AFM image of nanoisland surface formed by OTS/APS mixed monolayer (2 mM; bulk ratio 3 : 1) in anhydrous chloroform and 0.02% (v/v) water for 2 hr; contact angle = 98°. Cross-section analysis shows it to be 50 nm in diameter and 1.5 nm recessed from matrix. Bright spots on friction image correspond to higher friction of amino group of APS.

pillars is about 150 nm and the height from the surrounding APhMS matrix, 1.5 nm. The simple explanation for these different results is that because of the strong intermolecular interaction between the long alkyl chains, for the mPEG-rich sample (Fig. 3), the short chain APhMS tends to form islands, whereas when the composition ratio is changed to 1 : 1, mPEG becomes the minority phase and forms pillars within an amine terminated matrix. The discrepancy in the island depth and pillar height in Figs. 3 and 4 is also due to the different phase coverage on the surface. In Fig. 3, the long chain mPEG on the surface is the majority phase, so that the chains are densely packed and do not have much space to sway but extend perpendicularly, while in Fig. 4, the mPEG is the minority phase on the surface, so that the extruded chains have more spatial freedom to sway around, thus leading to the lower height value measured when scanned with an AFM tip.

The steric repulsion between the ethoxylated head groups of the oligomeric PEG terminated silanes

makes it difficult to form a condensed SAM. For most situations this is undesirable for nanopattern formation because of the loose structure. However, if we can control the formation conditions and manipulate the deposition parameters, like the deposition time, solvent polarity, etc., the defective structure with well-distributed holes on the surface can serve as the first step of the backfilling process. Fig. 1 is the AFM image of an mPEG surface with defect nanowells. With short deposition time, the mPEG silanes did not have enough time to fully cover the surface and formed the partially packed monolayer with nanoscale defects. The AFM height image and friction image both give good distribution and the correct friction pattern, in which the lower holes on the height image appear to be bright (because of the partially negatively charged hydroxylated silicon bare surface). Cross-section analysis gives the size of the spherical defect to be about 100–300 nm and the depth, 2.5 nm. Also due to the loose structure and disordered packing, this length is understandably a little lower than the fully extended

**Fig. 3** AFM image of nanoisland surface from mPEG/APhMS mixed monolayer (1 mM; bulk ratio 3 : 1) in anhydrous chloroform for 3 hr and toluene rinsed for 1 min. Cross-section analysis gives size of 300 nm and depth of 3.0 nm (average).

length of 3.0 nm. The in situ three-dimensional image gives the direct visualization of the distribution of holes on the surface. After the mPEG surface with the defects is prepared, further backfilling with other desired functional groups can be undertaken, since the bottom surface of the defect holes is still bare hydrated surface, so that further hydrolysis can take place. Fig. 5 is the mPEG nanoisland surface after APhMS monolayer backfilling. Compared to the pure mPEG nanoisland pattern in Fig. 1, the most distinct change is that the bright spots on the friction image (right) have disappeared after amino group modification. The possible explanation is that the frictions of the amino terminal groups and methoxy terminal groups of mPEG are very similar in aqueous buffer solution, so that they are hardly to be detected by AFM imaging.

Oligo(ethylene glycol) (OEG) spacer is recognized as a resistant material that prevents non-specific adsorption of proteins, so that it has been incorporated into SAMs to form nanoisland surfaces because of its ability to render surfaces biocompatible.<sup>[45]</sup> As one of the important applications of nanoisland surfaces, we immobilized intact small unilamellar liposome vesicles (SUV) onto the abovementioned nanoisland for future biosensing application. In general, the liposome

vesicles tend to unravel and spread on the solid surface and eventually form multiple layers when exposed to either hydrophobic or hydrophilic solid supports. This is undesirable for many special situations, for example when the conformation and fluidity of lipid membrane are necessary for the embedded protein receptors to function in biosensor and molecular-recognition applications. The nanoisland surfaces in our research provide an alternative mechanism to circumvent this problem and maintain the liposome vesicle intact. Fig. 6 is the AFM image (under fluid cell) of a nanoisland surface after liposome exposure. The negatively charged liposome (SUV) was prepared from pre-liposome formulation-4 [L- $\alpha$ -phosphatidylcholine- $\beta$ -oleoyl- $\gamma$ -palmitoyl (POPC), L- $\alpha$ -phosphatidyl-DL-glycerol (PGDO), dioleoyl, and cholesterol from Sigma-Aldrich Co.] by standard extrusion through 0.2  $\mu$ m filter and has  $\sim$ 200 nm size distribution in solution (by light scattering measurement). Unlike the usual case of unraveling on the surface, most of the liposome vesicles under buffer solution maintained their intact structure, with a height of 40 nm and diameter of 400 nm (from cross-section analysis of the zoom-in image of Fig. 6B). The flattening deformation of the liposome shape was attributed to the gravity of the interior buffer liquid and the electronic attraction

Integrated - Island

**Fig. 4** AFM image of mPEG island from mPEG/APhMS mixed monolayer (1 mM; bulk ratio 1 : 1) in dry chloroform and 0.02% water (v/v) for 3 hr. Contact angle = 35°. Cross-section analysis gives approximately 150–200 nm diameter and 1.5 nm recessed from matrix. Lower friction of mPEG (methoxy terminal group) shows dark patches in friction image (right) corresponding to bright (higher) patches on height image (left).

**Fig. 5** AFM image of nanoisland surface of mPEG monolayer after APhMS backfilling. Bright spots on friction image (right) disappeared after amino group modification.

**Fig. 6** (A) AFM image (under fluid cell with buffer solution) of liposome ( $\varnothing = 0.2 \mu\text{m}$ ) exposed to nanoisland surface after buffer rinsing. (B) Cross-section analysis of zoom-in image shows height of 40 nm and size of 400 nm approximately.

of the island surface. The deformation of the spherical shape to square shape in the zoom-in image is the result of AFM tip scratch (especially in contact mode). The mechanism of intact liposome immobilization on the nanoisland surface is as follows: The nanoislands on the nanopattern surface have the same order of size range (100–300 nm) as the liposomes ( $\sim 200$  nm) so that a complete bilayer cannot be accommodated; the oppositely charged terminal groups (positively charged amino groups) of the island bind the liposome via electrostatic force; the inert surrounding mPEG matrix resists the liposome adsorption. In addition, because of recessing of the islands relative to the matrix so that liposomes are physically removed from the matrix, the nanoisland surface with specially tethered functionality is a good model to prevent the spreading and unraveling of the liposome bilayer on the surface and to maintain the intact conformation of liposome vesicles.

## CONCLUSIONS

Self-assembled monolayers provide a route for tailoring functionalities and submicrometer patterns on surfaces. The phase separation of SAMs has been explored to fabricate heterogeneous, robust arrays of nanodomains with variable functionalities. Uniformly arranged nanoisland (nanowell) domains with specific functionality have been patterned on solid surfaces through mixed adsorption and backfilling approaches. Given a well-defined binary system with specific molecular structure, functionalities and preparation approaches, the morphology of phase separation, to a certain extent, could be controlled by manipulating

the deposition conditions. Compared to other nanopattern techniques, these approaches provide a convenient alternative to pattern large surface areas and curved surfaces with nanoscale domains. As a future application of this work, intact liposome vesicles could be incorporated or loaded with desired reagents, drug molecules, or membrane protein receptors and arrayed onto our nanoisland surfaces for further bioassay, biosensor, or drug delivery studies.

## INTRODUCTION

Micro reactors, in their simplest form, consist of a network of micron-sized channels (typical dimensions are in the range 10–300  $\mu\text{m}$ ) etched into a solid substrate (see Refs.<sup>[1–9]</sup> for introductory overviews). The ability to move chemical reagents around the channel network enables spatial control of reactions, which can be exploited to alter yield and product selectivity in synthetic chemical processes. This extra dimension of reaction control, not achievable in bulk reactors where concentrations are uniform, is comparable with compartmentalized biosynthetic processes in biological cells. Hence, in addition to their applications in analysis, micro reactors open up new horizons for the controlled synthesis of fine chemicals. This entry discusses the current and future applications of micro reactors in the fields of chemical synthesis and drug discovery. The fabrication and physical characterization of micro reactors, together with details of their use and operation, is described. Examples of liquid and gas phase reactions are used to illustrate some key advantages of performing chemical reactions in micro reactors.

## BACKGROUND

For solution-based chemistry, the channel networks of the micro reactors are connected to a series of reservoirs containing chemical reagents to form the complete device or “chip” with overall dimensions of a few centimeters, a simple example of which is illustrated in Fig. 1. In the micro reactor, reagents can be brought together in a specific sequence, mixed and allowed to react for a specified time in a controlled region of the channel network using electrokinetic or hydrodynamic pumping. For electrokinetically driven systems, electrodes are located in the appropriate reservoirs to which specific voltage sequences can be delivered under automated computer control. This control offers a simple but effective method of moving

and separating reactants and products within a micro reactor, without the need for moving parts. Hydrodynamic pumping exploits conventional or microscale pumps, notably syringe-type pumps, to maneuver solutions around the channel network. However, for hydrodynamic pumping, either an interface between large external pumps and the chip is required or it is necessary to fabricate complex small moving parts within the device itself.

Alongside the continuing development of miniaturized total analytical systems ( $\mu\text{-TAS}$ ) and related analytical applications,<sup>[10–17]</sup> a concerted effort is now underway to establish the benefits that micro reactors can bring to the field of reaction chemistry. The ability to manipulate reagent concentrations in space and time by electrokinetic control within a micro reactor provides a level of reaction control that is not possible in traditional batch reactors where concentrations are generally uniform. Interestingly, the spatial and temporal control of chemical reactions in micro reactors, coupled with the features of very small reaction volumes and high surface interactions, makes this technology akin to the conditions under which reactions occur within biological cells. Nature has become very effective at exploiting the organized distribution of reagents within the micron-sized domains of cells to control the chemical selectivity of compound production, relative to the situation of large-scale synthetic methodology. Based on this notion, it has now been demonstrated that many chemical reactions show improved reactivity, product yield, and selectivity when performed in micro reactors compared with the same reaction performed using conventional laboratory procedures with macroscale reactors. Reported research confirms that micro reactor methodology is applicable to performing both gas and liquid phase reaction chemistry. From the work cited in this entry, the evidence is that the unique modus operandi of micro reactors (namely, the low-volume spatial and temporal control of reactants and products in a diffusive, laminar flow mixing environment) offers a novel method for chemical manipulation and product

Fig. 1 Borosilicate glass micro reactors.

generation. In short, micro reactors are new tools with which to generate molecules and increase our knowledge of complex chemical processes.

In the authors' experience, a reaction performed within a micro reactor can commonly be speedily optimized to generate relatively pure products in higher yield and in shorter time, when compared with the equivalent bulk reaction. Product amounts, although relatively small, are generally sufficient to perform full instrumental characterization. One of the immediate and obvious applications is therefore in drug and process discovery, where the generation of compounds either with different reagents or under variable conditions is an essential factor. An interesting twist to the micro reactor chemistry carried out in the authors' laboratories is not just the opportunity to separate reactants and products in real time, but also the capability to manufacture and use reagents in situ.

## MICROREACTOR FABRICATION

Materials such as silicon, quartz, glass, metals, and polymers have all been used to fabricate micro reactors.<sup>[9,11]</sup> Important considerations in material choice include chemical resistance, ease and reproducibility of fabrication, compatibility with detection methods, and, if relevant, whether the material supports electro-osmotic flow (EOF) with the solvents of interest. Glass is a popular choice because it allows EOF with many common solvents, is chemically inert, enables the use of a range of visible light detection methods, and fabrication techniques are well established.

Depending on the material used, a range of channel microfabrication methods such as photolithography, hot embossing, powder blasting, injection molding, and laser microforming are available.<sup>[18]</sup> For glass micro reactors, photolithographic fabrication of

Fig. 2 Photolithographic fabrication of channel networks in glass.

channel networks is performed as shown schematically in Fig. 2.<sup>[19,20]</sup> First, the channel network is designed and printed using suitable computer drawing software and a film negative of the desired final size is then prepared by photoreduction to form the optical mask. Commercially available borosilicate glass photolithographic plates (thickness of 3 mm) coated with a thin metal etch mask layer (normally chromium) plus an upper layer of positive photoresist (0.5–2.0  $\mu\text{m}$  depth) are used for channel network fabrication. The pattern of interconnecting channels is transferred from the optical mask to the photoresist layer. After light exposure, the photoresist is developed and removed, together with the chromium layer, to reveal the areas of glass to be etched. The patterned plate is then heated to allow the volatiles to evaporate before performing the chemical etch. The channels may be etched, for example, using a mixture of 1% HF and 5%  $\text{NH}_4\text{F}$  in water at 65°C, resulting in an etch rate of typically 0.3 to 0.5  $\mu\text{m min}^{-1}$ . During the etch process, the system must be well agitated to ensure a consistent supply of etchant to the surface and the efficient removal of etch debris. In our laboratories, we have found that

**Fig. 3** Exploded view of a micro reactor constructed from a base plate containing the etched channel network and thermally bonded to a thick upper plate containing reagent reservoirs.

ultrasound irradiation during the etch process is effective.<sup>[20]</sup>

The base plate containing the etched channel network must next be sealed by bonding to an upper plate (17 mm thick) containing predrilled holes to act as reservoirs for reagents and products. In our laboratories, the upper plate is aligned with the channel geometry and thermally bonded to the base plate (typically at 575°C for 3 hr).<sup>[19,20]</sup> Thermal bonding is aided by placing a weighting block of non-adhering quartz of high softening temperature on the upper plate. A schematic of the device produced by this method is illustrated in Fig. 3, and a photograph of such a micro reactor is shown in Fig. 1. For good thermal bonding, it is important to ensure that both pieces of glass have the correct thermal softening and expansion properties. In addition, the surfaces to be bonded must be clean and flat. More recently, the thermal bonding of ceramic adaptors to glass has enabled hydrodynamic pumping to be more effectively realized. Fig. 4 shows a glass

**Fig. 4** Micro reactor with ceramic fittings. *Source:* Micro Chemical Systems Ltd.

**Fig. 5** Micro reactors fabricated from polymers. *Source:* Epigem Ltd.

micro reactor with ceramic adaptors, enabling high-performance liquid chromatography (HPLC)-type fittings to be connected directly to the chip.

Fabrication in polymeric materials, while attractive from an engineering and cost perspective, poses a number of reagent compatibility issues. However, the U.K. Lab-on-a-Chip consortium project has demonstrated that devices containing channels fabricated from an epoxy resin (SU-8) coated onto a polymer support, such as methacrylate, are relatively robust to chemical attack (Fig. 5). This methodology has the advantage that the non-wetted bulk of the chip can be fabricated from low-cost commodity polymers.

Of all the fabrication media, perhaps metal is the most robust in terms of engineering requirements and, more specifically, micromixers have been constructed and applied in chemical processing.<sup>[9]</sup> A number of alternative methods for producing channels in glass have also been reported, such as deep reactive ion etching, powder blasting, and laser ablation.<sup>[9]</sup>

## PRINCIPLES OF REACTION CONTROL IN MICROREACTORS

Pumping of solutions around a channel network by EOF, using voltages applied via electrodes placed in the reservoirs, has several significant advantages over alternative pumping methods. It can be easily miniaturized because no mechanical moving parts are involved and the required voltage sequences can be readily applied under automated computer control. For a glass micro reactor, the channel wall-solution interface normally has a negative charge, arising from ionization of immobile surface silanol groups. This immobile surface charge attracts a diffuse layer

**Fig. 6** Voltage-driven movement of the diffuse layer of cations adsorbed at the negatively charged channel wall (left-hand figure) produces a flat EOF velocity profile across the channel except within the nanometer-thick diffuse counterion layer (right-hand figure).

(of thickness of the order of nanometers) of mobile, oppositely charged counterions in the solution adjacent to the channel wall (cations for a negatively charged glass channel wall). As shown schematically in Fig. 6, application of an electric field along the channel length causes the nanometer-thick “skin” of mobile cations to move toward the more negative electrode and drags all the intervening solution in the bulk of the channel with it.<sup>[21–23]</sup> An important feature of EOF is that the liquid EOF velocity is constant across the channel except in the nanometer-thick regions of the diffuse layer of counterions very close to the wall. Unlike EOF, pressure-driven flow produces a parabolic velocity profile with high velocities in the channel center and slow velocities near to the wall, giving rise to increased “blurring” of reagent zones along a channel length. The imaging of velocity profiles induced by EOF and pressure-driven flow has been described by Paul et al.<sup>[24]</sup>

The EOF fluid velocity  $v_{\text{eof}}$  is given by Eq. (1)

$$v_{\text{eof}} = \frac{E\epsilon\epsilon_0\zeta}{\eta} \quad (1)$$

where  $E$  is the electric field (voltage divided by electrode separation),  $\epsilon$  is the relative dielectric constant of the liquid,  $\epsilon_0$  is the permittivity of free space,  $\zeta$  is the zeta potential of the channel wall–solution interface, and  $\eta$  is the liquid viscosity.<sup>[21–23]</sup> For the glass–aqueous solution interface, the value of  $\zeta$  varies from  $-50$  to  $-150$  mV at pH 7 (dependent on ionic strength), but decreases in magnitude to 0 at pH around 2.5.<sup>[25]</sup> The magnitude of the electric field applied in micro reactors (typically some hundreds of volts per centimeter) gives EOF velocities in the range  $0.1$  to  $1$  mm  $\text{sec}^{-1}$  for aqueous solutions at pH 7.

From Eq. (1), it can be seen that  $v_{\text{eof}}$  is proportional to the applied voltage and depends on the properties of both the liquid and the channel material. Electroosmotic flow does not occur with low polarity solvents such

as alkanes where no diffuse layer of surface counterions exists. The EOF velocity  $v_{\text{eof}}$  is independent of the channel cross-sectional dimensions, whereas the EOF volumetric flow rate (given by the product of  $v_{\text{eof}}$  multiplied by the channel cross-sectional area) depends on the channel dimensions.

Under EOF voltage control, the solvent and any uncharged solutes move with a velocity  $v_{\text{eof}}$ . Within the electric field, charged solutes have an additional electrophoretic velocity  $v_{\text{ph}}$  which is given by Eq. (2)

$$v_{\text{ph}} = \frac{zeED}{kT} \quad (2)$$

where  $z$  is the charge number on the species,  $e$  is the electronic charge,  $D$  is the diffusion coefficient of the species,  $k$  is the Boltzmann constant, and  $T$  is the absolute temperature.<sup>[21,23]</sup> The magnitude of  $v_{\text{ph}}$  for typical micro reactor operating voltages is commonly comparable with  $v_{\text{eof}}$ . The total velocity of a charged species is given by the vector sum of  $v_{\text{eof}}$  and  $v_{\text{ph}}$ . The direction of EOF for aqueous solutions in a glass micro reactor is normally toward the more negative electrode, whereas for a cationic solute species,  $v_{\text{ph}}$  will be in the same direction as the EOF (i.e., toward the more negative electrode) and will move faster down the channel than the solvent and neutral species. Anionic solutes will be retarded and may, if the magnitude of  $v_{\text{ph}}$  is greater than  $v_{\text{eof}}$ , move in the opposite direction. In this way, electrophoretic separation of solutes occurs along with EOF in the micro reactor channels when operated under electrokinetic control. The ability to use electrophoretic mobility to spatially locate charged reagents and products within a micro reactor independently of the solvent forms a useful aspect of reaction control. Differential electrophoretic mobilities have been exploited to selectively control product detection times in the capillary electrophoresis technique of electrophoretically mediated microanalysis (EMMA).<sup>[26–29]</sup>

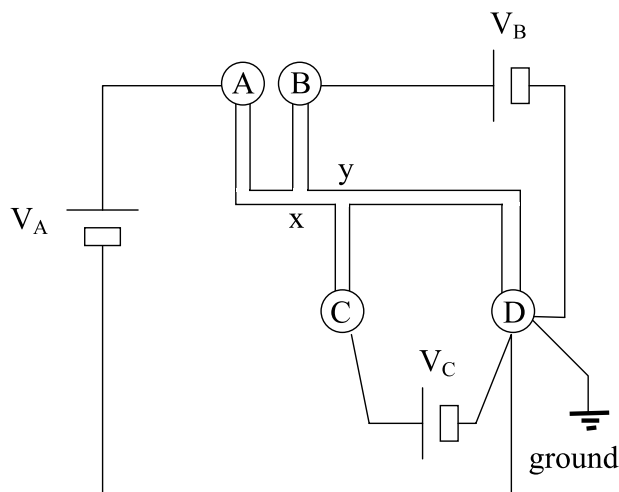

The strategy of using micro reactors to electrokinetically control the spatial and temporal evolution of chemical reactions relies on the ability to use voltage sequences to direct reagents to selected points at specified times within a channel network. For an intricate channel network with many reservoirs and electrodes, the relationships between the applied voltages and the liquid flow rates and solute mobilities in the different sections of the network can be very complex. The basic approach is to analyze the channel network in terms of an equivalent d.c. circuit where the different channel sections correspond to resistance elements and, as will be shown, the electrical currents are proportional to the volumetric liquid flow rates within the corresponding channel sections.<sup>[30–32]</sup> As an illustrative example, we discuss the channel network

**Fig. 7** Double T-junction channel network and flow-inject-flow required to achieve a “slug” of one reagent within a flowing stream of a second reagent.

shown in Fig. 7 where we wish to achieve a flow-inject-flow sequence to obtain a “slug” of one reagent in a flowing stream of a second reagent. In the “flow” mode, we require flow from reservoir A to D with zero flow from both B and C to D. In the “inject” mode, we require flow from B to C with zero flow from A to D. To obtain both modes, a multichannel voltage supply operating under computer control using LabVIEW software is used to deliver the correct voltage sequences to the electrodes in reservoirs A, B, and C (voltages  $V_A$ ,  $V_B$ , and  $V_C$ ) relative to reservoir D, set to ground voltage. The following analysis shows how the voltages are related to the electrical currents ( $I_A$ ,  $I_B$ , and  $I_C$ ) which, in turn, are related to the volumetric flow rates in the corresponding channel sections  $F_A$ ,  $F_B$ , and  $F_C$ .

We consider the simplest possible situation in which the channel network of Fig. 7 is filled with a liquid of uniform electrical conductivity  $\kappa$  and the zeta potential of the channel wall is equal in all channel sections. Experimentally, this situation can be achieved even when mixing different reactant solutions by ensuring a high background concentration of an inert electrolyte. For the sake of simplicity, we ignore the (normally

**Fig. 8** Direct current circuit used to drive the channel network of Fig. 6. Reservoir voltages (relative to ground in D) are  $V_A$ ,  $V_B$ , and  $V_C$  and  $x$  and  $y$  denote the channel junctions. The electrical current in channel section Ax is  $I_A$ , section Bx is  $I_B$ , section Cy is  $I_C$ , section xy is  $(I_A + I_B)$ , and section yD is  $(I_A + I_B + I_C)$ .

small) contribution to the overall conductivity of a channel section, which arises from surface conduction.<sup>[21–23,31]</sup> With these approximations, the electrical resistance of the  $i$ th channel section  $R_i$  is given by Eq. (3)

$$R_i = \frac{L_i}{\kappa A_i} \tag{3}$$

where  $L_i$  and  $A_i$  are the length and cross-sectional area of the  $i$ th channel section, respectively. The d.c. circuit used to drive flow in the channel network of Fig. 7 is shown in Fig. 8 and serves to define the current values in the different channel sections. In each of the loops of the coupled circuit, the applied voltages equal the sums of the products of the resistances and currents. Writing these gives a series of  $(n - 1)$  simultaneous equations, where  $n$  is the number of reservoirs containing electrodes (it is  $n - 1$  because one electrode is set to ground). For the channel network considered here, we have the set of three equations shown below.

$$\begin{aligned} V_A &= R_{Ax}I_A + R_{xy}(I_A + I_B) + R_{yD}(I_A + I_B + I_C) \\ V_B &= R_{Bx}I_B + R_{xy}(I_A + I_B) + R_{yD}(I_A + I_B + I_C) \\ V_C &= R_{Cy}I_C + R_{yD}(I_A + I_B + I_C) \end{aligned} \tag{4}$$

Solving these simultaneous equations (using a software package such as MathCAD) yields the corresponding expressions for the electrical currents shown in Eq. (5). The volumetric liquid flow rate in the  $i$ th channel section  $F_i$  is proportional to the corresponding

**Fig. 9** Illustrative plots of electrical currents versus  $V_A$  for  $V_B$  and  $V_C$  both set to 200 V. The data refer to the channel network of Fig. 6 filled with 50 vol.% ethanol/water containing 35 mM phosphate buffer at pH 7.5.

**Fig. 10** Correlation between measured volumetric liquid flow rates and the corresponding electrical currents for the channel network of Fig. 6 filled with 50 vol.% ethanol/water containing 35 mM phosphate buffer at pH 7.5.

electrical current  $I_i$  according to Eq. (6).<sup>[21,23]</sup>

$$F_i = -I_i \left( \frac{\varepsilon \varepsilon_0 \zeta}{\eta \kappa} \right) \quad (6)$$

To determine the voltages required to achieve a particular pattern of flow rates (e.g., “flow” or “inject” modes described above), all the resistance values of the different channel sections, filled with the liquid of interest, must be known. This can be performed by measuring the currents as a function of the various voltages within the micro reactor and computer fitting the resistance values. Alternatively, one can measure the liquid conductivity (using a conventional conductivity meter) and all the channel dimensions and calculate the required resistances according to Eq. (3). Calibration measurements of liquid flow rates within the micro reactor as a function of different set currents yield the value of  $\zeta$ , which then enables the conversion of measured currents (logged during a run) to liquid flow rates from Eq. (6).

Representative plots of electrical currents vs. one of the voltages (with the remaining voltages being fixed) are shown in Fig. 9. The current values are typically

in the microampere range, and, as expected from Ohm’s law, they are proportional to the voltage. However, because of the linking together of the different limbs of the overall circuit, the voltages required to produce zero current in a particular channel section are determined by a complex function of all resistance and voltage values. An example of the linear correlation between the electrical current and liquid flow rates in corresponding channel sections is shown in Fig. 10. Applying this type of information, Table 1 lists the calculated voltage settings required to achieve flow and injection modes with set flow rates for the system shown in Fig. 10.

Full details have been published<sup>[31]</sup> where it is demonstrated that measurement of the liquid conductivity  $\kappa$ , zeta potential  $\zeta$ , and all channel dimensions enables the correct calculation of the voltages needed to achieve any set of flow rates. However, several notes of caution should be emphasized. First, the results reported indicate that correction of the overall electrical current for surface conduction along the channel walls is sometimes required. The surface conduction may become non-negligible when the bulk conductivity of the liquid is relatively low. Second, the analysis

$$\begin{aligned}
 I_A &= \frac{(R_{Cy}R_{xy} + R_{Cy}R_{yD} + R_{Bx}R_{yD} + R_{xy}R_{yD} + R_{Cy}R_{Bx})V_A - (R_{Cy}R_{yD} + R_{Cy}R_{xy} + R_{xy}R_{yD})V_B - R_{Bx}R_{yD}V_C}{R_{Cy}R_{Bx}R_{Ax} + R_{Cy}R_{xy}R_{Bx} + R_{Cy}R_{xy}R_{Ax} + R_{Cy}R_{yD}R_{Bx} + R_{Cy}R_{yD}R_{Ax} + R_{Bx}R_{yD}R_{Ax} + R_{xy}R_{yD}R_{Bx} + R_{xy}R_{yD}R_{Ax}} \\
 I_B &= \frac{-(R_{Cy}R_{xy} + R_{Cy}R_{yD} + R_{Bx}R_{yD})V_A - (R_{Cy}R_{xy} + R_{Cy}R_{yD} + R_{Cy}R_{Ax} + R_{xy}R_{yD} + R_{yD}R_{Ax})V_B - R_{Ax}R_{yD}V_C}{R_{Cy}R_{Bx}R_{Ax} + R_{Cy}R_{xy}R_{Bx} + R_{Cy}R_{xy}R_{Ax} + R_{Cy}R_{yD}R_{Bx} + R_{Cy}R_{yD}R_{Ax} + R_{Bx}R_{yD}R_{Ax} + R_{xy}R_{yD}R_{Bx} + R_{xy}R_{yD}R_{Ax}} \\
 I_C &= \frac{-(R_{Bx}R_{yD})V_A - (R_{yD}R_{Ax})V_B - (R_{Bx}R_{Ax} + R_{yD}R_{Ax} + R_{xy}R_{Ax} + R_{xy}R_{Bx} + R_{Bx}R_{yD})V_C}{R_{Cy}R_{Bx}R_{Ax} + R_{Cy}R_{xy}R_{Bx} + R_{Cy}R_{xy}R_{Ax} + R_{Cy}R_{yD}R_{Bx} + R_{Cy}R_{yD}R_{Ax} + R_{Bx}R_{yD}R_{Ax} + R_{xy}R_{yD}R_{Bx} + R_{xy}R_{yD}R_{Ax}} \quad (5)
 \end{aligned}$$

$v_{eof}$ (C) (mm sec <sup>-1</sup> )	0	-0.03

given here applies to the situation in which the liquid conductivity and the zeta potential are both uniform throughout the channel network. Mixing of reagent solutions, which possess different conductivities and/or different zeta potentials, with the channel walls will produce moving channel zones with non-uniform properties and EOF mobilities. Obviously, this situation requires a considerably more complex analysis. Last, the simplified analysis presented here, although sufficient to illustrate the main features of flow control, takes no account of flow inertial effects and the non-uniformity of the electrical field around channel junctions. At a microscopic level, the effects cause complex local flow patterns in these regions, which can be modeled using sophisticated fluid dynamics software.<sup>[33–38]</sup>

In addition to its use in determining the required electrokinetic flow control parameters, in situ monitoring of electrical currents in channel networks provides useful diagnostic information on micro reactor operation. First, the observation of a current dropping to zero in a branch of the channel network can indicate the position of a channel blockage. Second, application of an excessive voltage across a channel network can cause electrochemical reactions, which may result in the release of gas bubbles. Electrolysis occurs in micro reactors when the overall voltage difference between an electrode pair (typically several hundred volts) is sufficiently high or the electrical resistance of the relevant channel section is low such that the voltage change across an electrode / solution interface (typically a fraction of a volt) exceeds the redox potential required for an electrochemical reaction. Last, for chemical reactions, which result in a change of conductivity of the solution, in situ current monitoring can, in principle, be exploited to monitor the extent of a reaction within the channel network.

Except for unimolecular reactions, two or more reactant solutions must be mixed as a necessary first step to achieving reaction. Two main modes of mixing are possible which have very different characteristics. The first mode, denoted “diffusive mixing,” is illustrated in Fig. 11 which shows the 3-D concentration profile resulting when a dye solution (entering from the left channel) is combined with solvent entering from the right-hand channel of a T-junction. The two solutions flow together down the leg of the T. For typical EOF conditions, the linear fluid velocities are of the order of 0.1–1 mm sec<sup>-1</sup>. The Reynolds number  $R_e$  (equal to  $D_e v \rho / \eta$  where  $D_e$  is the effective channel diameter,  $v$  is the velocity,  $\rho$  is the liquid density, and  $\eta$  is the liquid viscosity) for such flow is  $< 10$ , well below the transition from laminar to turbulent flow,

**Fig. 11** 3-D plot of dye concentration vs. position within a T-junction. The dye solution enters from the left and is combined with solvent entering from the right. The flow velocity down the “leg” of the T is 0.48 mm sec<sup>-1</sup>. Detailed analysis of the diffusional broadening of the dye–solvent interface seen as the laminar streams move down the channel (corresponding to different times after contact) yields the diffusion coefficient of the dye ( $4.0 \times 10^{-10}$  m<sup>2</sup> sec<sup>-1</sup> in this example).

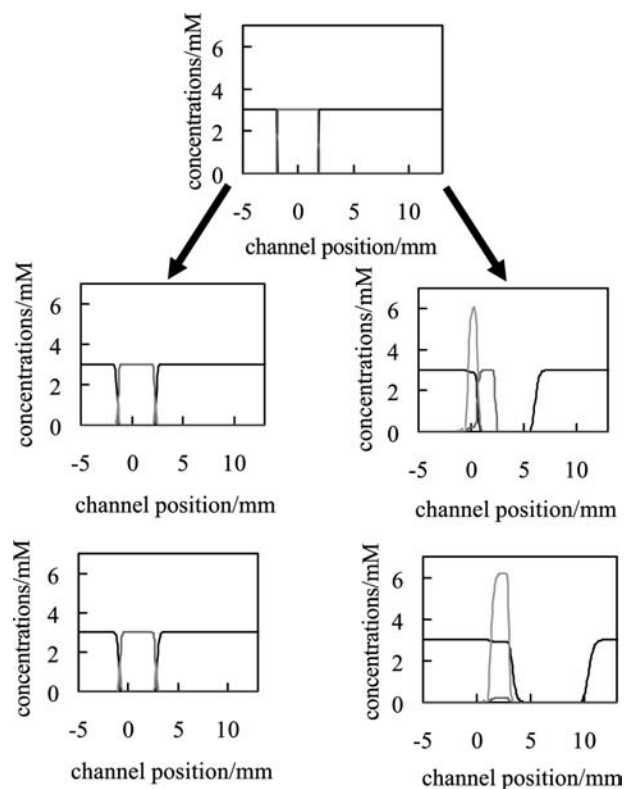

which occurs at  $R_e$  values of around 2500. The co-flowing reagent streams therefore retain their laminar flow pattern and mixing occurs only by interdiffusion. From the 3-D concentration plot of the dye, it can be seen that only a small extent of diffusional mixing occurs in the time between the first contact of the solution streams flow to a position corresponding to the bottom edge of the image. For the flow velocity used ( $0.48 \text{ mm sec}^{-1}$ ), this time corresponds to approximately 2 sec. In this mode of mixing, at very long times, the reagent concentrations are diluted by a ratio equal to the ratio of the flow rates of the incoming streams. A crude estimate of the time required for mixing across the complete width of the channel ( $w$ ) is given by  $t \approx 5w^2/D$ , where  $D$  is the diffusion coefficient of the solute species. For a typical channel width of  $100 \mu\text{m}$  and a value of  $D$  of  $5 \times 10^{-10} \text{ m}^2 \text{ sec}^{-1}$ , this time is of the order of 100 sec. It can be seen that the mixing of two streams flowing at  $1 \text{ mm sec}^{-1}$  in a typical channel length of a few centimeters will normally be very incomplete. Imaging of the diffusive broadening of the concentration gradient perpendicular to the laminar-flowing streams at different times has, in fact, been used to determine diffusion coefficients of absorbing or fluorescent species.<sup>[32,39]</sup>

Complete mixing by diffusion can be achieved by using slow (or stopped) flow to increase the contact time. Alternatively, faster flow or smaller channel cross sections, within long channels (generally folded to reduce overall device size), will achieve the same result. Elegant designs of networks containing cascades of T-junctions connected by suitably long, tortuous channels have produced output channels giving simultaneously a series of fully mixed dilutions of the original input solution<sup>[40,41]</sup> or concentration gradients of complex shapes.<sup>[42]</sup> This type of multiple outputs is useful when using a micro reactor to determine, for example, a calibration plot of detector signal vs. the concentration of an analyte species. The fact that the laminar flows of reagent streams interdiffuse only relatively slowly has been exploited by using chemically reactive reagent streams. Reactions between appropriate reagents at the interface between laminar, co-flowing streams of the reactants have been used, for example, to deposit very thin lines of metals (plus a range of other species) at the channel base as a novel means of fabricating “nanowires” in specified locations.<sup>[43]</sup>

The second mode of mixing, “slug injection,” is illustrated in Fig. 7. Using a pair of offset T-junctions and the “flow–inject–flow” sequence described earlier, a slug of one reagent is produced within a flowing stream of a second reagent. We illustrate the main features of this mode by considering the behavior of a slug of a reagent X in a flowing stream of a reagent Y where X and Y can chemically react to give product Z. We consider the situation where the reactant concentrations and the reaction rate constant are such that chemical

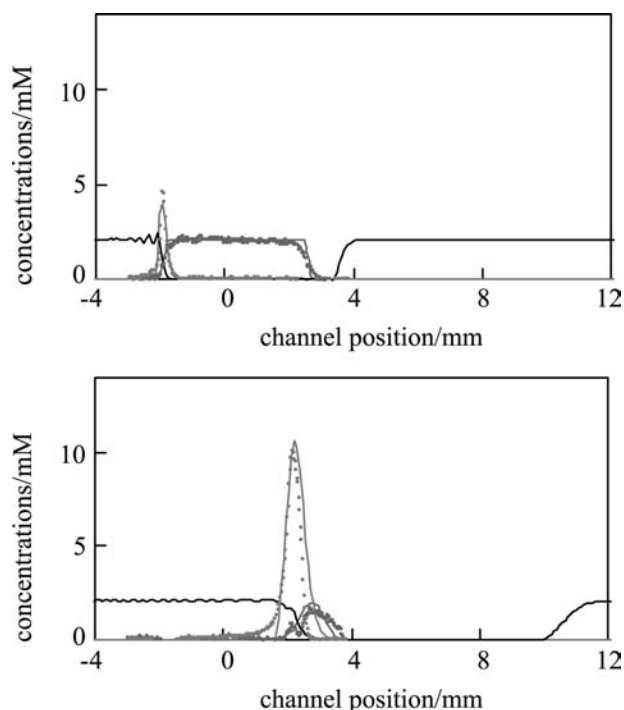

reaction occurs fast; that is, virtually immediately, the reagents are locally mixed in a particular channel section. Using the simulation procedure described in Ref.<sup>[30]</sup>, we are able to calculate the concentrations of all the species X, Y, and Z as a function of the distance along the flow channel length for different times after the production of the initial rectangular slug of X in the stream of Y. Input variables include the initial concentrations of X, Y, and Z, the forward and reverse rate constants for the reaction  $X + Y \rightleftharpoons Z$ , the EOF velocity, and the electrophoretic velocities of X, Y, and Z. The first simulation (Fig. 12) shows a series of time snapshots for the situation in which the electrophoretic velocities of X, Y, and Z are all zero (corresponding to these species all being uncharged). In this case, all species move with velocities equal to  $v_{\text{eof}}$  and mixing (and hence reaction) occurs only by interdiffusion at the leading and trailing edges of the slug of X. For the wide slug and the short time shown, the interdiffusion and therefore

**Fig. 12** Time snapshots at 0, 10, and 20 sec of the concentration profiles of reactants X (red) and Y (black) and product Z (blue). The top plot shows the initial configuration of a rectangular slug of X in a stream of Y, centered at channel position = 0. The left-hand plots correspond to  $v_{\text{eof}} = 0.05 \text{ mm sec}^{-1}$  with  $v_{\text{ph}}$  of all species = 0 (diffusive mixing only). The right-hand plots correspond to  $v_{\text{eof}} = 0.05 \text{ mm sec}^{-1}$  and  $v_{\text{ph}}$  (X) = 0,  $v_{\text{ph}}$  (Y) =  $0.76 \text{ mm sec}^{-1}$ , and  $v_{\text{ph}}$  (Z) =  $0.23 \text{ mm sec}^{-1}$ . In this case, mixing of X and Y occurs mainly as a result of the different electrophoretic velocities.

the extent of the reaction are low. The time for diffusive mixing across the slug (approximately  $5w_s^2/D$ , where  $w_s$  is the slug width) can be made shorter by reducing the slug width. To maximize the conversion to products in this mixing mode, a series of many narrow slugs are therefore more effective than a single, broad slug. Elegant methods to achieve very narrow slug widths have been described.<sup>[35]</sup>

In the second simulation shown in Fig. 12,  $v_{ph}$  for X is set to zero, but  $v_{ph}$  for Y and Z are set to positive values corresponding to these species bearing positive charges. Y now moves slowly with a velocity  $v_{eof}$ , whereas X moves faster with a velocity  $v_{eof} + v_{ph}$ . In this situation, the slug of X becomes displaced relative to the concentration “gap” in Y and mixing of X and Y therefore occurs relatively rapidly as a result of the different electrophoretic mobilities of the two species and results in reaction at the trailing edge of the slug of X. It should be noted that, in contrast to the “diffusive mixing” mode discussed above, mixing by differential electrophoretic mobilities does not result in dilution of the localized reagent concentrations. Fig. 13 shows the experimental realization of this type of mixing and reaction. A slug of the uncharged ligand,

**Fig. 13** Comparison of simulated (solid lines) and measured (data points) concentration profiles for the reaction between  $Ni^{2+}$  ions (black) and a slug of the ligand PADA (red) to form the  $NiPADA^{2+}$  complex (blue) at the trailing edge of the PADA slug. Concentration profiles of the coloured PADA and complex species were determined by analysis of digitized video images. The concentration profiles correspond to 10 sec (upper plot) and 70 sec (lower plot) after PADA slug injection.

pyridine-azo-dimethylaniline (PADA), is injected into a flowing stream of  $Ni^{2+}$  ions. As seen in the measured concentration profiles along the channel length, fast complexation to form the  $NiPADA^{2+}$  complex occurs at the trailing edge of the PADA slug and can be successfully modeled using the kinetic rate parameters measured for the forward (complexation) and reverse (complex dissociation) reactions.<sup>[32]</sup>

Following the time sequence shown in Fig. 13, it is possible to reverse the flow, which moves the  $NiPADA^{2+}$  complex product peak back into the concentration “gap” of  $Ni^{2+}$ . Because the complex formation reaction is reversible, the complex dissociates via the back reaction into PADA and  $Ni^{2+}$ . This example, using a mechanistically very simple reaction, demonstrates how micro reactors can be used to realize an extra dimension of spatial and temporal control of reactions, which is unachievable in bulk solution reactors where all concentrations are uniform.

## REACTIONS PERFORMED IN MICRO REACTORS

To date, most reactions that have been performed in micro reactors have been conducted simply to demonstrate that it is possible to perform reactions within such devices. A summary of the reactions that have been performed in micro reactors is presented in Table 2, and many of these are reviewed in detail in Refs.<sup>[44]</sup> and <sup>[45]</sup>. The following section reviews some reactions that have been performed within micro reactor systems that have demonstrated interesting results.

Skelton et al. have reported the application of micro reactors for the Wittig reaction<sup>[66,67]</sup> where they prepared *cis*- and *trans*-nitrostilbene esters **1** and **2** (Scheme 1). A number of features such as stoichiometry and stereochemistry were investigated in the micro reactor environment. When two equivalents of the aldehyde **3** to the phosphonium salt **4** were used in the reaction, a conversion of 70% was achieved. The micro reactor demonstrated an increase in reaction efficiency of 10% over the traditional batch synthesis. The reaction stoichiometry was subsequently reduced to 1:1, but using continuous flow of reagents, as above, the conversion was poor (39%). The conversion was increased to 59% using an injection technique, where slugs of the phosphonium salt **4** were injected into a continuous flow of the aldehyde **3**.

The research was extended to investigate the stereochemistry of the reaction. The ratio of isomers **1** and **2** was controlled by altering the voltages applied to the reagent reservoirs within the device, which, in turn, affected the EOF and electrophoretic velocities of the reagents. The variation in the external voltage subsequently altered the relative reagent concentrations within the device, producing *Z/E* ratios in the region

0.57 to 5.21. In comparison, the authors report that when a traditional batch synthesis was performed based on the same reaction time, concentration, solvent, and stoichiometry, a *Z/E* ratio of approximately 3:1 was observed. This demonstrated that significant control was possible in a micro reactor compared with batch reactions. The authors also demonstrated that micro reactors could be used for the rapid reaction development and optimization, based on analog chemistry, by using other aldehydes in the reaction.<sup>[66,67]</sup>

Carbanion chemistry is one of the most common methods of C–C bond formation used in the pharmaceutical

industry. Wiles et al.<sup>[68]</sup> reported the preparation of the enolates from a series of 1,3-diketones using an organic base and their subsequent reaction with a variety of Michael acceptors such as **5** to afford 1,4-addition products within a micro reactor (Scheme 2).

When using a continuous flow of the reagents **5** and **6**, 15% conversion to the adduct **8** was observed, compared with 56% when the diketone **7** was reacted with **5** forming the Michael adduct **9**. The authors, however, demonstrated enhancements in conversions through the application of the stopped flow technique. This procedure involved the mobilization of reagents through the device for a designated period of time, using an applied field, and the flow was subsequently paused by the removal of the applied field, prior to reapplying the field. Using the regime of 2.5 sec on and 5 sec off, the conversion to the product **8** was improved to 34%, while lengthening the stopped flow period to 10 sec resulted in a further increase to 100%. This was compared with the preparation of **9**, in which the regime of 2.5 sec on and 5 sec off resulted in an increase in conversion to 95%. This demonstrated that the enolate of 2,4-pentanedione **7** was more reactive than the corresponding enolate of benzoyl acetone **6**. The authors propose that the observed increase in conversion, when using the technique of stopped flow, was a result of an effective increase in residence time within the device corresponding to the different kinetics associated with these reactions. This approach is clearly relevant to those wishing to study the kinetics of such reactions, and the results demonstrate the ease with which reactions may be optimized in micro reactors when conducting combinatorial synthesis.

Although the previous result demonstrates the ease with which reaction conditions may be optimized, it is still sometimes necessary to heat reactions to achieve high yields of products. Industrially, special equipment is required when performing large-scale reactions at elevated temperature. However, Fernandez-Suarez, Wong,

**Scheme 1**

Warrington<sup>[69]</sup> have demonstrated the synthesis of a series of 2-aminothiazoles using a Hantzsch synthesis within a micro reactor. During the experiments, the T-shaped micro reactor was heated to 70°C using a Peltier heater, which was aligned with the channels, and the heat generated by the device was applied to the base of the micro reactor. Reaction of  $\alpha$ -bromoketones such as **10** with a thiourea derivative such as **11**, using NMP as solvent, resulted in the preparation of the aminothiazoles **12** in up to 85% conversion (Scheme 3).

Nitration reactions in organic synthesis are problematic because of the use of excess quantities of concentrated nitric and sulfuric acids. The reactions are extremely exothermic and it is hence difficult to control the temperature of such reactions when performed on a large scale. As a result, micro reactors have a considerable attraction for these reactions because the reactor enables excellent temperature control of the reaction. Doku et al.<sup>[70]</sup> have reported the nitration of benzene **13** in a borosilicate glass micro reactor. The benzene was mobilized by electroosmotic flow as a microemulsion using the surfactant sodium dodecyl sulfate (SDS). The nitronium ions, which were produced in

situ by mixing sulfuric and nitric acids, underwent electrophoretic-induced mobility. A co-solvent, butan-1-ol, was used to enhance the solubility of the benzene in the aqueous system. The authors report that mononitration occurs in 65% conversion to give nitrobenzene **14** (Scheme 4) and that approximately 8% of 1,3-dinitrobenzene **15** and 5% of 1,3,5-trinitrobenzene **16** were obtained. Importantly, Doku et al. demonstrated that it is possible to mobilize a nonpolar liquid, such as benzene, using EOF by dissolving it in a microemulsion.

Lu, Schmidt, and Jenson<sup>[71]</sup> have reported a photochemical reaction within a micro reactor. The reactor was fabricated by bonding a patterned silicon wafer to a quartz wafer, the advantage of this fabrication technique being that the quartz substrate allows reaction and detection using UV light of lower wavelengths than permitted by Pyrex substrates. The authors investigated the pinacol formation reaction of benzophenone **17** in propan-2-ol (Scheme 5). The reaction is known to follow a radical reaction pathway, and it is reported that the longer the residence time of the reaction, the greater the conversion to benzopinacol **18**. The authors report that there

Scheme 2

Scheme 3

Scheme 4

Scheme 5

Scheme 6

was no detectable product formation for flow rates  $> 10 \mu\text{l min}^{-1}$ . With reduced flow rates, having larger residence times, the conversion improves because the amount of light absorbed increases, and there is therefore sufficient time for the excited species to diffuse and react with the benzophenone. The authors report conversions of up to 60% when using flow rates of  $4 \mu\text{l min}^{-1}$ .

Greenway et al.<sup>[72]</sup> have demonstrated the Suzuki reaction within a micro reactor device using an immobilized heterogeneous catalysis where 1.8% palladium on silica was placed in the central channel of the micro reactor. The catalyst was immobilized between microporous silica frits prepared from potassium silicate and formamide. The micro reactor was optimized using flow injection analysis principles, producing a conversion of 67% of cyanobiphenyl **19** at room temperature. The flow injection method adopted allowed the periodic injection of the aryl halide **20** into a continuous flow of the phenylboronic acid **21** (Scheme 6). Traditionally, tetrahydrofuran (THF) is used as the solvent in this reaction. As has been found with many organic solvents, however, THF has very low natural EOF properties, and for this reason, it was mixed with water (75:25). The conversions obtained were comparable with Suzuki reactions carried out on a batch scale using homogeneous catalysis. Importantly, there were negligible levels of the palladium catalyst in the product, which was demonstrated using inductively coupled-mass spectrometry (ICP-MS), thus illustrating that the catalyst was not leaching from the reactor.

One of the interesting observations of the reaction was that, unlike conventional Suzuki reactions, an additional base was not required. Although the exact reason for this is not clear, it is postulated that the electric field may be sufficient to cause ionization of the water at the metal surface. Possibly the hydroxide formed in this way may be sufficient to perform the function of the conventional organic or inorganic base. Alternatively, a more basic environment may be formed at the surface of the micro reactor.

The use of elemental fluorine in organic synthesis is problematic because of the difficulties associated with the safe handling of gaseous fluorine.<sup>[73,74]</sup> In addition, fluorination reactions are generally extremely exothermic and it is difficult to control the temperature of such reactions when performed on a large scale. Microreactors have a considerable attraction for direct fluorination processes because there is only a small amount of fluorine in the reactor at any given time. In addition, the micro reactor enables excellent thermal dissipation and temperature control of the reaction as well as an opportunity for scale up by the simultaneous use of many such reactors.

Chambers and Spink<sup>[75]</sup> and Chambers et al.<sup>[76]</sup> have reported the use of micro reactors for the fluorination and perfluorination of organic compounds using elemental fluorine. A nickel or copper micro reactor was used for the investigation, and the liquid reactants and solvents were introduced into the reaction chamber via a syringe using a syringe pump. Fluorine, in a nitrogen carrier gas, was introduced from a cylinder using a mass-flow controller. The liquid-gas mixing proceeded via "cylindrical flow," where the liquid forms an outer cylinder coating the reactor surface with the gas flowing through the center. This flow regime has enormous benefits in that it provides very large surface-to-volume ratios for the liquid phase, producing a very efficient reaction over a short distance. The products were trapped in a tube, which was cooled with either a salt/ice bath ( $0^\circ\text{C}$ ) or an acetone/carbon dioxide bath ( $-78^\circ\text{C}$ ). The fluorination of  $\beta$ -dicarbonyl compounds proceeded with a high efficiency using 10% fluorine in nitrogen at  $5^\circ\text{C}$  and with formic acid as the solvent. Ethyl acetoacetate **22** was fluorinated in 99% conversion to give ethyl 2-fluoroacetoacetate **23**, while ethyl 2-chloroacetoacetate **24** was fluorinated in 90% conversion, yielding ethyl 2-chloro-2-fluoroacetoacetate **25** (Scheme 7). Importantly, under these conditions, no perfluorination of the substrates was observed, with only the

Scheme 7

monofluorinated derivatives being isolated. The authors report that the bulk fluorination of ethyl 2-chloroacetate **24** gives only a low conversion to **25**,<sup>[77]</sup> illustrating that the flow system is more efficient. This illustrates the catalytic effect of the fluorinated metal surface.

Watts et al.<sup>[78,79]</sup> have recently demonstrated the first example of a multistep synthesis in a micro reactor where they have used their devices in peptide synthesis. Reaction of pentafluorophenyl ester **26** with amine **27** formed dipeptide **28**, which was reacted with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to effect Fmoc deprotection. The amine **29** was then reacted in situ with another equivalent of pentafluorophenyl ester **26** to prepare tripeptide **30** in 30% overall conversion (Scheme 8). The approach clearly demonstrates that intermediates may be generated in situ and used in subsequent reactions enabling the combinatorial synthesis of peptides, which are of biological and pharmaceutical interest.

Having demonstrated that peptide bonds could be successfully formed when using a micro reactor, the authors then investigated racemization in peptides derived from  $\alpha$ -amino acids.<sup>[80]</sup> Reaction of the pentafluorophenyl ester of *R*-2-phenylbutyric acid **31**, at 0.1 M concentration, with  $\alpha$ -methylbenzylamine **32**, gave the product **33** in quantitative conversion with

Scheme 9

4.2% racemization (Scheme 9). Importantly, there was less racemization than observed in the batch reaction at the same concentration and temperature. The reduced level of racemization was attributed to the reduced reaction times observed within the micro reactors. This demonstrates that there would be real advantages to performing the combinatorial chemistry in microfluidic reactors compared with traditional batch systems.

## CONCLUSION

Micro reactor chemistry currently shows great promise as a novel method on which to build new chemical technology and processes in which the reactions generally produce the desired product in higher yield and purity in shorter periods of time. The technology is still in its early development, but some early trends are clear. One of the immediate and obvious applications is in combinatorial chemistry and drug discovery, where the generation of compounds with different reagents or under variable conditions is an essential factor. Perhaps more intriguing, micro reactors may bring new approaches to reaction chemistry and these possibilities are only now emerging. For example, extending the heterogeneous catalyst work already described, one can see how immobilized or supported reagents could be placed within a device to impart functionality to a reaction while maintaining spatial and temporal control. A microchannel system may provide a potential separation column and integration of a micro reactor device to one of the many highly sensitive microchannel-based biological assay systems and may also address some of the pharmaceutical

Scheme 8

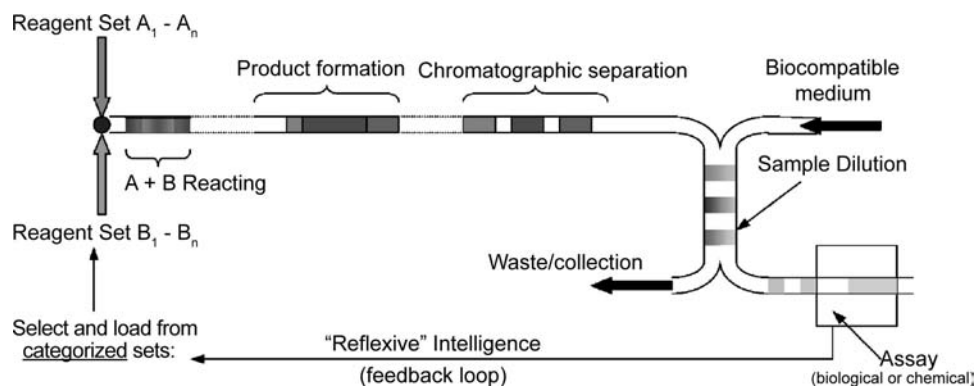

Fig. 14 Integration of a micro reactor with a bioassay system.

industries' potential requirements. Apart from the greatly reduced reaction times demonstrated for the micro reactors, handling times to assay and chemical reagent costs may be virtually eliminated. This paradigm is shown diagrammatically in Fig. 14.

Reactions within the micro reactors are found to be more atom-efficient, which is of significant environmental importance as this reduces the quantities of raw materials required and minimizes waste. Furthermore, the technology allows the temperature of reactions to be controlled, enabling reactions to be conducted safely, where explosion may be observed if the reaction was conducted on a batch scale.

The use of solvent for purification of products is often the largest contributor to waste in a chemical

process. Research is currently underway to investigate the purification of chemicals within the micro reactors by exploiting the electrophoretic mobility of the chemical species, which would not require any solvent to be moved within the reactor.

In terms of Green Chemistry, micro reactors offer considerable potential in performing safer and more efficient chemical reactions by the use of novel methodologies such as solvent-free mixing, in situ reagent generation, and integrated separation techniques. The capability of producing a parallel network of micro reactors, the so called "scaling out" of the process, offers a clear route to generating product volume, as shown schematically in Fig. 15. Furthermore, this methodology would enable chemicals to be prepared

# Langmuir-Blodgett Films

Ursula Mazur

*Department of Chemistry and Materials Science, Washington State University,  
Pullman, Washington, U.S.A.*

## INTRODUCTION

Very often thin organic films, such as Langmuir-Blodgett (LB) films, are designed for chemical, optical, electrical, or magnetic applications. The Langmuir-Blodgett technique is a unique methodology for building up nanoscale supermolecular assemblies from designed organic molecules under fully controlled processes involving intermolecular interactions at the air-liquid interface. With three different vertical film withdrawing protocols (X, Y, and Z), a horizontal film lift option, and an alternating layer buildup capability, a great variety of supermolecular structures can be assembled.<sup>[1-3]</sup> These diverse architectural strategies provide an elegant and efficient way to fabricate molecular electronic devices. It has been well demonstrated that the optical, electronic, and magnetic properties of LB based nanoscale devices are highly dependent on the relative orientation and distance of the molecules from each other.<sup>[4-6]</sup> Furthermore, reliable operation of these devices requires quantitative control over the nanomechanical and nanotribological properties of the molecular structures that comprise them. Structural and chemical characterization can be carried out using established techniques (AFM, STM, XPS, Surface Enhanced Raman, and FTIR), and processing conditions can be well characterized. Commercial indentation instrumentation and scanning probe microscopy techniques have been shown to be an effective means for nanomechanical characterization of submicron thick organic films. One critical component of testing the mechanical properties of thin film systems is the relationship between the structure and the chemistry of the film. Measuring and quantifying the mechanical properties to close the feedback loop in the ability to tailor nanoscale supermolecular organic LB assemblies with specific properties has been an active area of research within during the last few years. The systems of interest include those with highly ordered films with non-covalent  $\pi$ - $\pi$  interaction (e.g., phthalocyanines and thiophenes), those with van der Waals interactions between paraffinic chains, and systems driven primarily by H-bonding and polar interaction.<sup>[7-10]</sup> These all have potential use in molecular electronics.<sup>[11,12]</sup> This report summarizes some of the

recent work on the surface properties and nanomechanical behavior of well-organized Langmuir-Blodgett layers. The nanomechanical properties of well-organized LB systems will be discussed in terms of their relationship to the physical structure and the chemistry of monolayer and multilayer films.

## FABRICATION OF LANGMUIR-BLODGETT FILMS

Langmuir films are (most often) mechanically assembled 2-D arrays of molecules upon the surface of a liquid. Once the molecules are compressed to the desired organization, the monolayer film can be transferred on to a solid support. Film characteristics, such as thickness and molecular arrangement can be controlled at the molecular level with the LB deposition method. There are numerous excellent review articles as well as books that provide comprehensive information about the field of LB monolayers and multilayers.<sup>[1-3,13-16]</sup>

Langmuir and LB films are generally composed of amphiphilic molecules containing both hydrophobic and hydrophilic moieties, as in the fatty acids. A monolayer of insoluble amphiphiles at the air/liquid interface is referred to as a Langmuir monolayer. Films of Langmuir monolayers transferred onto a solid substrate are known as Langmuir-Blodgett films; they can be single or multiple layers.

To fabricate a Langmuir monolayer one needs a trough with movable barriers that can glide over the surface of the subphase (water, mercury, hydrocarbons, and alcohols) and an electrobalance (Wilhelmy balance) that measures surface tension. In addition to temperature control, the aqueous subphase can be monitored for pH and ionic content. Molecules of interest are dissolved in a volatile organic solvent (chloroform, benzene, or hexane) and placed on the surface of the subphase. Since the number of molecules spread on the surface is a known quantity the monolayer area can and is generally expressed as area per molecule. The physical state of the monolayer on the water is monitored by measuring the surface pressure,  $\Pi$ , defined as the difference between the surface tension

of the monolayer and that of the bare subphase. A measurement of the surface pressure as a function of molecular area at constant temperature is the standard thermodynamic measurement made on Langmuir monolayers known as a  $\Pi$ - $A$  isotherm. As an example of such an isotherm for a long-chain fatty acid is depicted in Fig. 1.<sup>[17]</sup> Thermodynamic phase transitions of the 2-D monolayer system are signaled by changes in the slope of the curve which correspond to the gas, liquid, and solid phases analogous to phase changes in 3-D systems. With increasing surface pressure the 2-D crystalline film will eventually collapse, either sliding over upon itself or folding under into the subphase. By extrapolating the steepest part of the curve to zero pressure, just prior to film collapse, one can estimate of the cross sectional area per molecule. This is known as the Pockel's point.

The processing of the Langmuir monolayers involves the judicious selection of a solid support. Typical solid supports include mica, glass, silicon, and quartz. The choice of substrate is expected to play at least three significant roles in the overall film properties. It will affect the electrical and optical properties (e.g., the surface plasmons of a conducting substrate can have a pronounced effect on the lifetime of excited states). It will strongly influence the overall uniformity and quality of the LB film (through differences in adsorption energy and the presence of specific interactions with the substrate surface). The choice of substrate can significantly affect the nanomechanical properties of the films.<sup>[18-20]</sup>

Transferring the Langmuir monolayers from the water-air interface onto a solid substrate to form Langmuir-Blodgett layers can be accomplished with

**Fig. 1** Spreading pressure vs. area of cadmium stearate acquired on a water subphase at pH 3.5 and 20°C.

two different trough set-ups: the Langmuir-Blodgett and the Langmuir-Schaefer methods, Fig. 2. The Langmuir-Blodgett trough facilitates three different vertical film withdrawing procedures. These protocols in turn yield different film architectures. Y-type multilayers (alternating upstroke and down stroke) are commonly prepared from long carbon chain amphiphiles. The head-head and tail-tail interactions lead to the stability and strength of the film. X-type (down stroke only) and Z-type (upstroke only) deposition can be applied to the build up of films composed of molecules that are weakly hydrophilic or non-polar. Both X and Z category films are non-centrosymmetric and, therefore, important for non-linear optical and pyroelectric applications.

Another way of building LB structures is to horizontally lift the Langmuir layers onto a substrate; this is the Langmuir-Schaefer method. In this method, a flat substrate is placed horizontally on a compressed Langmuir layer at the air-water interface. When the substrate is lifted the monolayer is transferred onto the solid support. The Langmuir-Schaefer method is especially useful for depositing very rigid high viscosity films.

The molecular building blocks used for fabricating LB monolayers and multilayers range from simple paraffinic amphiphiles,<sup>[1,21]</sup> to complex aromatics,<sup>[4,5]</sup> biomolecules,<sup>[4,22]</sup> transition metal complexes,<sup>[23,24]</sup> and hybrid organic-inorganic systems.<sup>[23,25-27]</sup> The intra and interlayer architecture of the films can be further diversified by combining different classes of molecules together during the processing of a Langmuir layer or by altering layer by layer film composition. The LB structural designs rely for the

**Fig. 2** Langmuir-Blodgett (A) and Langmuir-Schaefer and (B) film withdrawal methods.

most part on intermolecular forces, such as van der Waals attraction, ionic and hydrogen bonding,  $\pi$ - $\pi$  interaction, and entropic effects. It is also possible to change the nature of the LB molecular interactions by post deposition treatments of the layers such as annealing or irradiation.<sup>[28]</sup> Thus, the LB platform with its exceptional and varied capabilities of controlling the orientation and placement of molecules in monolayers has allowed researchers to engineer supermolecular condensed phases with unique optical, electronic, and magnetic properties. There exists an enormous body of literature on the fabrication of these types of materials. Several excellent general reviews are recommended.<sup>[1-5,7,13-16]</sup>

## STRUCTURAL CHARACTERIZATION OF LANGMUIR-BLODGETT FILMS

Nanomechanical properties of molecular films depend on their chemical and physical characteristics. Properties, such as chemical composition, molecular orientation and packing, film thickness and coverage, interlayer spacing, and surface morphology play critical roles in measuring and quantifying the elastic modulus, hardness, and adhesive strength of the molecular layers. Consequently, it is useful to first characterize the fabricated LB film as completely as possible prior to its mechanical testing. The ultimate goal of such an approach is of course to facilitate chemical tuning of the film's structure in order to optimize its mechanical properties. The chemical and structural characterization can be carried out using established techniques, such as X-ray diffraction, XPS, FTIR, Raman, solid state NMR, AFM, and STM. The application of all these and other spectroscopic and microscopic tools to the study of LB films is extensively described elsewhere.<sup>[1-5,7,13-16]</sup> What follows is a brief synopsis of the capabilities of some of the more routine methods for analyzing the molecular composition and structure of the films.

One of the earliest techniques employed in characterizing LB films was x-ray diffraction. This is a reliable technique for investigating concentration profiles, molecular organization, interlayer spacing, and film thickness.<sup>[13,29]</sup> Depths of micrometers can be probed depending on the material. Monolayer sensitivity can be obtained with synchrotron radiation. Grazing-incidence x-ray diffraction (GIXD) is a method for determining the arrangement of molecules within a floating Langmuir monolayer. This method can be applied to films transferred onto solid support, but this is more problematical because the substrates may not be as flat as the surface of water subphase.<sup>[13,29]</sup>

X-ray photoelectron spectroscopy, XPS, is an ultra high vacuum surface analytical technique that can

probe up to a few nanometers of depth and determine the elemental composition and homogeneity of the deposited LB films. In addition to distinguishing the elements in the sample, it is also possible to identify the chemical state of the elements present and their bonding environments.<sup>[30]</sup> The relative concentrations of the elements can be determined from the measured photoelectron intensities.<sup>[31]</sup>

Fourier Transform Infrared Spectroscopy, FTIR, is an essential tool for characterizing the chemical makeup of LB films: transmission, reflection absorption (RAIR), and attenuated total reflectance (ATR) spectroscopy are the most suitable sampling techniques. These methods are sensitive enough to study monolayer films and can also probe substrate adsorbate interfaces. In transmission mode the measured vibrational transitions and their intensities provide quantitative information about the chemical composition of the film.<sup>[1,2]</sup> In the RAIR and ATR modes quantitative estimates of the orientation of molecules within the LB layers relative to the substrate can also be obtained.<sup>[32-34]</sup> Raman spectroscopy is a complementary vibrational technique to infrared spectroscopy. This technique is not only used to identify chemical species, but can also be employed for characterizing the structural order, phase transitions, and strain states in both thin and thick films. Because Raman scattering is an intrinsically weak process, some enhancement mechanism is usually needed to study LB layers. An increase in the signal can usually be achieved by depositing films onto the surfaces of noble metals or by the interaction with surface plasmons (Surface Enhanced Raman Spectroscopy).<sup>[35,36]</sup> For materials with electronic transition in the visible light region, the resonance Raman effect can be used to enhance certain vibrational bands.<sup>[37,38]</sup>

Magic angle spinning (MAS) solid state NMR can yield both qualitative and quantitative identification of chemical species well as characterization of the local chemical bonding environments and conformations in ordered and disordered surface bound molecules.<sup>[39]</sup> This technique has not been extensively applied to the study of LB films largely because of sampling limitations.<sup>[40,41]</sup> LB films are typically deposited on low surface area substrates and consequently the number of nuclei per monolayer is not very high unless isotopic enrichment is employed.<sup>[39]</sup>

The use of Scanning Probe Microscopy, SPM, has become a routine surface analysis tool in LB research. The SPM techniques are unsurpassed as high resolution, 3-D profilometers. They can provide information about surface structure ranging from atomic resolution to surface morphology of about 100  $\mu\text{m}$ . Scanning Tunneling Microscopy, STM, records the overlap of the local electron density of states between the probe and the adsorbate molecules on a conducting

substrate. Consequently, STM can provide not only morphological information, but also spectroscopic data about HOMO and LUMO states of molecular systems.<sup>[42]</sup> Atomic Force Microscopy, AFM, and its variants (frictional force microscopy and magnetic force microscopy) do not require conducting substrates and can be used to image both soft and stiff samples. AFM measures the elastic response of the molecules to the force exerted by the scanning probe. Thus, it can provide direct images of surfaces and also be employed in measuring mechanical properties of molecular assemblies.<sup>[10,43,44]</sup>

### NANOMECHANICAL MEASUREMENTS OF LANGMUIR-BLODGETT FILMS

The most common quantitative method of measuring the mechanical properties of thin films is nanoindentation, followed closely by scanning probe microscopy techniques. Nanoindentation, also known as instrumented indentation, is depth-sensing indentation testing of materials in the submicron range. When used in conjunction with an atomic force microscope, in situ imaging of the nanoindentation deformation and cracking can be obtained. A dynamic indentation system (commonly referred to as continuous or dynamic stiffness testing, CSM), allows one to determine the properties of materials as a function of time and depth during a given indentation (Fig. 3). There are significant advantages to this type of test for studying organic systems.<sup>[45–47]</sup> The CSM technique makes the continuous measurement of mechanical properties of materials possible in one sample experiment without the need for discrete unloading cycles. The measurements of contact stiffness, elastic modulus, hardness, creep resistance, and fatigue properties can be made on nanometer thick films. Furthermore, CSM has a relatively small time constant that makes it especially useful for measuring the properties of polymeric materials, non-homogeneous materials, and layered films, where the microstructure and mechanical properties change with indentation depth.<sup>[45,47]</sup>

For organic films indented by a diamond tip the elastic modulus of the tip is much greater than the film being indented and the reduced modulus is considered to be a function of the elastic properties of the surface. The material hardness  $H$  is defined as the maximum load  $P_{\max}$  divided by the corresponding projected indentation area  $A_{\max}$ . The hardness values of the LB molecular layers are not expected to be the same as those of the corresponding bulk compounds. Further, the hardness of the multilayers will depend on the loading rate, the temperature of the material, and the substrate material.<sup>[18–20]</sup> Therefore, the hardness values

**Fig. 3** A typical load–displacement curve and the deformation pattern of an elastic–plastic sample during and after indentation:  $h_{\max}$  represents the displacement at the peak load,  $P_{\max}$ . The contact depth  $h_c$  is defined as the depth of the indenter in contact with the sample under load.  $S$  is the initial unloading contact stiffness. The elastic modulus of the indented sample can be inferred from the initial unloading contact stiffness,  $S = dP/dh$ , i.e., the slope of the initial portion of the unloading curve.

are usually considered to be “effective hardness” values that are related to the particular testing conditions. Elastic modulus and hardness values are estimated for indentation depths of less than 30% of the total film thickness in order to minimize the contributions from the substrate. Although nanoindentation testing has been performed on thick organic layers,<sup>[48–55]</sup> it has only recently been applied to LB films.<sup>[2]</sup> The application of frictional force mode in Scanning Force Microscopy (SFM) allows estimation and quantitative description of elasticity (or stiffness), hardness, adhesion, viscosity, and other properties of monolayer films.<sup>[11,56]</sup> Acquisition of data relating to these properties can often be performed simultaneously with topography imaging. The mechanical response of the sample is typically modeled using Hertzian mechanics, for the case of a spherical contact on a flat, infinitely thick plane. There are numerous reports of mechanical properties of LB monolayers studied by SFM.

LB films of derivitized metal phthalocyanines (MPc) are of interest because they exhibit the strong tendency to aggregate in columnar assemblies (through Pc–Pc ring  $\pi$ – $\pi$  interaction), many with discotic liquid crystalline properties. These systems are extremely likely candidates for molecular electronic and photonic applications.<sup>[57,58]</sup> Symmetrically substituted copper phthalocyanine complexes,  $\text{CuPc}(\text{OCH}_2\text{CH}_2\text{OBz})_8$ ,

CuPc(OCH<sub>2</sub>CH<sub>2</sub>OCH<sub>2</sub>CH=CHPh)<sub>8</sub>, and CuPc(OCH<sub>2</sub>-CH<sub>2</sub>CH=CHPh)<sub>8</sub> reported by Armstrong<sup>[8,32,59]</sup> and peripheral and non-peripheral, butoxy and octyloxy copper phthalocyanine, CuPc(OBu)<sub>8</sub>, and CuPc(OOC)<sub>8</sub>, studied by Mazur<sup>[10,43,44]</sup> make beautifully stable, stiff, and highly organized monolayer and bilayer LB films. All these molecules formed coherent and rigid Pc columns with the expected Pc-Pc macrocycle interactions and the added interactions between the terminal R groups (Fig. 4). RAIRS provided important insights into film order and the orientation of chromophores relative to the substrate.<sup>[8,10]</sup> The measured angle of incline relative to the substrate ranged from 15° to 30° and a twist angle from 30° to 40° was reported for pCuPc(OR)<sub>8</sub> LB discotic assemblies. Mazur et al. found that the mechanical properties of CuPc(OR)<sub>8</sub> LB films depended strongly on the level of organization of the phthalocyanine molecules within the layered structures.<sup>[10]</sup> Small tilt angles of the Pc rings optimized the  $\pi$ - $\pi$  interaction between the CuPc chromophores which formed highly stable rigid columns. With the increase in tilt angle associated with the introduction of non-peripheral substituents, the  $\pi$ - $\pi$  overlap was reduced and the rings began to twist to recover electronic stability. This molecular motion

produced strain in the cofacial arrangement, which lead to disorder within the columnar aggregates. Thus, significant softening and reduction in stiffness occurred in the LB layers (low values of modulus of elasticity), Fig. 5. The long C-8 paraffinic chains, also play a significant role in reinforcing the interlayer structure of the LB layers through interdigitation.<sup>[41]</sup> This interdigitation is indicated by solid state <sup>13</sup>C NMR of the multilayer CuPc(OR)<sub>8</sub> assemblies. The measured Young's modulus of the LB multilayers is between 83 and 63 GPa, with the greatest value for pCuPc(OBu)<sub>8</sub>, and the smallest for nCuPc(OOC)<sub>8</sub>. The hardness values for the three best elastomers are similar, averaging to approximately 0.57 GPa (Table 1). Both elasticity and hardness of CuPc(OR)<sub>8</sub> multilayers were comparable to those of metal surfaces such as Al, Mg, and Cu and were greater than for organic polymers such as polyethylene. This is a remarkable result because CuPc(OR)<sub>8</sub> films are molecular films that possess no intermolecular covalent bonds as in the case of polymers. An AFM topograph in Fig. 6 shows indented regions of a pCuPc(OBu)<sub>8</sub> 10 LB layers film on mica. This film actually fractures sequentially, monolayer by monolayer, without causing discontinuities in the underlying layers and illustrates the incredible

**Fig. 4** (A) A Langmuir-Blodgett pressure-area isotherm of CuPc(OCH<sub>2</sub>CH<sub>2</sub>OBz)<sub>8</sub> and a schematic of its structure; (B) 100 nm × 100 nm AFM (friction) image of a single bilayer the complex on Si(100) modified with silazanes showing an average column-column separation distance of  $d = \sim 27$  Å and a rms roughness along the top of each Pc column of  $\sim 6$  Å. Source: Reprinted with permission from American Chemical Society, © 2004 (see Ref.<sup>[8]</sup>).

**Fig. 5** AFM tapping mode  $5\ \mu\text{m} \times 5\ \mu\text{m}$  area images of 10 LB monolayers of (A) peripheral CuPc(OBu)<sub>8</sub> and (B) non-peripheral CuPc(OBu)<sub>8</sub> multilayers on hydrophilic mica substrate acquired in air. To the right of each AFM image is a corresponding load vs. depth curve for each of the films. The 10 LB layers of the peripherally substituted CuPc(OBu)<sub>8</sub> the indentation response is reversible with virtually no hysteresis at loads of  $30\ \mu\text{N}$  or less. This means that the film deforms elastically; this involves stretching, rather than breaking of the coherent columnar assemblies. Consequently, when the applied load is removed, the material reverts to its original undeformed condition cycle due to creep. The nanoindentation profile of the non-peripherally substituted CuPc(OBu)<sub>8</sub> multilayer indicates the indent probe has penetrated this material substantially deeper than the total film thickness of 10 LB layers ( $\sim 15\ \text{nm}$ ). The permanent deformation in this multilayer is likely due to contributions from plastic deformation involving permanent breaking of cofacial stacks, sample roughness, and variation in film stiffness near or at the surface. Localized deformation is less than the total thickness of the compliant coating ( $<30\%$ ) in order to eliminate the effects of the solid support.

rigidity of the pCuPc(OBu)<sub>8</sub> material which is an excellent candidate for deposition strategies such as mechanical stamping, allowing the rapid transfer of film sections to various substrates without the loss of order.<sup>[10]</sup>

Poly(3-alkylthiophene)s are excellent candidates for field-effect transistors (FET) because they exhibit good electrical and optical properties as well as good chemical stability. These molecules aggregate through a variety of modes including  $\pi$ - $\pi$  interaction between thiophene units that favors parallel stacking, van der Waals interactions between alkyl chains, and H-bonding and polar interactions.<sup>[11,60]</sup> Salmeron and coworkers studied the structural and mechanical

properties of Langmuir-Blodgett monolayer and multilayer films of heptathiophene-acetic acid on mica by atomic force microscopy (AFM) as a function of humidity, temperature, and applied force.<sup>[11,60]</sup> In the presence of coadsorbed water the film height was 2 nm when imaged at loads of a few nanonewtons (Fig. 7). This height was a fully stretched molecular conformation (2.1 nm tall), likely helped by hydrophobic interactions of the alkyl chains with the water sitting in the vicinity near the carboxyl and polar thiophene units. In the presence of coadsorbed water the molecules were oriented with the carboxylic acid group pointing toward the mica surface and the alkyl side chains exposed to the air interface. With increased

**Table 1** Young's modulus (as measured by indentation) and effective hardness for different thin film materials obtained from nanoindentation experiments

Molecule	Indentation based Young's modulus (GPa)	Hardness (GPa)
pCuPc(OBu) <sub>8</sub> (by AFM)	110 ± 15 (on mica)	
pCuPc(OBu) <sub>8</sub>	83 ± 5.0 (on W)	0.60 ± 0.03
pCuPc(OOc) <sub>8</sub>	71 ± 4.2 (on W)	0.60 ± 0.03
nCuPc(OOc) <sub>8</sub>	63 ± 5.7 (on W)	0.52 ± 0.02
W	411 (on glass)	3.4
Copper	130	0.6
Aluminum	70 (on Si)	0.4
Polyfluoroethylene	7.5	0.1
Magnesium	45	0.3
Polyethylene	3.0 ± 0.8	0.10 ± 0.03
Alpha-keratin fiber	3.0 ± 0.6	0.048 ± 0.01
Polyformaldehyde	2.9	0.21

All CuPc(OR)<sub>8</sub> films measured were ten monolayers thick. *Source:* Reprinted with permission from American Chemical Society, © 2004 (see Ref.<sup>[8]</sup>).

load, the film is compressed easily from an initial height of 2 to 1.2 nm (Fig. 6). After compression the films supported higher loads without loss of height due to the tilting of the alkyl segments. Annealing monolayers or multilayers resulted in film breakdown, which was irreversible above 100°C.

LB films of long chain paraffinic amphiphiles, their fluorinated derivatives, and polymer composites have potential applications as no-wear and low-friction

**Fig. 6** AFM tapping mode image of a surface following an AFM based indentation. The film is 10 LB layers of pCuPc(OBu)<sub>8</sub> on mica. The surface of the sample appears very smooth except for the defects induced by the silicon tip with a nominal load of 50 nN. The induced defect in the center has a depth of 14 nm with material expelled by the penetrating tip appearing as a pileup on the sides of the indent. Monolayers detach sequentially with increasing probe penetration.

lubricants. The alkyl chains in paraffinic acids tend to arrange themselves in a trans-trans fashion in LB layers resulting in highly homogeneous films. Tsukruk used SPM to study the dynamics of wear and reconstruction of LB monolayers of stearic acid under the shear forces.<sup>[61]</sup> Significant compression of the stearic acid monolayers was observed under the tip reaching 35% of initial thickness before producing fatal film damage. Film compression was related to the cooperative tilting of the alkyl chains due to formation of gauche conformers. The estimated Young's modulus ranged from 0.2 to 0.7 GPa for very small deformations (<3% of thickness). The elastic modulus decreased sharply to tens of megapascal with higher deformations.

Oishi performed AFM based mechanical studies of behenic acid, CH<sub>3</sub>(CH<sub>2</sub>)<sub>20</sub>COOH, monolayers on mica prepared at different temperatures.<sup>[43,44]</sup> The elastic modulus of the behenic acid monolayer fabricated at room temperature was 5.2 GPa. This value is close to that for the monolayers of stearic acid and cadmium stearate, 1–5 GPa, or for the LB film of cadmium arachidate, 21 GPa.<sup>[43,44]</sup> A monolayer of behenic acid fabricated at a lower subphase temperature deformed to either an elastic or a plastic state depending on the normal force, whereas at higher temperatures the monolayer is in a plastic state irrespective of normal force. This difference was attributed to the introduction of gauche conformation units into the alkyl chain. The normal force acting on the films was within the range of the activation energy (15–26 kJ/mol) required to create trans-gauche transformation of surface bound alkanes.

Salmeron investigated the structural, mechanical, and spectroscopic properties of highly ordered alkane thiol SAM and LB monolayers on quartz, mica and gold by SFG (sum frequency generation) and AFM.<sup>[62]</sup> He found that that under moderate pressures of a few tens of megapascal, the methyl end group of the alkane chains rotated to accommodate a terminal gauche distortion. The alkane chain, however, retained its upright close-packed structure with a lattice periodicity in registry with the substrate when ordered. At pressures above 0.1 GPa, changes in the form of collective molecular tilts take place that lower the height of the monolayer. Only certain angles of tilt are allowed because of the interlocking of methylene units in neighboring chains. The discrete angular tilts are accompanied by increases in friction. Upon removal of the load the molecules recovered to their original steric configuration. The author developed a model based on the van der Waals attractive energy between chains to explain the stability of the films and to estimate the cohesive energy changes during tilt for various paraffinic chain lengths. Their calculations indicated that stabilization effect of the van der Waal

**Fig. 7** AFM images of a freshly drawn LB film of  $\beta$ -substituted-T7 oligothiophene acquired at a 0-nN external load. (A) topographic image and (B) simultaneous acquired friction force image showing low friction over the film relative to the surrounding mica. To the right are graphs of height and friction vs. load of  $\beta$ -substituted-T7 islands. The height is  $2.0 \pm 0.1$  nm at small loads and decreases to a value around 1.2 nm when the load is above  $-15$  nN. This height decrease suggests a large tilt of the alkyl chains due to gauche distortions generated near the thiophene units. In the bottom graph the friction force on the  $\beta$ -substituted-T7 islands increases rapidly first and more slowly after the decrease in film height. The friction force curve obtained in the surrounding mica is shown for comparison. *Source:* Reprinted with permission from American Chemical Society, © 2005 (see Ref.<sup>[61]</sup>).

forces on the individual methylene chains saturates at about eight to ten carbon atoms.

Swalen measured dynamic friction and wear of tribological pairs of silicon substrates and ceramic sliders, both with oxidized surfaces coated with Langmuir-Blodgett (LB) monolayers and multilayers of cadmium arachidate. He showed that the most stable couple had one LB film on each surface and had wear rates up to five orders of magnitude lower than those of uncoated surfaces at contact pressures up to  $10^8$  N/m<sup>2</sup>.<sup>[55]</sup> In comparison with physisorbed, fully fluorinated lubricants of the same thickness, mechanical durability of orders of magnitude higher was observed with LB layers. Cong et al. used thermodynamic analysis of the LB  $\Pi$ -A isotherms combined with contact angle and pin-on-plate friction measurements to study partially fluorinated acid ethyl ester LB films.<sup>[63]</sup> It was found that the coefficient of friction for a single monolayer correlated well with film energy and modulus of elasticity. The frictional properties depended on film strength. They suggested that enhancing intermolecular forces may be an

effective way to improve lubricating properties of ultra-thin films.<sup>[63]</sup>

Overney et al. studied LB films with mixtures of fluorocarbons and hydrocarbons on the nanometer scale by AFM.<sup>[64]</sup> Local elastic compliance was measured simultaneously with topography and friction. On phase separated fluorocarbon domains, higher friction and lower Young's modulus was found than on isolated hydrocarbon domains. The authors used changes in cohesion of the LB film molecules to probe the effects of cohesion on the adhesive wear. It also has been demonstrated that variations in pH during LB film formation of these mixed fluorocarbon/hydrocarbon systems leads to variations in topography, elasticity, and friction (as measured by AFM).<sup>[18-20]</sup> On increasing pH, both the Young's modulus and the friction force are found to decrease. For films prepared at pH 4.5, the Young's modulus was measured as 0.4 GPa; at basic pH the elastic compliance of the monolayers was lowered to 0.2 GPa. The simultaneous influence of pH on morphology and density was directly observed. At low pH, both friction and

in-plane molecular density increased. This was attributed to molecular “roughness” resulting from incorporation of extraneous free acid molecules into the film. Interest in these mixed LB films continues, with recent efforts directed at determining the compression moduli.<sup>[65]</sup>

## CONCLUSION

Highly ordered LB films show great promise as supermolecular assemblies for molecular electronics applications. As the dimensions of molecular based devices shrink toward the nanometer scale a new approach is required for designing Langmuir-Blodgett films with predictable performance characteristics. In this approach, the mechanical properties of thin film systems need to be systematically evaluated in terms of their relationship to the physical structure and the chemistry of the film. Furthermore, generalized models for the interplay of structural, mechanical, and optical and electronic properties have to be developed. With these models, new LB thin film structures can be designed and fabricated with optimized optical, electronic, and magnetic properties and great strength and durability.

## ACKNOWLEDGMENTS

I would like to thank my students and collaborators, T. Oshiro, K. Stevenson, N. Miyashita, K. W. Hipps, D. F. Bahr, and J. Smieja for contribution to the research reported in this article. This work was supported in part by the National Sciences Foundation under grants CHE 0138409 and CHE 0234726.

## INTRODUCTION

The laser-based particle deposition (LBPD) technique is one of “direct-write” techniques that can be used for patterning nanoparticles into a variety of microstructures. If properly developed, LBPD may have wide application in manufacturing novel electronic, sensing, catalytic, and other devices that require specific structures, combinations of unlike materials, and unconventional substrates. The technique makes use of laser-induced optical forces to guide particles by a narrow laser beam from an atomizer source until depositing them on a substrate. One of the LBPD versions based on aperture guidance is reviewed in this entry.

The discussion covers both the fundamentals of both laser guidance and solid–liquid interactions during patterning, including recommendations for the best setups, as well as a more detailed description of optical and other forces exerted on particles inside the LBPD apparatus. Some examples of nanoparticle deposition and patterning are also presented.

## LASER-BASED PARTICLE DEPOSITION TECHNOLOGY

A wide range of techniques generally referred to as “direct-write technologies” have recently emerged in response to the needs for rapid prototyping of micro-patterns made of continuous phase or fine particles.<sup>[1]</sup> Technologies such as inkjet printing, micropen writing, plasma spray, laser particle guidance, and matrix-assisted pulsed-laser evaporation are capable of direct fabrication of microstructures on a variety of substrates using a wide range of materials. All of these approaches have the advantage of avoiding the need for masks and complicated lithographic technologies associated with microscale electronic device fabrication. These rapid prototyping techniques are often able to consolidate powder materials into three-dimensional structures.

Laser-based particle deposition technique is one of many such techniques under recent development that has a promising potential for the fabrication of electronics and sensors based on microvolume materials. The LBPD technique makes use of laser-induced optical forces to guide particles by a narrow laser beam until depositing them on a substrate. As described in Ref.<sup>[2]</sup>, LBPD has many advantages over existing patterning techniques. “...In contrast to photolithography, the process adds material to the surface (as opposed to etching material) and does not require harsh or corrosive chemicals. In contrast to robotic microspotting, deposition, inkjetting, and screenprinting, particles are strongly localized within the laser beam and the deposition accuracy can be below one micrometer. Most importantly, nearly any material in either liquid or aerosol suspension can be captured and deposited as long as convection and gravity are weaker than the guidance forces (typically in the nanonewton range).”

Additionally, LBPD allows one the fabrication of various porous structures of nanoparticles, which can serve, for example, as microsensors.<sup>[3]</sup> Although perfection in nanoparticle arrays is not required in such applications, achieving sufficient control over deposited micropatterns to manufacture porous microstructure is not a trivial task. There are only two promising techniques for such applications at present, inkjet writing and LBPD. Each of them has different merits and demerits, so that they rather complement each other being suitable for a different range of applications. Although both techniques can produce similar structures, the resolution of inkjet writing at present reaches only 10–20 μm; LBPD is not restricted either by solvent viscosity to the degree required by inkjet techniques. More importantly, LBPD is also temperature-flexible: When the transporting particles absorb laser light, the resulting heat, if required, can activate chemical reactions and/or phase transformations during and after deposition. At the same time, the laser-induced heat can also be rather low: Because of

high transporting velocities and such option as cooling carrier gas, both the droplet and substrate temperatures can be controlled allowing only moderate short-duration temperature increases. Because the LRPD-transported material is in the form of either liquid precursor or colloidal suspension atomized to micrometer-size droplets, the deposited particles can be of any size between several nanometers to about a micron. Finally, LRPD is capable of codepositing dissimilar materials offering a potential to fabricate both heterostructured and porous patterns that combine distinct electronic, organic, and biological materials using the same basic fabrication technology.

The LRPD technique, although still in its early stages of development, has been used to fabricate micron-scale structures from a wide variety of materials, such as metals (Au, Ag, In, Cu, Pt), semiconductors (Si), oxides (CuO, RuO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>), ferroelectrics (BaTiO<sub>3</sub>), ionic crystals (NaCl, KI), biological cells (neurons, others) on such various substrates as glass, alumina, silicon, sapphire, and various polymers.<sup>[2–8]</sup> In principle, LRPD allows depositing virtually any material that can be suspended in a liquid or formed by decomposition of a precursor. The primary restrictions on the LRPD technique are that the substrate is transparent to light at the laser frequency (to avoid substrate heating) and that the particles being deposited should not undergo unwanted reactions (e.g., decomposition) during transport in the laser beam.

Historically, it was Ashkin<sup>[9]</sup> who was the first to demonstrate the optical “levitation” that moved and

suspended micrometer-sized particles against gravity in a focused laser beam. Stable three-dimensional trapping of such particles in the minimum-waist region of a highly focused laser beam was demonstrated later.<sup>[10]</sup> These and other findings formed the basis of the so-called optical tweezers used in many applications.<sup>[11]</sup> Renn and Pastel<sup>[4,5]</sup> were the first to demonstrate laser guidance and trapping of mesoscale particles from suspensions and liquid droplets in hollow-core optical fibers. The obtained data gave rise to industrial applications of a laser-guided direct write of electronic and biological components.<sup>[2]</sup> Finally, LRPD technique with aperture guidance was demonstrated recently.<sup>[12]</sup> Unlike optical trapping techniques,<sup>[9–11]</sup> LRPD utilizes optical transverse gradient forces to confine particles inside weakly focused laser beams and take advantage of the radiation pressure to move particles axially along through an aperture onto a substrate within the near-field region. This version of the LRPD technique as developed at Michigan Technological University is described in this review.

The principal LRPD setup is shown schematically in Fig. 1. It includes a mist chamber (MC), source chamber (SC), process chamber (PC), and a laser system. The mist chamber includes an atomizer and delivery system to make a mist of micron-sized liquid droplets (or particles) that are precursors for the deposited material. The droplets are delivered from the atomizer to the source chamber by a carrier gas, and a mass flow meter measures and controls the gas flow. The source chamber is connected to a process chamber by a micron-sized aperture, with a typical size in the range

**Fig. 1** Schematic of the MTU LRPD system: source of deposited material (carrier gas supply and atomizer inside mist chamber MC); supply (SC) and process (PC) chambers linked by a high-power laser aperture (details shown in the insets); laser system (laser and focusing lenses); movable substrate on a translational stage.

from 15 to 35  $\mu\text{m}$ . The droplets are usually much smaller, of the order of a micron or less. The laser beam is coupled into the aperture by an optical lens of low numerical aperture to allow particle guidance to a substrate that is mounted on a translational stage. The supply chamber both provides an environment suitable for the deposition process and shields the particles from convection currents that can deflect particles out of a laser's confinement.

As shown in Fig. 1, in contrast to optical tweezers,<sup>[9–11]</sup> LBPD allows droplets to be captured continuously from the supply chamber and transport them onto the substrate to “write” on it. Guidance in the LBPD aperture-based system is achieved by a weakly focused laser beam and diffracted laser radiation within near-field limits at the front and the rear of the aperture, respectively.<sup>[12]</sup> Also shown in Fig. 1 (inset b) are the main forces exerted on a particle in the apparatus. Three of them, the optical radiation force  $F_z$ , the optical transverse gradient force  $F_\rho$ , and optical axial gradient force  $F_{\text{ga}}$ , are resulted from the interaction of the particle with incident laser beam, and the drag force  $F_D$  is due to the interaction of a moving particle with the ambient. They and other forces will be discussed in detail below.

Examples of different materials deposited by the LBPD apparatus can be found elsewhere.<sup>[2,3,7,8,13]</sup> Several additional examples are shown in Fig. 2.

## LBPD BASICS

### Optical Field Inside the LBPD System

It is important to discuss the spatial distribution of laser optical field near an aperture as the light intensity provides both axial and transverse guidance of particles. In particular, it is the optical axial force  $F_z$  and the optical transverse gradient force  $F_\rho$  that determine the guidance efficiency, the particle velocity, and the throughput rate of an LBPD apparatus.

We will consider the laser beam with a TEM<sub>00</sub> (or fundamental) mode that can be represented by an ideal Gaussian intensity profile. Such a beam with the total power  $P$  propagates in free space along the  $z$  direction toward a centered circular aperture with radius  $a$  (Fig. 1B). The intensity (or irradiance)  $I(z, \rho)$  of such a beam is then.<sup>[14]</sup>

$$I(z, \rho) = I_0 e^{-2\rho^2/w^2} \quad (1)$$

where  $I_0(z) = 2P/\pi w^2$  is the axial (peak) intensity at  $\rho = 0$ ,  $w(z)$  is the spot radius diverging with the distance as  $w(z) = w_0 \sqrt{1 + (z/z_R)^2}$ , and the smallest spot radius  $w_0$  (at the beam waist) is at  $z = 0$ . For such a beam, the distance  $z_R$ , the waist spot radius  $w_0$ , and the beam full-angle divergence  $\theta$  are beam parameters

**Fig. 2** Examples of materials deposited by the LBPD apparatus: (A) SEM micrograph of microspheres formed by 7-nm Au-S(CH<sub>2</sub>)<sub>7</sub>CH<sub>3</sub> particles deposited by a 200-mW laser; (B) AFM image of a cluster of 100-nm polystyrene particles; (C) SEM micrograph of an array of 400-nm polystyrene spheres partially coated with 100-nm polystyrene spheres; (D) optical image of the 7-nm Au-S(CH<sub>2</sub>)<sub>7</sub>CH<sub>3</sub> particles deposited on an array of gold microelectrodes by a 200-mW laser; (E) similar to (D), after an electrode was produced by in situ melting by a 500-mW laser beam. (F) Structure made of ~20-nm Au-S(CH<sub>2</sub>)<sub>7</sub>CH<sub>3</sub> particles deposited after atomization of 2–4 g/L suspension of nanoparticles in toluene.

defined as<sup>a</sup>

$$z_R = \pi w_0^2 / \lambda, \quad \theta = 2\lambda M^2 / \pi w_0 \quad (2)$$

where  $M^2 \geq 1$  is a factor representing the beam quality (for an ideal Gaussian beam,  $M^2 = 1$ ), and for a beam behind a circular aperture with radius  $a$ ,  $z_R = \pi a^2 / \lambda$ . The parameter  $z_R$  is referred to as the Rayleigh range indicating an approximate border between the near-field diffraction region (at  $z < z_R$ ) and the far-field diffraction region (at  $z > z_R$ ). The extent along the beam between  $\pm z_R$  points relative to the beam waist is commonly considered as the collimated waist region. The diffraction angle  $\theta$  of a beam spreads in the far field, where  $w(z) \approx w_0 z / z_R = \lambda z / \pi w_0$  at  $z \gg z_R$ . The angle  $\theta$  is often considered as a laser primary parameter because divergence is of fundamental importance for many laser applications. However, any one of the beam parameters completely characterizes the optical field along the entire Gaussian beam because only one is independent at a particular wavelength  $\lambda$ . Therefore the axial intensity  $I_0$  of a laser cannot be increased by reducing  $w_0$  without also increasing its divergence. As we will see, this is especially important for the LRPD systems. The beam intensity falls off very fast with radius  $\rho$  beyond the spot size  $w$ : at  $\rho = w$  the intensity decreases to  $0.135I_0$  ( $1/e^2$  criterion) and to about  $0.01I_0$  (often called 99% criterion) at  $\rho = \pi w / 2$ .

The circular aperture, which links the supply and process chambers of the LRPD apparatus (Fig. 1), changes the beam optical field by two different ways. First, due to aperture truncation, the power transmission of the passing beam can be cut off considerably depending on the ratio  $a/w_0$ , especially at  $a/w_0 \leq 1$ . Even an aperture with radius  $a = w_0$  transmits only  $\approx 86\%$  of the total beam power  $P$ . However, this effect can be avoided by increasing the ratio: An aperture transmits as much as 99% after the ratio increase to  $a/w_0 \geq \pi/2 = 1.6$ . Secondly, diffraction of the beam on an aperture produces more complex intensity patterns in both the near-field and far-field regions.<sup>[14,15]a</sup> In the far field, the axial intensity decreases due to standard Gaussian beam divergence: According to Eq. (1), the axial intensity changes with distance as  $I_0(z) = (z_R/z)^2 I_{00}$ , where  $I_{00}$  is the axial intensity at the beam waist. Additionally, a diffracting aperture perturbs the beam creating well-known diffraction effects that significantly change the optical field distribution including the central far-field lobe intensity. In the near field, the changes in the

characteristics of the diffracted beam are the most essential. The intensity ‘‘Fresnel’’ ripples appear and become more and more distinguished as the ratio  $a/w_0$  decreases. The intensity variation  $\Delta I/I$  can be as large as  $\pm 20\%$  even for a 99% aperture. (The far-field central intensity will also be decreased by 20% by such an aperture.) As a result, rings of a higher and lower intensity are typical in the near-field region, their location, amplitude, and number changing with distance and with the ratio  $a/w_0$  (Fig. 3). On the other hand, the average intensity is practically a constant or even increasing with distance in the near-field region at  $z < z_R$ . Finally, there is a peak at or near the beam axis that might be rather spiky closer to the aperture.

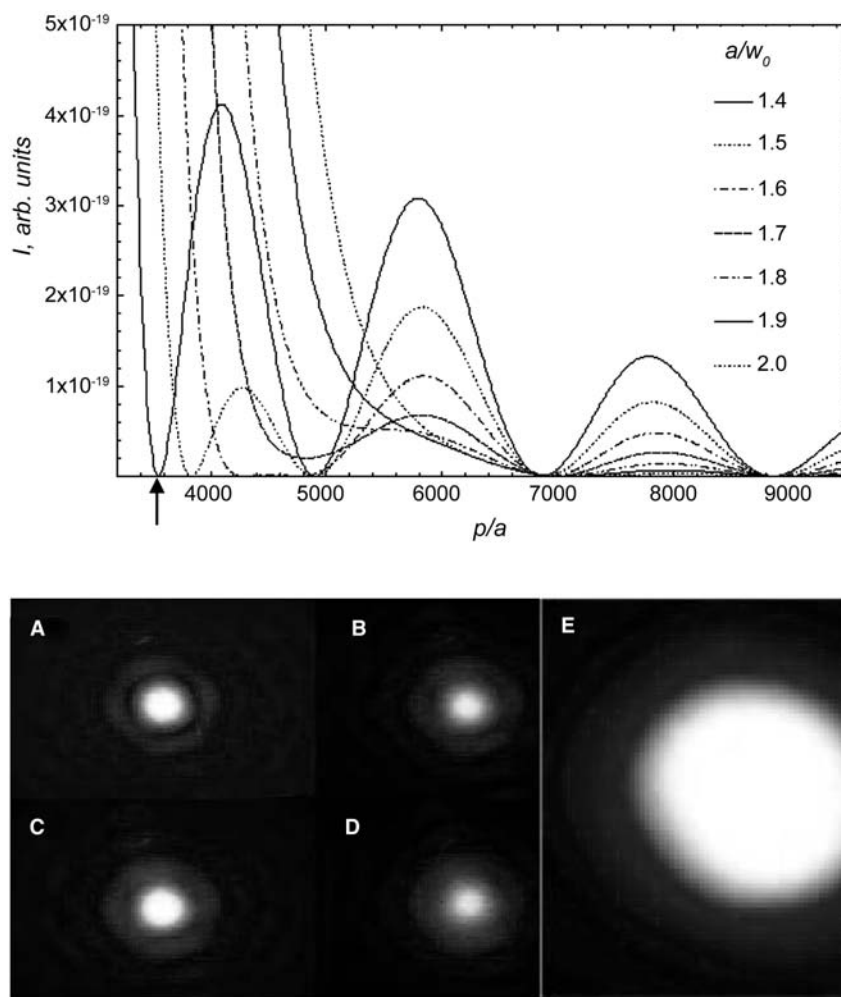

For a typical double-frequency YAG-laser ( $\lambda = 532$  nm,  $\theta = 0.5$  mrad and  $M^2 = 1$ ), Eq. (2) then gives  $w_0 \approx 0.7$  mm and a long collimated waist region of  $2z_R \approx 5.4$  m. Focusing such a collimated beam with a lens of the focal length  $f = 35$  mm decreases the original waist spot diameter  $2w_0$  to  $2w_0' = 2\theta f = 35$   $\mu$ m. At the same time, the divergence increases to  $\theta' = w_0\theta/w_0' \approx 20$  mrad and the beam Rayleigh range  $z_R$  diminishes to 1.8 mm. Obviously, the same  $z_R = 1.8$  mm is for the beam after passing an aperture with the diameter  $2a = 2w_0' = 35$   $\mu$ m.

The intensity of a real laser beam can be different than that of an ideal Gaussian beam because of both a possible mixture with higher-order modes and effects of nonideal optics. Although the Rayleigh range is still the same in such cases, the waist spot size and divergence are larger, as can be seen from Eq. (2) for  $M^2 > 1$ . The most distinguished feature, however, is the more complex intensity profile of such laser beams: Instead of Eq. (1), the intensity distribution exhibits local maxima and minima inside the collimated region or focus.

## Setup Optimization of the LRPD System

The discussion above and computational results based on the paraxial approximation of a Gaussian beam diffracted by a circular aperture<sup>[15–17]</sup> suggest several factors important for the optimal setup of LRPD. The calculations and experimental comparison of the diffraction patterns with the best particle flux through the 25- and 35- $\mu$ m apertures have shown that one of the most important factors is the ratio  $a/w_0$ . The ratio affects the far-field diffraction pattern as can be seen in Fig. 3 for seven ratios  $a/w_0$ . The calculations are performed for conditions close to real experimental setups: Gaussian beams with  $w_0 = 3$ –20  $\mu$ m and circular apertures with diameters from 35 to 5  $\mu$ m. Only three pairs of maxima and minima without a

<sup>a</sup>Eq. 2 is analogous to the optical (the Smith–Helmholtz) invariant in an optical system comprising only lenses. In practice, lasers as a rule are characterized not only by the beam-waist spot  $w_0$  but also by the beam divergence  $\theta$ .

**Fig. 3** The transverse diffracted intensity  $I$  calculated for different ratios  $a/w_0$  as a function of the transverse distance  $\rho$  from the beam axis normalized by the aperture radius  $a$ , and corresponding diffraction images. The arrow in the plot marks the first minimum for the ratio  $a/w_0 = 1.4$ . The ratio  $a/w_0$  increases from (A) to (E); the latter corresponds to a typical working setup with  $a/w_0 \approx 1.8$ . In (A), the size of the first ring is about 70 mm. The images were obtained with a digital camera in the far-field diffraction region of the 35- $\mu\text{m}$  aperture.

much higher central maximum are displayed. As seen, both the positions of the first minima and the diffraction contrast (determined as the intensity difference between the first maximum and minimum) depend on the ratio  $a/w_0$ . The contrast decreases as the ratio increases, and the first minimum completely vanishes at  $a/w_0 \geq 1.8$ .

Experimentally, the ratio  $a/w_0$  can be changed by either displacing different focusing lenses relative to the laser (changing the waist radius  $w_0$  only), or changing the aperture size, or both. The experimental data confirm the calculation results (Fig. 3). The images are obtained by axially displacing a 35- $\mu\text{m}$  aperture closer and closer to the beam waist, until the first minimum cannot be seen anymore in Fig. 3(E). Using such images, one can find the best alignment of the laser-lens-aperture system. Numerous deposition experiments with apertures and laser beam waists of various

sizes confirmed that deposition is impossible when the contrast between the first minimum and the first maximum is high, such as in Fig. 3(A) through (D). As the contrast decreases, deposition is finally made possible near  $a/w_0 \approx 1.7$ . This number is larger than the ratio of 1.125 required for a maximum axial intensity in the far-field range but closer to  $\pi/2$  that corresponds to  $\geq 99\%$  power transmission.<sup>[14]</sup> The other important factor is the divergence of the beam ahead of the aperture. A large divergence in the region near the beam waist (as utilized in optical tweezers)<sup>[11]</sup> can lead to reverse radiation pressure, especially for small  $w_0 \leq \lambda$ .<sup>[18]</sup> Our experiments with 100-nm polystyrene spheres, 25- $\mu\text{m}$  circular aperture, and 30-mm focusing lens have shown that the setup can be optimized to provide guidance at as low laser power as  $P \approx 100 \text{ mW}$ .<sup>[17]</sup>

High accuracy is essential for direct-write applications. Because it is determined by many factors,

systematic studies are required to estimate their contributions. Preliminary experiments with five different materials<sup>[19]</sup> have shown that the deposition accuracy is inversely proportional to the transport distance. The accuracy also strongly depends on the material properties of the transported particles, such as the refractive index and absorption, and relatively weakly on the laser power when measured inside a relatively low-power range. To increase deposition precision and utilize the features of the near-field intensity pattern, the substrates during LRPD operations are usually located at  $z < z_R$ , i.e., closer to the aperture.

### Particle Dynamics and Forces in the LRPD System

Two special features critically influencing the forces exerted on droplets inside a LRPD apparatus are a nonuniform optical field with on-axis maximum intensity and a droplet small size of  $R \leq \lambda$ . There are three types of forces important for LRPD: optical forces, radiometric forces, and the drag force. The optical forces arise from scattering and absorption of light by the particle; the radiometric forces result from the temperature gradients either inside the particle or in the medium; and the drag force develops due to the resistance of the medium to a moving particle. Additionally, the force of gravity and hydrodynamic interaction forces between particles are also present. However, a characteristic feature of the dynamics of droplets inside the LRPD system is that the interaction forces between particles and the force of gravity are, in most cases, considerably less than the other three. For submicron particles typical of the LRPD technique, the force of gravity is below the  $10^{-14}$ -N range and decreases significantly with the particle size, so that we can safely ignore the gravity force. The droplets can also be considered independent of one another inside the supply chamber because of their relatively low concentration so that we can neglect hydrodynamic forces as well. On the other hand, the particle interaction might be important during delivery from the atomizer to the supply chamber, as the clouds of particles not only move faster than the individual particles<sup>[20]</sup> but also the particles can coagulate forming larger droplets or clustered particles.

When a particle is illuminated by an incident beam, its electromagnetic energy and momentum are lost because of absorption and scattering processes. The use of conservation of energy and momentum allows calculating the beam-induced stress tensor on the surface of the particle and the corresponding optical force field; such forces are collectively called the radiation forces. They depend on the size, shape and material of the particle, the beam polarization and intensity

distribution, and the position of the particle inside the beam.<sup>[21–23]</sup> Then the forward force exerted on a spherical particle of radius  $R$  inside a gaseous medium with the refractive index  $n_b \approx 1$  by a beam with the axial intensity  $I_0$  and the waist spot  $w_0 \gg R$  is given by<sup>[21]</sup>

$$F_z = \frac{\pi R^2 I_0}{c} Q_{pr} = \frac{\pi R^2 I_0}{c} (Q_{ext} - Q_{sca} \overline{\cos \theta}) \quad (3)$$

where  $Q_{pr}$ ,  $Q_{ext}$ , and  $Q_{sca}$  are the so-called efficiencies for radiation pressure, extinction, and scattering, respectively,  $Q_{ext} = Q_{sca} + Q_{abs}$  (where  $Q_{abs}$  is the efficiency for absorption),  $c$  is the velocity of light in free space, and the average cosine of the scattering angle  $\overline{\cos \theta}$  is the scattering asymmetry parameter. Because the refractive index of gases is very close to 1, we can use  $c$  instead of the velocity of light in the medium in Eq. (3). For low-absorbing particles (such as liquid droplets of water-based dilute solutions),  $Q_{pr} \approx (1 - \overline{\cos \theta}) Q_{sca}$ ; in the opposite limit of particles with no scattering (ideal “black” particles),  $Q_{pr} \approx Q_{abs}$ . Eq. (3) allows calculating the forward axial force  $F_z$  based on various approximations of light scattering models.<sup>[21–23]</sup> To include both absorption and scattering processes into the calculations, the refractive index  $m$  of the particle is represented by a complex number,  $m = n + i\kappa$ , where the real part  $n$  is responsible for scattering and the imaginary part  $\kappa$  (or the extinction coefficient) is responsible for absorption. The extinction coefficient  $\kappa$  is related to the absorption coefficient  $\alpha$  (sometimes also called the turbidity or attenuation coefficient) of the Beer–Lambert law,  $I_t = I_i \exp(-\alpha l)$ , as  $\kappa = \lambda \alpha / 4\pi$ , where the incident intensity  $I_i$  decreases to  $I_t$  over the path length  $l$ . The refractive index  $m$  can vary over a wide range of  $1 \leq m < \infty$ , where the lower limit corresponds to translucent liquids and solids, and the upper limit, typical of metals in the infrared region, corresponds to total reflection. The other way to characterize particles is through the relative dielectric constant  $\epsilon_r = \epsilon_1 + i\epsilon_2 = m^2$ , so that  $\epsilon_1 = n^2 - \kappa^2$  and  $\epsilon_2 = 2n\kappa$ .

In the calculation, the particle size is represented by the normalized size parameter  $x = 2\pi R/\lambda$ , which for particle sizes typical for LRPD,  $50 \leq R \leq 500$  nm, is approximately within a range of  $0.6 \leq x \leq 6$ .<sup>b</sup> Such a range requires a rigorous calculation to find  $F_z$ , and it can be performed using the generalized Lorenz–Mie theory (GLMT).<sup>[21]</sup> If the particle is spherical, scattering can be simulated with the GLMT independently of the spheres’ diameter and refractive

<sup>b</sup>Note that although we have propelled and deposited as small solid particles as 7 nm,<sup>[3,7,8]</sup> they were in suspensions.

**Fig. 4** Typical size dependence of the efficiency factor  $Q_{pr}$  for a polystyrene sphere (the refractive index  $m = 1.431$ ) obtained by numerical calculation based on a generalized Lorentz–Mie theory with no absorption. The arrows show the corresponding radii  $R$  for  $\lambda = 532$  nm. Source: From Ref.<sup>[19]</sup>.

index. An example of such a calculation is shown in Fig. 4;<sup>[19]</sup> similar calculations were performed for weakly absorbing spheres.<sup>[21–23]</sup> As seen, the average envelope of the  $Q_{pr}-x$  curve shows a relatively small change as  $x$  decreases from 20 to 3 remaining at  $Q_{pr} \approx 0.5$ , with a flat maximum near  $x = 6$ . Taking LRPD typical conditions for a collimated beam of  $w_0 \approx 10 \mu\text{m}$  and  $P = 1$  W yields  $F_z \approx 6 \times 10^{-12}$  and  $1 \times 10^{-12}$  N for the particles of  $R = 500$  and  $200$  nm, respectively.<sup>c</sup> The other feature is a superposition of ripple structures with maxima and sharp spikes that originate in resonant electromagnetic normal modes of a sphere.<sup>[22]</sup> Such structures are typical of the morphology-dependent resonances (MDRs); they were both predicted by the Mie theory and observed in experiments involving several different techniques.<sup>[25]</sup> During the deposition process, laser-induced evaporation of the moving droplets changes the particle size so that the forward force experiences the corresponding fluctuations of MDRs. However, the droplet motion in gaseous medium is normally overdamped because of the drag force (see below) so that such short peaks should not affect the particle motion.

The classical Mie–Lorentz theory assumes only planar waves in the incident optical field,<sup>[24]</sup> but it can also be applied to a real laser beam provided that the waist spot  $w_0 \gg R$ . To include into consideration also gradient forces, important for both LRPD and optical trapping, other approach is required. A gradient force arising from electrical forces on a polarizable particle

can be calculated directly from a standard expression,

$$F_g = (\alpha/2) \nabla E^2 \quad (4)$$

where  $\nabla E$  is the gradient of laser electric field  $E$  and  $\alpha = 4\pi R^3(\epsilon_r - 1)/(\epsilon_r + 2)$  is the particle polarizability for small particles when  $x \ll 1/\kappa$ .<sup>[23]</sup> For larger particles, the expression for  $\alpha$  can be corrected.<sup>[26]</sup> Alternative models have also been proposed to calculate both gradient and forward forces for small particles of  $2R \leq \lambda$ . The models use either an extended GLMT<sup>[18]</sup> or a two-component approach,<sup>[27]</sup> and in all cases the transverse gradient force  $F_\rho$  is larger than the axial force  $F_z$ . Such gradient force  $F_g$  is large enough to confine the particles to the laser beam: The force is attracted toward high intensity for positive  $\alpha$  and thus provides the necessary guidance along the laser-beam axis. Estimates also demonstrate<sup>[4]</sup> that the potential created by such gradient forces is several orders of magnitude larger than the thermal energy of the ambient molecules, which ensure particle guidance under ambient conditions. The models also revealed that an additional, axial gradient force  $F_{ga}$  can exist in tight-focused systems that can produce trapping in the diverging part of the beam (the inverse radiation pressure). To avoid this, a better optical design with focusing lenses of low numerical aperture is required.

The drag force  $F_D$  is given by the well-known Stokes' formula

$$F_D = 6\pi\eta Rv \quad (5)$$

where  $\eta$  is the ambient shear viscosity ( $R/l \gg 1$ ,  $l$  is the mean free path of the ambient molecules), and  $v$  is the particle velocity. Depending on the particle radius  $R$ , the force  $F_D$  diminishes either linearly or steeper with  $R$ . As  $l \sim 10$  nm in air at atmospheric pressure,  $F_D$  decreases linearly as far as  $R$  is less than several hundreds of nanometers, and approximately quadratically at  $R \leq 20$  nm (molecular kinetics regime). A transition region exists at intermediate particle sizes where one of the two dependencies trends to the other. The drag force  $F_D$  can be reduced substantially, practically almost to zero, by decreasing the ambient pressure.

Absorption not only directly increases the forward force but also determines the guided particle temperature and therefore creates two additional effects: the appearance of the radiometric force  $F_T$  and initiation of such thermal processes as evaporation, in-flight chemical reactions inside transported droplets, and even melting of strongly absorbing particles. Estimates show that the absorption becomes especially important for the particles with  $R \leq 50$  nm as the scattering contribution into the forward force decreases as  $R^6$  in

<sup>c</sup>Note that the force on particles with stronger absorption might be significantly higher; we deposited metallic particles in suspension at as low laser power as less than 100 mW.

this size range, while the absorption contribution only as  $R^3$ . The radiometric force  $F_T$  arises from a temperature gradient  $\Delta T$  inside the particle illuminated from one side and points against the gradient, i.e., in the forward axial direction. Because in LBD systems  $R/l \gg 1$ ,  $F_T$  provides an additional axial forward force due to a rather complicated and different than normal viscous flow process, often called radiometric flow or thermal creep. Under a simplified assumption that  $\Delta T$  is constant over a spherical particle (which is rarely the case for dielectric particles<sup>[6]</sup> but provides a reasonable estimate) with the thermal conductivity  $\chi$ , the radiometric force is given as.<sup>[20]</sup>

$$F_T = \frac{3\pi\eta^2 R_g}{pM} R \Delta T \approx \frac{3\pi\eta^2 R_g \alpha_b}{2pM\chi} R I_0 \quad (6)$$

where  $R_g$  is the molar gas constant,  $p$  the pressure,  $M$  the molecular weight of the gas, and  $\alpha_b$  the absorption factor (for the absolutely black particle,  $\alpha_b = 1$ ). Estimates show that proper illumination can create  $F_T$  that is comparable with  $F_z$  in strongly absorbing particles; an effect of such a radiometric force was also observed experimentally.<sup>[28]</sup>

## SOLID-LIQUID INTERACTIONS DURING PATTERNING

The LBDP technique relies on precise and controlled deposition of liquid droplets, suspensions, and wet formulations. The capillary forces operating in these multiphase systems govern the dimensions and morphology of the deposited clusters as well as the extent of fusion among deposited clusters. An understanding of the solid-liquid interactions is crucial in achieving three major objectives in laser-deposition technology: 1) to prepare suspensions that remain stable during the time of deposition; 2) to control phase separation (promote or avoid, depending on the need) in solid particle-in-liquid droplets transported by a beam; and 3) to manipulate the spread of deposited droplets and formation of pattern over a substrate. Fulfillment of these tasks requires an understanding and the manipulation of the surface properties of solids, both dispersed in liquid and used as substrates for patterning. If surface properties of particles or substrates cannot be manipulated, selection of the appropriate solvent or solution is needed.

The solid-liquid interactions specific for the processes important for laser-deposition systems have not been considered in depth so far. The discussion presented below relies rather on fragmentary experimentation and observations during the laser deposition process combined with the knowledge of solid-liquid interactions

extracted from broad surface chemistry research activities. A unified (but simplified) theory on solid-liquid interactions is reviewed in the first part of this section and then the applicability of this theory to laser-deposition systems is discussed in subsequent parts.

## Solid-Liquid Interfacial Energy

The interfacial interactions are analyzed in this paper using the Lifshitz-van der Waals Lewis acid-base interaction theory developed by van Oss, Good, and Chaudhury at the end of 20th century.<sup>[24,29,30]</sup> According to this theory, the total free energy of interaction between two surfaces, e.g., liquid and solid, is given by

$$\Delta G_{SL} = \Delta G_{SL}^{LW} + \Delta G_{SL}^{AB} \quad (7)$$

where  $\Delta G_{SL}^{LW}$  and  $\Delta G_{SL}^{AB}$  are the Lifshitz-van der Waals component and Lewis acid-base component, respectively, of the free energy of interaction between a solid (S) and a liquid (L). The  $\Delta G_{SL}^{LW}$  component refers to interfacial apolar interactions caused by orientation, induction, and dispersion forces, whereas the  $\Delta G_{SL}^{AB}$  component reflects the contribution from the (Lewis) acid-base (polar) interfacial interactions. Both components, as well as their combination, are assumed in this theory to follow the Dupre equations,<sup>[24,30]</sup>

$$\Delta G_{SL}^{LW} = \gamma_{SL}^{LW} - \gamma_S^{LW} - \gamma_L^{LW} \quad (8)$$

$$\Delta G_{SL}^{AB} = \gamma_{SL}^{AB} - \gamma_S^{AB} - \gamma_L^{AB} \quad (9)$$

$$\Delta G_{SL} = \gamma_{SL} - \gamma_S - \gamma_L \quad (10)$$

where  $\gamma$  is the surface or interfacial free energy; the subscripts S, L, and SL refer to solid and liquid surfaces, and solid-liquid interface, respectively; and the superscripts LW and AB denote the Lifshitz-van der Waals and acid-base interactions, respectively.

Because of the symmetrical nature of the LW interactions, both the total LW interaction energy and the LW surface free energy components follow a combining rule,<sup>[24,29,30]</sup>

$$\Delta G_{SL}^{LW} = -2\sqrt{\gamma_S^{LW}\gamma_L^{LW}} \quad (11)$$

$$\gamma_{SL}^{LW} = \left( \sqrt{\gamma_S^{LW}} - \sqrt{\gamma_L^{LW}} \right)^2 \quad (12)$$

The combining rule does not apply to asymmetrical AB interactions; instead, they have been defined

(a priori) by the following two equations,

$$\Delta G_{SL}^{AB} = -2\left(\sqrt{\gamma_S^- \gamma_L^+} + \sqrt{\gamma_S^+ \gamma_L^-}\right) \quad (13)$$

$$\gamma_i^{AB} = 2\sqrt{\gamma_i^+ \gamma_i^-} \quad (14)$$

where the superscripts  $-$  and  $+$  refer to the electron donor (Lewis base) parameter and electron acceptor (Lewis acid) parameter, respectively. Combining Eqs. (11) and (13) with Eq. (7) then yields

$$\Delta G_{SL} = -2\left(\sqrt{\gamma_S^{LW} \gamma_L^{LW}} + \sqrt{\gamma_S^+ \gamma_L^-} + \sqrt{\gamma_S^- \gamma_L^+}\right) \quad (15)$$

Another expression for the total free energy of interaction between two surfaces  $\Delta G_{SL}$  can be obtained by substituting the Young's equation,

$$\gamma_S - \gamma_{SL} = \gamma_L \cos \theta \quad (16)$$

into Eq. (10), in the form

$$\Delta G_{SL} = -\gamma_L(1 + \cos \theta) \quad (17)$$

where  $\gamma_L$  is the surface tension of liquid and  $\theta > 0$  is the contact angle for liquid on the solid surface.

The two equations (15 and 17) are commonly used for the calculations of the surface free energy and surface free energy components of a solid surface and a liquid from contact angle measurements. Because Eq. (15) contains three unknowns ( $\gamma_S^{LW}$ ,  $\gamma_S^-$ ,  $\gamma_S^+$ ), the contact angles of three liquids with known surface tension must first be measured, so that three simultaneous equations can then be solved.<sup>[24,29,30]</sup>

The  $\gamma^{LW}$ ,  $\gamma^+$ , and  $\gamma^-$  components of surface free energy were determined for a number of liquids and solids and several examples are shown in Tables 1 and 2; the values for  $\gamma^+$  and  $\gamma^-$  are relative, as they refer to a standard value assumed for water,  $\gamma^+ = \gamma^- = 25.5 \text{ mJ/m}^2$ .<sup>[24,30]</sup>

## Preparation of Suspensions

The stability and homogeneity of the suspension used for the generation of a mist in laser-based deposition technology is crucial for maintaining a constant concentration of solid particles carried by droplets. The quality and reproducibility of patterned structures strongly depend on the concentration of particles and reproducibility of this concentration in the droplets. The stability of suspensions is controlled by particle-particle forces, which include the van der Waals (apolar) interactions, Lewis acid-base (polar)

interactions, electrostatic interactions, and Brownian movement forces.<sup>[24,30,31]</sup> As intense mixing results in dynamic conditions of suspension, the effect of Brownian movement forces on the stability of suspensions used in the formulation of mist can be ignored. For the same reason, any flocculation effects caused by long-range forces and by the presence of a secondary minimum in attraction<sup>[24,30,31]</sup> can also be neglected in this simple analysis. A more accurate analysis of the interactions between surfaces as a function of distance is beyond the scope of this paper and therefore is excluded from further discussion. Finally, although the electrostatic forces originating from the Coulomb interaction between surface charges are important to many aqueous suspensions and some other organic solvent-based suspensions (and can be used in stabilization of suspensions), they are also ignored to simplify our analysis; the electrostatic interactions in apolar and weakly polar solvents have often only negligible effect on the stability of suspensions.

Keeping the abovementioned simplifications in mind, it can be said that suspensions of particles remain stable if solid-liquid adhesion exceeds the cohesion forces for liquid molecules and particles. As a result, the interaction energy between two solid surfaces immersed in a liquid can be estimated from the Lifshitz-van der Waals Lewis acid-base interaction theory using the following equation:<sup>[24,30]</sup>

$$\begin{aligned} \Delta G_{\text{SLS}} = & -2\left(\gamma_{\text{S}}^{\text{LW}} + \gamma_{\text{L}}^{\text{LW}} - 2\sqrt{\gamma_{\text{S}}^{\text{LW}}\gamma_{\text{L}}^{\text{LW}}}\right) \\ & + 4\left(\sqrt{\gamma_{\text{S}}^+ \gamma_{\text{L}}^-} + \sqrt{\gamma_{\text{S}}^- \gamma_{\text{L}}^+}\right) \\ & - \sqrt{\gamma_{\text{S}}^+ \gamma_{\text{S}}^-} - \sqrt{\gamma_{\text{L}}^+ \gamma_{\text{L}}^-} \end{aligned} \quad (18)$$

Spontaneous dispersion and complete stability of the suspension can only be accomplished when the  $\Delta G_{\text{SLS}}$  value is positive.<sup>[24,30]</sup> However, such a strong stability of suspension is not always necessary in the formulation of the mist for laser deposition. In our research, different suspensions with small negative  $\Delta G_{\text{SLS}}$  values were successfully used in making the mist and used for patterning.<sup>d</sup> For example, 8–20-nm gold nanoparticles modified with self-assembled monolayers of thiols terminated with either methyl or benzyl functionality have been used for patterning of porous chemiresistor sensors.<sup>[3,13]</sup> The gold-thiolate particles functionalized with  $\text{CH}_3$ - groups disperse well in many apolar or weakly polar solvents such as saturated hydrocarbons,

chloroform, and toluene, but because of the hydrophobic nature of these particles they flocculate in polar solvents such as water and, to a lesser extent, in ethanol and methanol. The behavior of  $\text{Au-S}(\text{CH}_2)_n\text{CH}_3$  particles, or other particles, in solvents can be predicted from the calculated  $\Delta G_{\text{SLS}}$  value.<sup>e</sup> Examples of calculation of the  $\Delta G_{\text{SLS}}$  value for  $\text{Au-S}(\text{CH}_2)_n\text{CH}_3$  dispersed in different solvents are shown in Table 3. It can be seen that the  $\Delta G_{\text{SLS}}$  value for  $\text{Au-S}(\text{CH}_2)_n\text{CH}_3$  particles is close to zero for such good solvents as chloroform, toluene, or dodecane but increases for polar solvents from  $-5.4 \text{ mJ/m}^2$  for ethanol to over  $-102 \text{ mJ/m}^2$  for water.<sup>f</sup>

The surface free energy characteristics for gold-thiolate particles change drastically if the self-assembled monolayer of a “long-chain” thiol with  $\text{CH}_3$ - functionality is replaced with a monolayer of a short-chain thiol ended with the benzyl group (Table 3). The  $\text{Au-S}(\text{CH}_2)_2\text{C}_6\text{H}_5$  particles disperse spontaneously in chloroform, ethylene glycol, and water but have a tendency to flocculate in toluene, dodecane, ethanol, and methanol. As water is a convenient liquid carrier in the laser-based deposition technique because of its high surface tension and limited evaporation, the formulation of stable suspensions of  $\text{Au-S}(\text{CH}_2)_2\text{C}_6\text{H}_5$  nanoparticles in water without stabilizing chemicals is advantageous.

The selection of a carrier liquid for polymeric particles is often more difficult. For example, Table 3 shows the calculated  $\Delta G_{\text{SLS}}$  values for polystyrene dispersed in different apolar and polar liquids. Positive or close-to-zero negative value is predicted for chloroform and toluene. These two solvents, unfortunately, dissolve polystyrene.<sup>g</sup> In such cases more polar solvents are required for use in the formulation of suspension.

<sup>e</sup>Long-range colloidal forces should be included in detailed analysis of the system; see Ref.<sup>[33]</sup> and footnote 8 for more details.

<sup>f</sup>The drawback of the Lifshitz-van der Waals Lewis acid-base theory is that small  $\Delta G_{\text{SLS}}$  values are not very reliable. The values of electron-acceptor and electron-donor parameters for both solids and liquids can change significantly with only a small variation in measured contact angles. For example, it should be recognized that the  $\Delta G_{\text{SLS}}$  values in Table 3 were calculated based on not always precise surface free energy components of solids and liquids and therefore the values shown in Table 3 should be treated as estimates. This is particularly true for methanol and ethanol, for which electron-donor and electron-acceptor parameters need to be determined with better accuracy. Additionally, ethanol can carry a trace amount of water as a contaminant or pick it up from the laboratory humid environment. Such a contamination might affect the suspension stability if water separates or adsorbs on the particle surface. The other concern is that gold nanoparticles might carry less perfect self-assembled monolayers of thiols as those commonly formed on flat macroscopic surfaces of gold. Any uncoated areas of gold particles will enhance the attractive interactions between suspended nanoparticles.

<sup>g</sup>Entropic term must be added to the equation on  $\Delta G_{\text{SLS}}$  to calculate the interaction energy of dissolution and predict the behavior of the polymer in a solvent (Ref.<sup>[33]</sup>).

<sup>d</sup>Spherical and relatively large particles, 100 nm and larger, are easier to disperse in liquids than nanoparticles having a diameter of a few nanometers and crystalline shape due to increasing adhesion expressed per volume of the particle with decreasing particle size.

<sup>b</sup>Estimate due to uncertain values for the electron-donor and electron-acceptor parameters for ethanol and methanol<sup>h</sup>.

Because of the poor compatibility between polystyrene and polar solvents such as ethanol, ethylene glycol, or water, the suspensions formulated without stabilizing agents will flocculate even under intense mixing conditions. A modification of the surface properties of polystyrene particles is required and it can be accomplished by using surfactants that reduce the hydrophobicity of the polymer and improve the polar interaction with liquid and enhance the repulsive interactions between surfactant-coated particles.

### Nanoparticles in Transported Droplets

Suspensions with a reduced solid-liquid interaction favor the formation of aggregates, as discussed in the previous section, and also often promote accumulation of particles at the liquid/droplet surface. A film of particles formed at a liquid surface increases the droplet's surface rigidity and influences the structure of deposited clusters. The particles carried on the surface of a droplet form more-or-less regular monolayer structures that often promote the formation of spherical clusters with a well-organized assembly of particles. Also, due to reduced liquid-air area, the rate of liquid evaporation is reduced during transportation by the laser beam.

The tendency for particles to attach to the liquid droplet surface can be predicted by the Lifshitz-van der Waals Lewis acid-base interaction theory by calculating the interaction energy between a particle and a liquid-gas interface:<sup>[24,30]</sup>

$$\Delta G_{SLV} = -\gamma_L^{LW} + \sqrt{\gamma_S^{LW}\gamma_L^{LW}} + 2\left(\sqrt{\gamma_S^-\gamma_L^+} + \sqrt{\gamma_S^+\gamma_L^-} - 2\sqrt{\gamma_L^-\gamma_L^+}\right) \quad (19)$$

The positive  $\Delta G_{SLV}$  value indicates that the particle will avoid the liquid-gas interface, whereas the negative value indicates the preferential adhesion of particles to this interface. More negative  $\Delta G_{SLV}$  values point toward stronger adhesion of the particle to the liquid-air interface, which ultimately leads to a larger portion of the particle that is exposed to a gas phase after attachment. The position of the particle at the liquid-gas interface is determined by the wetting characteristics of the solid expressed in contact angle values.<sup>[33]h</sup> Table 3 shows examples of calculated  $\Delta G_{SLV}$  values for polystyrene and gold-thiolate particles. Because of the positive  $\Delta G_{SLV}$  values, polystyrene does not adhere to the surface of ethanol, methanol, and dodecane, although because of negative  $\Delta G_{SLS}$  values the polystyrene particles will likely flocculate inside the bulk of these liquids. Therefore the structure and, to a lesser extent, shape of the deposited clusters might become unpredictable.

It can be seen from the data in Table 3 that it requires the use of liquids with relatively high surface tension value such as ethylene glycol or water to generate droplets coated with films of polystyrene particles. Unfortunately, as also discussed in the previous section, the formulation of suspensions of polystyrene in water (or ethylene glycol) that are stable for at least a few seconds (time required to prepare a mist and transport the droplets to a substrate) is a challenge. In such systems the use of surface-active compounds or additional particulates that adsorb on the surface

<sup>h</sup>The contact angle measured for a liquid in contact with a nanoparticle is usually different from the contact angle measured on large (millimeter-sized) particles as a result of a contribution of the linear free energy at the highly curved three-phase line (Ref.<sup>[34]</sup>).

of polystyrene and strengthen the interactions of the particles with liquid is usually a need.

The surface free energy of self-assembled monolayers of  $\text{HS}(\text{CH}_2)_n\text{CH}_3$  ( $n > 7$ ) on a gold surface is much smaller than the surface free energy of polystyrene, and, therefore, the gold-thiolate particles can coat almost any liquid listed in Table 3. However, small negative  $\Delta G_{\text{SLV}}$  values for chloroform, dodecane, and toluene indicate that adhesion of  $\text{Au-S}(\text{CH}_2)_n\text{CH}_3$  particles to these liquids is weak and the particles can easily detach from the liquid-air interface. As a result, irregular and irreproducible clusters usually result from deposited suspensions formulated using one of these three solvents. The use of polar solvents such as ethanol, methanol, water, and ethylene glycol promotes the accumulation and alignment of  $\text{Au-S}(\text{CH}_2)_n\text{CH}_3$  particles at the droplet surface. Again, due to strong particle-particle interactions in these liquids, good stability of  $\text{Au-S}(\text{CH}_2)_n\text{CH}_3$  suspension is difficult to maintain.

The scenario is completely different for  $\text{Au-S}(\text{CH}_2)_2\text{C}_6\text{H}_5$  particles. As the  $\Delta G_{\text{SLV}}$  values shown in Table 3 indicate these particles will avoid the liquid-air interface when suspended in chloroform, toluene, dodecane, ethanol, and methanol. Although the  $\text{Au-S}(\text{CH}_2)_2\text{C}_6\text{H}_5$  particles disperse extremely well in chloroform, they tend to flocculate in toluene, dodecane, ethanol, and methanol. The  $\Delta G_{\text{SLV}}$  values are also negative for the  $\text{Au-S}(\text{CH}_2)_2\text{C}_6\text{H}_5$  particles dispersed in ethylene glycol and water. These two systems, with positive  $\Delta G_{\text{SLS}}$  values and negative  $\Delta G_{\text{SLV}}$  values, seem to be exceptionally suitable for the deposition of uniformly shaped clusters of particles. Particles with negative  $\Delta G_{\text{SLV}}$  values tend to form well-organized films on the surface of a liquid droplet during transportation and at the same time particle-particle repulsive forces (positive value of  $\Delta G_{\text{SLS}}$ ) are responsible for a good dispersion of the remaining particles in the liquid bulk, protecting them against aggregation.

As discussed above, the control of adhesion of particles to the droplet surface promotes the structuring of deposited clusters. Fig. 5 shows two extreme cases. Irregular clusters made of  $\text{Au-S}(\text{CH}_2)_7\text{CH}_3$  particles that were deposited on a hydrophobized glass slide from particle-in-toluene suspensions are shown in Fig. 5A:  $\Delta G_{\text{SLS}} = -0.3 \text{ mJ/m}^2$  and  $\Delta G_{\text{SLV}} = -2.0 \text{ mJ/m}^2$ . The negative value of  $\Delta G_{\text{SLS}}$  is disadvantageous for uniform alignment and tight packing of the particles in a cluster. On the contrary, the negative value of  $\Delta G_{\text{SLV}}$  is advantageous, although  $\Delta G_{\text{SLV}} = -2.0 \text{ mJ/m}^2$  indicates a weak adhesion of particles to the interface and easy disturbance of particle-at-interface organization process. Spherical clusters made of regularly aligned polystyrene particles were deposited from suspension formulated in

**Fig. 5** AFM phase images of clusters made of (A)  $\sim 20$ -nm  $\text{Au-S}(\text{CH}_2)_7\text{CH}_3$  particles and (B) 100-nm polystyrene particles. Gold nanoparticles were deposited from toluene suspensions whereas polystyrene particles were deposited from aqueous suspensions stabilized with surfactants and addition of avidin.

phosphate buffer solution with the addition of proteins and are shown in Fig. 5B;  $\Delta G_{\text{SLS}} \cong 0 \text{ mJ/m}^2$  and  $\Delta G_{\text{SLV}} \ll 0 \text{ mJ/m}^2$  (exact values have not been determined).

Packing density and alignment of nanoparticles in the film formed over the droplet surface are controlled by the size and shape of particles and interparticle interactions operating through both liquid and gas phases.<sup>[33,35]</sup> Capillary forces are negligible in these systems because of the small dimensions of particles and resulting flat menisci formed by the liquid between particles.<sup>[33]</sup> This is not necessarily true for the transported and deposited droplets if the laser beam strongly interacts with the droplet content. The resulting increase in temperature of the transported droplet causes the liquid to evaporate at a higher rate. Consequently, depletion of the liquid volume in the droplet that carries a high concentration of particles forces the liquid to shrink into interparticle space, and capillary forces start to operate among newly formed menisci aligning particles into regular spherical clusters with particles tightly bound to each other.<sup>1</sup>

### Capillarity Phenomena for Droplet-on-Substrate Deposits

The laser beam guides droplets or clusters (wet or dry) and deposits them on a substrate. Dry clusters and clusters carrying inside a small volume of liquid practically remain intact after deposition on a substrate. It is well documented that large droplets and wet clusters

<sup>1</sup>On the contrary, fast evaporation of a liquid carrying a small quantity of particles leads to droplets of such small sizes that the laser beam cannot guide them effectively so that the droplets spread in almost every direction instead of following the path of the beam.

**Fig. 6** Scanning electron micrographs of intact clusters made of (A) 7-nm Au-S(CH<sub>2</sub>)<sub>7</sub>CH<sub>3</sub> deposited from toluene suspension and (B) plate-like structure made of the same particles but formed from wet clusters that fused to each other.

might deform during impact with the substrate, particularly if they travel at high velocity.<sup>[36,37]</sup> However, because of very small Reynolds number,  $Re = (1.5 \text{ to } 6.0) \times 10^{-4}$ , and Weber number,  $We = 10^{-15}$  to  $10^{-8}$  for the micron-sized droplets impacting substrates during the deposition with a laser beam,<sup>j</sup> droplet deformation is negligible and has no practical consequences in patterning process.

The deposited droplets with no particles or particles weakly adhered to the liquid–gas surface will spread over the substrate and the extent of spreading is governed by the substrate–suspension interactions. Droplets and wet clusters will also fuse into each other and spread to form larger clusters if one is deposited on top or at very close proximity of another droplet or cluster. Fig. 6 shows two examples of gold-thiolate nanoparticle clusters deposited over a silanized glass slide in either dry (or almost dry) (a) or wet (b) form. Dry spherical clusters with a diameter of about 0.2 to 1  $\mu\text{m}$  remain intact after deposition, although they have a tendency to form chains and aggregates of clusters—likely as a result of attractive interactions among clusters stronger than interactions between clusters and substrate (Fig. 6A). Fig. 6B shows, on the other hand, that wet clusters formed plate-like structures as a result of liquid spreading and evaporation. Partially fused (disintegrated) clusters are also visible on top of the plate-like structure in Fig. 6B. Cracks between “plates” reflect boundaries between fused clusters and also some of them result from contraction of the volume of the deposited material during drying.

Spreading of deposited liquid drops (or wet clusters) over a substrate surface is controlled by the competition between the substrate–liquid adhesion and

cohesion forces of liquid. This can be analyzed through the spreading coefficient  $S_{SLV}$ ,<sup>[38]</sup>

$$S_{SLV} = \gamma_S - \gamma_{SL} - \gamma_L \quad (20)$$

which for finite contact angles ( $\theta > 0$ ) becomes

$$S_{SLV} = \gamma_L(\cos \theta - 1) \quad (21)$$

where  $\gamma_S$ ,  $\gamma_L$ , and  $\gamma_{SL}$  are the surface free energy of solid, liquid, and solid–liquid interfacial free energy; and  $\theta$  is the contact angle.

Using the Lifshitz–van der Waals Lewis acid–base model, the spreading coefficient can also be calculated from the following equation:

$$S_{SLV} = 2 \left( \sqrt{\gamma_S^{LW} \gamma_L^{LW}} + \sqrt{\gamma_S^+ \gamma_L^-} + \sqrt{\gamma_S^- \gamma_L^+} \right) - 2\gamma_L \quad (22)$$

A spontaneous and complete spreading of liquid to form a thin film occurs when the  $S_{SLV}$  value is positive or zero, which corresponds to zero contact angle. This situation is very undesirable in patterning technology because of lack of control of the size and shape of the deposited droplets/wet clusters, and the resulting structures. It is therefore necessary to select the substrate on deposition of liquid droplets and wet clusters with such a wetting characteristic that  $\theta \gg 0$ . The contact angle from about  $\theta = 60$  to  $110^\circ$  is usually preferable if control of the size of deposited individual clusters is desired.

The base diameter of the deposited liquid droplet or wet cluster ( $d_b$ ) is an important parameter if the size of the deposited clusters must be controlled. This parameter can be predicted from the volume of the droplet delivered by a nebulizer to a deposition chamber and the geometry of formed spherical cap using the following equation,

$$d_b = \left( \frac{4}{2 - 3 \cos \theta + \cos^3 \theta} \right)^{1/3} 2R \sin \theta \quad (23)$$

## CONCLUSION

It has been demonstrated that the LBPD technique makes it possible to deposit a variety of materials at the micron scale in the form of individual particles or clusters, with the particle size ranging from tens of nanometers to less than a micron. A weakly focused, relatively low-power laser beam guides micron-sized droplets through a micron-sized aperture toward a substrate after the droplets are generated by an

<sup>j</sup>Reynolds number  $Re$  describes a balance between inertial and viscous forces,  $Re = Dv\rho/\eta$ , and Weber number  $We$  expresses a ratio of inertial to capillary forces,  $We = \rho v^2 D/\gamma$ , where  $D$  is the diameter of the droplet [ $\sim 1$  (m)],  $v$  the droplet velocity at impact [200–600 (m/sec)],  $\rho$  the density of liquid or suspension [ $\sim 1000$  (kg/m<sup>3</sup>)], and  $\eta$  the liquid viscosity [ $\sim 10^{-3}$  (kg/msec)].

atomizer from a liquid precursor or a suspension of particles. The technique allows depositing, codepositing, and patterning materials of different classes making use of the same basic fabrication technology. Another essential asset of the technique is that the light-matter interaction inside the LBDP apparatus allows controllable activation of the chemical reactions and/or phase transformations inside the droplets making the technique even more flexible. Due to such distinct features, LBDP differs from the other direct-write techniques. At the same time, as the technique is still at the early stages of its development, many material aspects of the technique are not yet well understood, so that further research is required for successful development of LBDP.

## ACKNOWLEDGMENTS

We thank our students, Changgong Zhou and Juntao Xu, for their help in the development of the LBDP technique.

# Layer-by-Layer Assembly of Electroactive Thin Films to Layered Carbon Electrodes

Tarek R. Farhat

Department of Chemical Engineering, Massachusetts Institute of Technology,  
Cambridge, Massachusetts, U.S.A.

## INTRODUCTION

The science of depositing thin polymer films over the surface of electrodes is widely used by electrochemists for sensor technology.<sup>[1–3]</sup> Applications include studying mass transport of molecules across these films, thin-film electrochemical detection, and electroactive sites or species embedded within the polymer backbone.<sup>[4,5]</sup> Electroactivity of thin polymer films on the surface of inert electrodes is the major topic covered in this article with emphasis on polyelectrolytes, ion complexes, and colloids. Thin films discussed here are not of the classical ion-exchange type,<sup>[6]</sup> nor their composites or complexes.<sup>[7,8]</sup> It focuses on layer-by-layer (LBL) thin films introduced by Decher, Hong, and Schmitt,<sup>[9]</sup> where many different types of polyelectrolytes, ion complexes, and colloids are alternately deposited to assemble multilayer thin films.<sup>[10,11]</sup> Even at this juncture research has diversified and segregating electroactive LBL thin films into separate families or categories would be helpful to scientists browsing this field. Because of the intensive work done on electroactive LBLs, the entry discusses briefly each citation with emphasis on the newly fabricated “carbon-polymer electrodes.” It includes as many references as possible starting from the early 1990s when the LBL field was born. In all the topics discussed, emphasis is made on the chemicals involved in making the LBL thin film, the type of the electrode used and the functionalization needed for thin film deposition, the application of cyclic voltammetry, and the type of electroactive or electrocatalytic center involved.

Topics that are covered in this entry comprise LBL thin films containing:

1. Phthalocyanin, porphyrins, and dendrimers
2. Electroactive complex salts
3. Polyoxometallates
4. Redox polymers
5. Metallic, semiconductor, and metal-oxide colloids
6. Conducting polymers
7. Graphite oxide and graphite carbon colloids

In each case a brief introduction is given about the mechanism of assembly and the electrochemical activity of the chemical species involved.

## PHTHALOCYANIN, PORPHYRINS, AND DENDRIMERS

The molecules of the phthalocyanin and porphyrin family possess a potential electroanalytical capability to detect soluble ions and molecules. Using LBL technique these molecules can be assembled with bipolar pyridine salts, polyelectrolytes, diazo resins, metalloporphyrins, and polyoxometallates.

**Assembly with bipolar pyridine salts.** Layer-by-layer ultrathin films containing water-soluble copper(II) phthalocyanine-3,4',4'',4'''-tetrasulfonic acid (CuPcTs) and bipolar pyridine salt  $\text{Py}^+-\text{C}_6\text{H}_{12}-\text{Ph}-\text{Ph}-\text{C}_6\text{H}_{12}-\text{Py}^+$  where ( $\text{Py}^+ = \text{C}_6\text{H}_5\text{N}^{\oplus}$ ) were assembled on gold electrodes. Six bilayers yielded a cyclic voltammogram of two redox peaks within a potential range +0.8 to -0.5 V using an acetate buffer of pH 4.5. The detection limit of the modified electrode toward Cu(II) ions is  $7 \times 10^{-6}$  M, yielded an acceptable selectivity, and a response time of 15–30 sec.<sup>[3,12]</sup> The copper center can be replaced by cobalt for carbohydrate and hydrazine detection.<sup>[1]</sup>

**Assembly with polyelectrolytes.** Layer-by-layer ultrathin films containing water-soluble copper(II) phthalocyanine CuPcTs and the polycation poly(diallyldimethylammonium chloride) (PDAC) were assembled on inert electrodes. The cyclic voltammogram of the fabricated films in 0.1 M KCl aqueous solution showed redox peaks of the CuPcTs at approximately +0.9 and +0.05 V vs. Ag/AgCl.<sup>[13]</sup> Layer-by-layer electroactive films of iron tetrasulfonated phthalocyanine (FeTsPc) and polycationic poly(allylamine hydrochloride) PAH showed reproducible pairs of oxidation–reduction peaks at 0.92 V and 0.70 V for a 50-bilayer PAH/FeTsPc film at a sweep rate of 50 mV/sec vs Ag/AgNO<sub>3</sub>.<sup>[14,15]</sup>

**Assembly with diazo resins.** A covalently attached multilayer film of a diazo-resin<sup>[16]</sup> and cobalt phthalocyanine tetrasulfonic acid tetrasodium salt (CoTsPc) was fabricated on the surface of a glassy carbon electrode by UV irradiation. Cyclic voltammetry showed the modified electrode had an excellent electrocatalytic response to the oxidation of hydrazine at a lower potential. The modified electrode also exhibited fast response, good stability, and repeatability.<sup>[17]</sup> Layer-by-layer film of a diazo-resin and CoTsPc on glassy carbon electrode induced a potentiometric response to iodide ions.<sup>[18]</sup>

**Other selected examples.** Layer-by-layer films of [tetrakis(*N*-methylpyridyl) porphyrinato] cobalt and polyoxometallate  $[M(H_2O)_n P_2 W_{18} O_{62}]^{6-}$  where  $M = Co$  or  $Eu$  were assembled on 4-aminobenzoic acid (4-ABA) modified glassy carbon electrode. Cyclic voltammetry showed remarkable electrocatalytic activity for the four-electron reduction of the oxide ion to water and the two-electron reduction of  $O^{2-}$  ion to  $H_2O_2$  in pH 1–6 buffer solutions.<sup>[19]</sup> Electrochemical and photoelectrochemical measurements on LBL ordered substituted phthalocyanine or conducting poly(thiophene-3-acetic acid)-sensitized  $TiO_2$  multilayers were used to study Gratzel-type photo-voltaic cells.<sup>[20]</sup> Layer-by-layer films of polycationic *meso*-tetra(4-pyridyl)porphyrin-4-[Ru-II(bipy)<sub>2</sub>Cl]<sup>4+</sup> and anionic porphyrins was capable of displaying electrochemical, electrocatalytic, and photochemical interactions.<sup>[21]</sup> Multilayer films of polycationic tetraruthenated zinc porphyrin, Zn[*meso*-tetra(4-pyridyl)porphyrin-4-(Ru-II(bipy))]<sup>4+</sup> and anionic *meso*-tetraphenyl porphyrin sulfonate, deposited on inert electrodes exhibited a reversible wave at 0.94 V and were photocatalytically active toward the reduction of the oxide ion.<sup>[22]</sup> Layer-by-layer films of the positively charged pentaerythritol-based metallodendrimer with ruthenium(II) terpyridine units and Poly(styrene sulfonate) (PSS) were assembled on a glassy carbon electrode to catalyze the oxidation of L-methionine and insulin at neutral pH.<sup>[23,24]</sup>

## ELECTROACTIVE COMPLEX SALTS

Complex salts such as Prussian blue can be assembled layer by layer either in combination with each other or with polyelectrolytes. The electrochromic and electrocatalytic activity is a major lure to scientists in this field.

**Layer-by-layer electroactive (salt-on-salt) deposition.** Layer-by-layer ultrathin films of metal hexacyanometallates were prepared by alternate electrostatic assembly between metal cations  $M^{m+}$  (i.e.,  $Fe^{3+}$ ,  $Fe^{2+}$ ,  $Co^{2+}$ , and  $Ni^{2+}$ ) and hexacyanometallate anions

$[M(CN)_6]^{n-}$  such as  $Fe(CN)_6^{3-}$ ,  $Fe(CN)_6^{4-}$ , and  $Co(CN)_6^{3-}$  on solid supports with typical electrochemical activity on top of their separation properties.<sup>[25–27]</sup>

Layer-by-layer films of Dawson-type tungstodiphosphate anion,  $P_2W_{18}O_{62}^{6-}$ , and cationic  $Ru(NH_3)_6^{3+}$  were alternately assembled on a 1,7-diaminoheptane functionalized glassy carbon electrode. The  $P_2W_{18}O_{62}^{6-}$  multilayers exhibited high electrocatalytic response and sensitivity toward the reduction of  $IO_3^-$  and the catalytic potential shifted positively with layer number.<sup>[28]</sup> Electrochemically assembled LBL films of Pt(IV/II) and Pd(IV/II) complexes displayed interesting electrocatalytic and electrochromic properties.<sup>[29]</sup> Layer-by-layer multilayer films of *tris*(2,2'-bipyridyl) ruthenium(II) and sodium decatungstate ( $W_{10}O_{32}^{4-}$ ) deposited on indium-tin oxide (ITO) electrode showed electrocatalytic activities manifested by the reduction of  $IO_3^-$  and the oxidation of oxalate ions.<sup>[30]</sup>

**Layer-by-layer polyelectrolyte with electroactive salts deposition.** Layer-by-layer films of Prussian blue nanoparticles and novel polyelectrolytes have been carefully monitored by cyclic voltammetry.<sup>[31]</sup> These ranged from Prussian blue nanoparticles and linear poly(ethylene imine) assembled on ITO and gold electrodes that were characterized spectroelectrochemically to silicotungstate and cationic redox polymers on cysteamine-coated Au electrodes studied by cyclic voltammetry.<sup>[32,33]</sup> Layer-by-layer films of PDAC and anionic sodium decatungstate ( $W_{10}O_{32}^{4-}$ ) were assembled onto quartz, mica, and ITO-electrode substrates. The electrochemical properties of the S-(PDAC/( $W_{10}O_{32}^{4-}$ ))<sub>n</sub> films were found to differ from those in which the polyelectrolyte remained at the outermost layer, i.e., S-(PDAC/( $W_{10}O_{32}^{4-}$ ))<sub>n</sub>/P.<sup>[34]</sup>

## POLYOXOMETALLATES

The polyoxometallates (POMs) are large crystals with multiple negative charges that can reach 42<sup>-</sup>. Most common are the molybdates, usually abbreviated as  $Mo_N$  where  $N$  is the number of the molybdenum atoms within the cluster (e.g.,  $Mo_{132}O_{372}(CH_3COO)_{30}(H_2O)_{72}^{42-}$ ). There are the metallo POMs abbreviated as M-POM where “M” symbolizes a certain metallic atom (e.g., Eu-POM =  $[Eu^{III}(H_2O)P_5W_{30}O_{110}]^{12-}$ ). The POMs have been successfully assembled with positively charged polyelectrolytes such as PDAC, PAH, and polyethyleneimine.

Using electrostatic LBL self-assembly, the formation of multilayers with polyelectrolytes and nanoscopic POM clusters of different sizes and charges is extensive.<sup>[12]</sup> Cyclic voltammetry indicates that the electrochemical properties of the POM clusters are fully maintained in the polyelectrolyte matrix, which

opens a route toward practical applications such as sensors or heterogenous catalysis.<sup>[35]</sup>

Cyclic voltammograms of (Co-POMs/PAH)<sub>10</sub> LBL film on modified ITO electrode using a 0.5 M NaCl solution produced multiple redox peaks at a potential range of -0.8 V to -0.2 V vs. Ag/AgCl.<sup>[12,36]</sup> Under similar conditions (Eu-POMs/PAH)<sub>20</sub>, LBL film yielded multiredox cyclic voltammograms.<sup>[37]</sup> Layer-by-layer electrostatic assembly was used to prepare films comprising generation-4 polyamidoamine dendrimers and dirhodium polyoxometallates on glassy carbon electrodes pretreated with a monolayer of 4-ABA. Electrocatalytic activity showed the reduction of nitrites and the oxidation of arsenites.<sup>[38]</sup> The electrochemical behavior of ultrathin multilayer films of sphere-shaped polyoxomolybdate Mo<sub>8</sub>V<sub>2</sub>O<sub>28</sub>·7H<sub>2</sub>O/PAH and wheel-shaped molybdenum POM clusters (Mo-38)<sub>n</sub>, (Mo-36)<sub>n</sub>/PAH was investigated at room temperature.<sup>[39-41]</sup> Through LBL assembly, a series of undecatungsto-zincates substituted by transition metals, ZnW<sub>11</sub>M(H<sub>2</sub>O)O<sub>39</sub><sup>n-</sup> (M = Cr, Mn, Fe, Co, Ni, Cu, or Zn) were successfully immobilized on a 4-ABA modified glassy carbon electrode surface. The electrochemical and electrocatalytic response of such LBL films toward the reduction of H<sub>2</sub>O<sub>2</sub> and BrO<sub>3</sub><sup>-</sup> was analyzed.<sup>[42]</sup> Layer-pairs of oppositely charged cationic PDAC and silicotungstate, SiW<sub>12</sub>O<sub>4</sub><sup>4-</sup>, were grown on grafted carbon substrates. The multilayer films electrocatalytically reduced NO<sub>2</sub><sup>-</sup> in acidic solution while the catalytic currents increased as more SiW<sub>12</sub>O<sub>4</sub><sup>4-</sup> layers were deposited.<sup>[43]</sup>

## REDOX POLYMERS

Most famous of these are the quaternized poly(4-vinylpyridine)-osmium complex [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup>] and the polyviologens. The redox polymers were assembled with biological molecules, polyelectrolytes, and heteropolytungstates.<sup>[44]</sup> The metallopolymer provides an LBL film with electrocatalytic and light-emitting effects.

**Redox polymer with polyelectrolytes.** Layer-by-layer films of [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup>] with two kinds of polyanions, PSS and poly[aniline-co-N-(3-sulfopropyl) aniline] assembled on gold electrodes showed different electrocatalytic response for the reduction of nitrites. High-efficiency LBL solid-state light-emitting devices have been fabricated from polymeric ruthenium (II) complex, Ru(bpy)<sub>3</sub><sup>2+</sup>, polyester and poly(acrylic acid) (PAA).<sup>[45]</sup> Redox polyelectrolytes characterized by the electrocatalysis of viologen polyelectrolyte films on platinum electrodes showed higher currents with layer number.<sup>[46,47]</sup> Layer-by-layer films of ditopic ligand 1,4-bis(2,2':6',2''-terpyridine-4'-yl) benzene and

Co(II) metallo-supramolecular coordination polyelectrolyte and PSS assembled on inert electrodes showed a reversible one-electron redox transition in the potential range of -0.15 to 0.35 V. The iron ions showed strong ion-exchange properties within the multilayer by forcing a removal of the cobalt ions. Charge transport through the multilayer was induced by electron hopping and self-exchange reactions.<sup>[46,48]</sup>

**Redox polymer with biological molecules.** Multilayers of glucose oxidase (GOD) and poly(4-vinylpyridine) complex of osmium [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup>] on gold electrodes showed that osmium exchanged electrons effectively between the immobilized GOD and the electrode surface.<sup>[2,49]</sup> Electrochemical behavior of LBL films of negatively charged horseradish peroxidase and [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup>] assembled on gold electrodes showed that multilayer films containing the enzyme and the redox polymer were highly stable. The enzyme-multilayer electrode was sensitive to the electrocatalytic reduction of hydrogen peroxide.<sup>[50]</sup> Multilayer immobilization of antibody IgG on [Os(bpy)<sub>2</sub>ClPyCH<sub>2</sub>NH poly(allylamine)] redox polymer adsorbed on thiolated gold electrodes was harnessed for molecular recognition of horseradish peroxidase-biotin conjugate as the enzyme was a part in the electrocatalytic reduction of H<sub>2</sub>O<sub>2</sub>.<sup>[51]</sup>

**Redox polymer with heteropolytungstates.** Layer-by-layer ultrathin multilayer films have been prepared by means of alternate adsorption of iron(III)-substituted heteropolytungstate anions and osmium-based cationic redox polymers on 4-ABA modified glassy carbon electrode.<sup>[52]</sup> The resulting multilayer films can effectively catalyze the reduction of H<sub>2</sub>O<sub>2</sub>, NO<sub>2</sub><sup>-</sup>, and BrO<sub>3</sub><sup>-</sup>. Layer-by-layer films were also assembled from tri-vanadium-substituted heteropolytungstate V<sub>3</sub>(P<sub>2</sub>W<sub>15</sub>O<sub>53</sub>) and a cationic polymer of [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup>] on a 4-ABA modified glassy carbon electrode. The vanadium-centered redox reaction of V<sub>3</sub>(P<sub>2</sub>W<sub>15</sub>O<sub>53</sub>) in the multilayer films effectively catalyzed the reduction of NO<sub>2</sub><sup>-</sup>, BrO<sub>3</sub><sup>-</sup> and induced the catalytic oxidation of ascorbic acid.<sup>[53]</sup> Layer by layers of silicotungstic heteropolyanion (SiW<sub>12</sub>O<sub>4</sub>)<sup>4-</sup> and [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup>] assembled on a 4-ABA modified glassy carbon electrode showed electrocatalytic reduction activities of four probes HNO<sub>2</sub>, H<sub>2</sub>O<sub>2</sub>, NO<sub>2</sub><sup>-</sup>, and BrO<sub>3</sub><sup>-</sup>.<sup>[54,55]</sup>

## METALLIC, SEMICONDUCTOR, AND METAL-OXIDE COLLOIDS

Colloidal nanoparticles have been prepared as stable suspensions in aqueous solution using a variety of methods. Therefore, many scientists utilized these

colloidal solutions to assemble LBL films that showed interesting electrochemical activity.

**Layer-by-layer films containing metallic nanoparticles.** Layer-by-layer films of Pt nanoparticles assembled by  $\text{PtCl}_6^{2-}$  and [tetrakis-(*N*-methylpyridyl)porphyrinato] cobalt on a 4-ABA modified glassy carbon electrode possessed catalytic activity for the reduction of the oxide ion to water in 0.5 M  $\text{H}_2\text{SO}_4$  solution.<sup>[56]</sup> Following LBL assembly of  $\text{PdCl}_4^{2-}$  and polycation  $[(\text{Os}(\text{bpy})_2\text{Cl})^{2+}]$  on 4-ABA modified glassy carbon electrodes, Pd nanoparticles were embedded in LBL films by electrochemical reduction of  $\text{PdCl}_4^{2-}$ . The resulting Pd nanoparticle multilayer-modified electrode possessed electrocatalytic activity for the reduction of dissolved oxygen and oxidation of hydrazine compounds in aqueous solution.<sup>[57]</sup> Layer-by-layer gold colloidal nanoparticles assembled with 1,6-hexanedithiol as cross-linker yielded a gold-multilayer electrode with electrochemical properties similar to metallic Au.<sup>[58]</sup> Gold nanoparticles functionalized with a monolayer of mercapto-decanoic acid were suitably assembled with PAH/PSS on inert electrodes. These LBL films were probed electrochemically using ferrocene as the active probe vs. Ag/AgNO<sub>3</sub>.<sup>[59]</sup>

**Layer-by-layer films containing semiconductor and/or metal oxide colloids.** Layer-by-layer films were assembled using trioctylphosphine oxidecapped *n*-type CdSe nanoparticles, 1,6-hexadecanethiol, onto *p*-doped semiconducting polymers [for example, either chemically deposited poly(3-methylthiophene) or electrochemically deposited poly(pyrrole)]. Dissymmetrical junctions showed rectification in the forward bias and a Zener breakdown in the reverse.<sup>[60]</sup> Micrometer-size gold nanowires were coated with nanoparticles of TiO<sub>2</sub> or ZnO in combination with polymer multilayer LBL film inside porous membranes to give concentric structures of TiO<sub>2</sub>/PSS, ZnO/PSS, and ZnO/polyaniline (PANI). The current–voltage characteristics of the nanowires/semiconductor nanoparticles showed some current rectification.<sup>[61]</sup> Layer-by-layer films of vanadium oxide V<sub>2</sub>O<sub>5</sub>/PANI nanocomposites were assembled to utilize the electrochemical behavior of V<sub>2</sub>O<sub>5</sub> and the chromogenic properties of PANI.<sup>[62]</sup> For example, LBL films of V<sub>2</sub>O<sub>5</sub>/PANI nanocomposites built for charge storage devices showed a charge storage capability of 2.25 mC/cm<sup>2</sup> in comparison with 1.86 mC/cm<sup>2</sup> for PANI and V<sub>2</sub>O<sub>5</sub> combined storage.<sup>[63]</sup> Positively charged tris(2,2'-bipyridyl)ruthenium (II)  $[\text{Ru}(\text{bpy})_3^{2+}]$  and negatively charged SiO<sub>2</sub> nanoparticles were assembled on ITO electrodes by LBL method. Electrochemical and electrogenerated chemiluminescence of the SiO<sub>2</sub>/[Ru(bpy)<sub>3</sub><sup>2+</sup>]<sub>*n*</sub> multilayer film-modified electrodes were studied by cyclic voltammetry.<sup>[64]</sup>

## CONDUCTING POLYMERS

Conducting polymers such as PANI, polypyrrole, PANI-sulfonate, and 3,4-polyethylenedioxythiophene–PSS can be suspended in aqueous solution in their colloidal form. In LBL films conducting polymers can be rendered electronically conductive by doping with strong acidic solutions or dopants such as anthraquinone.<sup>[65–67]</sup>

Layer-by-layer films of PANI and PSS multilayers deposited onto polystyrene colloidal particles showed that PSS/PANI multilayers maintained their chemical stability and electrochemical properties after removal of the core.<sup>[68]</sup> Layer-by-layer nanostructured films of two conducting polymers, poly(*o*-methoxyaniline) (POMA) and poly(3-thiopheneacetic acid), showed a different electrochemical response from a pure POMA cast film.<sup>[69]</sup> Layer-by-layer films of polycation, PDAC and polyanion, sulfonated polyaniline (SPANI) on ITO plates showed that PDAC/SPANI LBL films were electrically active.<sup>[70]</sup>

Layer-by-layer film of polycationic PANI and poly(anions), such as SPANI, PAA, poly(vinyl sulfonate), and PSS were successful in electrocatalyzing the oxidation of beta-nicotinamide adenine dinucleotide in neutral solution where the catalytic activity of the PANI/SPANI system showed the best performance.<sup>[71]</sup> Ultrathin multilayer films of polypyrrole and PSS deposited on various substrates (glass, mica, ITO coated glass plates) were embedded with glucose oxidase to study multielectron transfer processes.<sup>[72]</sup> Layer-by-layer stable electroactive films of myoglobin or horseradish peroxidase and PSS were grown on SPANI functionalized rough pyrolytic graphite electrodes. A highly efficient coupling between the enzymes and electrode, PDAC/SPANI/(enzyme/PSS)<sub>3</sub> films exhibited a higher sensitivity for the electrochemical catalytic reduction of hydrogen peroxide and a sensitivity for up to 14 μA/μM/cm<sup>2</sup> and a detection limit of 3 nM.<sup>[73]</sup>

## GRAPHITE OXIDE AND GRAPHITE CARBON COLLOIDS

Unfortunately, LBL conducting polymer films are weak ionic conductors and unstable in the long term. A more resilient combination is a polyelectrolyte–colloid composite such that the colloid is electronically conducting and ready to assemble. Many colloids can assemble with polyelectrolytes, but in most cases the LBL films are nonconducting. Only one original approach used exfoliated graphite oxide (GO) that is not conducting to assemble polyethyleneoxide/PDAC/GO LBL films. The problem with graphite is that it is difficult to disperse in water and it “forms

micrometer-sized irregular aggregates in organic solvents.” After assembly the GO can be converted to graphite under severe reduction conditions with H<sub>2</sub> gas.<sup>[74,75]</sup>

Recently, a new method, devised at Massachusetts Institute of Technology, directly employs polyelectrolyte graphite mixtures to assemble LBL electrodes<sup>[76,77]</sup> without having to convert the graphite powder to exfoliated GO and then back to graphite, where in both processes severe chemical, electrochemical, and thermal conditioning was applied. The LBL polyelectrolyte-carbon electrodes (LPCE) have major advantages over LBL conducting polymers. The electronic conductance of LPCE is pH independent and its structure showed good stability because it did not degrade as conducting-polymer based LBLs do. The graphite powder can be assembled as catalyzed carbon or pure carbon loaded with a suitable catalyst. In electrochemical systems, especially fuel cells, the LPCE is expected to perform multiple tasks due to their complexity. The LPCE should be ionically conducting ( $>10^{-4}$  S/cm); electrically conducting ( $>1.0$  S/cm); deposit as micrometer-thin film; hydrophobic to expel water; stable to chemical and mechanical degradation; loaded with catalysts and intimately adhere to the proton-exchange membrane and the gas-diffusion layer. Finally, its open-circuit potential should be similar to a pure metal.

Layer-by-layer polyelectrolyte-carbon electrodes assembled using the 20% Pt-Hispec3000 fuel cell carbon black catalyst showed good dispersion of platinum particles as in the powder form, with a catalyst loading that approached half that of a commercial electrode (i.e., 0.5 mg/cm<sup>2</sup>) verified by scanning electron microscopy (SEM) x-ray analysis. Depositing LPCEs on LBL membrane of PDAC and poly(2-acrylamido-2-methyl-1-propane sulfonic acid) (PAMPS) resulted in a “soft” membrane-electrode assembly (MEA) with no hot pressing applied (Fig. 1A). A cross-sectional view of a linear poly(ethyleneimine)/PAA/Pt/carbon flake LPCE using SEM revealed an electrode thickness of 5–6.0 μm with a surface roughness of less than 400 nm (Fig. 1C).

Scanning electron microscopy revealed that the graphite particulates are held in intimate contact and an electronic conductivity up to 2.0 S/cm was recorded. The electronic conductance of the LPCE decreased as humidity increased but even when soaked in water the electronic conductivity remained higher than 0.5 S/m. Unlike LBL conducting films that use conducting polymers such as poly(aniline) or poly(pyrrole), the LPCE required no dopants and was remarkably stable. It is crucial that the LPCE should maintain integrity after prolonged use in the severe environment of electrochemical devices such as fuel cells. The open circuit potential (OCP) of a solid platinum electrode

**Fig. 1** Scanning electron microscopy pictures of (A) [poly-(diallyldimethylammonium chloride)/poly(2-acrylamido-2-methyl-1-propane sulfonic acid)/20% Pt-Hispec3000 fuel cell carbon black catalyst] (i.e., PDAC/PAMPS/Hispec3000) LPCE, resolution = 100 μm;  $E_e = 5$  kV; (B) a PDAC/PAMPS/Hispec 3000 LPCE, resolution = 100 nm;  $E_e = 5$  kV; and (C) a cross sectional view of a linear poly(ethyleneimine) /PAA/Pt/carbon flake LPCE with a thickness of 4–5.0 μm and a surface roughness ~500 nm,  $E_e = 5$  kV.

vs. saturated calomel electrode (SCE) in 0.02 M·H<sub>2</sub>SO<sub>4</sub> purged in hydrogen [Pt/0.02M·H<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>(g)//SCE] measured +0.32 to +0.359 V. For Au/0.02 M·H<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>(g)//SCE the OCP = 0.005 to +0.02 V; and for a carbon coated gold electrode: [C/Au]/0.02 M·H<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>(g)//SCE the OCP = +0.005 to +0.03 V; while for LPCE coated gold electrode: [Pt-C/Au]/0.02M·H<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>(g)//SCE the OCP = +0.345 to +0.347 V. In a galvanic cell of acidified dichromate and basic borohydride solutions the OCP

**Fig. 2** (A, B) [Poly(diallyldimethylammonium chloride)/poly(2-acrylamido-2-methyl-1-propane sulfonic acid)/20% Pt-Hispec3000 fuel cell carbon black catalyst] (i.e., PDAC/PAMPS/Hispec3000) LPCE deposited on porous stainless steel. (C) MEA of a PDAC/PAMPS/Hispec3000 LPCE deposited on Nafion112® membrane. (D) MEA of a PDAC/PAMPS/Hispec3000 LPCE deposited on LBL PDAC/PAMPS/Nucleopore® composite membrane.

of LPCE deposited on stainless steel electrode measured +1.63 V (Figs. 2 and 2B), while pure platinum electrodes yielded an OCP = +1.58 V, and an uncoated stainless steel SS316L electrode yielded an OCP = +0.89 V. The difference in the power generated is 2.0 mW/cm<sup>2</sup> by the LPCE-Hispec3000 coated SS316L, 0.088 mW/cm<sup>2</sup> by the uncoated SS316L electrodes, and 0.6 mW/cm<sup>2</sup> by the pure platinum electrodes. Results from the power generated signify effective platinum loading in the matrix of the LPCE and resiliency to acidic/basic and reductive/oxidative aqueous solutions.

The ionic conductivity  $\sigma_i$  of the LPCE reached a maximum of  $2.0 \times 10^{-4}$  S/cm in 0.02 M-H<sub>2</sub>SO<sub>4</sub> indicating the porous nature of the LPCE and efforts under way to measure  $\sigma_i$  around the catalyst. The LPCE was successfully deposited on membranes such as Nafion112® and LBL PDAC/PAMPS composite membrane (Figs. 2C and 2D), to fabricate the MEA.<sup>[76]</sup> The LPCE was found to adhere intimately to the ion conducting membrane eliminating the need to apply extreme hot pressing methods to fabricate the MEA. When properly mounted, a soft MEA, running on H<sub>2</sub> and air produced a stable OCP up to +0.9 V, similar to any commercial MEAs; however, the power delivered was only a few milliwatts per square centimeter, which should be attributed to the low ionic conduction that affects the catalyst performance.

## CONCLUSIONS

A brief review on nonbiological electroactive LBL thin films was provided to illustrate the versatility of the

LBL technique in thin film assembly. Multilayers of the phthalocyanin and porphyrin family possess a potential electroanalytical capability to detect soluble ions and molecules. The electrochromic and electrocatalytic activity of multilayer complex salts and the complexity of the polyoxometallate clusters made them potentially adaptable toward practical applications such as sensors and heterogenous catalysts. Metallo-polymer based LBL films possessed electrocatalytic and light-emitting effects. Layer-by-layer films assembled from metallic, semiconductor, and metal-oxide colloids showed interesting electrochemical activity, while those containing conducting polymers and doped with strong acids become electronically conductive. More resilient electronically conductive films can be assembled from polyelectrolyte-graphite oxide LBLs. One new method of direct assembly of carbon-polymer electrodes can combine the electrochemical activity of all the systems mentioned earlier to produce highly adaptable electrodes. The porous graphitic nature of the LBL carbon-polymer electrodes opens a wide range of application such as fuel and galvanic cells, batteries, supercapacitors, electrolyzers, and catalytic converters.

## INTRODUCTION

The formation of ordered monolayers and multilayers of both organic and inorganic materials on solid substrates with various functionalities has been a subject of intensive research in view of the possible applications in a wide variety of fields in nanotechnology and nanoscience.

Metal and semiconductor nanoclusters are the good candidates as building blocks for the multilayer formation because they have various interesting characteristics, which are different from those of the bulk materials. Since the report by Brust et al.,<sup>[1]</sup> gold nanoclusters (GNCs) covered by self-assembled monolayers (SAMs) of alkanethiols have attracted many research groups<sup>[2–17]</sup> because SAM-covered GNCs have a high stability and those of a certain size with a narrow size distribution can be prepared relatively easily. Gold nanocluster with special functionalities can be constructed by using thiol molecules with special functional groups. One can utilize the rich references on alkanethiol SAMs with various functionalities<sup>[18,19]</sup> including ours.<sup>[20–27]</sup>

Structurally organized GNC multilayers have been constructed on solid substrates by various wet processes, including bond formation between a sulfur atom of an alkanedithiol, a linker, and metal atoms of a substrate as well as of a nanocluster<sup>[8,28–31]</sup> and the Langmuir–Blodgett (LB) method.<sup>[32]</sup> The electrostatic layer-by-layer (LBL) assembly method, which was initially developed for thin film fabrication of pure polymeric materials of oppositely charged polyelectrolytes,<sup>[33]</sup> has been extended to the construction of alternate multilayer assemblies composed of oppositely charged nanoparticles and polyions.<sup>[10–12,14,34,35]</sup> The simplicity and versatility of the LBL technique as well as the resulting high-quality films provide broad perspectives in both fundamental and applied research in nanostructure systems.

## OVERVIEW

In this study, multilayers composed of two types of GNC, one covered by mixed SAMs of mercaptoundecanoic acid (MUA), hexanethiol (C<sub>6</sub>SH), and ferrocenylhexanethiol (FcC<sub>6</sub>SH), MHF-GNC, and the other covered with MUA and C<sub>6</sub>SH, MH-GNC, are constructed on Au(111) and ITO surfaces using a cationic polymer, poly(allylamine hydrochloride) (PAH), as the binding layer based on the carboxylate/PAH/carboxylate electrostatic interaction. The electrochemical characteristics of these multilayers are investigated and the effects of the substrates are examined. The charge transfer mechanism within the GNC multilayers is also discussed.

## EXPERIMENTAL

### Materials

Poly(allylamine hydrochloride) (average Mw = 70,000) was purchased from Aldrich. Perchloric acid (ultrapure grade), sodium chloride, and sulfuric acid (ultrapure grade) were obtained from Wako Pure Chemicals. All chemicals were used as received. Indium–tin-oxide (ITO)-coated glass was obtained from Tokyo Kinoene Optics. Ultrapure water was obtained using a Milli-Q water purification system (Millipore), and ultrapure N<sub>2</sub> (99.999%) was obtained from Air Water.

### Substrates

A gold single crystal was prepared from a gold wire (99.999%,  $\phi = 1$  mm, Tanaka Precious Metals) by Clavilier's method.<sup>[36,37]</sup> It was cut to expose the

(111) face, mechanically polished, and then annealed at 800°C for 8 hr in an electric furnace (Denken, KDF S-70) under an ultrapure N<sub>2</sub> atmosphere. Gold substrates used for the electrochemical quartz crystal microbalance (EQCM) measurements were prepared by the vacuum evaporation of 10-nm-thick titanium followed by 100-nm-thick gold onto a 5-MHz quartz crystal plate (double-side polished) kept at 300°C with an evaporation rate of less than 0.01 nm sec<sup>-1</sup>. This procedure is known to provide a highly ordered Au(111) phase with wide terraces.<sup>[38]</sup> For the X-ray photoelectron spectroscopy (XPS) measurements, a gold disk (99.99%,  $\phi = 8$  mm, thickness = 3 mm, Tanaka Precious Metals) was used as the substrate after mechanical polishing and electrochemical treatment by cycling the potential between -0.2 and +1.5 V vs. Ag|AgCl in 0.1 M H<sub>2</sub>SO<sub>4</sub>. The ITO substrate was cleaned by immersing it in a 1:3 H<sub>2</sub>O<sub>2</sub> (30%)–H<sub>2</sub>SO<sub>4</sub> (conc.) solution for 5 sec, then thoroughly rinsing it with Milli-Q water, and finally drying it with ultrapure nitrogen.

### Preparation of Gold Nanoclusters

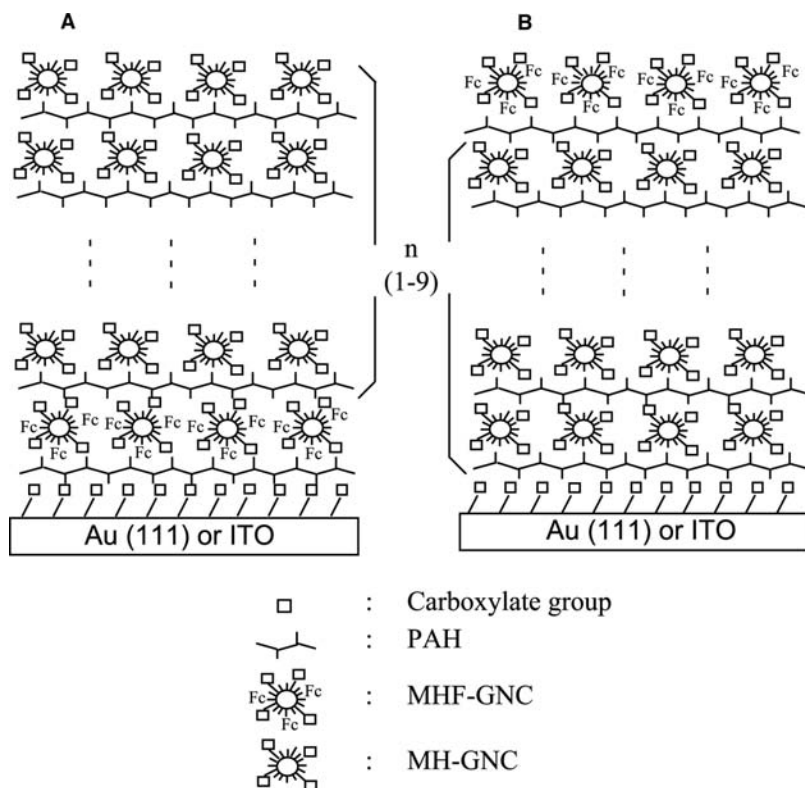

Two types of GNC protected by mixed alkanethiol SAMs, one covered by mixed SAMs of C<sub>6</sub>SH, FcC<sub>6</sub>SH, and MUA (MHF-GNC), and the other covered by C<sub>6</sub>SH and MUA (MH-GNC), were prepared by the procedures reported previously.<sup>[39–41]</sup>

Transmission electron microscopy (TEM, JEOL-2000EX, 200 kV) proved that the core diameter of the GNCs was 1.8 ± 0.4 nm in both cases. The molar ratios of C<sub>6</sub>SH:FcC<sub>6</sub>SH:MUA on the MHF-GNC surface and C<sub>6</sub>SH:MUA on the MH-GNC surface estimated by <sup>1</sup>H-NMR (Hitachi, R-1900, 90 MHz) were 47:19:34 and 26:74, respectively. Based on these results, the number of FcC<sub>6</sub>SH molecules adsorbed on one GNC is calculated to be 10 because 53 thiol molecules adsorb on a GNC with a core size of 1.8 nm.<sup>[9]</sup>

### Preparation of Multilayers of Gold Nanoclusters

Multilayers of MHF-GNC were constructed on Au(111) and ITO substrates based on the carboxylate/polycation electrostatic interaction. All the gold substrates were annealed by a hydrogen flame and cooled in air just before dipping in the thiol solution. The cleaned ITO substrate was immediately transferred to an ethanol solution containing 1 mM MUA and kept in the solution for at least 36 h.

Gold nanocluster multilayers with the following three different arrangements as described in Scheme 1 were formed on the carboxylate-terminated (MUA) SAM-modified gold substrates based on the carboxylate/PAH/carboxylate electrostatic interaction. 1) A multilayer containing only MHF-GNC/PAH [Au(111)/MUA/(PAH/MHF-GNC)<sub>n</sub>] was prepared on a gold surface by repeating the two-dip and rinse cycle as

**Scheme 1** Schematic view of the idealized layer structure of (A) Au(111) or ITO/MUA/(PAH/MHF-GNC)<sub>n</sub>, (B) Au(111) or ITO/MUA/PAH/MHF-GNC/(PAH/MH-GNC)<sub>n</sub>, and (C) Au(111) or ITO/MUA/(PAH/MH-GNC)<sub>n</sub>/PAH/MHF-GNC electrodes.

reported before.<sup>[40]</sup> 2) A multilayer of MH-GNC and MHF-GNC with only one layer of MHF-GNC existed in the layer closest to the gold electrode, i.e., the first layer, and MH-GNC in the other layers [Scheme 1a: Au(111)/MUA/PAH/MHF-GNC/(PAH/MH-GNC)<sub>n</sub>]. 3) A multilayer of MH-GNC and MHF-GNC with only one layer of MHF-GNC existed only in the outermost layer and MH-GNC in the other layers [Scheme 1b: Au(111)/MUA/(PAH/MH-GNC)<sub>n</sub>/PAH/MHF-GNC].

The gold substrate precoated with MUA SAM was dipped in a 2 wt.% PAH aqueous solution (pH = 6) containing 1 M NaCl for 30 min followed by a Milli-Q water rinse and then dipped in a 0.75 wt.% GNC ethanol solution for 30 min followed by a rinse with ethanol. This two-dip and rinse cycle was repeated to construct the multilayers.

After the MUA SAM-coated ITO substrate had been thoroughly rinsed with ethanol and dried with ultrapure nitrogen, the MHF-GNC multilayer was constructed by alternately dipping the ITO substrate in a 2.0 mg/mL PAH solution containing 1 M NaCl for 10 min and 1.0 mg/mL MHF-GNC solution for 10 min.

### Structural Characterization of the Gold Nanocluster/Poly(Allylamine Hydrochloride) Multilayers

Atomic force microscopy (AFM) was carried out using a PicoSPM (Molecular Imaging) in a contact mode. Atomic force microscopy tips were made of Pt/Si<sub>3</sub>N<sub>4</sub> with a typical spring constant of 0.12 N/m. Measurements were carried out at room temperature (ca. 20°C) and ambient humidity (ca. 38 ± 2%). X-ray photoelectron spectroscopy measurements were performed using a Rigaku XPS-7000 spectrometer with an MgK $\alpha$  X-ray source (1253.6 eV). The takeoff angle between the sample surface and the analyzer was fixed at 90° in all cases. The narrow-scan spectra of the Fe2p region were taken with a resolution of 0.1 eV and the signals of 64 scans were averaged. Cross-sectional transmission electron microscopy of a GNC multilayer was carried out using a JEOL electron microscope JEM-2010F with 200-kV acceleration voltage. A multilayer with 10 MHF-GNC/PAH deposition cycles was prepared on a silicon wafer with a pre-evaporated Au film of 150 nm. After the multilayer formation, the multilayer was further covered with the evaporated Au and epoxy resin to protect the multilayer for the preparation of a sliced sample.

### Electrochemical and Electrochemical Quartz Crystal Microbalance Measurements

Cyclic voltammograms (CVs) were recorded with an automatic polarization system (Hokuto Denko,

HSV-100). A potentiostat/galvanostat (Hokuto Denko, HA-151) and a function generator (Hokuto Denko, HB-111) were used for the EQCM measurements, which were carried out in a three-compartment cell. The resonant frequency of the quartz crystal electrode, which was oscillated using a homemade oscillation circuit, was simultaneously monitored with the electrode potential and current by a frequency counter (Hewlett-Packard, HP53131A) controlled by a personal computer (NEC, PC9821cb2) through a general purpose interface bus (GPIB) interface. The frequency stability of the EQCM system was better than 0.1 Hz for a sampling gate time of 0.1 sec. Pt wire and Ag|AgCl|NaCl(sat) were used as the counter and reference electrodes, respectively. The measurements were carried out in a 0.1 M HClO<sub>4</sub> aqueous solution, which was deaerated by passing ultrapure N<sub>2</sub> gas through it for more than 30 min before each measurement.

## RESULTS AND DISCUSSION

### Structure and Electrochemical Characteristics of the MHF-Gold Nanocluster/Poly(Allylamine Hydrochloride) Multilayers

Fig. 1 shows the cross-sectional micrograph of a multilayer with 10 MHF-GNC/PAH deposition cycles on an evaporated gold film. The substrate, GNC/PAH multilayers, and the protecting layers, i.e., the evaporated Au and epoxy resin, are clearly visible in Fig. 1A. From this image, the total thickness of the GNC multilayer with 10 GNC/PAH cycles was estimated to be about 58 nm, which is in good agreement with the previously reported value of 51 nm determined by ellipsometry for the same system.<sup>[40]</sup> This and the higher resolution image [Fig. 1B] reveal that the GNCs

**Fig. 1** Cross-sectional TEMs of (A) a MHF-GNC multilayer film with 10 deposition cycles on an evaporated Au film on the silicon wafer and (B) a higher-resolution image of the GNC/PAH multilayer region. *Source:* From Ref.<sup>[41]</sup>.

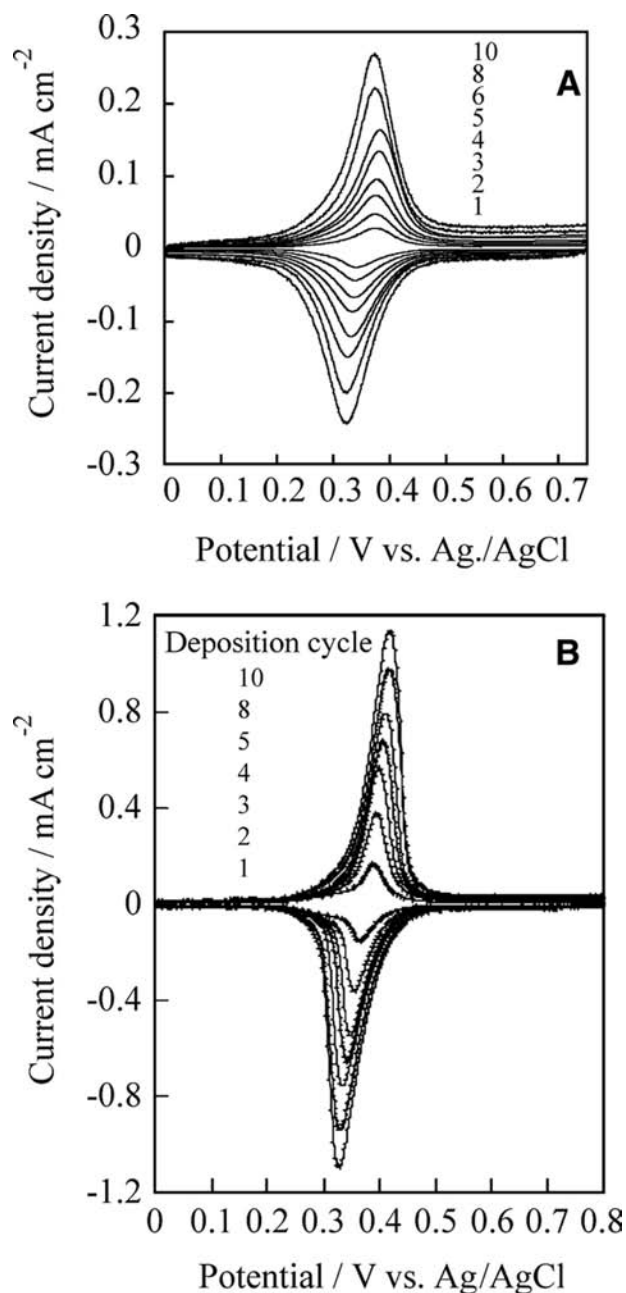

are dispersed within the polymeric matrix rather uniformly and the well-defined layered structure as illustrated in Scheme 1 is not observed, suggesting a homogenous mixture of the GNCs and PAH in the LBL film rather than the expected vertically ordered structure with sharp interfaces between the two components. This is reasonable because the layered LBL assembly might be obscured in the case of globular nanoparticles alternatively assembled with flexible linear polymeric chains because of the interpenetration between the adjacent layers and high interlayer roughness or by embedding of the GNCs on the polymeric chains. The spherical nanoparticles are separated from each other by the organic shells and the mean size of the immobilized GNC core is about  $1.8 \pm 0.3$  nm, which is almost the same as that of the GNC in solution, revealing the absence of aggregation or reshaping of the linked GNC particles to those of larger core size in the LBL multilayers. The average separation distance of the immobilized GNCs was estimated by measuring the edge-to-edge distances of the particles in the cluster regions in Fig. 1B. The result yields an almost uniform spacing close to the cluster core size. Similar features are expected for the multilayers with the ferrocene group either existing in the innermost and or outermost layers because both types of GNCs used for the fabrication of LBL multilayers with PAH spacing layers have same core size and similar activity.

### Redox Properties of the MHF-Gold Nanocluster/Poly(Allylamine Hydrochloride) Multilayers

Fig. 2A shows the CVs of the gold electrode modified with MHF-GNC/PAH multilayers of 1–10 deposition cycles measured in a 0.1 M  $\text{HClO}_4$  aqueous solution at a scan rate of  $100 \text{ mV sec}^{-1}$ . The oxidation and reduction peaks due to the redox of  $\text{Fc}/\text{Fc}^+$  are observed around +360 mV (vs.  $\text{Ag}|\text{AgCl}$ ) in all cases. The full width at half maximum (fwhm) of the MHF-GNC multilayer-modified electrode was constant at around 90 mV regardless of the GNC deposition cycles, suggesting a simple Langmuir-type redox process of the ferrocene moieties. The peak-to-peak separation was less than 60 mV in all cases, suggesting a facile charge transfer within the MHF-GNC multilayers.

Fig. 2B shows CVs of ITO electrodes modified with MHF-GNC multilayers of various layer thickness [ITO/MUA/(PAH/GNC) $_n$ ,  $n = 1, 2, 3, 4, 5, 8$  and 10] measured in a 0.1 M  $\text{HClO}_4$  aqueous solution at the scan rate of  $100 \text{ mV sec}^{-1}$ . For all cases, quasi-reversible peaks due to the redox of the ferrocene moiety were observed around +350 mV (vs.  $\text{Ag}/\text{AgCl}$ ).

**Fig. 2** Cyclic voltammograms of Au(111)/MUA/(PAH/MHF-GNC) $_n$  for  $n = 1$ –10 (A) and an MUA SAM-precoated ITO electrode modified with MHF-GNC multilayers of various thickness (B) measured in 0.1 M  $\text{HClO}_4$  aqueous solution at a scan rate of  $100 \text{ mV sec}^{-1}$ . Number of deposition cycles is shown in the figure. *Source:* From Ref.<sup>[41]</sup> and Song et al., *Phys. Chem. Chem. Phys.* **2003**, *5*, 5279–5284.

These redox peaks were sharp in all cases with full width at half maximum (fwhm) of 45 mV ( $n = 1$ ), 47 mV ( $n = 2$ ), 52 mV ( $n = 5$ ), and 60 mV ( $n = 10$ ), which are much narrower than that expected for a simple Langmuir-type redox process observed at

**Table 1** Redox potential and peak separation of Fc/Fc<sup>+</sup> couple of an MHF-GNC/PAH multilayer-modified ITO electrode in aqueous solutions containing 0.1 M of various anions at two pH values

Anions	PH 1			PH 7		
	E <sub>pa</sub> (mV)	E <sub>pc</sub> (mV)	ΔE <sub>p</sub> (mV)	E <sub>pa</sub> (mV)	E <sub>pc</sub> (mV)	ΔE <sub>p</sub> (mV)
ClO <sub>4</sub> <sup>-</sup>	420	320	100	450	345	105
NO <sub>3</sub> <sup>-</sup>	470	370	100	490	380	110
SO <sub>4</sub> <sup>2-</sup>	625	500	125	630	500	130

the gold electrode. The peak separation increased as the MHF-GNC layers increased from 23 mV ( $n = 1$ ) to 39 mV ( $n = 2$ ), 75 mV ( $n = 5$ ), and 100 mV ( $n = 10$ ).

The electrochemical responses of the MHF-GNC multilayer film-modified ITO electrode were also investigated in acidic (pH = 1) and neutral (pH = 7) solutions containing ClO<sub>4</sub><sup>-</sup>, NO<sub>3</sub><sup>-</sup>, or SO<sub>4</sub><sup>2-</sup>. The peak potentials of the wave due to the redox of the ferrocene/ferrocenium cation (Fc/Fc<sup>+</sup>) couple were almost independent of the pH but strongly dependent on the nature of the electrolyte as shown in Table 1. The results are in good agreement with those reported for ferrocene thiol SAMs-modified gold electrodes,<sup>[42–44]</sup> indicating that the ferrocene molecules adsorbed on the GNCs behaved essentially in the same manner as those of the SAMs on planar electrodes.

The amounts of redox-active ferrocene groups of the multilayer-modified gold and ITO electrodes estimated from the anodic charge of the redox peak are plotted as a function of the number of deposition cycles in Fig. 3. Although the amount of the

**Fig. 3** Amount of electroactive Fc groups as a function of number of MHF-GNC deposition cycles on ITO (○) and Au (□) electrodes. *Source:* From Song et al., Phys. Chem. Chem. Phys. **2003**, 5, 5279–5284.

electroactive Fc moiety increased with increase in the number of deposition cycles in both cases, the manner and the magnitude of increase in the amount of the electroactive ferrocene moiety with increase in the number of deposition cycles depended on the substrate. While the amount of the redox-active Fc group on the gold substrate increased almost linearly with increase in deposition cycles, the increment of that on the ITO substrate at each deposition cycle became smaller at higher deposition cycle. The increment of the adsorbed Fc groups at each deposition cycle on gold was  $1.8 \times 10^{-10}$  mol/cm<sup>2</sup> in average and that on ITO was  $12.5 \times 10^{-10}$  mol/cm<sup>2</sup> initially and decreased to  $5.5 \times 10^{-10}$  mol/cm<sup>2</sup> as the number of deposition cycles increased. Because one GNC contained 10 FcC<sub>6</sub>SH molecules on the surface as mentioned above, the numbers of adsorbed GNCs per deposition cycle on ITO and Au substrates were estimated to be  $7.6\text{--}3.4 \times 10^{13}$ /cm<sup>2</sup> and  $1.1 \times 10^{13}$ /cm<sup>2</sup>, respectively. Both values are greater than that calculated for a hexagonally packed monolayer of thiol-covered GNCs,  $(3.8\text{--}8.8) \times 10^{12}$ /cm<sup>2</sup>,<sup>[40]</sup> as well as that of a previously reported GNC assembly with a comparable core size.<sup>[14]</sup> One possible reason for this discrepancy is that not the monolayers but the relatively thick GNC/PAH layers were adsorbed on both surfaces at each deposition cycle under the present preparation conditions. We used a rather high concentration of salt in the PAH adsorbing solution (1 M NaCl), and it is known that the use of an adsorbing solution of high ionic strength usually results in the thicker adsorbed layers.<sup>[33]</sup> The reason for the larger amount of deposited GNC and the decrease in the deposited amount as the number of deposition cycles increased on the ITO substrate will be discussed later.

#### Differential Capacitance of MHF-Gold Nanocluster/Poly(Allylamine Hydrochloride) Multilayers

Figure 4 shows the deposition cycle dependencies of the apparent differential capacitances of GNC multilayers on ITO and gold electrodes calculated by dividing the charging currents observed before and after the

**Fig. 4** Apparent differential capacitances before ( $\Delta$  and  $\square$ ) and after ( $\circ$  and  $\diamond$ ) oxidation of ferrocene moiety as a function of MHF-GNC deposition cycles on the ITO ( $\Delta$  and  $\circ$ ) and Au ( $\square$  and  $\diamond$ ) electrodes. *Source:* From Song et al., *Phys. Chem. Chem. Phys.* **2003**, 5, 5279–5284.

redox peak by the scan rate.<sup>a</sup> For all cases, the apparent differential capacitances after the ferrocene oxidation were greater than those before the oxidation and increased with increase in the number of deposition cycles. Increase in capacitance upon oxidation of the ferrocene moiety has been observed at a ferrocene SAM-modified electrode and is known to be a result of an increase in hydrophilicity.<sup>[45]</sup>

The capacitance increased with increase in the number of deposition cycles in both cases, suggesting that the immobilized GNCs act as an ensemble of numerous nanosized electrodes. It is notable that the capacitance increased linearly with increase in the number of deposition cycles at the GNC-modified gold electrode, but the capacitance increment per deposition cycle became smaller as the number of deposition cycles increased at the GNC-modified ITO electrode. This observation is in accordance with the observation for the deposition cycle dependencies of the amount of redox-active Fc groups. The surface area of one GNC with a core size of 1.8 nm is ca.  $1.02 \times 10^{-13} \text{ cm}^2$ . Using the number of GNCs adsorbed on the ITO surface estimated from Fig. 3, the total electrode surface area of the GNCs assembled on an ITO surface of  $1 \text{ cm}^2$  can be calculated to be ca. 7.5 (1 cycle)–54 (10 cycles)  $\text{cm}^2$ . Because the capacitances of the

GNC-modified ITO electrode before and after the redox peak were ca. 50 (1 cycle)–140 (10 cycles)  $\mu\text{F}/\text{cm}^2$  and 73 (1 cycle)–280 (10 cycles)  $\mu\text{F}/\text{cm}^2$  based on the apparent surface area of the ITO electrode, the capacitances of the GNC assembly on the ITO surface in reduced and oxidized states of the ferrocene moiety based on the *real* electrode surface area were ca. 6.7–2.6 and 9.7–5.2  $\mu\text{F}/\text{cm}^2$ , respectively. Similarly, the capacitances of the GNC assembly on the Au electrode surface based on the real electrode surface area were estimated to be ca. 7.0 and 13.0  $\mu\text{F}/\text{cm}^2$  in reduced and oxidized states of the ferrocene moiety, respectively. Thus although the apparent capacitances of the GNC/PAH-modified ITO electrode were much greater than those of the GNC/PAH-modified gold electrode, the capacitances of the GNC/PAH-modified ITO electrode based on the real surface area were smaller than those of the GNC/PAH-modified gold electrode. The difference between the capacitances of the GNCs on the ITO electrode and those on the gold electrode may reflect the higher conformational order of the SAMs on the GNCs assembled on the ITO electrode than those on the gold electrode. Actually, the redox peaks at the GNC-modified ITO electrode were sharper than those at the gold electrode as mentioned before, indicating a stronger interaction between the ferrocene groups on the GNCs assembled on the ITO electrode than on the gold electrode. Thus the difference is essentially because of the difference in the amount of deposited GNCs on these surfaces, and the GNC/PAH layer on the ITO electrode is more compact than that on the gold electrode.

These capacitance values are comparable to those of ferrocene SAMs on a planar Au surface,<sup>[42]</sup> confirming that the order of ferrocene SAMs formed on a GNC surface is essentially the same to that of ferrocene SAMs formed on a planar Au surface.<sup>[7]</sup>

### Effect of the Underlying Substrate on the Formation of Gold Nanocluster/Poly(Allylamine Hydrochloride) Multilayers

The amounts of adsorbed GNC multilayers on the ITO electrode were always greater than those on the Au electrode of the same deposition cycle, suggesting that the underlying substrate plays an important role in GNC multilayer formation. Atomic force microscopy measurements of the two substrates showed that while the Au surface consisted of very large and almost atomically flat terraces, a number of hemispherical islands of ca. 100 nm in diameter and several tens of nanometers in height were observed on the ITO surface. An ordered and closely packed MUA SAM is expected to form on a gold surface as it has been well documented for the formation of

<sup>a</sup>For more accurate determination of capacitance, it needs to carry out impedance measurements using wide range of a.c. frequencies, but the values obtained in this work are still accurate enough for the purpose of this paper.

various alkanethiol SAMs, and both the adsorbed PAH and the GNC layers are expected to be well organized and closely packed when the gold surface with uniformly distributed charged sites of the carboxylate group was alternately immersed in PAH and GNC solutions.<sup>[33]</sup>

The amount of adsorbed GNC of the multilayer-modified ITO electrode was 3–7 times greater than that of the Au electrode, although the surface roughness of the ITO electrode was only ca. 2.5 times greater than that of the Au electrode, as determined from the AFM images. These findings suggest that the multilayer formation of GNC on an ITO surface and therefore the electrochemical behavior were related to but not solely determined by surface roughness. The nature of the underlying metal oxide layers on the ITO electrode as well as the adsorbed MUA molecules should play important roles in the GNC packing arrangement and therefore its electrochemical behavior. We have already demonstrated that alkanethiol molecules tend to form an island structure on the ITO surface with surface coverage of only 1/3–1/4 of that on the gold surface, although the formed SAM was well organized.<sup>[46]</sup> A nonuniform MUA SAM layer on the ITO surface and/or intrinsically dangling Sn–O<sup>−</sup> bonds resulted in disordered polymer layer adsorption. The GNCs can both adsorb on top of the polymer surface and diffuse into the layers, binding to internal sites of PAH through ion exchange of uncompensated anions. This is one possible reason for the large amount of adsorbed GNC on the ITO. The deviations from linear relations of both the adsorption amount and the capacitance of the ITO-modified electrode with the number of deposition cycles shown in Figs. 3 and 4, respectively, may be the result of the less-ordered multilayer structure on ITO than that on Au.

The decreases in the deposited amount of GNC per deposition cycle and the capacitance per unit real area with increase in the number of deposition cycles can also be explained by considering that the surface became smoother as more GNC/PHC layers were deposited.

### Electrochemical Characteristics of the Multilayers Consisting of Only One MHF-Gold Nanocluster Layer and MH-Gold Nanocluster as the Other Layers with Two Different Sequences

The electrochemical characteristics of multilayers of MHF-GNC and MH-GNC with two different sequences containing only one layer of MHF-GNC, as described in Scheme 1A and 1B, were investigated. In the first system, MHF-GNC existed in the layer

closest to the electrode surface, i.e., the first layer, and MH-GNC existed in the other layers [Scheme 1A: Au or ITO/MUA/PAH/MHF-GNC/(PAH/MH-GNC)<sub>n</sub>, *n* = 1–9]. In the other system, MHF-GNC existed only in the outermost layer and MH-GNC existed in the other layers [Scheme 1B: (Au or ITO/MUA/(PAH/MH-GNC)<sub>n</sub>/PAH/MHF-GNC, *n* = 1–9)].

The X-ray photoelectron spectra of the multilayer assemblies (A) Au(111)/MUA/PAH/MHF-GNC/(PAH/MH-GNC)<sub>n</sub> for *n* = 1, 3, and 5 and (B) Au(111)/MUA/(PAH/MH-GNC)<sub>n</sub>/PAH/MHF-GNC for *n* = 1, 3, 5, and 9 in the Fe2p region showed that while the Fe peak was observed only for *n* = 1 and no peak was observed even at *n* = 3 in the former, the peak intensity did not change with *n* in the latter, confirming that the ferrocene group definitely existed at the innermost and outermost layers in the former and the latter systems, respectively, as suggested in Scheme 1A and 1B.

The redox peaks of the ferrocene group were observed in the CVs of the former and the latter multilayer-modified gold and ITO electrodes measured in a 0.1 M HClO<sub>4</sub> aqueous solution. Although the double-layer charging currents increased with increase in the number of MH-GNC deposition cycles, suggesting sequential LBL deposition of MH-GNC on the ITO surface, the charges in the Fc redox peaks did not depend on the number of MH-GNC deposition cycles and are in good agreement with that of the electrodes modified with only one MHF-GNC layer, implying that all of the Fc groups in the innermost or outermost layer were electrochemically active regardless of the number of MH-GNC layers, showing that the transport of both electrons and anions through these two types of multilayers was rather facile.

### Charge Transfer through the Gold Nanocluster Multilayers

Because the redox process of the surface-attached ferrocene group is known to be represented by<sup>[42,47]</sup>:

where  $-\text{Fc}$  and  $-\text{Fc}^+$  are the neutral and oxidized states of the ferrocene group, respectively,  $\text{X}_s^-$  is the solvated anion in solution,  $-\text{Fc}^+\text{X}^-$  is an ion pair between the ferricenium cation and the anion, and solv. is a solvent molecule; the electron and anion should be transferred between the ferrocene moiety and the electrode, and between the electrolyte solution and the ferrocene moiety, respectively, upon the redox reaction of the ferrocene group. Thus the results shown in

Figs. 2 and 4 strongly suggest that perchlorate anion, which forms an ion pair with  $\text{Fc}^+$ , is transferred between the electrolyte solution and the ferrocene group at the innermost layer through the 1–9 PAH/MH-GNC layers at the Au/MUA/PAH/MHF-GNC/(PAH/MH-GNC) $_n$  ( $n = 1, 3, 5,$  and  $9$ ) electrodes, and an electron is transferred between the ferrocene group at the outermost layer and the gold electrode through the 1–9 PAH/MH-GNC layers at the Au/MUA/(PAH/MH-GNC) $_n$ /PAH/MHF-GNC ( $n = 1, 3, 7,$  and  $9$ ) electrodes.

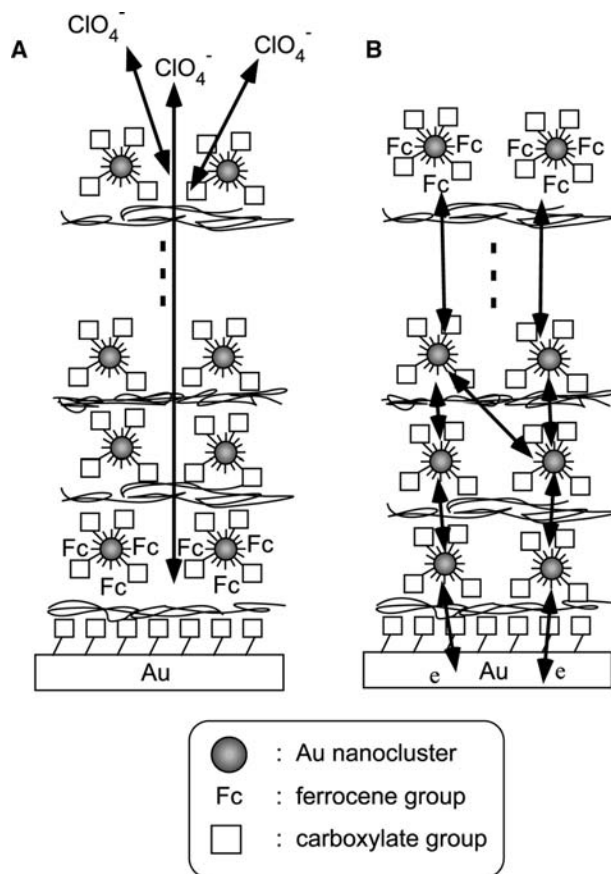

Fig. 5 shows the potential dependencies of current and EQCM frequency shift at the Au/MUA/PAH/MHF-GNC/(PAH/MH-GNC) $_9$  electrode obtained simultaneously in 0.1 M  $\text{HClO}_4$  aqueous solution at a scan rate of  $10 \text{ mV sec}^{-1}$ . A significant frequency decrease and increase, i.e., weight increase and decrease, were observed when the current due to the oxidation and reduction of the ferrocene moiety, respectively, flowed. A linear relation was observed between the mass change calculated from the frequency change by using Sauerbrey's equation and the charge in the region of the ferrocene oxidation (250–550 mV) with a slope of  $216 \text{ g/mol electron}$ . A similar EQCM response was observed for the Au/MUA/PAH/MHF-GNC/(PAH/MH-GNC) $_3$  and Au/MUA/PAH/MHF-GNC/(PAH/MH-GNC) $_6$  electrodes. The slopes for the mass change–charge relations, i.e., mass per electron (mpe), for the former and the latter were 233 and 177, respectively. Furthermore, essentially the same EQCM response was obtained at the Au/MUA/(PAH/MH-GNC) $_9$ /PAH/MHF-GNC. These results clearly show that the EQCM response was not

**Fig. 5** EQCM response of the Au(111)/MUA/PAH/MHF-GNC/(PAH/MH-GNC) $_9$  electrode measured in 0.1 M  $\text{HClO}_4$  aqueous solution at a scan rate of  $10 \text{ mV sec}^{-1}$ . Source: From Ref.<sup>[41]</sup>.

affected by the number of the PAH/MH-GNC overlayers, confirming that perchlorate ions are transferred between the electrolyte solution and the ferrocene group at the innermost layer through the PAH/MH-GNC. The mpe values obtained for Au/MUA/PAH/MHF-GNC/(PAH/MH-GNC) $_n$  ( $n = 3, 6,$  and  $9$ ) are in good agreement with the value observed at the gold electrode modified with PAH/MHF-GNC multilayers ( $245 \text{ g/mol electron}$ ) and are much larger than the molar mass of perchlorate ion ( $99.5 \text{ g/mol}$ ), suggesting that each perchlorate ion moves into and is released from the modified layer accompanied by 5–7 water molecules upon the oxidation and reduction of the ferrocene moiety, respectively.

Because the distance between the ferrocene group in the outermost layer and the gold electrode in the GNC multilayers with 10 deposition cycles is far too long for an electron to tunnel, i.e., more than 50 nm as evidenced from both cross-sectional transmission electron microscopy and ellipsometry, electron should be transferred between the ferrocene group and the gold electrode not by direct tunneling, but through the GNCs by hopping.

**Scheme 2** Schematically idealized model for the charge transfer during the redox of the ferrocene moiety.

## CONCLUSION

Two types of GNCs, one covered by SAMs of MUA, C<sub>6</sub>SH, and FcC<sub>6</sub>SH, MHF-GNC, and the other with MUA and C<sub>6</sub>SH, MH-GNC, were used for the construction of GNC multilayers on the MUA-modified Au(111) and ITO surfaces based on the carboxylate/polycation (PAH)/carboxylate electrostatic interaction. Electrochemical measurements at the GNC/PAH multilayer-modified gold and ITO electrodes showed that the amount of GNC adsorbed on the ITO surface was larger than that of the Au electrode, indicating the different packing arrangements of GNC on the two surfaces. Both the underlying substrate and the adsorbed MUA molecules seem to play important roles in the GNC/polymer multilayer organization. Results of electrochemical studies on the two series of multilayers of MHF-GNC and MH-GNC layers of different sequences on Au and ITO surfaces by placing MHF-GNC either as the layer closest to the gold electrode, i.e., the first layer, or as the outermost layer with MH-GNC in the other showed that both electrons and anions transferred readily through these multilayers. The results of the present study imply that 1) stable GNC multilayers can be constructed on gold and ITO surfaces through LBL assembling processes, 2) the amount of GNCs and their packing arrangement in the multilayers can be tuned by the number of deposition cycles and selection of underlying substrate, and 3) the charges, i.e., electron and anion, are transported through these multilayers as shown in Scheme 2 and the charge transport is facile.

## INTRODUCTION

Polyelectrolyte multilayers prepared upon alternate electrostatic adsorption of positively and negatively charged polymers have recently shown promise as membranes and catalysts. Recent progress in the preparation of membranes for gas separation, separation of liquid mixtures under pervaporation conditions, ion separation under dialysis conditions, salt transport under nanofiltration (NF) and reverse osmosis conditions, separation of enantiomers, and others have been reported. The purpose of this article is to summarize recent activities in the field of membrane<sup>[30–50]</sup> and catalyst applications<sup>[51–78]</sup> of polyelectrolyte multilayer assemblies. It describes the use of polyelectrolyte multilayers as carriers for catalysts and biocatalysts, and then covers examples of catalyzed reactions such as enzyme reactions, photocatalytic reactions, and metal-catalyzed processes.

## BACKGROUND OF MULTILAYER FILMS

About a decade ago, Decher and coworkers<sup>[1–4]</sup> reported on a new method to prepare ultrathin polymer films, based on the alternate electrostatic adsorption of cationic and anionic polyelectrolytes on solid substrates. Meanwhile, the layer-by-layer deposition technique developed into a standard method for preparation of polymer films with controlled structure and thickness in the nanometer range. Numerous studies appeared, which were either concerned with fundamental aspects of film growth, structure, and morphology,<sup>[5–22]</sup> or with the preparation and characterization of functional polyelectrolyte multilayers with photo- and electroactive properties applicable in micro- and optoelectronic devices. The state of the art has recently been reviewed in books<sup>[23,24]</sup> and articles.<sup>[25–29]</sup>

Probably one of the most interesting properties of polyelectrolyte multilayer assemblies is their selectivity in the transport of gases,<sup>[30–34]</sup> solvent mixtures,<sup>[35–42]</sup>

ions,<sup>[43–47]</sup> and enantiomers.<sup>[48]</sup> In several studies, the use of polyelectrolyte multilayers as membranes was demonstrated, e.g., for dehydration of organic solvents under pervaporation conditions,<sup>[35–42]</sup> for water softening and desalination under nanofiltration<sup>[49,50]</sup> and reverse osmosis<sup>[49]</sup> conditions, respectively. Furthermore, the incorporation of biocatalysts<sup>[51–68]</sup> and inorganic catalysts<sup>[69–78]</sup> opened a new area for the formation of membrane reactors and catalytic membranes. Early studies demonstrate the utility of the polyelectrolyte multilayers as reactors and catalysts.<sup>[51–78]</sup>

## PREPARATION OF MEMBRANES

Soon after the method of layer-by-layer assembly of polyelectrolytes was reported, ultrathin polyelectrolyte multilayers were studied as permselective membranes. In a typical process of membrane preparation, a negatively charged porous or nonporous supporting membrane is dipped into a dilute aqueous solution of a positively charged polyelectrolyte so that the polymer is adsorbed at the substrate surface as a molecularly thin film and the surface charge is reverted (Fig. 1). After careful washing, the coated substrate is dipped into the aqueous solution of a negatively charged polyelectrolyte so that this polymer is adsorbed on top of the previous one and the surface charge is reverted again. By repeating the adsorption steps several times, a polyelectrolyte multilayer is obtained, whose thickness is adjustable between a few nanometers and about half a micrometer by varying the number of dipping cycles. Scanning electron micrographs<sup>[44,79]</sup> indicate that the polyelectrolytes do not enter and block the pores of the support, but a smooth coating of the substructure with a dense and defect-free polyelectrolyte skin layer is obtained. Previous studies of materials transport across polyelectrolyte multilayer membranes have recently been reviewed.<sup>[79–87]</sup> Here an updated summary of the research activities is presented.

**Fig. 1** Scheme of layer-by-layer assembly of polyelectrolytes on activated porous supporting membrane. The separating membrane is obtained upon multiple repetition of steps A and B. In reality, pore diameters are 20–200 nm, while polymer chains are less ordered and partially overlapping. *Source:* From Ref.<sup>[38]</sup>.

## STUDIES OF MATERIALS TRANSPORT ACROSS POLYELECTROLYTE MULTILAYERS

### Gas Permeation

At first, studies on the transport behavior across polyelectrolyte multilayers were concerned with gas permeation.<sup>[30–33]</sup> Membranes were prepared from porous supports (Celgard,<sup>[30,32]</sup> Isopore,<sup>[32]</sup> and polyacrylonitrile/polyethylene terephthalate PAN/PET<sup>[32]</sup>), as well as nonporous supports (silicone,<sup>[30]</sup> polymethylpentene,<sup>[31]</sup> and Nafion<sup>[33]</sup>). Poly(allylamine hydrochloride) (PAH) and poly(styrenesulfonate sodium salt) (PSS) were mostly used as the polyelectrolytes. Up to a hundred layer pairs were deposited, which caused a reduction of the membrane permeability by more than a factor of  $10^3$ . Theoretical selectivities in gas permeation were generally low. For  $\text{CO}_2/\text{N}_2$  separation, a selectivity of 2.4 was reported,<sup>[32]</sup> for oxygen/nitrogen permeation the highest selectivity was 3.5.<sup>[33]</sup> This value was obtained by using a polyelectrolyte couple of PSS and poly(*N*-octadecyl-2-ethynylpyridinium bromide), a substituted polyacetylene derivative. The selectivity was ascribed to the high affinity of the unsaturated  $\text{C}=\text{C}$  bonds to oxygen.

Only recently, better results were obtained, when PAH and polyamic acids were alternately deposited followed by heat-induced imidization at  $250^\circ\text{C}$  for 2 hr.<sup>[34]</sup> The resulting polyimide multilayer membranes showed  $\text{O}_2/\text{N}_2$  selectivities of up to 6.9 and  $\text{CO}_2/\text{CH}_4$  selectivities of up to 68.

### Pervaporation of Alcohol/Water Mixtures

Polyelectrolyte multilayer assemblies were also tested as pervaporation membranes. An initial study was reported by van Ackern et al.<sup>[32]</sup> Using PAH/PSS separating membranes on a PAN/PET support, they tried to separate ethanol/water and benzene/cyclohexane mixtures. The separation was only modest, but

after a careful adjustment of several parameters the ethanol–water separation could be considerably improved.<sup>[35–40]</sup> It was found that membranes with high efficiency in alcohol/water pervaporation separation require the following.

- The use of polyelectrolytes of high charge density such as polyethyleneimine (PEI),<sup>[37,38]</sup> polyvinylamine (PVA),<sup>[38–40]</sup> polyvinylsulfate (PVS),<sup>[38–40]</sup> polyacrylic acid (PAA),<sup>[40]</sup> or polyvinylsulfonate (PVSu).<sup>[40]</sup> These polyelectrolytes form complexes with small pore size and large hydrophilicity, which favors the transport of water across the membrane.
- The use of polyelectrolyte solutions of either low pH (1.7) with a high concentration of supporting electrolyte (e.g., 1 M NaCl),<sup>[38,40]</sup> or neutral pH without supporting electrolyte for preparation of the membranes.<sup>[40]</sup> In the former case, very thick polyelectrolyte layers are adsorbed,<sup>[2,3]</sup> a thick membrane with low flux and good separation is obtained. In the latter case, very thin and smooth layers are adsorbed.<sup>[16]</sup> A thin but very dense membrane with good separation efficiency is obtained.
- Deposition of a large number of layer pairs (approximately 60) to avoid voids and defects in the membrane.<sup>[35,40]</sup>
- Annealing<sup>[35–38]</sup> of the membrane for 1 hr at  $90^\circ\text{C}$  to smoothen the surface and to heal defects in the

**Fig. 2** Separation characteristics of polyelectrolyte multilayer membranes (60 layer pairs) as a function of the charge density  $\rho$  of the polyelectrolyte complex. polyelectrolyte multilayer, which was especially useful in case of PEI/PVS membranes.<sup>[37]</sup>

- A pervaporation temperature of about 60°C or higher.<sup>[35,37]</sup>

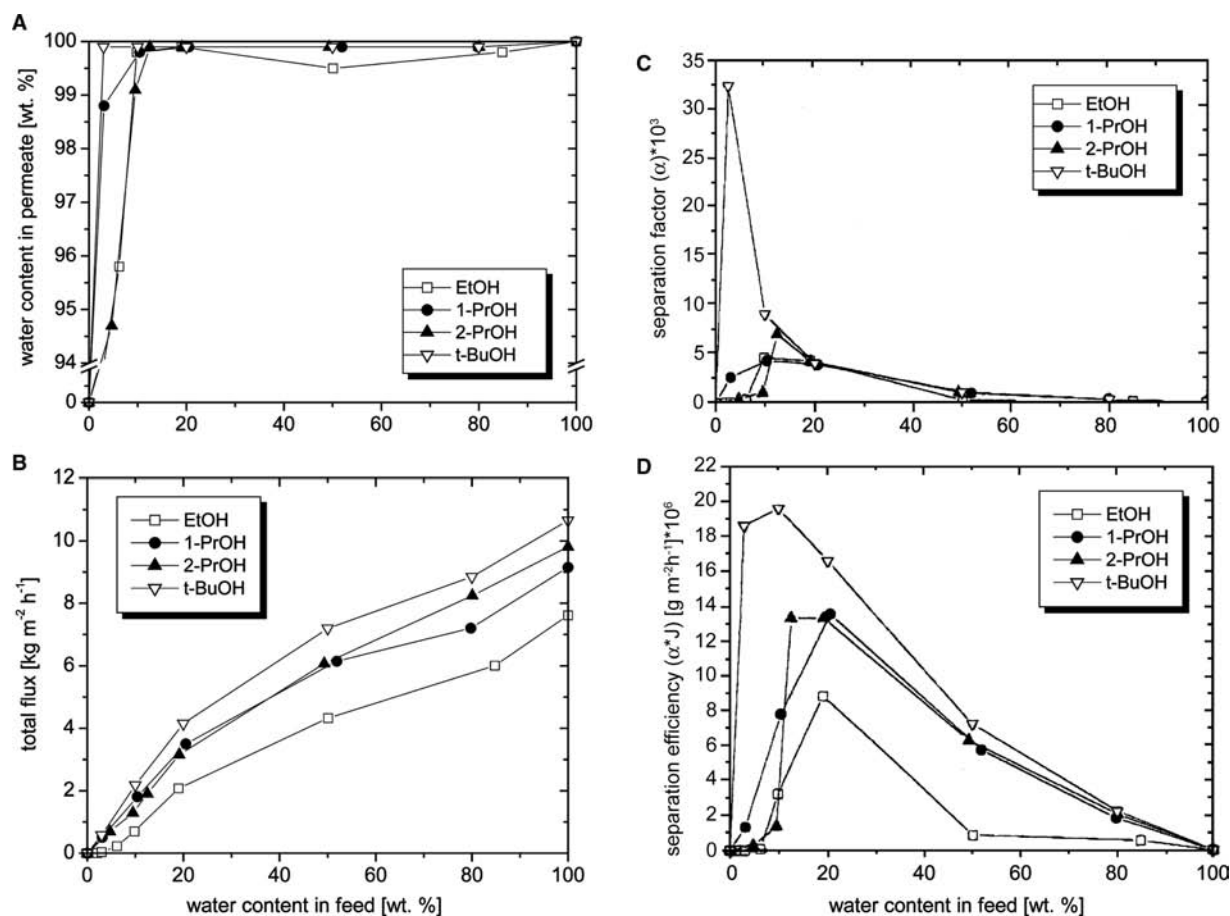

The use of polyelectrolytes of high charge density<sup>[37–40,42]</sup> is especially crucial for obtaining high selectivities. This is demonstrated in Fig. 2, which shows a plot of the total flux and water content in the permeate vs. the charge density  $\rho_c$  of the polyelectrolyte complex. It can be seen that the lowest flux and the highest water content in the permeate are obtained for the membranes made from polyelectrolytes of the highest  $\rho_c$  values. The separation behavior was explained in terms of the nanopores model<sup>[86,87]</sup> shown in Fig. 3. The alternately adsorbed polycations and polyanions form a network structure, in which the polymer-bound ion pairs represent the cross-linking units. For polyelectrolytes of high charge density, a much closer network is obtained as for polyelectrolytes of low charge density. Because each pore of the network contains an ion pair, a network with narrow pores will be more hydrophilic and preferentially permeable for the small and polar water molecules, while a network with larger pore size will be less hydrophilic and more permeable for the bigger, more hydrophobic alcohol molecules. The correlation between  $\rho_c$  and the membrane selectivity holds for most of the polyelectrolytes and can even be used to predict the separation capability of unknown polyelectrolyte couples. This is surprising, because specific structural elements, such as the presence of aromatic rings, chain branching, or nature of the ionic groups, have not been taken into account yet. More detailed studies on structure/property relationships were undertaken by Toutianoush and Tieke,<sup>[40]</sup> when they studied influences of the nature of the anionic polyelectrolyte groups on the separation behavior. For this purpose, three multilayer membranes with same high charge density, but different anionic substituent groups were investigated. The polycation was always

PVA, the polyanion was either PVSu, PVS, or PAA. With increasing acidity of the polyanion, i.e., from PAA to PVSu, the membranes became increasingly hydrophilic. Therefore PVA/PVSu membranes were especially suited to remove small amounts of water from organic solvents, while the less hydrophilic PVA/PAA membranes showed the best performance at high water content of the mixture.

Using the PVA/PVSu membrane, a series of alcohol/water mixtures with alcohols of different hydrophobicity were studied.<sup>[40]</sup> As can be derived from Fig. 4, the flux and separation increased, if the hydrophilicity of the alcohols decreased. For a *t*-butanol/water (9:1) mixture, for example, a total flux  $J$  of about 2.18 kg<sup>-2</sup> h<sup>-1</sup>, a water content in the permeate of 99.9%, a separation factor  $\alpha$  of about 9000, and a separation efficiency (pervaporation separation index, PSI)  $\alpha J$  of  $1.96 \times 10^7$  were found, the pervaporation temperature being 58.5°C. The PVA/PVS membrane showed similar behavior.<sup>[39]</sup> The excellent separation is primarily a result of the lower solubility of the more hydrophobic alcohols in the multilayer membrane, and secondly, a weaker hydrogen bonding between the more hydrophobic alcohol and water molecules.

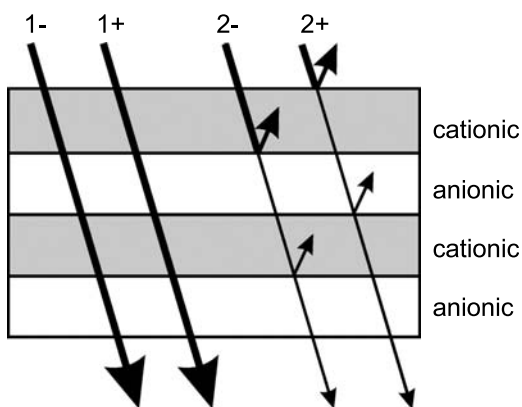

### Ion Permeation

From earlier studies,<sup>[88,89]</sup> it is known that the sequential solution casting of a cationic and an anionic polyelectrolyte leads to a so-called bipolar membrane. In such a membrane, permeating ions receive strong repulsive forces from the equally charged parts (Donnan rejection) and attractive forces from the oppositely charged parts (Donnan attraction) of the membrane. For divalent permeating ions, the interactions are much stronger than for monovalent ones and thus, a high selectivity in ion transport occurs. Polyelectrolyte multilayers resemble in their architecture the bipolar membranes except that the multilayer structure causes

**Fig. 4** Separation characteristics of a PVA/PVSV membrane (60 bilayers) for various alcohol/water feed mixtures. Source: From Ref.<sup>[79]</sup>.

a multipolar character of the membrane. A corresponding structure model<sup>[43]</sup> is shown in Fig. 5 and indicates that divalent ions will receive much stronger repulsive forces than monovalent ones. The model agrees with experimental results showing that the

**Fig. 5** Rejection model of the multipolar polyelectrolyte multilayer membrane. Source: From Ref.<sup>[45]</sup>.

permeation rate of sodium chloride across a PAH/PSS membrane is at least 15 times higher than for magnesium chloride.<sup>[36]</sup> After careful adjustment of several parameters, Krasemann and Tieke<sup>[43]</sup> reported theoretical selectivities  $\alpha(\text{Na}^+/\text{Mg}^{2+})$  of up to 112.5 and  $\alpha(\text{Cl}^-/\text{SO}_4^{2-})$  of up to 45. The  $P_R$  values were dependent on the number of deposited layers, the charge density of the polyelectrolytes, pH, and ionic strength of the polyelectrolyte solutions used for membrane preparation. The high transport selectivity was confirmed by the study of Harris et al.<sup>[44]</sup> on anion permeation. The authors used porous aluminum oxide as support, the pore size in the skin layer was about 20 nm. The inorganic substrate was coated with several PAH/PSS layers, the  $\alpha(\text{Cl}^-/\text{SO}_4^{2-})$  and  $\alpha(\text{Cl}^-/\text{Fe}(\text{CN})_6^{3-})$  values being 7 and 310, respectively. For PAH/PAA membranes, the selectivity was comparable, but the anion flux was three times smaller.

In a more recent study, Toutianoush and Tieke<sup>[45]</sup> investigated the ion transport across highly charged PVA/PVSV membranes. In agreement with the transport model based on Donnan exclusion/inclusion, it

**Fig. 6** Plot of the permeation rates of various chloride salts against the charge density  $z^+e^-/4\pi r^2$  of the nonhydrated metal cations ( $z^+$ : charge number of ion;  $r$ : radius of metal cation). Membrane: 60 layer pairs PVA/PVS. Electrolyte concentration of aqueous feed solution: 0.1 M. Source: From Ref.<sup>[79]</sup>.

could be shown that the permeation rates of alkali and earth alkaline metal cations increase from Li to K, and from Mg to Ba, that is in the direction of decreasing charge density of the naked ions (Fig. 6). In the study of the permeation of NaCl, MgCl<sub>2</sub>, Na<sub>2</sub>SO<sub>4</sub>, and MgSO<sub>4</sub>, it was found that  $P_R$  values increased in the sequence 2.2-electrolyte < 2.1-electrolyte  $\cong$  1.2-electrolyte < 1.1-electrolyte, again in the direction of decreasing charge density of the ions. Furthermore, it was found that the influence of the surface charge on the permeation rates was negligible for thick membranes consisting of more than 50 bilayers. The effect of salt concentration on  $P_R$  was also studied. Up to a concentration of 0.3 mol L<sup>-1</sup>, the  $P_R$  values of NaCl or MgCl<sub>2</sub> changed only slightly, and the selectivity of the membrane was essentially maintained. However, at higher electrolyte concentration, a significant increase in ion flux was found and the selectivity dropped strongly. The effect can be explained by considering the equilibrium (1) of polyelectrolyte complex formation<sup>[46,80,83]</sup>

with  $P^+$  and  $P^-$  being charged segments of the cationic and anionic polyelectrolytes. At high concentration of permeating  $M^+$  and  $X^-$  ions, the equilibrium begins to shift to the left side. Dissociation of the polymer-bound  $P^+P^-$  pairs sets in, the pore size of the membrane increases and the flow of the electrolyte solution becomes progressively higher and less selective.

Lebedev et al.<sup>[90]</sup> modeled the salt permeability of a fixed-charge multilayer membrane taking into account the charge number of the salt ions, the diffusion

boundary layers flanking the membrane, and the different values of the ion diffusion coefficients in these layers and the membrane. The theoretical model was used in the Nernst–Planck equations together with the Donnan theory for the ionic equilibria at the membrane boundaries. Their calculations qualitatively reproduced the experimental results, but the theoretical permeabilities were considerably higher, if the experimental layer thickness was introduced.

The model of Donnan exclusion/attraction is based on the assumption that some of the polymer-bound charges within the polyelectrolyte multilayer are not balanced by polymer repeat units of opposite charge, but by small, exchangeable counterions. The excess polymer-bound charges act as ion-exchanger sites and are responsible for the high transport selectivity. The extent of polymer charge compensation in polyelectrolyte multilayers is still a matter of debate. In some studies,<sup>[91,92]</sup> evidence for incomplete polymer charge compensation and presence of small ions within the multilayers was found, while in other studies,<sup>[11,12]</sup> especially on polydiallyldimethylammonium bromide (PDADMA)/PSS multilayers, the polymer charge compensation was found to be essentially complete, the charge stoichiometry being 1:1. In that case, no selectivity in ion transport can be found, as was demonstrated by Krasemann and Tieke<sup>[43]</sup> studying PDADMA/PSS multilayers. Riegler and Essler<sup>[93]</sup> suggested that polymer charge stoichiometry depends on the charge density of the polyelectrolytes. If the distance between the charges is less than the Bjerrum length, the strong binding of the counterions (Manning condensation) prevents their release during multilayer formation, and the ion exchanger sites are permanently included in the film. This applies to the PAH/PSS multilayers, while in PDADMA/PSS membranes, the charge density is low enough to cause a complete complexation.

However, Farhat and Schlenoff<sup>[46]</sup> pointed out that small ion exchanger sites can be forced into these membranes if salt is added to the external bathing solution. Under these conditions, equilibrium (1) is partially shifted to the left because some of the polymer ion pairs dissociate. The authors demonstrated that the ion exchanger sites created in this way have a strongly nonlinear effect on the transport of redox-active ferro- and ferricyanide ions across the membrane.<sup>[46]</sup> The authors also developed<sup>[94]</sup> a theoretical base for their observations by introducing a model of ion hopping between discrete sites of polymer-bound exchanger sites. However, the model does not take into account that several kinds of permeating ions, especially multivalent ions, may also receive other than electrostatic forces within the membrane. As reported by Toutianoush and Tieke,<sup>[95]</sup> di- and multivalent Cu<sup>2+</sup>, La<sup>3+</sup>, Ba<sup>2+</sup>, and hexacyanoferrate(II) ions become permanently fixed in PVA/PVS membranes, either because of a complex

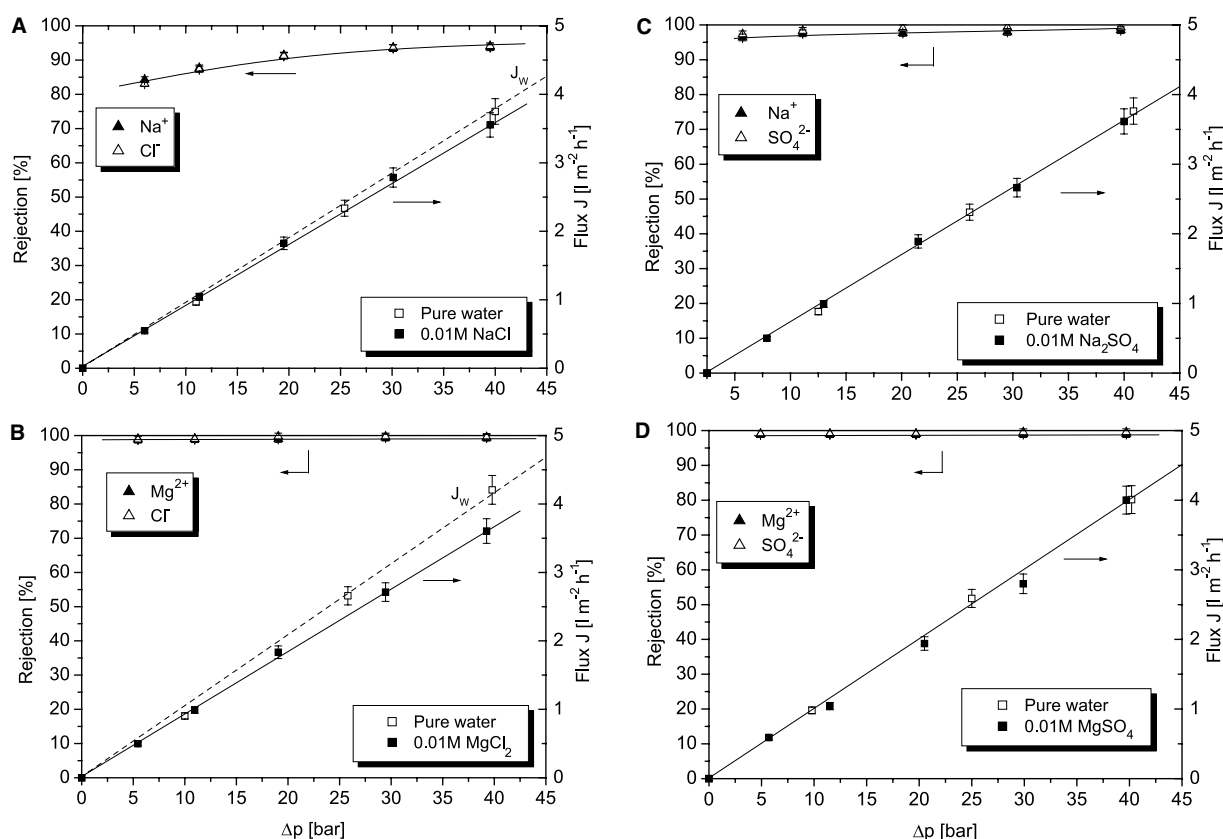

formation with the polymer-bound charged sites, as in the case of copper and hexacyanoferrate ions, or to a replacement of polymer-bound charged sites by the permeating barium ions, as indicated in Eq. 2:

### Salt Transport Under Nanofiltration and Reverse Osmosis Conditions

Very recent studies<sup>[49,50]</sup> were concerned with pressure-driven transport of aqueous inorganic salt solutions across polyelectrolyte multilayer membranes. Using either a dead-end<sup>[49]</sup> or a cross-flow apparatus,<sup>[50]</sup> ion permeation was investigated under nanofiltration (NF) (5–20 bar) and reverse osmosis conditions (more than 30 bar). In a first comprehensive study, Jin et al.<sup>[49]</sup> investigated the transport of aqueous electrolyte solutions containing NaCl, Na<sub>2</sub>SO<sub>4</sub>, MgCl<sub>2</sub>, and MgSO<sub>4</sub> across multilayer membranes consisting of 60

bilayers PVA/PVS. For the two magnesium salts, a complete rejection was found independently from the concentration of the feed solution and the pressure applied (Fig. 7). For sodium chloride and sulfate, the rejections were 84% and 96% at 5 bar, and 93.5% and 98.5% at 40 bar, respectively. The ion rejection was comparable with those of commercial membranes, but the flux was lower because the less permeable PAN/PET membrane was used as the support. Nevertheless, the study demonstrated that at low pressure, polyelectrolyte multilayers are suitable for NF applications such as water softening, while at high pressure, they can be used for water desalination. In a subsequent study, Stanton et al.<sup>[50]</sup> reported NF measurements across PAH/PSS membranes consisting of only five bilayers on porous alumina. Because of the ultra-thin polyelectrolyte membrane, water flux was higher, but the ion rejection was lower than in the previous study. Again, the authors point out that the membranes are potentially attractive for NF applications such as water and salt purification.

**Fig. 7** Plot of salt rejection and permeation flux  $J$  of  $10^{-2}M$  aqueous solutions of sodium chloride (A), magnesium chloride (B), sodium sulfate (C), and magnesium sulfate (D) as a function of the operative pressure  $\Delta p$ . Experiments carried out at  $20^\circ C$ ; feed solution stirred at 700 rpm.  $J_w$  indicates pure water flux. Membrane: 60 layer pairs PVA/PVS. Permeate solution was analyzed by measuring cation and anion concentration using high-performance liquid chromatography. Source: Some data were taken from Ref.<sup>[49]</sup>.

**Table 1** Percent selectivities for different membranes and chiral probes

Membrane	Percent selectivity for AA enantiomer	Percent selectivity for DOPA enantiomer
PLGA/PLL	28.1 D/L	14.1 L/D
PdGA/PdL	28.9 D/L	13.8 D/L
PdGA/PLL	0.4 D/L	0.3 D/L
PLGA/PdL	0.3 D/L	0.1 D/L

### Separation of Organic Compounds and Enantiomers

Besides small gas and solvent molecules or inorganic ions, polyelectrolyte multilayer membranes are also permeable for organic neutral molecules and ions provided they are small enough to pass the nanoporous structure of the membrane (Fig. 2). This allows the membrane to separate organic monoanions from dianions, for example, or naphthalene from the much larger pyrene or triphenylene, or phenol from hydroquinone.<sup>[96]</sup> If chiral polyelectrolytes are used for preparation of the membranes, even mixtures of enantiomeric compounds can be separated. In a recent study,<sup>[48]</sup> polyelectrolyte multilayers were prepared from polypeptides such as L- and D-poly(lysine) (PLD; PdD), L- and D-polyglutamic acid (PLGA; PdGA), and an optically active, quaternized polyvinylpyridine. As chiral probes, L- or D-ascorbic acid and 3,4-dihydroxyphenyl-L/D-alanine were used. Selectivities of up to nearly 29% were found for D/L-ascorbic acid, if PdGA/PdL membranes were used, the flux was very high (Table 1). Multilayers made from two optically active polyelectrolytes were always more selective than multilayers containing only one optically active polyelectrolyte.

### Separation of Proteins and Fouling Behavior

Polyelectrolyte multilayers were also deposited on substrates used for protein separation and filtration.<sup>[97]</sup> Celgard membranes were first treated with CO<sub>2</sub> plasma, followed by grafting of polyacrylic acid to the surface. Then a bilayer of PDADMA/PAA was adsorbed. The bilayer-modified membrane showed a much lower tendency for protein adsorption and fouling than the unmodified membrane. The flux of an aqueous solution of human serum albumin (HSA) through the modified membrane was twice as high as the flux across the merely grafted membrane.

Müller et al.<sup>[98]</sup> studied the fouling behavior of CO<sub>2</sub> plasma-treated polypropylene films modified with PEI/PAA multilayers. For the modified films,

the fouling was much lower than for the unmodified samples. Interaction of various charged model proteins such as HSA and lysozyme immunoglobulin G, and the polyelectrolyte multilayer were also investigated. Using infrared spectroscopy, small amounts of adsorbed protein were found, if the top polyelectrolyte layer and the protein were equally charged, whereas enhanced adsorption occurred for electrostatic attraction between the protein and the polyelectrolyte layer.

Graul and Schlenoff<sup>[99]</sup> also reported on the resistance of polyelectrolyte multilayers to irreversible protein adsorption. Fused silica capillaries were coated with polyelectrolyte multilayers and used for capillary zone electrophoretic separations. Basic proteins could be separated with good efficiency, and the columns were resistant to irreversible protein adsorption.

### Other Work

In a number of studies, the transport behavior of polyelectrolyte multilayers was investigated on a more fundamental, less application-oriented base. In the following, some of the papers are briefly reviewed. von Klitzing and Möhwald<sup>[100]</sup> were the first to study proton and molecular transport through polyelectrolyte multilayers. Proton transport was investigated by using PAH/PSS multilayers on glass. A fluorescent, pH-sensitive dye was embedded in the multilayers at different distances from the glass surface and the pH dependence of the fluorescence emission was studied as a function of film thickness, surface charge, and ion concentration. The data showed that the films were permeable for protons. In subsequent work,<sup>[101]</sup> the time dependence of the fluorescence of a fluorescein-labeled PAH embedded at different depth in PAH/PSS multilayer films on glass substrates was studied. Adding rhodamine to the outer phase, a quenching of the fluorescence was observed as a result of energy transfer to the permeating rhodamine molecules. Paramagnetic quenching using a spin-labeled amine-N-oxide-based compound was also studied. Because this molecule was smaller than rhodamine, the diffusion coefficient was found to be at least 2 orders-of-magnitude larger.

Harris and Bruening<sup>[102]</sup> investigated the transport of hexacyanoferrate(III) and hexaammineruthenium(III) ions across PAH/PSS and PAH/PAA films on gold electrodes using electrochemical and ellipsometric measurements. The permeability of these ions was found to depend on solution pH, number of layer pairs in the film, presence or absence of a supporting electrolyte during film deposition, and the nature of the constituent polyelectrolytes. pH-dependent measurements of ion permeation were also carried out.

In other studies, polyelectrolyte multilayer membranes were subsequently cross-linked to reduce the permeability. Upon heating, it was possible to replace the polymer-bound ion pairs of PAH/PAA multilayers by amide linkages.<sup>[103]</sup> Cross-linking of the multilayers at 130°C was found to reduce the permeability of hexacyanoferrate(III) ions to 1% of its original value. In another approach,<sup>[104]</sup> multilayer films were prepared from PAH and a maleate-based copolymer with carboxylic acid and monomethylester groups. Heating in vacuum caused more than one-half of the amino groups to be converted into imide linkages with the substituent groups of the copolymer. After cross-linking, the films displayed selective permeation of methylorange against myoglobin (Mb).

Permeability studies were also reported from polyelectrolyte multilayer capsules. Transport of small molecules such as fluorescein, 6-carboxyfluorescein, pyrene, rhodamine 6G, or ibuprofen through the multilayer wall was investigated, either from the outside to the interior of the capsules, or in the opposite direction.<sup>[105–110]</sup> The capsules were usually prepared from PAH and PSS. Capsules were found to be permeable in either direction, and the permeability could be controlled by a lipid coating of their surface,<sup>[111]</sup> by varying pH<sup>[108]</sup> or salt<sup>[109]</sup> concentration of the outside solution, or by annealing.<sup>[112]</sup> Effects of these parameters on the permeability were similar to flat multilayer membranes discussed above and thus are not further treated here.

## CATALYST APPLICATIONS

The use of polyelectrolyte multilayers as catalytic surfaces is a rather new, but interesting topic, and comparatively few publications regarding this subject are available yet. Biocatalytic films may be obtained by incorporating enzymes into the films or binding them physically or chemically to the surface; inorganic catalytic films might be obtained by incorporation of inorganic nanoparticles in the films or binding catalytically active sites to the surface. A review on biocatalytic polyelectrolyte multilayers appeared recently.<sup>[113]</sup> In the next section, the research activities on biocatalytic multilayer assemblies are compiled; then, the multilayers containing inorganic catalysts are reviewed.

### Biocatalytic Multilayer Assemblies

In an early study by Kong et al.,<sup>[51]</sup> negatively charged glucose oxidase (GOD) and bolaamphiphiles with bipyridine head groups were alternately built up on quartz slides and porous beads. For the assemblies, a high enzyme activity was reported. In a subsequent

paper,<sup>[52]</sup> the same group prepared a bolaamphiphile-based multienzyme reactor by using a 3-mercaptopropionic acid-modified gold electrode as support. The authors alternately adsorbed the cationic bolaamphiphile and anionic GOD or glucoamylase (GA). The multilayer assemblies catalyzed both the hydrolysis of maltose and the oxidation of glucose. The enzymatic activity increased with the number of GOD and GA layers, but the activity per layer decreased. The reason for this might be a limited diffusion of substrates in such condensed films.

In the following years, Kunitake et al.<sup>[53–57]</sup> prepared alternate assemblies of polyelectrolytes and enzymes and studied their catalytic activity. For example, PEI/GOD films were assembled on a quartz plate, and the reaction catalyzed by GOD was analyzed. GOD converts glucose and oxygen into gluconolactone and hydrogen peroxide, and H<sub>2</sub>O<sub>2</sub> oxidizes an indicator dye in the presence of peroxidase (POD) in aqueous solution. Finally, the blue oxidation product of the dye is monitored by ultraviolet (UV) spectroscopy. The study<sup>[55]</sup> clearly demonstrated that the activity of the enzyme was not lost in the multilayer assembly. In another study,<sup>[56]</sup> a multienzyme reactor containing PEI/GOD and PEI/GA bilayers was constructed on an ultrafiltration membrane. For the study of enzymatic activity, an aqueous starch solution was employed. When flowing across the membrane, GA decomposed starch to glucose, and GOD converted glucose to gluconolactone, thereby producing hydrogen peroxide as the product. The H<sub>2</sub>O<sub>2</sub> concentration was analyzed as described above. A high catalytic activity was found, and the efficiency of the glucose oxidation was observed to be affected by PEI/PSS intermediate layers, flow rate, and starch concentration. In another study,<sup>[57]</sup> it was found that premixing of GOD and PEI followed by alternate adsorption with PSS showed a significant increase in enzymatic activity.

Coating electrodes with enzyme/polyelectrolyte multilayers provides the basis of a biocatalytic device including an enzymatic bioreactor. Lvov et al.<sup>[58]</sup> prepared myoglobin (Mb) containing alternately assembled films at an electrode. Electrochemical reduction of the Fe<sup>III</sup> in Mb to Fe<sup>II</sup> is accompanied by H<sub>2</sub>O<sub>2</sub> formation from oxygen. H<sub>2</sub>O<sub>2</sub> is able to oxidize Fe<sup>III</sup> in the Mb into the active oxidant form ferrylmyoglobin (MbFe<sup>IV</sup>), and is thereby reduced to water. In the paper, it is demonstrated that MbFe<sup>IV</sup> is able to epoxidize styrene at the multilayer surface. Calvo et al.<sup>[59]</sup> demonstrated that GOD, lactate oxidase, and soybean peroxidase can be electrically wired to an underlying electrode through PAH with a covalently attached osmium complex. This multilayer system was able to indirectly drive lactate oxidation by the electrode via the corresponding enzyme. Earlier,

Hodak et al.<sup>[60]</sup> assembled GOD with a redoxactive poly(allylamine)ferrocene mediator on alkanethiol modified gold electrodes. GOD was found to be catalytically active in glucose oxidation, but only a small fraction of the active enzyme was electrically wired by the ferrocene polymer. Ma et al.<sup>[61]</sup> reported on electroactive Mb films grown layer-by-layer with PSS on pyrolytic graphite electrodes. Cyclic voltammetry showed the expected reversible peaks of the Mb  $\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}}$  redox couple. Oxygen and trichloroacetic acid could be catalytically reduced by the Mb in the multilayer assemblies. He et al.<sup>[62]</sup> reported on multilayer devices consisting of PDADMA and the anionic bacteriorhodopsin (BR). The biological activity of BR in these assemblies could be confirmed by measuring the generation of a photocurrent.

Use of spherical particles as substrates for the enzyme-containing multilayer assemblies is advantageous because these particles offer a high surface area and a large amount of enzyme can be incorporated. Schüler and Caruso<sup>[63]</sup> reported on the construction of enzyme/polyelectrolyte multilayer films on submicrometer-sized polystyrene (PS) spheres using the layer-by-layer approach: PEI and glucose oxidase (GOD) were alternately adsorbed. Up to three layer pairs were deposited. The enzymatic activity was measured by following the coupled enzymatic reaction of GOD and horseradish peroxidase. The activity increased regularly with increasing number of GOD layers immobilized, indicating that the multilayer films were sufficiently permeable for substrate diffusion. In another study,<sup>[64]</sup> GOD, POD, or preformed enzyme-polyelectrolyte complexes were assembled in alternation with oppositely charged polyelectrolytes onto PS particles. Particles coated with the preformed enzyme-polyelectrolyte complexes displayed a significantly lower enzymatic activity (by up to 70%) than those fabricated by direct adsorption of the free enzyme. Furthermore, experiments were conducted with particles exhibiting both magnetic and catalytic functions. Magnetic support materials are widely used in biotechnology because they can easily be separated. For this purpose, 200 nm PS particles that were pre-coated with four layers of  $\text{Fe}_3\text{O}_4$  nanoparticles and PDADMA, followed by two PAH/PSS additional polyelectrolyte layers and an outer GOD layer were prepared by using the layer-by-layer approach. Then, the particles were repeatedly used as catalysts following their rapid and easy separation with a magnet.<sup>[64]</sup> Santos et al.<sup>[65]</sup> constructed biocatalytic thin films by incorporating enzymes, specifically alkaline phosphatase (AP) and GOD into multilayers of PEI and PSS supported on a glass substrate. For both enzymes, the reactive films demonstrated increased activity with the successive number of deposited enzyme layers. In hybrid films consisting of alternating layers of AP

and GOD, both enzymes retained their activities similar to those of their corresponding films of either enzyme alone.

Biocatalytic and magnetic particles prepared upon the layer-by-layer approach were also reported by Fang et al.<sup>[66]</sup> The authors started from 420-nm latex particles, onto which they alternately assembled silica or magnetite nanoparticles, GOD, and oppositely charged polyelectrolytes. The inclusion of silica layers on latex yields a higher surface area resulting in greater GOD adsorption, thereby increasing the catalytic activity. The enzymatic activity was proportional to the core surface area and also to the number of GOD layers in the shell. The presence of magnetic nanoparticles allowed the self-stirring of the nanoreactor with a rotating magnetic field and enhanced the productivity.

In a very recent study,<sup>[67]</sup> enzyme activity of organophosphorus hydrolase (OPH) in polyelectrolyte-encased multilayer assemblies coated on glass beads was reported. The stability of the multilayer systems (e.g., against exposure to high salt concentration) could be strongly enhanced by anchoring monomers, such as 1,2-dihydroxypropyl-4-vinyl-benzylether, to the outer PAA layer and subsequently polymerizing the systems by UV irradiation. The OPH activity was not affected. Preparation of high-activity, enzyme-containing multilayer films on planar substrates was reported by Jin et al.<sup>[68]</sup> Catalase microcrystals were first encapsulated by the alternate adsorption of PSS and PAH on their surface yielding extremely high enzyme loading in the polyelectrolyte multilayer capsules. Subsequently, layer-by-layer deposition of the polyelectrolyte-coated catalase microcrystals and oppositely charged polyelectrolytes was used to construct multilayer films on glass supports. The catalyze achievement of these high enzyme content films was up to 50 times higher than of those prepared by conventional layer-by-layer deposition of the enzymes.

### Multilayer Assemblies Bearing Inorganic Catalysts

Polyelectrolyte multilayers are not only able to bind bioactive compounds, such as enzymes to produce highly efficient biocatalytic surfaces, but also inorganic compounds with high catalytic activity was reported. There are many studies on the incorporation of small inorganic particles in polyelectrolyte multilayer assemblies, but applications of these systems as catalysts are only scarcely demonstrated. Mecking and Thomann<sup>[69]</sup> reported on the adsorption of a catalytically active rhodium complex on anionic latex particles, which were previously coated with a PDADMA layer. The rhodium complex was bound

to the PDADMA layer via electrostatic interactions of its sulfonated phosphine ligands. The structurally well-defined core-shell particles were able to catalyze hydroformylation reactions such as the conversion of methyl acrylate into methyl 2-formylpropionate. Wang et al.<sup>[70]</sup> fabricated PAH/PAA multilayers by using the layer-by-layer approach and selectivity bound palladium catalysts for electroless nickel plating to the surface. Depending on whether the surface was cationic or anionic, either the negatively charged tetrachloropalladate or the positively charged tetraamine palladium ion was bound to the surface. Upon immersion into an electroless nickel plating bath, the palladium-coated parts of the surface were selectively plated. Using inkjet printing, the facile patternability of the polyelectrolyte multilayers was demonstrated. Wang et al.<sup>[71]</sup> also prepared palladium nanoparticles within PAH/PAA multilayers as seeds for binding tetraamine palladium from aqueous solution to PAA carboxylic acid functionalities in the polymer film and subsequent reduction. Two-nanometer catalytic palladium particles were obtained, onto which a nickel shell of arbitrary thickness could be grown. Up to 14-nm particles were obtained. Liu et al.<sup>[72]</sup> described a similar route to the fabrication of polyelectrolyte multilayers containing catalytically active palladium nanoparticles. A 4-aminobenzoic acid-modified glassy carbon electrode was alternately coated with tetrachloropalladate dianions and a quaternized poly(4-vinylpyridine) complexed with osmium. Three-dimensional palladium particle multilayers were subsequently formed upon electrochemical reduction of the tetrachloropalladate anions. The palladium nanoparticles in the film effectively catalyzed the reduction of dissolved oxygen and the oxidation of hydrazine compounds in aqueous solution. Antipov et al.<sup>[73]</sup> prepared PAH/PSS multilayer capsules containing silver ions. Subsequently, the silver ions were reduced via photoirradiation, or by chemical methods. The potential of the prepared silver-containing capsules to serve as catalysts was checked by the reduction of 4-nitrophenol into 4-aminophenol in the presence of sodium borohydride. The system under investigation was found to possess higher activity than the pure silver solution.

In some studies, multilayers of redoxactive compounds and polymers were assembled on electrodes to obtain electrocatalytic surfaces. Sun et al.<sup>[74]</sup> prepared layer-by-layer assemblies of polycations bearing an osmium complex and PSS or poly(aniline-co-*N*-(3-sulfopropyl)aniline) on gold electrodes. The chemically modified electrodes showed electrocatalytic response for the reduction of nitrite. Cheng and Cox<sup>[75]</sup> used the layer-by-layer approach to prepare nanocomposite multilayer films of a ruthenium metallodendrimer and a Dawson-type polyoxometalate. These multilayers

were used as bifunctional electrocatalysts, able to catalyze both reductions and oxidation. Using cyclovoltammetric studies, the mediated reduction of iodate by the polyoxometalate (phosphotungstate) and the oxidation of arsenite by the ruthenium dendrimer were demonstrated. Photocatalytic porphyrin multilayer assemblies were reported by Araki et al.<sup>[76]</sup> Electrodes modified with these films were photocatalytically active toward the reduction of O<sub>2</sub>.

Finally, Sasaki et al. prepared multilayer films of PDADMA and titania nanosheet crystallites,<sup>[77]</sup> and of titania nanoparticles and PSS.<sup>[78]</sup> UV irradiation of both types of films did not cause the expected photocatalytic decomposition of pollutants or water, but instead, the entire organic polyelectrolyte inside the multilayers was decomposed, and a polymer-free inorganic film was obtained. The photocatalytic reaction was monitored via infrared and X-ray photon spectroscopy.

## CONCLUSION

In the last decade, a variety of studies demonstrated that the alternate layer-by-layer assembly of cationic and anionic polyelectrolytes is a suitable method to prepare ultrathin, dense separation membranes on solid porous or pore-free supports. The main advantages are the simple, yet elegant preparation method; the environmentally sound, purely water-based chemistry; the use of low-cost, easily available compounds; the potential to precisely control structure and thickness of the membrane in the nanometer range; and the wide variety of compounds that can be chosen for the construction of the membranes. Previous studies also demonstrated that polyelectrolyte multilayers represent multipurpose membranes, which are well suited for dehydration of organic solvents under pervaporation conditions, for separation of mono- from multivalent ions under dialysis conditions, for water softening and desalination under nanofiltration and reverse osmosis conditions, as antifouling coatings for protein separation. Although the thickness of the multilayer membranes is usually below 100 nm, the efficiency of the membranes is comparable to commercial membranes of macroscopic thickness applied in modules.

The nanoporous, physically cross-linked structure of the membrane favors the permeation of small, hydrophilic molecules and ions of low charge density. In general, the selective transport behavior and the possibility to control the transport by adjusting pH and ionic strength of the feed solution, or by a chemical modification of the membrane, are two of the most interesting properties of polyelectrolyte multilayers. Future studies will be concerned with further

improvement of the efficiency of the membranes, either by modifying hydrophilicity or cross-linking density, or by incorporating permselective compounds such as calixarenes, cyclodextrines, zeolithes, or inorganic complex salts acting as molecular filters and ion sieves. Furthermore, studies will be concerned with a better theoretical understanding of the transport behavior.

For catalyst applications, the electrostatic buildup of polyelectrolyte multilayers with catalytic sites either embedded in the films or physically attached at the surface offers great advantage over covalent coupling and chemisorption methods. As recently demonstrated, the adsorbed or embedded enzymes and inorganic nanoparticles retain, at least partially, their catalytic activity rendering the multilayer assemblies attractive as new bioactive and catalytic materials. Although this review may be incomplete, the examples presented indicate a high potential of the polyelectrolyte multilayers to serve as carriers for catalytic substances. The experiments indicate that a binding of the catalyst to the surface leads to higher efficiencies than the dispersion of the catalyst within the multilayer. Furthermore, the use of spherical particles or capsules as a substrate is superior to a binding of the catalysts to flat multilayers. The reason is the much larger surface area providing a higher catalytic activity. Future work will be concerned with more systematic studies on incorporation, mobility, and activity of catalytic compounds in polyelectrolyte multilayers. Further systems demonstrating the suitability of polyelectrolyte multilayers as bioreactors and chemical nanoreactors need to be developed.

## INTRODUCTION

In the early 1990s, Decher and Hong extended the pioneering work of Iler,<sup>[1]</sup> and introduced the layer-by-layer method of constructing multilayers on surfaces.<sup>[2-4]</sup> They demonstrated that multilayers could be prepared simply by dipping a charged substrate sequentially into solutions containing a negatively and positively charged polyelectrolyte. Because of the ease of processability and wide array of molecules that can be incorporated into these multilayers, the layer-by-layer method has become one of the most useful and widespread techniques for fabricating ultrathin films. Successful assembly has been demonstrated for a variety of materials, some of which include DNA,<sup>[5]</sup> latex particles,<sup>[6]</sup> clay,<sup>[7-10]</sup> proteins,<sup>[11,12]</sup> nanoparticles,<sup>[13-18]</sup> dyes,<sup>[19-26]</sup> semiconducting oligomers,<sup>[27,28]</sup> conjugated polymers,<sup>[29-32]</sup> and bolaform amphiphiles.<sup>[33-37]</sup>

Amphiphiles are interesting molecules that contain both hydrophilic and hydrophobic parts. A conventional water-soluble amphiphile usually consists of a long hydrocarbon chain tail and a hydrophilic head group, which is either highly polar or ionically charged, to impart some water solubility to the molecule. If the molecule bears a positive charge, such as a quaternary ammonium group, or a negative charge, such as a sulfate group, the amphiphile is categorized as a cationic or anionic amphiphile, respectively.<sup>[38]</sup> Bolaform amphiphiles, or bolaamphiphiles, are described as molecules containing two hydrophilic moieties connected by a hydrophobic chain. It has been shown that bolaform amphiphiles have unusual aggregation behavior at the air-water interface and in lyotropic<sup>[39,40]</sup>

and thermotropic phases.<sup>[41]</sup> Their self-assembly via physical adsorption on charged surfaces has been demonstrated and characterized using a variety of methods.

Bolaform amphiphiles with ionic end groups can form layers that produce charged surfaces upon their adsorption. These charged surfaces can be used to electrostatically assemble multilayer structures. The first account of the layer-by-layer assembly of bolaform amphiphiles was reported by Decher et al., where ordered multilayers of more than 70 layers were fabricated.<sup>[2-4]</sup> Electrostatically attractive interactions of the hydrophilic head groups and appropriately charged substrates (such as mica, quartz, glass, Si/SiO<sub>2</sub>, gold, etc.) force molecules to pack closely on the substrate. Short-range van der Waals forces affect the packing density and orientation of the molecules within the layered structure.

The synthetic design of the bolaamphiphile must take into account these intermolecular forces to achieve a buildup of multiple layers. End-on adsorption of the molecules would maintain a maximum charge density on the surface and is crucial to make well-ordered films. The flexible alkyl spacer in the amphiphile must be of a certain length for end-on adsorption to occur.<sup>[2]</sup> When the molecule is too short, the charges are separated by a small distance and adsorption occurs flat on the surface. At short chain length, electrostatic effects are dominant and the bolaform amphiphiles lie down on the substrate. If the length of the alkyl spacer is too long, a loop-type adsorption may occur. Either type of adsorption would lead to a reduction of charged groups on the surface making it difficult to build the consecutive adsorption of layers.

The aim of this article is to provide an overview of the layer-by-layer electrostatic adsorption and characterization of bolaform amphiphile multilayers. The rest of the entry will be divided into three parts: (1) semiconducting bolaform amphiphiles, (2) photoreactive bolaform amphiphiles, and (3) photochemical isomerization of bolaform amphiphiles. Factors such as the aggregation behavior of the molecules in solution and as ultrathin films will be discussed.

## SEMICONDUCTING BOLAFORM AMPHIPHILES

Conjugated oligomers have recently gained interest not only as model compound polymers but as active organic semiconducting materials. Thiophene oligomers, especially sexithiophene (6T), have been utilized for their potential application in organic molecular electronics. This includes field effect transistors (FETs), organic light-emitting diodes (OLEDs), and photoconductive and photovoltaic devices.<sup>[42–46]</sup> In the oligothiophenes, as with other conjugated oligomers, an increase in conjugation length typically leads to a dramatic increase in charge transport properties but also brings about a decrease in their solubility. This makes purification and device fabrication very difficult, especially by solution casting methods.

Recently, we have synthesized a bolaform amphiphile (6TN) by introducing pendant cationic alkyl end groups at the  $\alpha$  and  $\omega$  positions of 6T, preserving the conjugation of the backbone and affording water

solubility to the molecule. This molecule showed unique aggregation behavior in solution and multilayers were successfully fabricated using the layer-by-layer technique. This approach may provide for a new fabrication method for FETs.

## Solution Studies of the 6TN Bolaform Amphiphile

As stated above, bolaamphiphiles show very interesting aggregation behavior in solutions of varying composition. The absorption spectrum of 6TN in water (Fig. 1) exhibits fine structure probably due to coupling of the fundamental  $\pi-\pi^*$  electronic transition with vibrational levels of the excited state<sup>[47]</sup> or Davydov splitting of the exciton levels,<sup>[48]</sup> or both. The origin is primarily due to the  $\pi-\pi$  stacking of the sexithiophene central core. The fine structure disappears at elevated temperature (80°C) indicating that the aggregates formed in solution are tight and dominated by the hydrophobic sexithiophene part of the bolaform amphiphile.

Adding tetrahydrofuran (THF) to the aqueous solution results in red shift of the peak maximum and disaggregation of the  $\pi-\pi$  stacks, which is a reasonable observation because THF is a better solvent for the hydrophobic part of the amphiphile. When the THF concentration is higher than 80%, the absorption maximum shifts back to the blue and the fine structure begins to appear again, similar to that found in the aqueous solution. The charged ends of the bolaform

**Fig. 1** (A) Structure of the bolaform amphiphile 6TN. (B) UV-vis absorption spectra and plot of absorption maxima (inset) of 6TN in water/THF mixtures. amphiphile are not soluble in THF and can be dissolved only in an aqueous environment. At high THF concentrations, another type of aggregate is formed, where the aggregation is dominated by the ionic interactions of the quaternary amine groups. By varying the composition of the solvent (water/THF), adsorption of the molecules onto charged surfaces can be studied in an aggregated and disaggregated state.

### Adsorption of 6TN with Polyelectrolytes

Multilayers of the 6TN bolaform amphiphile and poly(styrene sulfonate) (PSS) were fabricated from solutions of different compositions (water and water/THF, 30/70) where the molecules were in an aggregated and disaggregated state. In both cases, adsorption occurred end-on and proceeded in a stepwise, linear fashion as shown in Fig. 2.

**Fig. 2** UV-vis spectra of 6TN/PSS multilayers (1–10 pair layers) prepared from 6TN in (A) water and (B) water/THF (70/30) on glass. *Source:* Reproduced with permission from<sup>[27]</sup>. © 2002, American Chemical Society.

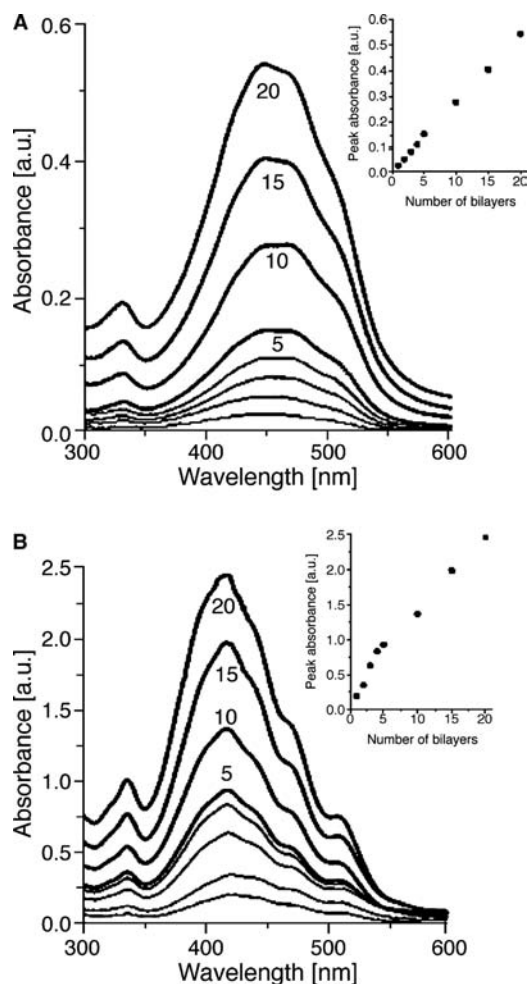

From the fine structure at the lower-energy end in the ultraviolet (UV)-vis absorption plots, it can be seen that the films have a highly aggregated structure with considerable  $\pi$ - $\pi$  stacking. The difference in the two deposition processes can be seen in the absorption intensity of the two graphs. The deposition from pure water has a larger amount of material deposited per dipping cycle indicating that more material is deposited with molecules in a preformed aggregate state than from single molecules in the solution. This was verified using a variety of supporting techniques including X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM).

### Adsorption of 6TN with Inorganic Platelets

Several research groups have found interesting effects by using clays and a semiconducting material to fabricate hybrid nanocomposites. Some types of silicate clay have a unique layered structure and are negatively charged upon hydration. Anisotropic conductivity has been seen in a polyphosphazene-montmorillonite (MONT) composite material prepared by a bulk mixing process.<sup>[49]</sup> Oligothiophenes have been intercalated into vermiculite clay and the orientation of the confined oligothiophenes was studied.<sup>[50]</sup> Also, Eckel and Decher have fabricated OLEDs that included an isolated montmorillonite layer at different cycles of the layer-by-layer process.<sup>[51]</sup> The authors found that the clay sheets increased the efficiency of the device by a factor of 14 or greater when compared to that of the pure polymer system.

We have recently investigated the role of MONT clay layers in the preparation of nanostructured multilayer films of 6TN using the layer-by-layer approach. Alternating multilayers were prepared from pure aqueous and salt solution. Distinct surface morphologies of samples prepared from the two types of solution were found. The presence of salts affected the aggregation behavior and deposition of these films.

Fig. 3 shows the UV-vis spectra of 6TN/MONT multilayer samples prepared from pure water and 0.1 M NaCl. The absorbance intensity for the 0.1 M NaCl system is 5 times as large as that of pure water for the same dipping cycle. As with the 6TN/PSS multilayers fabricated from pure water and 30% THF above, this means that more 6TN is deposited from saline solution. This result was further confirmed with X-ray diffraction (XRD) measurements. One big difference in the adsorption of 6TN with polyelectrolytes and MONT sheets was that the composition and conformation of the aggregates changes upon adsorption at the surface. The interaction between the 6TN molecules and the underlying clay sheets leads to a reordering of the aggregates on the surface.

**Fig. 3** (A) UV-vis spectra of 6TN/MONT multilayer films (1–20 layers) prepared from pure water. Peak absorbance vs. number of bilayers is plotted in the inset. (B) UV-vis spectra of 6TN/MONT multilayer films (1–20 layers) prepared from 0.1 M NaCl solution. Peak absorbance vs. number of bilayers is plotted in the inset. *Source:* Reproduced with permission from Ref.<sup>[28]</sup>. © 2002, American Chemical Society.

A study of the film morphology was also done using AFM. Fig. 4 shows the deposition of one 6TN layer from pure water and 0.1 M NaCl. The figure shows that the larger average aggregate size is shown from the saline system and that better surface coverage is achieved from this solution. Fig. 5 shows the AFM images of (A) 2.5, (B) 5, and (C) 10 bilayers of 6TN/MONT on glass. From the figure, it can be seen that the RMS roughness data for the saline deposition process does not increase dramatically when moving from 2.5 to 10 bilayers. However, with the pure water system, the RMS roughness increased from 22 to 27 to 40 nm for the three multilayer samples. The reason for the dramatic increase in roughness is probably because the clay sheets are unable to cover the sublayer defects since the 6TN aggregate size is on a comparable scale to the clay particle lateral dimensions. Moreover,

isolated and unevenly distributed aggregates make it harder for the subsequent layer of MONT plates to cover the empty spaces among them, leaving many holes or defects on the surface. The roughness of these defects is further magnified as the deposition process is continued.

In conclusion, a series of experiments on a bolaform amphiphile sexithiophene were done both in solution and as ultrathin films. The aggregation size and properties were studied under various conditions in solutions of different compositions. Ultrathin films were prepared using the layer-by-layer technique with polyelectrolytes and inorganic clay platelets and the morphology and film structure were characterized with a variety of surface-sensitive techniques. These results provide useful insight into many factors that affect the adsorption process and properties of ultrathin films.

## PHOTOREACTIVE BOLAFORM AMPHIPHILES

### Phenylenediacyrylic Acid Amphiphile Derivatives

In the last few years, one area that has required a large amount of attention concerning ultrathin film applications is the improvement of film stability against mechanical, chemical, and thermal degradation. One popular concept to increase film stability has been to incorporate cross-linkable molecules or polymers into the multilayer structure. Mao et al. used a phenylenediacyrylic acid bolaform amphiphile with two pyridinium headgroups in the  $\alpha$  and  $\omega$  positions (DIPY08) along with poly(sulfonic acid) on mica to fabricate multilayer films. The bolaform amphiphile was photopolymerizable on irradiation with UV light and formed 1,3-transcyclobutane rings in the polymer main chain as can be seen in Fig. 6.

The deposition process of the bolaform amphiphile multilayers proceeded in a linear fashion. This indicated that an equal amount of amphiphile molecules was adsorbed onto the substrate with each cycle. The photopolymerization was measured by monitoring the reduction of the monomeric  $\pi$ - $\pi^*$  absorption. Fig. 7 shows the UV spectra of eight bilayers on mica UV irradiated at different times. From the rapid reduction of the peak at 310 nm after the first 5 min of irradiation, it can be concluded that most of the monomeric C=C bonds were reacted. After 1 hr, the absorbance band did not change and the photopolymerization was said to be complete.

It was also found that the photopolymerization changes the apparent electrostatic properties of the layer interface through the use of surface force measurements. Also, the photopolymerization undoubtedly increases the lateral strength of the film while maintaining and increasing its uniformity.

**Fig. 4** AFM morphology of 6TN aggregates on mica (A) from pure water (left) and (B) from 0.1 M NaCl (right). *Source:* Reproduced with permission from Ref.<sup>[28]</sup>. © 2002, American Chemical Society.

## Diacetylene Derivatives

Ultrathin films of polydiacetylenes have attracted great interest because of their unusual non-linear optical and photophysical properties.<sup>[52,53]</sup> If the molecules are present in a crystal-like arrangement, typical solid-state reactions such as topochemical diacetylene polymerization can occur. Before 1993, work was almost exclusively concerned with Langmuir–Blodgett (LB) films of amphiphilic diacetylene derivatives, which were then polymerized upon irradiation with UV light or high-energy radiation on the substrate.<sup>[54]</sup> The LB technique provided advantages in ultrathin film formation such as controlled thickness and orientation of the monomers before polymerization. One problem with this technique was in the difficulty to reproduce results because of preparation parameters such as temperature, pH and concentration of the subphase, surface pressure of the monolayer, and purity of the spreading solvent and starting materials. Some of these problems were addressed and overcome by the Tieke group who used bolaform amphiphiles based on diacetylene derivatives along with polyelectrolytes in the layer-by-layer deposition technique [10e,<sup>[32,55]</sup>].

Saremi et al. published a series of papers where the authors synthesized diacetylene bolaform amphiphiles with different alkyl chain lengths and different end groups to be used in fabricating multilayer assemblies along with poly(allylamine hydrochloride) (PAH).

The general structure of the bolaform amphiphiles is shown in Fig. 8.

The compounds used to fabricate multilayers with PAH are the disodium salts of 2,4-hexadiyne 1,6-disulfate (HDDS), 5,7-dodecadiyne 1,12-disulfate (DDDS) and 10,12-docosadiyne 1,22-disulfate (DCDS).

Fig. 9 shows a schematic of the film structure before and after polymerization.

The polymerization properties of the films were studied using UV–vis spectroscopy and structure and morphology investigated by XRD and AFM.

The results of the multilayer fabrication indicate that ultrathin diacetylene multilayers can be built up on charged surfaces but photopolymerization was successful only for DCDS/PAH multilayer films. The different reactivities were explained by the different packing arrangements of each amphiphile. The packing of the short-chain HDDS and DDDS was determined by the pendant sulfate end groups, preventing a dense packing arrangement necessary for the photopolymerization to occur. In the case of the DCDS bolaform, van der Waals forces between the longer alkyl chains determined the packing density, creating aggregates similar to that found in the crystal structure of DCDS verified by X-ray diffraction. Fig. 10 shows the absorption spectra of self-assembled DCDS/PAH after 8 min of UV irradiation.  $n$  corresponds to the number of dipping cycles for each film.

**Fig. 5** (A)–(C) Comparison of AFM images of multilayer samples with 6TN on the surface prepared from two systems. (A) Comparison of 5-layer surface morphology and roughness. (B) Comparison of 10-layer surface morphology and roughness. (C) Comparison of 20-layer surface morphology and roughness. *Source:* Reproduced with permission from Ref.<sup>[28]</sup>. © 2002, American Chemical Society.

The molecular orientation was also investigated for DCDS/PAH multilayers by X-ray diffraction and the DCDS amphiphiles were found to be in a highly tilted arrangement (tilt angle =  $38 \pm 4^\circ$ ). Morphological studies were also performed on the ultrathin films using AFM, which indicated an aggregate domain size between 100 and 300 nm with the average distance between domains between 100 and 200 nm. This is considerably smaller than that found in LB films.<sup>[56]</sup> The domains are usually not in contact with each

other, so that the multilayers do not represent a homogenous film but a fairly regular coverage of the substrate with small islands of layered structure.

As an extension of the initial work, Saremi et al. used an all-bolaform-amphiphile system to fabricate polymerizable multilayers.<sup>[57]</sup> Along with the DCDS bolaform above, the authors synthesized a positively charged 10,12-docosadiyne 1,22-dipyridinium bolaamphiphile, DCDP. It was found that these multilayers were much more photoreactive than the diacetylene/

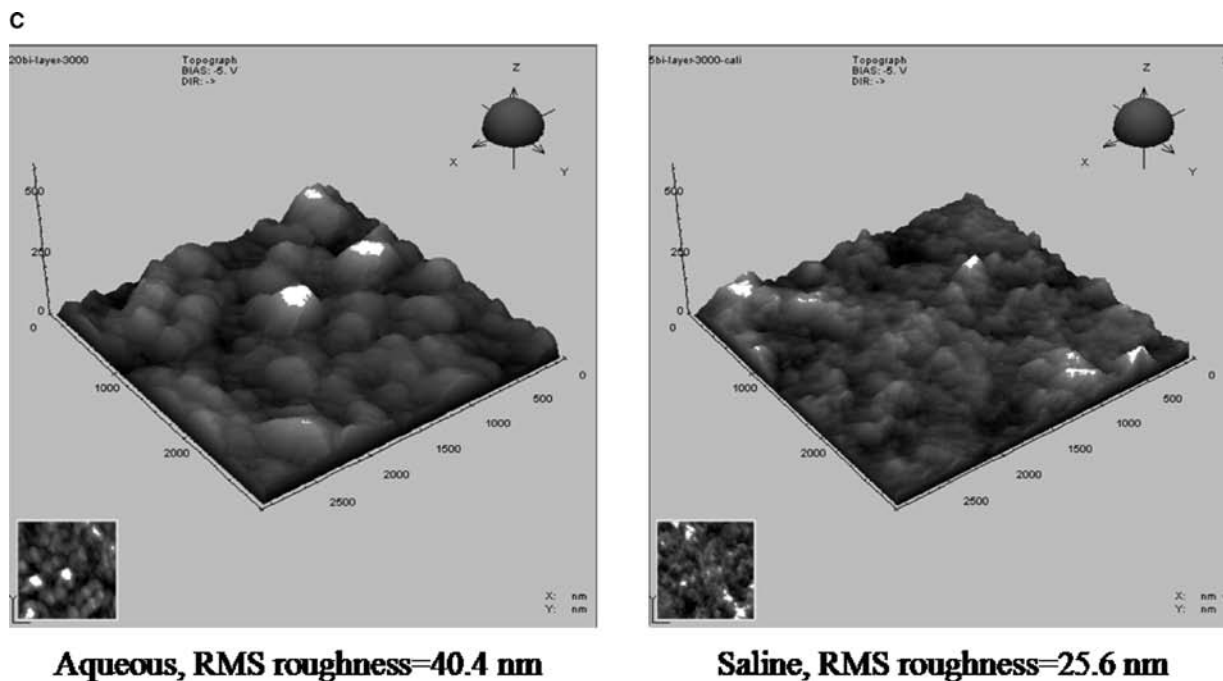

Fig. 5 (Continued).

polyelectrolyte films. The authors attributed this enhanced reactivity to a reordering of the multilayered structure into three-dimensional crystallites with a different packing geometry than either of the monomers

**Fig. 6** Idealized schematic structure of stepwise [2 + 2]-cycloaddition of the bolaform amphiphile DIPY08. Source: Reproduced with permission from *Langmuir* **1993**, *14*, 2184–2191. © 1993, American Chemical Society.

that provided for the enhanced photoreactivity. It was also shown that the reorganization of the multilayers produced reproducible surface inhomogeneities that are inherently typical of all bolaform amphiphile layer-by-layer systems. The tilt angle of the diacetylene bolaform amphiphiles in this system was calculated to be  $60.8^\circ$ .

Also, for reasons of comparison to the bolaform amphiphile systems, DCDS was polymerized in the solid state and a water-soluble polydiacetylene derivative was used to fabricate multilayers with PAH. The results were significantly different than the bolaform amphiphile system. From the UV-vis absorption spectrum, it was deduced that the polydiacetylene was adsorbed as a random coil rather than as a fully extended chain. This shows that order within the bolaform amphiphile multilayers is clearly much higher than that in the polyelectrolyte layers.

The works by the Tirrell, Ringsdorf, and Tiede groups have paved the way for the study of bolaform amphiphile molecules as useful candidates for the generation of photopolymerizable ultrathin films. The groups successfully demonstrated improved film stabilities using layer-by-layer deposition, which has many advantages over LB technique such as being independent of the substrate size and topology. It was also shown that a photopolymerizable, all-bolaform-amphiphile system can be superior to the deposition of an all-polyelectrolyte system in terms of the order within the bolaform amphiphile layers.

## PHOTOCHEMICAL ISOMERIZATION OF BOLAFORM AMPHIPHILES

### Azobenzene Containing Chromophores

Photochromic materials, whose optical properties can be reversibly varied upon exposure to light, are of great interest for potential electro-optical and optical applications.<sup>[58]</sup> Some promising applications include liquid crystal displays, holographic surface relief grating, and optical data storage media. Of particular interest in this area are those materials that contain azobenzene chromophores. Azobenzene derivatives, for instance, have been widely studied and are known to undergo photoisomerization from the thermodynamically more stable trans isomer (*E*) to the cis isomer (*Z*) upon irradiation with ultraviolet light ( $\lambda < 370$  nm), while the reverse reaction occurs either thermally or upon irradiation with visible light ( $\lambda > 450$  nm). Although this phenomenon has been observed in several different media, much of the earlier research effort was focused on photoisomerization of azobenzene in condensed phases such as LB films and self-assembled monolayers.

The first example of photoisomerization of an azobenzene-containing self-assembled multilayer came in 1998 when Saremi and Tieke<sup>[59]</sup> used layer by layer

**Fig. 8** General structure of the diacetylene bolaform amphiphiles used for layer-by-layer assembly. R is the pendant ionic end group, which is either sulfate or pyridinium as depicted in the text.

to assemble multilayers composed of anionic azobenzene bolaform amphiphiles and cationic polyelectrolytes. This study presented the first comparative study of photoresponsive multilayers assembled in which the thickness of the layers could be controlled with a high degree of precision. In their experiments, they synthesized a water-soluble disodium salt of 4,4'-di(6-sulfatohexyloxy)azobenzene (DSHA) to be used in the fabrication of multilayer assemblies. For the corresponding cationic polyelectrolytes, poly(allylamine hydrochloride) (PAH), poly(ethyleneimine) (PEI), poly(dimethyldiallylammonium chloride) (PDDA), and chitosan (CHI), were used. UV-vis absorption spectroscopy was used to follow the photoisomerization process. Results showed all four cationic polyelectrolytes were suitable for preparing multilayer assemblies with the azobenzene bolaamphiphile, although the resulting multilayers showed interesting differences in their UV-vis absorption spectra. In particular, two types of spectra were observed as shown in Fig. 11.

The first type of spectra obtained showed a strong and narrow absorption band with  $\lambda_{\text{max}}$  located at 314 nm. This type of spectrum was observed from samples containing DSHA in combination with PAH or PEI, two polyelectrolytes that exhibit a high degree of charged species along the backbone of the polymer. Alternately, when a polymer with a less densely charged backbone such as PDDA or CHI was used as the polyelectrolyte layer, the UV-vis spectra showed a broad absorption with  $\lambda_{\text{max}}$  located at 340 nm. The differences in these two types of spectra were attributed to the optical absorption behavior of the azobenzene chromophore, which is sensitive to electronic interactions with neighboring chromophores in different molecular arrangements.<sup>[60]</sup> With this in mind, spectra obtained from DSHA/PAH or DSHA/PEI multilayers are indicative of a highly crystalline parallel alignment of H-aggregated chromophores, whereas

**Fig. 9** Schematic of the UV polymerization of DCDS in the electrostatically assembled multilayer. The tilt angles of the dianions are arbitrary. *Source:* Reproduced with permission from Ref.<sup>[36]</sup>. © 1993, American Chemical Society.

spectra obtained from DSHA/PDDA or DSHA/CHI are indicative of dimeric chromophores in smectic layers above the phase transition  $T_c$ .

Photoisomerization studies also reflected a dependence on the choice of polyelectrolyte. For the H-aggregated systems (DSHA/PEI and DSHA/PAH), irradiation with UV light ( $<370$  nm) produced a negligible change in the UV-vis spectrum indicating the absence of any photoisomerization of the azobenzene chromophores. This is attributed to a reduction in free volume within the H-aggregated phase. Since the isomerization of the azobenzene unit involves a

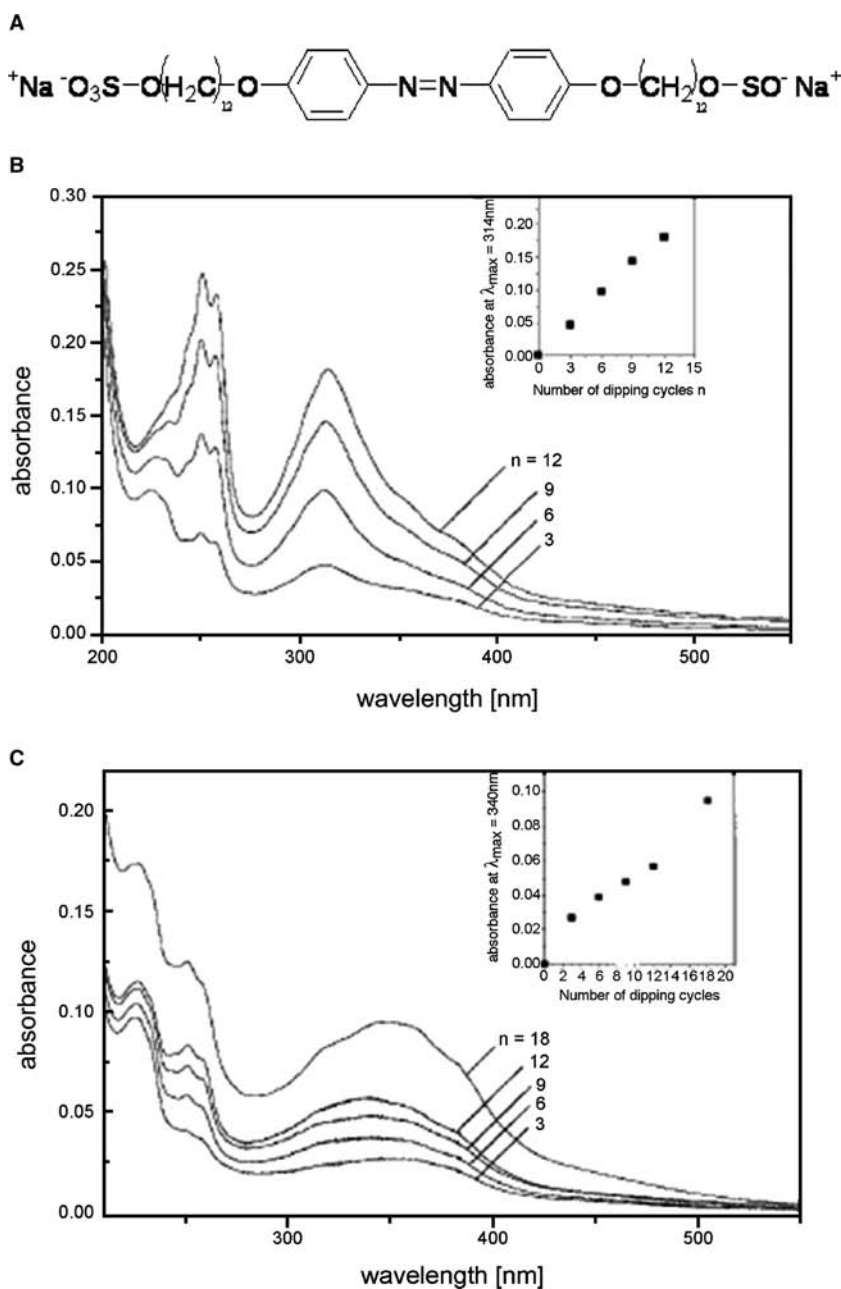

change in cross-sectional area, sufficient free volume is necessary for the photochemical reaction to occur. However, changes in the absorption spectra were observed for the DSHA/PDDA and DSHA/CHI multilayers in which the chromophores have sufficient free volume because of the less organized packing of azobenzene units in the smectic phase. A reduction in  $\lambda_{max}$  observed as a function of irradiation time indicating the photochemical conversion of *trans*-azobenzene to *cis*-azobenzene. The author's proposed orientation of DSHA dianions in both nonphotoresponsive multilayers and photoresponsive multilayers is depicted in Fig. 12. Although the effect of polyelectrolytes on the photochemical behavior of azobenzene has previously been demonstrated, the described work is unique to the application and characterization of azobenzene containing bolaform amphiphiles.

**Fig. 10** UV-vis absorption spectra of electrostatically assembled DCDS/PAH multilayers monitored after 8 min of UV irradiation.  $n$  depicts the number of dipping cycles applied. *Source:* Reproduced with permission from Ref.<sup>[36]</sup>. © 1995, American Chemical Society.

### Effect of Ionic Strength on Photochemical Isomerization

Similarly, Hong, Park, and Park studied the effects of added salts on the photoisomerization of azobenzene bolaform amphiphiles deposited with polyelectrolytes in multilayer assemblies.<sup>[61]</sup> With this study, Hong, Park, and Park described how bolaamphiphile aggregates formed in solution affect the structure of the resulting self-assembled multilayers and how the aggregate state affects the photoisomerization of the incorporated azobenzene chromophores. It is known that salt affects the conformation of the absorbing polyelectrolytes by shielding the charge on the polymer backbone,<sup>[62]</sup> thus dictating the amount of material

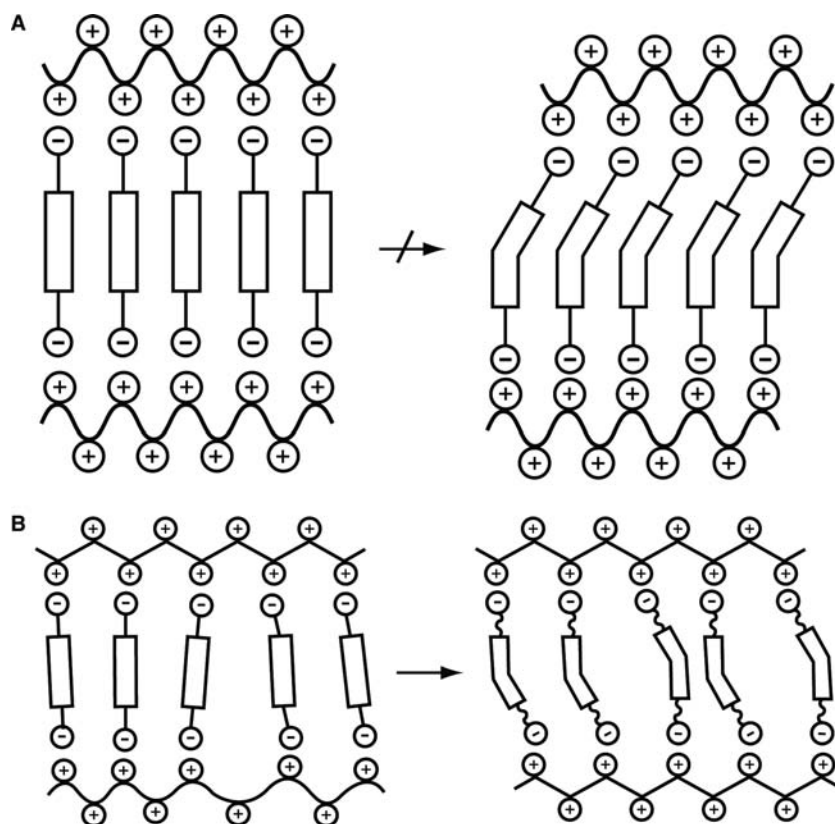

**Fig. 11** (A) Structure of bolaform amphiphile DSHA. (B) UV-vis absorption spectra of electrostatically assembled multilayers built up from alternated adsorption of DSHA and PAH, (C) DSHA and PDDA. Samples differ in the number of dipping cycles applied. The insets show the maximum absorbance of DSHA in the respective multilayer vs. number of dipping cycles applied. *Source:* Reproduced with permission from Ref.<sup>[59]</sup>. © 1995, John Wiley & Sons, Inc.

absorbed on the underlying substrate [1c]. A similar effect was observed in these bolaamphiphile systems.

Bolaform amphiphiles have previously been shown to exhibit unusual aggregation properties in dilute aqueous solution.<sup>[63]</sup> Building on these works, the authors used UV-vis absorption spectroscopy to investigate the formation of aggregates of their BA-12 azobenzene bolaamphiphile depending on both temperature and ionic strength. Fig. 13A shows the temperature dependence on the UV-vis spectra of dilute aqueous solutions of BA-12. Results show a blue shift in the  $\lambda_{\text{max}}$  of the absorption spectra from 357 nm at 58°C to 340 nm at 20°C. A strong decrease in absorption intensity was also observed with a decrease

in temperature. These results indicate the formation of H-aggregates of the azobenzene chromophores at lower temperatures. As the temperature is increased, the chromophores are then molecularly dispersed resulting in spectra corresponding to a single chromophore. Fig. 13B shows the plot of absorption maxima vs. temperature. These data indicate the existence of three phase transitions at 34°, 48°, and 58°C corresponding to a lyotropic mesophase, a biphasic lyotropic/isotropic, and an isotropic phase, respectively. The data presented is in good agreement with results published for other bolaamphiphile systems.<sup>[29]</sup>

The effect of ionic strength on the aggregation state of BA-12 at different salt (NaCl) concentrations was

**Fig. 12** Proposed orientation of DSHA bolaform amphiphiles in non-photoreactive samples of type (A) (top), and in photoreactive samples of type (B) (bottom). *Source:* Reproduced with permission from Ref.<sup>[59]</sup>. © 1995, John Wiley & Sons, Inc.

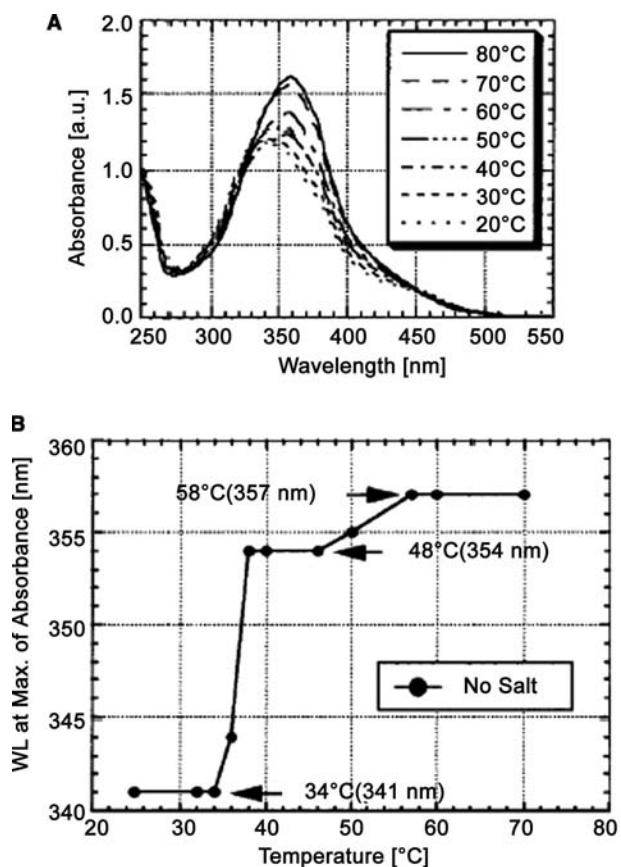

observed by UV-vis spectroscopy. The  $\lambda_{\max}$  of BA-12 in solution with no salt present was blue shifted from 341 to 335 nm by increasing ionic strength to 1.0 M indicating the aggregation of the BA-12 molecules. Similar results were observed on film formation and multilayer growth as a function of ionic strength. Fig. 14 shows the UV-vis spectra of a 10-bilayer self-assembled film of BA-12/poly(vinyl sulfate) (PVS) on fused silica. The authors prepared films BA-12 solution at four ionic strengths (0, 0.1, 0.5, and 1.0 M). UV-vis spectra of the multilayer films closely resemble the spectra of BA-12 in solution at corresponding ionic strengths. The absorption maximum was observed at 341 nm for no salt and was blue shifted to 335 nm for 1.0 M NaCl. This suggests that BA-12 molecules are deposited from solution as preformed aggregates. This is supported by the increase in absorption intensity with increased ionic strength.

Hong, Park, and Park<sup>[61]</sup> studied the structural dependence of azobenzene photoisomerization using polarized UV-vis absorption spectroscopy. Fig. 15 shows the birefringence observed from a BA-12/PVS multilayer film. The film is irradiated with linearly polarized light, which generates a reorientation of the azobenzene chromophores perpendicular to the direction of the electric field vector of the incident light. The spectra were recorded in parallel and perpendicular

directions with respect to the initial UV polarization. From Fig. 15, it can be seen that the absorbance ( $\parallel$ ) is much less than the absorbance ( $\perp$ ). This is indicative of the photoisomerization from trans to cis of those azobenzene chromophores with an electric field vector parallel to the electric field vector of the incident light. There is also a strong time dependence on the in-plane photoisomerization of the azobenzene chromophores at different salt concentrations. In the absence of salt, in-plane photoisomerization of the azobenzene chromophores reached a steady state within 5 min. This is in contrast to 15 min for the films deposited at higher ionic strengths. These observations are consistent with the idea that the BA-12 molecules are deposited as H-aggregated domains with increased ionic strength previously discussed. These results also support the numerous reports in literature on the effects of aggregation state on the photoisomerization and photoalignment process.<sup>[64-66]</sup>

## CONCLUSION

Bolaform amphiphiles are molecules that have interesting properties both in solution and as ultrathin films. The work covered in this paper has shown how molecular design can be used to explore the diversity of

**Fig. 13** (A) UV-vis absorption spectra of BA-12 in aqueous solution (0.1 mM) depending on temperature. (B). bolaamphiphiles in various ultrathin film applications. There are critical factors such as the chain length and choice of end group that must be considered when creating bolaamphiphiles for electrostatic adsorption.

**Fig. 15** Polarized UV-vis absorption spectra of the self-assembled 10-bilayer BA-12/PVS ( $S_{0.1 M}$ ) on fused silica before (●) and after 5 min (▲, ▼) of linearly polarized UV (360 nm) irradiation. Spectra are obtained for both parallel (▼) and perpendicular (▲) to the initial UV light polarization. For reasons of clarity, only absorbance (●) of the initial *trans*-azobenzene in the multilayer assemblies is shown. *Source:* Reproduced with permission from Ref.<sup>[61]</sup>. © 1999, American Chemical Society.

The works have demonstrated the versatility of the layer-by-layer method by fabricating multilayers with polyelectrolytes, inorganic clay platelets, and other bolaform amphiphiles for specific applications. On a more general scale, bolaform amphiphiles have provided insight into aggregation behavior in solution and the effect that aggregate size may have on adsorption and multilayer structure. It was demonstrated that factors such as ionic strength and temperature

**Fig. 14** (A) Structure of the bolaform amphiphile BA-12. (B) UV-vis absorption spectra of the self-assembled 10-bilayer BA-12/PVS on fused silica. The dipping solution of BA-12 is adjusted to different ionic strengths by addition of NaCl: no salt (A); 0.1 M (B); 0.5 M (C); 1.0 M (D). *Source:* Reproduced with permission from Ref.<sup>[61]</sup>. © 1999, American Chemical Society.

drastically affect the crystallinity and film morphology of electrostatically assembled films. These works have opened the door not only to the future design and characterization of new bolaform amphiphiles, but also on the surface dynamics of layer-by-layer ultrathin films.

## INTRODUCTION

In recent years, thin films of semiconductor nanoparticles have found an increasing number of applications in solar energy conversion, electronics, and light-emitting diodes (LEDs).<sup>[1–13]</sup> Different approaches, such as Langmuir–Blodgett (LB), self-assembly (SA), and layer-by-layer assembly (LBL), were developed to fabricate thin films.<sup>[4,11,14]</sup> Among these approaches, layer-by-layer assembly offers a simple scheme to fabricate films consisting of different layers. This may be potentially used to construct films with advanced functions, such as electron and energy transfer between component layers. Layer-by-layer assembly techniques which are based on electrostatic attraction between oppositely charged molecules in adjacent layers were successfully applied to the construction of multilayer films of molecules,<sup>[15]</sup> nanoparticle/polymer mixtures,<sup>[16–18]</sup> and other inorganic materials.<sup>[19]</sup> This LBL assembly method is quite simple and versatile.<sup>[11]</sup> In the preparation process, the substrate, functionalized with a charged layer, is first immersed in a solution containing materials of opposite charge to allow the deposition of the first layer. The resultant film is then rinsed and dried. To deposit the second layer, the same procedure is repeated for materials of opposite charges to the first layer. The deposition cycle can be repeated until the desired number of bilayers is reached. Because of the strong interactions between the oppositely charged layers, the LBL films have shown long-term mechanical stability in air, water, and other polar solvents.<sup>[20]</sup> Many nanoparticles, such as TiO<sub>2</sub>, CdSe, and Au, were successfully assembled into films, for which a number of advanced electronic and photonic applications were demonstrated.<sup>[16,17,19]</sup>

As an alternative method to electrostatic interaction-based LBL assembly, multilayer films based on hydrogen bonding have been reported by Stockton and Rubner<sup>[21]</sup> using polyaniline, and by Wang et al.<sup>[22,23]</sup>

using poly(vinyl pyridine)/poly(acrylic acid) (PVP/PAA). Recently, we extended this hydrogen bonding-based LBL approach to assemble inorganic nanoparticles.<sup>[24,25]</sup> In this report, we review our group's work on layer-by-layer assembly of metal and semiconductor nanoparticles. Both films of single- and multiple-particle types (size or chemical nature) have been fabricated. We will describe two approaches of LBL assembly based on hydrogen bonding interaction between adjacent layers. We will discuss the use of UV–visible absorption spectrum to monitor the buildup of the multilayers and Fourier transform infrared (FTIR) spectroscopy to investigate the hydrogen-bonding interaction between the layers.

## EXPERIMENTAL SECTION

### Materials

Poly(4-vinylpyridine) (PVP) ( $M_w = 6.0 \times 10^4$ ), poly(acrylic acid) (PAA) ( $M_w = 2.4 \times 10^5$ ), polyethylenimine (PEI) ( $M_w = 7.5 \times 10^5$ ), 4-mercaptobenzoic acid (4-MBA), selenium power (99.99%), sulfur powders, tellurium powders, hydrogen tetrachloroaurate(III) trihydrate, cadmium acetate dihydrate (98%), and sodium borohydride were purchased from Aldrich. Methanol and dimethylformide were used as they were found.

### Synthesis of Au Nanoparticles with Carboxyl Group Tailored Surfaces (4-MBA-Au)

4-Mercaptobenzoic acid (4-MBA, HS–C<sub>6</sub>H<sub>4</sub>–COOH)-capped Au nanoparticles were synthesized in methanol/acetic acid solution following a published procedure with a slight modification.<sup>[26]</sup> Briefly, 0.40 mmol of tetrachloroauric acid and 1.2 mmol of 4-mercaptobenzoic acid were codissolved in 35 mL of 6:1 methanol/acetic acid, producing a yellow solution. NaBH<sub>4</sub> (0.3 g,

8 mmol) in 15 mL of methanol was added with rapid stirring. The solution immediately changed to a black suspension. The suspension was stirred for an additional 30 min. The solvent was then removed under vacuum. The black product was washed several times with diethyl ether and dried under an N<sub>2</sub> stream. The sample was soluble in polar solvents such as water and methanol.

### Synthesis of Au Nanoparticles with Pyridine Group Tailored Surfaces (Py–Au)

A total of 55.8 mg of PVP was dissolved in 150 mL of methanol, into which 70.8 mg of HAuCl<sub>4</sub> dissolved in 10 mL of methanol was added under rapid stirring.<sup>[24]</sup> The molar ratio of metal salts to pyridine units was about 1:2. Ten minutes later, 27 mg of NaBH<sub>4</sub> in 10 mL of methanol was quickly added. A change of color from yellow to pink was immediately observed, indicating the formation of Au nanoparticles. After 30 min of further stirring, the solution was maintained at 278 K for further use.

### Synthesis of CdS (CdSe) Nanoparticles in N, N Dimethylformide (DMF)

Cadmium acetate dihydrate powder was suspended in ethanol and refluxed for 3–6 h, yielding a 0.1 M Cd precursor. NaHS (NaHSe) ethanolic solution (0.56 M) was prepared from the reaction between selenium and sodium borohydride in absolute ethanol.<sup>[27]</sup> For CdS (CdSe) nanoparticle preparation, 10 mL (1 mmol) of the Cd precursor was evaporated under reduced pressure. The resulting dry residue was dissolved in 100 mL DMF, into which 4-mercaptobenzoic acid (2.5 mmol) was added. The colorless solution was then reacted with 1.0 mL of NaHS (NaHSe) ethanolic solution under argon atmosphere, producing an orange CdS (brown CdSe) colloidal solution. After further stirring for 30 min, the solution was kept at 278 K for future use.

### Synthesis of 4-MBA-Capped CdTe Nanoparticles

4-MBA-capped CdTe nanoparticles were synthesized in two steps: first, we prepared TOPO-capped CdTe nanoparticles according to a published procedure,<sup>[28,29]</sup> then, the TOPO capping groups on CdTe nanoparticles were substituted by 4-MBA in DMF solutions, following literature procedures.<sup>[30]</sup>

### Fabrication of Polymer/Metal (Semiconductor) Nanoparticle Multilayer Films

To fabricate LBL films of polymer/metal (semiconductor)-nanoparticles, it was first necessary to pretreat the

substrates. In this step, we functionalized the substrate (e.g., quartz, CaF<sub>2</sub> plates, cover glass, and carbon-coated copper grids) with an NH<sub>2</sub>-tailored surface by immersing into a branched polymer (PEI, 0.5 wt.%) solution. Polyethylenimine is an attractive choice because it can adhere to a variety of substrate surfaces. Au nanoparticles with carboxyl group and pyridine group tailored surfaces were assembled according to the following two routes.

#### LBL assembly of PVP and 4-MBA-Au nanoparticles

The PEI-pretreated substrates were transferred to a PAA (0.252 g/L) methanol solution for 10 min, resulting in a COOH-tailored surface. The substrates were then immersed in a PVP (0.256 g/L) methanol solution for 5 min to add a layer of PVP. After rinsing with methanol, the substrates were then transferred to a methanol/acetic acid (10:1) solution of Au nanoparticles for 10 min to deposit one layer of Au nanoparticles. The procedure was repeated until the desired number of bilayers of PVP/4-MBA-Au was reached as shown in Fig. 1.

#### LBL assembly of PAA and Py–Au nanoparticles

As schematically shown in Fig. 2, the PEI-pretreated substrates were first immersed in a PAA (0.252 g/L) methanol solution for 10 min, resulting in a COOH-tailored surface. After washing with methanol, the substrates were transferred to a methanol solution of PVP-capped Au nanoparticles for another 10 min, adding one layer of Au nanoparticles. Multilayer films can be obtained by repeating the last two steps.

### LBL Assembly of PVP/CdSe and PVP/CdS Multiplayer Films

Briefly, the substrates treated with PEI solutions were transferred to a PAA methanol solution (0.252 g/L) to form a carboxylic acid terminated surface. The resulting substrates were immersed in PVP methanol solution (0.256 g/L) for 10 min to add a PVP layer. After being rinsed with methanol, the substrates were immersed into a dilute CdS (CdSe) colloid (DMF/methanol = 1:1) for 10 min to form a CdS (CdSe) layer. Multilayer films can be obtained by repeating the last two steps, as shown schematically in Fig. 1.

### LBL Assembly of CdSe/CdTe Mixed Multilayer Films

Cover glasses were first treated with PEI as described previously. The pretreated substrates were immersed into a CdSe colloid in DMF for 10 min to form a CdSe layer. The resulting substrates were rinsed with

**Fig. 1** Schematic representation of the buildup of multilayer assembly by consecutive adsorption of PVP and metal or semiconductor nanocrystals (NC).

**Fig. 2** Schematic representation of the buildup of multilayer assembly by consecutive adsorption of PAA and PVP capped metal or semiconductor nanocrystals.

methanol and then immersed in PVP methanol solution (0.256 g/L) for 10 min to add a PVP layer. The substrates, after rinsed by methanol, were immersed in a CdTe colloid in DMF for another 10 min to deposit a layer of CdTe. Multilayer films could be fabricated by depositing PVP/CdSe/PVP/CdTe layers alternately.

### LBL Assembly of CdS/Py–Au Multilayer Films

The CdS/Py–Au multilayer films were assembled according to the following procedure: CaF<sub>2</sub> plates were sequentially treated in PEI, PAA, and PVP solutions. The substrates were then immersed in a dilute CdS colloid solution (DMF/methanol = 1:1) for 10 min to form a CdS layer. The substrates were then rinsed in methanol and dried. After that, the substrates were immersed into the Py–Au solution for 10 min. Multilayer films could be fabricated by depositing CdS and Py–Au layers alternately.

## RESULTS AND DISCUSSION

### Layer-by-Layer Assembly of Single-Composite Nanoparticles

LBL assembly of gold nanoparticles

Poly(vinyl pyridine) (PVP) is known to be a strong metal-chelating agent.<sup>[31,32]</sup> We synthesized stable Au

**Fig. 3** UV-visible spectra of 4-MBA capped Au nanoparticles and Py-Au nanoparticles in methanol. *Source:* From Ref.<sup>[24]</sup>. © 2000 American Chemical Society.

nanoparticles in the presence of pure PVP, producing pyridine group tailored surfaces (hydrogen-bonding acceptors). The UV-vis spectrum of Py-Au methanol solution (Fig. 3, upper curve) showed a pronounced surface plasmon (SP) band around 530 nm. Although the UV-vis spectrum of 4-MBA-capped Au nanoparticles in methanol solution (Fig. 3, bottom curve) showed only a weak SP band, transmission electron microscopy (TEM) images indicate that the Au

nanoparticles were round in shape and had an average diameter of about  $2.6 \pm 0.9$  nm.

Multilayer film buildup of Au nanoparticles was monitored by using UV-vis spectroscopy. The observed absorption could be attributed to 4-MBA and Au particles because polymer absorption in the visible region was found to be negligible. Fig. 4A shows the UV-vis absorption spectra of the multilayer film of PVP/(4-MBA-Au) with different number of bilayers on a quartz slide. The absorption spectra of PVP/(4-MBA-Au) nanoparticle multilayer films were in agreement with that of the Au nanoparticle solution (Fig. 3), indicating the successful assembly of 4-MBA-Au nanoparticles into the film. In addition, a linear increase of the absorbance with the number of bilayers (Fig. 4A) was observed, suggesting that approximately the same amount of Au nanoparticles was adsorbed in every deposition cycle.

A similar linear increase of absorbance with the number of bilayers (Fig. 4B) was observed for the PAA/(Py-Au) LBL film, again indicating a stepwise and uniform assembly process. Such behavior has been observed in many layer-by-layer deposition systems based on electrostatic interaction.<sup>[16-18,33,34]</sup> Our result demonstrated that layer-by-layer assembly based on hydrogen bonding provided an alternative way to fabricate homogeneous organic/inorganic multilayer films.

The PVP/(4-MBA-Au) LBL film was also studied by small-angle X-ray diffraction (SAXD), which is a convenient and direct method for determining film thickness.<sup>[35,36]</sup> Fig. 5 shows the SAXD pattern of a 12-bilayer film of PVP/(4-MBA-Au) on a quartz substrate. The X-ray curve revealed well-defined Kiessig

**Fig. 4** (A) UV-visible absorption spectra of the PVP/(4-MBA-Au) nanoparticle multilayer film with different numbers of bilayers. From the lower to upper curves, the number of PVP/(4-MBA-Au) bilayers is 1, 2, 3, 4, and 5. Shown in the inset is a plot of the absorbance at 400 and 500 nm vs. the number of PVP/(4-MBA-Au) bilayers. (B) UV-visible absorption spectra of PAA/(Py-Au) nanoparticle multilayer thin film with different numbers of bilayers. From the lower to upper curves, the number of PAA/(Py-Au) bilayers is 1, 2, 3, 4, and 5. The inset is a plot of the absorbance at 530 nm vs. the number of PAA/(Py-Au) bilayers. *Source:* From Ref.<sup>[24]</sup>. © 2000, American Chemical Society.

**Fig. 5** Small-angle X-ray diffraction patterns of a 12-bilayer film of PVP/Au on a quartz substrate. *Source:* From Ref.<sup>[24]</sup>. © 2000 American Chemical Society.

fringes, which indicated that the PVP/(4-MBA-Au) LBL film was uniform and flat. The total thickness of the film was estimated to be about 39.6 nm from the oscillation period. Because the UV-vis results demonstrated a stepwise and uniform assembly process, the thickness of one PVP/Au bilayer was calculated to be about 3.3 nm.

The direct evidence for hydrogen bonding between PVP and 4-MBA on the surface of Au nanoparticles was obtained by using FTIR spectroscopy. Hydrogen bonding between pyridine groups and carboxyl groups resulted in a splitting pattern of the OH stretching bands.<sup>[37–40]</sup> Fig. 6 shows the IR spectra of a cast film of 4-MBA-Au nanoparticles, a cast film of PVP, and a 10-bilayer PVP/(4-MBA-Au) film on CaF<sub>2</sub> plates. The spectrum of the 4-MBA-Au nanoparticles shows a pronounced C=O band at 1678 cm<sup>-1</sup>, which is consistent with that of 4-MBA in KBr glass.<sup>[41,42]</sup> This band, as well as the broad OH stretch (~3450 cm<sup>-1</sup>), indicates hydrogen-bonding interaction between terminal carboxyl groups of 4-MBA on the surface of Au nanoparticles.<sup>[41–43]</sup> The absorption peaks at 1595.8, 1556.6, and 1414.2 cm<sup>-1</sup> in the spectrum of the cast film of PVP are assigned to ring vibrations of pyridine groups of PVP.<sup>[22]</sup>

After Au nanoparticles were assembled into multilayer film, the C=O stretching vibration was shifted to 1710 cm<sup>-1</sup>. Another striking feature is the appearance of new bands at 1937 and 2520 cm<sup>-1</sup>. These bands were assigned to the stretching bands of hydrogen-bonded OH groups based on a similar splitting pattern of OH groups observed in polymer blends containing carboxyl and vinylpyridine groups.<sup>[37–40]</sup> The presence of these bands in the multilayer thin films indicated strong

**Fig. 6** FTIR spectra of a cast film of PVP, a cast film of 4-MBA-Au nanoparticles, and a 10-bilayer PVP/Au film on CaF<sub>2</sub> plates. *Source:* From Ref.<sup>[24]</sup>. © 2000 American Chemical Society.

hydrogen bonding between the carboxyl groups (donors) on the surface of Au nanoparticles and pyridine groups (acceptors) of PVP. The peaks in the spectral region from 1650 to 1400 cm<sup>-1</sup> were difficult to assign because of overlapping absorption bands, although they arose mainly from the ring vibration of both 4-MBA and pyridine groups.

Fig. 7 shows the FTIR spectra of a cast film of PAA and a 10-bilayer PAA/(Py-Au) film on CaF<sub>2</sub> slides. The IR spectrum of pure PAA shows a broad absorption band around 3000 cm<sup>-1</sup> and the C=O stretching vibration at 1709 cm<sup>-1</sup>, indicating that the polymer was in an associated state.<sup>[22]</sup> For the PAA/Py-Au films, in addition to a shift of C=O stretching band to 1723 cm<sup>-1</sup>, O-H stretching vibrations at 2530 and 1943 cm<sup>-1</sup> were also observed. These spectral features indicated strong hydrogen bonding between the carboxyl groups of PAA and pyridine groups on the surface of Au nanoparticles.<sup>[37–40]</sup> Ring vibrations of pyridine groups at 1605, 1557, and 1416 cm<sup>-1</sup> were also observed.

#### LBL assembly of semiconductor nanoparticles

The PVP/4-MBA hydrogen bonding pair was also used to assemble semiconductor nanoparticles in

**Fig. 7** FTIR spectra of a cast film of pure PAA and a 10-bilayer PVP/Au film on  $\text{CaF}_2$  plates. *Source:* From Ref.<sup>[24]</sup>. © 2000 American Chemical Society.

nonhydrolytic solution. UV-visible spectroscopy was used to monitor the assembling process of PVP and CdS LBL films. Fig. 8A shows the UV-vis absorption spectra of a PVP/CdS multilayer film prepared on a quartz slide with different numbers of bilayers. The band at 370 nm was in agreement with the first exciton band of CdS colloidal particles as shown in Fig. 8A.

**Fig. 8** UV-visible absorption spectra of (A) the PVP/CdS multilayer film with different numbers of bilayers. From the lower to upper curves, the number of PVP/CdS bilayers is 1, 2, 3, 4, and 5, respectively. Inset: the absorbance at 370 and 300 nm vs. the number of PVP/CdS bilayers; (B) the PVP/CdSe multilayer film with different numbers of bilayers. From the lower to upper curves, the number of PVP/CdSe bilayers is 1, 2, 3, 4, and 5, respectively. Inset: the absorbance at 430 and 300 nm vs. the number of PVP/CdSe bilayers. *Source:* (B) From Ref.<sup>[25]</sup>. © 2000 American Chemical Society.

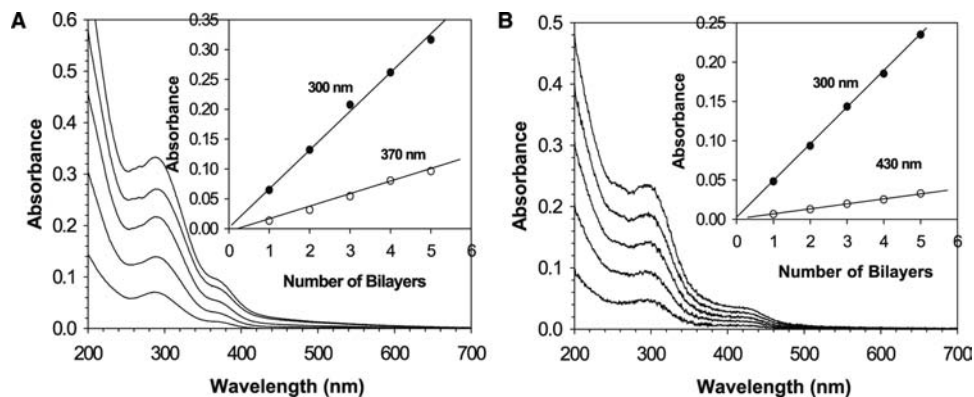

This illustrated that the CdS nanoparticles were successfully assembled into thin films. In addition, the observed linear increase of CdS absorbance vs. the number of bilayers (Fig. 8A) indicated a stepwise and uniform assembling process.

Similar results can be found for PVP/CdSe (Fig. 8B). UV-visible results for LBL assembly exhibits a well-resolved peak at 430 nm, which agrees very well with the first exciton band of CdSe colloid solution (Fig. 8A). Moreover, a linear increase of the absorbance with the number of PVP/CdSe bilayers (Fig. 8B) was observed, indicating that approximately the same amount of CdSe nanoparticles was absorbed in every deposition cycle. The flatness of PVP/CdSe film was also monitored by small-angle X-ray diffraction, as shown in Fig. 9. It revealed well-defined Kiessig fringes, which suggested that the PVP/CdSe LBL film was uniform and flat. The thickness of one PVP/CdSe bilayer was calculated to be about 24.7 Å. This is consistent with the average diameter of the CdSe particles of 17–20 Å determined by light scattering measurement.

The driving force for the construction of PVP/CdSe multilayer film was identified by infrared spectroscopy. For this study, we prepared a film without the step involving poly(acrylic acid) to avoid its strong infrared absorption. The multilayer film was fabricated by directly immersing PEI-coated  $\text{CaF}_2$  plates into CdSe and PVP solution alternately. Fig. 10 shows the IR spectra of a cast film of 4-mercaptobenzoic acid stabilized CdSe nanoparticles, a cast film of PVP, and a 10-bilayer PVP/CdSe film on  $\text{CaF}_2$  plates. The C=O band of 4-MBA-capped CdSe appeared at  $1670\text{ cm}^{-1}$  and the ring vibration of 4-MBA was observed at  $1589.7\text{ cm}^{-1}$ . The absorption peak at  $1541\text{ cm}^{-1}$  was assigned to the vibration of carboxylate salts of cadmium acetate (present in the CdSe nanoparticle solution). For the cast film of PVP, the absorption peaks at  $1595.8$ ,  $1556.6$ , and  $1414.2\text{ cm}^{-1}$  were assigned to the ring vibration of the pyridine groups of PVP. After CdSe nanoparticles were assembled into a multilayer film, a C=O stretching vibration appeared at  $1710\text{ cm}^{-1}$ , which suggested that carboxylic acid groups on the surface of CdSe were not ionized in the assembling process. In addition, broad O-H bands appeared at  $1930$  and  $2520\text{ cm}^{-1}$ , indicating the formation of hydrogen bonding between the carboxylic acid on the surface of CdSe nanoparticles and pyridine groups of PVP. These results provided the evidence that the multilayer film was assembled based on hydrogen bonding.

### LBL Assembly of Multicomposite Multilayer Films of Different Nanoparticles

As indicated above, we have successfully fabricated multiplayer films consisting of one type of nanoparticles

**Fig. 9** Small-angle X-ray diffraction patterns of a 12-bilayer film of PVP/CdSe on a quartz substrate. *Source:* From Ref.<sup>[25]</sup>. © 2000 American Chemical Society.

(metal or semiconductor) by using hydrogen bonding-based layer-by-layer assembly. We have demonstrated that two different approaches, as indicated in Figs. 1 and 2, can be used. More recently, we showed that the same strategies could be used to assemble thin films containing multiple types of nanoparticles. This will potentially enable the design of films with properties (such as spectral response and functionality) that cannot be easily achieved by using only one type of particles. Next, we will review our results in CdSe/CdTe and CdS/Py–Au LBL assembly.

TOPO-capped CdTe nanoparticles were prepared according the method of Peng et al.<sup>[28,29]</sup> To produce 4-MBA-capped CdTe nanoparticles, the TOPO ligands were replaced by 4-MBA, following the procedure of Mattoussi et al.<sup>[30]</sup> The 4-MBA-capped CdTe particles

were stable for over 1 month in the refrigerator. UV–visible spectrum shows a very clear first exciton peak at 660 nm, as indicated in Fig. 11C. The assembly process of a 12-bilayer LBL film of CdSe and CdTe was monitored by UV–visible spectroscopy, as indicated in Fig. 10. CdSe and CdTe nanoparticles were alternately assembled to form a film consisting of layers of CdSe /PVP/CdTe/PVP. The process is similar to the method indicated in Fig. 1. Two strong peaks

**Fig. 10** FTIR spectra of a cast film of 4-mercaptobenzoic acid stabilized CdSe nanoparticles, a cast film of PVP, and 10 bilayers of PVP/CdSe thin film on CaF<sub>2</sub> plates. *Source:* From Ref.<sup>[25]</sup>. © 2000 American Chemical Society.

**Fig. 11** UV–visible spectrum of (A) CdS; (B) CdSe; (C) CdTe nanoparticles in DMF.

**Fig. 12** UV-vis absorption spectra of CdSe/CdTe multicomposite film with different numbers of bilayers. From the lower to upper curves, the number of CdSe and CdTe bilayers is 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12 alternatively. Inset: the absorbance at 530 nm vs. the number of CdSe layers and the absorbance at 660 nm vs. the number of CdTe bilayers.

at 530 and 660 nm, attributed to CdSe and CdTe, respectively, were observed, indicating that CdSe and CdTe were successfully assembled into the film. A linear increase of both CdSe and CdTe absorbance as a function of layer number is also observed (Fig. 12, inset).

Multilayer CdS/Py-Au film was assembled by using the method shown in Fig. 2. The buildup was also monitored by using UV-visible spectroscopy as indicated in Fig. 13. In addition to the strong SP band of Au nanoparticles around 530 nm, a weak peak at 370 nm is also observed, which is attributed to CdS

**Fig. 13** UV-vis absorption spectra of the CdS/Py-Au multilayer film with different numbers of bilayers. From the lower to upper curves, the number of CdS/Py-Au bilayers is 1, 2, 3, 4, and 5, respectively. Inset: absorbance at 530, 360, and 250 nm vs. the number of PVP/CdS bilayers.

**Fig. 14** FTIR spectra of a cast film of Py-Au, and six bilayers of CdS/Py-Au thin film on CaF<sub>2</sub> plates.

on the basis of the UV-visible spectra of CdS solution (Fig. 11B). These absorption peaks suggest that both CdS and Au nanoparticles were successfully assembled into the film. In addition, a linear increase of CdS and Py-Au absorbance vs. the number of bilayers was also observed, as shown in the inset of Fig. 13. This illustrates a stepwise and uniform assembling of both CdS and Au layers.

The direct evidence for hydrogen bonding between 4-MBA-capped CdS nanoparticles and Au nanoparticles with poly (4-vinylpyridine) tailored surface was obtained via FTIR spectroscopy. Fig. 14 shows the FTIR spectra of a cast film of Py-Au and a cast film of six bilayers of CdS/Py-Au thin film on CaF<sub>2</sub> plates. For the Py-Au film, the peaks at 1594, 1546, and 1411 cm<sup>-1</sup> can be assigned to ring vibrations of the pyridine group. After the CdS and Au nanoparticles were assembled into multicomposite films, two broad peaks at 1882 and 2485 cm<sup>-1</sup> were observed, indicating hydrogen bonding between carboxylic acid on the surface of CdS and pyridine group on the surface of Au nanoparticles.

## CONCLUSION

We have presented two strategies for assembling single-composite and multicomposite multilayer thin films of inorganic nanoparticles based on hydrogen bonding. The multilayer buildups were monitored by UV-vis spectroscopy. Uniform layer deposition was achieved with this assembly technique, as indicated

by the linear increase of the film absorbance with the number of bilayers. Hydrogen bonding interaction is believed to be the driving force for the formation of multilayer films.

We demonstrated that both films of one and two types of nanoparticles could be assembled. In principle, many different nanoparticles (sizes and composition) can be assembled into different layers. Thus this technique may be potentially used to fabricate films with more complicated composition and advanced functionalities. For example, layers consisting of particles of different band gap and band edge position can be included in the film to allow directed energy and/or electron transfer. These films may find applications in LED and solar cells. Ongoing works are devoted to the understanding of interaction between different nanoparticles in the multicomposite films. Fabrication of LED or solar cells that are based on LBL assembly of highly luminescent quantum dots will also be explored.

## ACKNOWLEDGMENTS

This work is supported by the National Science Foundation grant CHE-9733796 and CHE-0135427. We would like to thank Dr. Angus Wilkinson (School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400) for performing the SAXD measurements and Dr. Karl Hagen for his help in synthesizing nanoparticles.

## INTRODUCTION

Layer-by-layer (LbL) self-assembly of multilayer films involves the construction of complex composite materials with nanoscale precision in film thickness, one layer at a time, enabling the development of novel structures and devices with properties tailored by controlling the molecular makeup and arrangement. Early fundamental studies of multilayer assemblies on planar substrates demonstrated the practicality and versatility of the approach, and work over the past decade has included further investigation into the internal structure and composition of LbL films, including dynamic and long-term interactions between film components, solvents, and solute, especially transport properties. Beyond assembly onto flat planar surfaces, the multilayer deposition via LbL has been extended to colloidal templates, leading to elaborate modification of micro/nanoparticles and even to hollow capsules, both of which are exciting and attractive for many applications. While the bulk of work in LbL has been in experimental investigations, some efforts to generate theoretical descriptions for the multilayer assembly have also been undertaken, although much more work is needed in this area to establish useful models for design of devices based on this approach. Finally, applications for LbL films abound and are now being pursued at the academic level, with some examples of industrial success. Examples given here particularly focus on the biomedical arena, where sensor technology and drug release are prime candidates to benefit from use of multilayer films.

## MOTIVATION AND BASIC CONCEPTS

“What could we do with layered structures with just the right layers?” was one of the questions asked by Richard Feynman in his now-famous speech to the American Physical Society in December 1959. Feynman, considered by many to be the “father of

nanotechnology,” because of his prophetic comments given in the lecture entitled “There’s plenty of room at the bottom,” continued: “I can’t see exactly what would happen, but I can hardly doubt that when we have some *control* of the arrangement of things on a small scale we will get an enormously greater range of possible properties that substances can have, and of different things that we can do.” Since that time, scientists have begun to provide answers to this marvelously insightful question by developing practical ways to deposit materials with dimensional control on the order of single molecules. One of the most promising methods for building functional nanostructures (i.e., nanodevices) using a sequential approach to defining multilayer thin (truly *ultrathin*) films is the electrostatic LbL assembly process, which has been developed and extensively studied over the last decade.<sup>[1–8]</sup>

## Fundamentals of Electrostatic Layer-by-Layer Self-Assembly

First proposed by Iler<sup>[9]</sup> in 1966, and then rediscovered by Decher et al.<sup>[1–3]</sup> in the early 1990s, the LbL electrostatic adsorption process has only recently been reduced to practice as a general method for alternately depositing dense monolayers of charged molecules onto oppositely charged surfaces.<sup>[1]</sup> The power of the approach is evident from the generality of the process, which relies mainly on the attractive force between oppositely charged molecules; materials employed in the assembly process range from charged polymers (“polyelectrolytes” or “polyions”) to proteins, dyes, and semiconductor nanoparticles.<sup>[4–8]</sup> Each layer has a thickness on the order of a few nanometers, and this thickness is controllable through careful selection of materials and reaction parameters.<sup>[6]</sup> Furthermore, the composition of films can be engineered through the sequential deposition of different materials; thus, complex film architecture may be achieved through a common process without need for complicated chemistry. Thus the LbL method provides a practical

procedure for building precisely engineered nanocomposite films, a basis for considering the question posed by Feynman.

The principal idea of the method consists of the resaturation of polyion adsorption, resulting in the alternation of the terminal charge after every subsequent layer deposition (Fig. 1).

This idea is general, implying that there is no fundamental restriction to the choice of polyelectrolytes. The technique suggests the possibility of designing ultrathin ordered films in the range of 5–1000 nm, with a precision better than 1 nm and a definite knowledge of their molecular composition (Fig. 2).

### From Planar Substrates to Micro- and Nano-Templates

The initial fundamental research on LbL assembly was performed on planar bulk templates: Layers defined by the electrostatic adsorption process were formed on the surface of relatively large, flat, smooth, charged substrates as they were dipped in solutions of charged materials. The LbL process, however, is in no way limited to such situations; that is, the films may just as well be deposited on charged roughened surfaces or small (micro/nano)templates, given that the dimensions and materials are sufficient for the necessary interactions. Thus the procedure has also been elaborated to demonstrate the fabrication of three-dimensional (3-D) layered structures by using charged substrates with micrometer and nanometer dimensions.<sup>[10–12]</sup> Specifically, microspheres and nanoparticles have been extensively studied because of the wide availability and

attractive surface properties of spherical particles. Functional nanocomposite films can be deposited on these carriers, which are attractive for controlling catalytic reactions and other interfacial phenomena because of the high surface-to-volume ratio.<sup>[13]</sup> The key to this process is the separation of the templates from the layering materials following adsorption, which is achieved via centrifugation or filtration (Fig. 3).<sup>[14]</sup>

### From Layered Colloids to Nanocapsules

In the past several years, a technique for fabrication of hollow micro/nanocapsules has been developed using an extension of the polyelectrolyte layering process applied to colloids. Subsequent to deposition of coatings comprising charged molecules around the templates, the core material is removed using chemical etching to achieve hollow shells (Fig. 4).<sup>[10,15–20]</sup> Dimensions and shape of the capsules is dependent on the chosen nano/microtemplates: These may be latex, silica, or lipid tubules ranging from 20 to hundreds of nanometers. Methods for “replication” of more complex particles such as viruses and cells are also under development. The method is very versatile, and shell properties can be controlled: Inner diameters are dependent upon the size of templates used for assembly, wall thicknesses can be controlled precisely to within a few nanometers, and walls may be constructed using a diverse selection of charged molecules (polyelectrolytes, proteins, dyes, inorganic particles, copolymers, etc.).<sup>[10,19]</sup> The versatility in construction of these tiny capsules and control over their properties makes them attractive for use in sensor applications.

**Fig. 1** Illustration of layer-by-layer nanofabrication approach, showing adsorption of charged materials to oppositely charged surfaces. Assembly on the surface results in stable immobilization via multiple electrostatic bonds, and surface charge reversal. Materials may be (A) charged molecules, (B) particles, or combinations thereof.

**Fig. 2** SEM cross-section view of multilayer films with different structural properties based on the varying components: (A) (PEI/40-nm silica)<sub>25</sub> multilayers; (B) (PEI/40-nm silica/PEI/50-nm diameter halloysite tubules)<sub>4</sub> multilayer; (C) (PAH/glucose oxidase)<sub>18</sub> multilayer on a silver electrode. The samples were coated with 2-nm Pt for imaging.

Polyelectrolyte capsules have been demonstrated to partition between solvents<sup>[18]</sup> as well as encapsulate small molecules such as dyes<sup>[20]</sup> and active materials such as enzymes.<sup>[19]</sup> Encapsulation depends on membrane permeability of polycation–polyanion complexes, which is strongly influenced by solution pH.<sup>[21]</sup> Opening of relatively large (~10–20 nm) pores in multilayer films is possible by varying solvent pH, which can then be used to modulate the diffusion rate

**Fig. 3** (A) Schematic of LbL assembly on colloids. Examples of nanoassembled films of nanoparticles deposited on slightly larger colloidal templates. (B) TEM image of 70-nm silica nanoparticles surrounding a negatively charged 250-nm diameter latex core, attached through interaction with PEI (polycation) interlayers; (C) SEM image of 400-nm latex covered with two monolayers of 12-nm magnetite particles in alternation with polycation. *Source:* From Ref.<sup>[14]</sup>.

of molecules through capsule walls. This concept has recently been demonstrated for encapsulation of dextran and albumin<sup>[22]</sup> and the process appears to be completely reversible. A similar effect has been noted when solution dielectric constant is changed by the addition of ethanol to aqueous solutions; however, the underlying mechanism is not yet understood<sup>[19]</sup> (Fig. 5).

Thus a prospective technology which may arise from these novel nanostructured materials is polymer

**Fig. 4** Scheme of capsule formation using adsorption of charged species to micro/nanotemplates, followed by removal of the core.

capsules with dynamically varying permeability, opening up possibilities for encapsulation and controlled release and possibly impacting environmental and medical areas such as remediation and drug delivery. With this overview of the present state and brief

suggestion of what may come from LbL multilayer films, the following sections will review candidate materials for substrates and adsorbates, the properties of LbL films and will conclude with a look at current and future applications.

## MATERIALS AND METHODS FOR LAYER-BY-LAYER ASSEMBLY

### Adsorbate Materials

Because of the general nature of the interactions dominating the LbL self-assembly process, primarily electrostatics, a large palette of materials is available for building multilayer assemblies—keeping in mind that the order and conditions of assembly also influence the properties of the assemblies, the possibilities to concoct novel nanocomposite materials from simple recipes are nearly limitless. Potential ingredients range from highly charged polymers, organic or inorganic nanoparticles, functional polymers, orientable chromophores, charged lipid micelles, and biopolymers such as short-chain polypeptides, proteins, and DNA.<sup>[2,23–26]</sup> The versatility of the multilayer formation process with respect to the variety of materials which can be used as building blocks, and the additional possibility of combination with other assembly procedures, results in a high application potential in a broad range of different areas of materials development.

The polyions predominately used in the electrostatic self-assembly process include: polycations—poly(ethylenimine) (PEI), poly(dimethyldiallyl ammonium chloride) (PDDA), poly(allylamine) (PAH), poly(lysine), and chitosan; and polyanions—poly(styrenesulfonate) (PSS), poly(vinylsulfate) (PVS), poly(acrylic acid) (PAA), and dextran sulfate. The dominant polyanion/polycation pair that has been used in published studies of LbL films to date, including microcapsules, is PSS/PAH. The specific properties of films assembled from various combinations are discussed below. In addition, multilayer assemblies of natural polyions, such as charged polypeptides, protamine sulfate, sodium alginate, and polysaccharides (e.g., heparin, chondroitin, and chitosan), are particularly interesting for biological and medical applications. DNA and polynucleotides (polyuridylic and polyadenylic acids) can be readily assembled in alternation with polycations (PEI, PAH, polylysine). Assembly of polysaccharides, such as dextran, is also possible as a means of biocompatible surface preparation.

Many proteins have been assembled in organized multilayers by alternation with oppositely charged linear polyions. Typical concentrations for assembly solutions fall within the range of 0.1–2 mg/mL, and adsorption saturation occurs within 20 min as long as the pH of the protein solutions is adjusted away from the isoelectric point so that proteins are sufficiently charged under the experimental conditions. Water-soluble proteins, including cytochrome *c* and P450, lysozyme, histones, myoglobin, pepsin, different peroxidases, hemoglobin, glucoamylase, concanavalin A, albumin, glucose oxidase, lactate oxidase, catalase,

invertase, diaphorase, bacteriorhodopsin, and immunoglobulin IgG, have been used successfully for LbL assembly.<sup>[26]</sup> A book on protein architectures reviews the materials, methods, and film characteristics of nanoassembled proteins.<sup>[26]</sup>

Advanced materials comprising nanocomposite multilayer assemblies of polymers and nanoparticles have been demonstrated using a variety of metal, semiconductor, and dielectric materials.<sup>[27–30]</sup> Ordered nanostructured films with desired periodicity have been created to tune mechanical, magnetic, electrical, optical, and optoelectronic properties.<sup>[27,30]</sup> Densely packed, conformable sheets of rigid crystals form in the adsorption process when alternated with flexible polyion “glue.”<sup>[28]</sup> Growth of nanoparticle–polyelectrolyte multilayers may occur in both normal (vertical) and in-plane (lateral) directions, depending upon assembly conditions and particle properties.<sup>[29]</sup> Nanoparticles also assemble into ordered films when alternated with globular proteins.<sup>[31]</sup> A review of nanoparticle assembly via LbL provides an excellent overview of the current state of knowledge and applications in this area.<sup>[30]</sup>

### Substrate Materials

The basic substrate for LbL assembly is a flat, charged surface, typically a slab of glass (e.g., microscope slide or cover slip) or quartz. There is essentially no limit to the template used—examples of practical cases include slides of optical materials (glass, quartz, etc.), gold-coated glass, silicon, metals, porous ceramics, plastics, filters, optical fibers—and, in reality, depend only upon the intended application. In addition to macroscale, largely planar substrates, colloidal particles have also been used as LbL templates. Typical materials used for this purpose range from dielectric nanoparticles, quantum dots, metal nanoparticles, core-shell structures, biological cells, carbon nanotubes, lipid tubules, and polymer microspheres. Methods have also been elaborated to allow coating of drug or dye crystals.

Capsules are formed by colloidal coating followed by dissolution or etching of the template core. Following core removal, hollow and closed structures are formed. These have exactly the same shape of the template, but now with walls comprising the ultrathin multilayer films deposited on the template surface; thus, it is a way to replicate structures with new materials, in effect a nanoscale version of molding. The initial demonstrations of capsules formed from core removal of LbL-coated templates used weakly cross-linked polymeric particles, e.g., melamine formaldehyde (MF), which dissolve at low pH.<sup>[32]</sup> A drawback to the use of MF is the residual polymer left in the capsule after exposure to acid, resulting in “contaminated” capsule interiors. Thus alternative templates that allow

more efficient removal of core material have been sought, such as organic particles,<sup>[33–35]</sup> inorganic microcrystals,<sup>[36]</sup> and even biological cells.<sup>[37]</sup> Examples of materials used in creation of micro/nanocapsules are melamine formaldehyde (acid removal), silica (acid etch), gold (acid etch), cadmium carbonate (acid removal),<sup>[38]</sup> manganese carbonate (acid removal), platelets,<sup>[39]</sup> and human erythrocytes (red blood cells) (oxidation removal).<sup>[40]</sup>

## Multilayer Coating Methods

### Multilayer film formation by alternate immersion

Nanoassembly by immersion of charged substrates into solutions of adsorbate is the typical procedure. Uncharged or weakly charged surfaces may be suitably modified with a layer of charged material using other interactions (e.g., SAMs) to provide the initial charged interface. For example, gold surfaces may be modified with molecules containing thiol groups [e.g., HS-(CH<sub>2</sub>)<sub>8</sub>-COOH],<sup>[41]</sup> and oxide surfaces can be similarly coated with silanes.<sup>[42]</sup> Once a suitable surface is available, LbL assembly proceeds by alternate dipping in solutions containing molecules of opposite charge from the current surface, and washing steps are used in between adsorption steps to remove weakly bound material. Typically, solutions are aqueous and adjusted to a pH at which the molecules of interest have sufficient and appropriate charge. Drying of films during assembly is optional and has been shown to affect the final film structure and properties.<sup>[43]</sup> Generally speaking, this process is inexpensive to perform and requires a minimum of specialized equipment and supplies; development work can be done under normal conditions in any reasonably clean lab. However, the dipping technique typically requires 10–30 min per adsorption step, making the assembly somewhat time-consuming.

In the case where colloids are to be coated, a method of alternate exposure of colloids to polycations and polyanions is still used, with intermediate rinse and separation cycles. The separation step is the key to this procedure, and centrifugation<sup>[44,32]</sup> and ultrafiltration<sup>[45]</sup> have been demonstrated as useful techniques for this purpose. Such methods allow multilayer assemblies to be deposited on curved surfaces in the size range of a few nanometers to several micrometers, with proof of film growth shown by microelectrophoresis and single-particle light-scattering measurements.<sup>[44,46,47]</sup>

### Spray and spin assembly of multilayer films

A disadvantage of the alternate immersion process for multilayer formation is the long time required to

assemble a single film (1 min to 1 hr, depending on adsorbing systems; typically 10–20 min). Another disadvantage is the difficulty in application of multilayers to large surface areas. In an attempt to overcome some of these problems, alternative methods for the application of multilayers using spraying and spinning approaches have been developed.<sup>[48–51]</sup>

Polyelectrolyte multilayers deposited by sequential spraying provides the advantage of rapidly obtaining a highly uniform thin film over a large area. Spray application over a large area is advantageous for rapid, high-throughput fabrication of devices bearing active or passive multilayers, for large-area membranes, and for external coatings as corrosion protection or adhesion modification. The morphology, uniformity, and chemical composition of films prepared by spraying were found to be identical to those from dipping. Disadvantages of spraying, however, include several minutes of contact time for maximum (steady-state) coverage and the inefficient use of polymer solution because it cannot be reused.<sup>[48]</sup>

Polyelectrolyte multilayers deposited by sequential spin coating (“spin-assisted” assembly) provides the advantage of drastic reduction in the preparation time per layer, i.e., from 20 min to 20 sec.<sup>[50]</sup> In spin coating using polyelectrolytes with the same molar concentrations used in alternate immersion, film thicknesses are thicker than those obtained in dipping methods.<sup>[49,52]</sup> The centrifugal force and hydrodynamic air drag, generated by a high spinning rate and short spinning time, act together to remove both water (accelerating drying) and loosely bound polymer chains from the substrate. The fast elimination of water significantly increases the local molar concentration of the polyelectrolyte solution during the short deposition time and hence the thicker films result.

A critical aspect of spun films is the lesser dependence upon charge densities; in fact, multilayer films have been successfully demonstrated using sequential adsorption of uncharged and even same-charge layers. Recently, water-soluble, cationic, anionic, and neutral polymers were used to form repeat trilayer (polycation/polyanion/uncharged polymer or polycation/polyanion/polyanion) films using spin assembly. These multilayer films assemble through physical entanglement, electrostatic, and/or H-bonding interactions.<sup>[53]</sup> Moreover, multiple deposition cycles of a single polyelectrolyte resulted in the formation of a film whose thickness grew linearly with each deposition.<sup>[53,54]</sup>

One must keep in mind a critical feature for the assembly of well-charged species: Electrostatic interactions not only drives binding between neighboring molecular layers but also recharges the surface to prevent additional adsorption of similarly charged polyions. Therefore the binding force is complemented by a force preventing uncontrollable increase in thickness that

would result from continuous deposition. From our experience, electrostatic LbL assembly of highly charged components results in more organized multilayer nanocomposites compared with multilayers assembled via biospecific or hydrogen-bonding interactions, where repulsion preventing nonspecific adsorption is absent.

Film thickness increases with increasing concentrations of the solution and decreases with spin speed due to shorter contact time.<sup>[50,51,53,54]</sup> The thickness may also be controlled by changing factors known to influence film thickness in immersion assembly, including ionic strength, pH,<sup>[50]</sup> hydrophobicity, and charge density.<sup>[53]</sup> The amount of material deposited on a substrate is inversely proportional to the logarithm of the molecular weight of polymers at low concentrations.<sup>[55]</sup> The air drag is believed to strengthen the electrostatic attraction between oppositely charged polymers.<sup>[49,52,55]</sup> In addition, spin assembly induces deposition through polymer chain entanglement between the deposited layer and the film's outer layer; as a result, spin assembly is controlled by mechanical rather than thermodynamic factors.<sup>[50,53,54]</sup>

An interesting and important difference in structure between films prepared by spinning compared to dipping lies at the interface between neighboring layers. The air shear force driven by the spinning process significantly enhances the surface planarization of the multilayer films, making them smoother compared to dip assembled films.<sup>[49,50,52]</sup> In contrast to the interpenetration of neighboring layers that is characteristic for adsorption during immersion, films prepared with the spin process possess distinct interfaces between respective layers, providing a well-ordered internal structure.<sup>[49,52]</sup>

### Nanofilm patterning

Micropatterning of LbL multilayers, an attractive extension beyond nondiscriminatory surface coverage, was initiated in the works of Hammond et al.<sup>[56–60]</sup> The interest in these systems arises from the potential for lateral definition of nanofilm features, providing further versatility in structures that may be realized. The ability to produce structures of composite materials with nanometer resolution in vertical and (ultimately, with advances in nanolithography) lateral dimensions in a simple, fast, and cost-effective process would enable manufacture of devices at increasingly smaller size and lower cost. The foundation for this has been laid using a combination of self-assembled monolayers and LbL films. For this, charged patterns are first created on gold surfaces by microstamping of thiol compounds terminated with negatively or positively charged groups. The remaining unstamped surface is then backfilled with additional hydrophobic-terminated thiols to define adsorption-resistant regions. Then, by alternate

dipping of the patterned substrates with short periods of sonication in between to remove nonspecific adsorption, multilayers of different materials following the template patterns were assembled.<sup>[56–59]</sup> Furthermore, with some additional efforts, filling of empty areas (between initially patterned strips) was achieved via hydrogen bonding with secondary materials.<sup>[60]</sup>

In another approach, traditional microlithography was combined with electrostatic LbL nanoassembly to produce 3-D structures. In contrast to the microstamping method described above, this technique integrates directly with standard silicon-processing lithographic procedures and allows for easy alignment of structures deposited in multiple steps. The process follows the typical lift-off procedure for metallization with aluminum via thermal evaporation. A layer of photoresist ( $\sim 1 \mu\text{m}$ ) is first applied to a substrate, then patterned through a mask by standard UV irradiation and photoresist development. Multilayers may then be deposited onto the substrate with patterned resist via the electrostatic LbL self-assembly technique. This step results in deposition on the exposed substrate regions as well as on top of the remaining photoresist. Finally, the photoresist with polyions on top of it is exposed to acetone, accompanied with sonication, leaving the nanofilm patterns on the substrate with intervening regions of bare substrate. As demonstrations of this process, cationic polymers (PEI or PDDA) alternated with anionic nanoparticles (silica or 40-nm fluorescent latex) were assembled into 5- $\mu\text{m}$  strips of ordered nanoparticle layers, as shown in Fig. 6.<sup>[61,62]</sup> In these patterns, the edge roughness was better than 0.2  $\mu\text{m}$ , as evident from SEM micrographs (Fig. 6A,B). In addition, the lithographic approach was used to generate clean patterns of multiple types of nanoparticles on a single 4-in. silicon wafer.<sup>[63]</sup> Metal oxide semiconductor capacitor arrays were fabricated on silicon wafers using LbL self-assembled insulator layers.<sup>[64]</sup> Recently, more complex field effect transistors based on LbL nanoassembly of tin oxide and silica nanoparticles were also demonstrated.<sup>[65]</sup>

Because of the conformal nature of LbL nanoassemblies, organized multilayers may also be used to functionalize existing microstructures. That is, substrates with preformed features may be completely modified with an overlying multilayer. As an example, multilayers of nanoparticle catalysts have been assembled in microchannels for miniature reactors (Fig. 6C).

## PROPERTIES OF LAYER-BY-LAYER FILMS

### Electrostatic and Secondary Interactions

The principal requirement for multilayer film deposition is the availability of charged species of

**Fig. 6** Examples of patterned LbL films—SEM images of: (A and B) (200-nm SiO<sub>2</sub> particles/PDDA)<sub>4</sub>, with 5- $\mu$ m lines; (C) (78-nm silica/PDDA)<sub>4</sub> multilayers deposited in 100- $\mu$ m channel.

sufficient charge density and molecular weight. It is clear that while small molecules are attracted and stick to oppositely charged surfaces, these do not provide a stable layer for adsorption of other molecules; generally speaking, a molecular weight greater than 10 kDa is preferable for efficient and stable film formation.<sup>[66]</sup> A number of attempts to form multilayers through alternation of linear polyanions with smaller molecules have been reported, such as boladications and Yt<sup>3+</sup> ions,<sup>[67]</sup> polycations and citric acid,<sup>[68]</sup> and via sequential deposition of Zr<sup>4+</sup> ions and diphosphonic acid.<sup>[69]</sup> Besides, in these cases, the main idea was to create an excessive charge (due to special steric structure of these ions) at every stage of assembly that leads to recharging of the outermost surface at every step of film formation.

Although the formation of LbL multilayers is typically attributed to the strong attraction arising from

multiple electrostatic bonds, other forces may also play significant roles in formation, stabilization, or rearrangement of the resulting assemblies. Other important influences include hydrophobic interactions between polymer segments<sup>[70]</sup> and specific binding based on molecular recognition. As an example of the potential importance of these interactions, the thickness of multilayers was found to depend directly on temperature and ionic strength, reflecting the increasing contribution of hydrophobic interactions, especially when charges are screened.<sup>[71]</sup> Thus the choice of adsorption species and control of assembly conditions can be critical in determining the structure of the resulting assemblies.

It is interesting to note that the adsorption of a polyion layer to preformed multilayers differs largely from adsorption to rigid, charged surfaces. An important characteristic of the films structure is the entanglement of molecules in outer multilayers. Studies have shown that about one-third of the charges of the superficial layer are complexing with exposed charges from the underlying layer (“intrinsic” compensation), whereas the remaining charges on the molecules in the outer layer are compensated by counterions (“extrinsic” compensation).<sup>[72]</sup> Some or all of the counterions are then released upon adsorption of an additional layer. The first layer, close to the surface, and the exposed “loops” of the superficial layer are less dense than the complexation region, resulting in a periodicity in film density for multilayer films.<sup>[73]</sup>

The strong interpenetration of components between neighboring film layers has been demonstrated, resulting in the concept of “fuzzy nanoassemblies,”<sup>[2]</sup> due to these blurred boundaries. This property contrasts sharply with the two-dimensional (2-D) stratification observed in Langmuir–Blodgett multilayers. The interpenetration, or overlap, of neighboring layers has been measured to be approximately 1–2 layers,<sup>[74–76]</sup> therefore, the physically separated segments of ultrathin films are not the neighboring layers, but rather the first and the third or fourth layers.

Finally, it is interesting to discuss dissolution of LbL multilayers. Generally, these ultrathin films are amazingly stable, and it is difficult to remove them from a solid substrate. There are two possibilities to remove LbL films. First, high pH ( $\sim 12$ ) can be used, which will discharge the first polycation layer and destroy the ionic bonds that stabilize the films. A second method is to expose the LbL multilayers to solution with very high ionic strength, such as 3 M NaCl, under sonication for approximately 2–3 hr. In this second method, the combination of ultrasonic energy and high concentration of free ions in solution can disrupt polycation/polyanion bridging and neutralize exposed charges with Na<sup>+</sup> and

$\text{Cl}^-$  ions. This process is well established for interpolyelectrolyte complexes and for multilayer films which never were dried. However, LbL multilayers that are dried are much more difficult to dissolve, probably as a result of additional hydrophobic interactions between polymer chains incurred during dehydration.

### Ionic Strength and pH Dependence

As noted above, the condition of electrical neutrality is met by intrinsic or extrinsic charge compensation. In the latter, complexation of polymers with exact 1:1 stoichiometry may leave uncompensated regions because of the inability of the adsorbing species to rearrange and match the exposed surface charges exactly. In this case, neutrality is maintained by counterions associated with exposed uncompensated charged groups on the polymers. Again, this situation is not completely understood, and remains an intriguing question that is still under intense investigation: While it is believed that about one-third of charges on polymers are free for binding of ions (as demonstrated by dyes adsorption into preformed layers), small counterions also appear to be removed during washing, which demands local film rearrangement to achieve neutrality or leaves a nonneutral situation.<sup>[2,24,25,71,77–80]</sup>

From a practical standpoint, it is desirable to control the thickness of film layers during deposition. Using salt solutions of varying ionic strength was the first approach to control layer thickness over a wide range.<sup>[1]</sup> The solution salt ions screen neighboring charges on the polymer, allowing linear chains stretched by electrostatic repulsion to collapse and adopting a more compact, coiled 3-D conformation. While the dependence of thickness on salt concentrations is recognized, reliable models for this behavior have been elusive. For different polyanion/polycation pairs, findings range from linear dependence of thickness on salt concentration to power-law scaling with  $[\text{salt}]^\alpha$ , where  $\alpha$  ranges from 0.05 to 0.5.<sup>[81–84]</sup> There appears to be a minimum requirement in which approximately half of monomers are ionized to achieve saturation and charge reversal as a result of overcompensation.<sup>[86,89]</sup> Above this threshold, film growth is reliable and thickness is proportional to solution ionic strength; at lower ionization levels are flat layers with minimal looping and few uncompensated charged form, resulting in neutral or weakly charged surfaces that are poor substrates for further electrostatic adsorption. For very high charge densities, the effective charge density is controlled by counterions, and the adsorption is essentially independent of

charge density in this range.<sup>[88]</sup> However, for lower charged fractions still above the threshold, thicker layers form because of the increased ability of polymer chains to adopt more highly coiled conformations in solution.<sup>[89]</sup>

Multilayers comprising weak polyelectrolytes have drawn great attention recently because the molecular charge density can be adjusted by changing solution pH value, thereby controlling the resulting film properties. For multilayers wherein both components are weak polyions, the pH of both adsorption solutions influences the thickness of layers formed.<sup>[90]</sup> Combining two fully ionized chains results in very thin layers, whereas when one of the species is kept close to full dissociation, large thicknesses are obtained.<sup>[91]</sup> Moving from one extreme to another, thickness may change over more than an order of magnitude. For weak polyelectrolyte combinations, the thickness of the adsorbing layer is determined primarily by the surface charge of the previous layer or by the charge of the adsorbing polyion chain.<sup>[90,91]</sup>

In addition, the dissociation of weak polyelectrolytes in preformed multilayers, resulting in film decomposition, can be varied by controlling external conditions. Small charged molecules can be absorbed into and released from weak polyion films, by modulating ambient pH to control dissociation within the films.<sup>[92]</sup> The local  $\text{p}K_a$  of a weak polyion assembled in a multilayer is decreased relative to the solution value and is dependent on the salt concentration.<sup>[93]</sup> The superficial layer of preformed multilayer films also influences the internal film properties; for example, the dissociation of carboxylic groups within multilayers increases when the outer layer is polycationic and decreased for a polyanionic terminal layer.<sup>[94]</sup> This behavior, in turn, affects the amount of material adsorbed in the terminating layer.<sup>[78,95]</sup> The surface potential directly determines water mobility in multilayer films as a result of changes in dissociation, swelling, or water structuring.<sup>[96]</sup>

The swelling properties of LbL multilayers have also been investigated. Films prepared from salt solutions take up water in humid air and aqueous environments, and multilayers prepared in the absence of additional salt swell when exposed to salt solutions.<sup>[81,84]</sup> In all cases, the film thickness and total volume increase as a consequence of swelling. The interaction of multilayers with water molecules is similar to that of hydrophobic polymers.<sup>[81,97–99]</sup> The swelling behavior of LbL nanoassemblies is dependent upon salt concentration and is apparently correlated with the internal hydrophobicity for a given polyion pair.<sup>[100,101]</sup> Environmental salt and pH conditions have also been shown to affect film roughness and porosity,<sup>[100,102]</sup> as has solvent.<sup>[103]</sup>

## Permeability

Because of short path lengths and tunable properties, one of the most promising uses of multilayers, in either planar or capsule form, is as a selective transport barrier, which may find application in many fields requiring filtration, controlled uptake or release, or immunoisolation. The key design goal, in most cases, is to produce materials with high transport rates, which are guaranteed by the nanometer thickness of LbL nanoassemblies and are controlled by the number of layers, layer thickness, and layer composition. A second property that is critical to many applications is a high selectivity for a target molecule or a class of molecules, which can be controlled by the chemical composition of the films.<sup>[104,105]</sup> For example, high selectivity for different ions has been reported based on film composition.<sup>[106–109]</sup> A third feature, desirable in some cases, is the ability to dynamically control the transport properties, i.e., change the permeability over time in response to a stimulus (e.g., solvent properties,<sup>[33]</sup> pH,<sup>[34,110]</sup> ionic strength,<sup>[111]</sup> temperature,<sup>[109]</sup> etc.).

While multilayer films offer the promise of fulfilling all of the needs of systems with controlled transport properties, a great deal of effort is still required to reduce these concepts to practice. Some progress has been made toward a general understanding of permeability properties of LbL nanoassemblies, but the complex, dynamic interactions between molecular components and external conditions that determine transport rates make this a difficult task. It has been noted that changes in pH or salt concentration during or after film deposition result in increased porosity, and it is still unclear whether these effects are reversible or permanent.<sup>[102,112,113]</sup>

This complex interplay between films composition, fabrication conditions, and environmental variables becomes especially important when attempting to design and prepare multilayer capsules with specific permeability. This is because the dissolution process of the template, typically involving large pH changes and high osmotic pressures, adds an additional degree of complexity that must also be considered to impact the final form and function of the multilayers. It has been shown that hollow capsules are semipermeable, although this is clearly dependent upon film composition and assembly conditions.<sup>[44]</sup>

A remarkable property of polyelectrolyte microcapsules is that the capsule interior can provide chemical conditions different from the surrounding medium. Thus the capsules act as membranes to provide a specialized, partially isolated microenvironment with internal volumes on the order of femtoliters, even attoliters, with phenomenal surface-to-volume ratios. For example, using a typical 5- $\mu\text{m}$ -diameter MF or  $\text{MnCO}_3$

template, a resulting capsule, would have an internal volume of  $\sim 65$  fL and a surface area of  $\sim 8 \times 10^{-7}$   $\text{cm}^2$ ; scaling the template down to a 50 nm silica particle would result in a volume and a surface area of  $\sim 0.065$  aL and  $\sim 8 \times 10^{-11}$   $\text{cm}^2$ , respectively. The corresponding change in surface-to-volume ratio scales directly with the change in diameter: approximately 12,000  $\text{cm}^2/\text{cm}^3$  for 5  $\mu\text{m}$  capsules and 1,200,000  $\text{cm}^2/\text{cm}^3$  for capsules with 50-nm diameter. These features form the basis for interest in performing chemical reactions within the unique volumes defined by the capsules. Several demonstrations of exploiting the partitioned environment within microcapsules have been given. Capsules have been used to selectively partition organic solvents<sup>[114]</sup> and for controlled precipitation of organic and inorganic materials.<sup>[115]</sup> Additionally, polymer synthesis within microcapsules has been performed.<sup>[116]</sup>

## Electrical Properties

In spite of efforts to use in LbL assembly of water-soluble derivatives of polypyrrole or polythiophene, no stable conductive LbL multilayers of these materials have been produced to date. Most interesting works in this direction were performed by Ferreira et al.,<sup>[117]</sup> wherein electrical conductivity of up to 100 S/cm in 50-nm-thick polypyrrole/poly(styrenesulfonate) film was achieved. More promising results were reached in semiconducting LbL films based on water-soluble derivative of well-known polyphenylene vinylene [PPV, e.g., poly(*p*-phenylene(1-tetrahydrothiophene)-ethylene chloride)].<sup>[118]</sup> Light-emitting diodes based on multilayer heterostructure of alternate poly(phenylene vinylene) and sulfonated polyaniline have also been demonstrated. A 20-nm-thick light-emitting diode device had a turn-on voltage of about 1 V, and green light was clearly observed under normal room illumination.<sup>[119]</sup> Light-emitting diodes and display devices of large area and low operating voltage is one interesting application of LbL multilayers, although such ultrathin conducting systems could also find application in biomedical devices for neuroprosthetics, e.g., retinal implants or functional electrical stimulation devices. Furthermore, neural networks may benefit from the ability to integrate living tissue by controlled cell adhesion and direction (see below) with functional electrical systems.

## THEORIES REGARDING ASSEMBLY

A number of theories have been developed to describe LbL nanoassemblies. These deal primarily with the

adsorption process and multilayer formation as well as the properties of preformed films. Models range from mathematical descriptions derived from fundamental physical theory to those that deal directly with experimental data. An initial theoretical model for adsorption and surface charge inversion was derived from first principles including the effect of solution ionic strength.<sup>[120]</sup> A theoretical phase diagram has been constructed to describe charge-reversal mechanisms with dependence on screening length and charge density,<sup>[121,122]</sup> in which model applies directly to semiflexible chains with increased rigidity, where adsorbing layers are thin and flat, and a mean field description does not apply. A Debye–Huckel model for multilayer formation was also derived, concentrating on flexible chains.<sup>[123]</sup> A phenomenological approach has also been developed to describe the excess charge of the outer layer as distributed over several underlying layers using charge overcompensation level and the charge decay length into the multilayer.<sup>[124]</sup>

Attempts to describe the kinetics of multilayer formation have also been made. The typical approach involves a two-step model, i.e., a fast adsorption phase involving the transport of chains to the surface by diffusion, followed by slow rearrangements at the surface where ionic bonds are formed because of electrostatic force.<sup>[25,73]</sup> Subsequent slow rearrangements enable segments of the adsorbing molecules to move into the inner regions of the previously deposited layer, resulting in a final irreversible complexation within deeper regions while the outer region maintains some flexibility.<sup>[82,125,126]</sup> The interaction of an adsorbing polyelectrolyte layer with a previously immobilized layer can be sufficiently strong to result in desorption of a soluble complex. In this situation, an initial increase in adsorbed mass is observed, then over time (a few minutes), the adsorbed amount decreases again, suggesting desorption of material complex from the surface.<sup>[127]</sup> This behavior has been described as the equilibrium between a solid complex phase and soluble complexes in solution as viewed by a phase diagram, including liquid and glassy states, with dependence upon ionic strength.<sup>[127]</sup>

Preformed LbL nanoassemblies are most commonly viewed as soft materials, essentially hydrogels with a cross-linking density dependent upon the charge distribution along the polymer chain.<sup>[104,108]</sup> However, multilayer films have also been described as being in a glassy, quasifrozen state<sup>[123]</sup> and as “layered complexes” which exhibit the same local interactions as identical soluble complexes, only possessing great density and a defined 2-D molecular architecture. The internal dynamics of multilayers have been probed, from which it appears that multilayers are in fact structurally similar to polyelectrolyte complexes in solution, as swelling and temperature changes result

in rearrangement processes that occur on the order of hours.<sup>[97,98,126]</sup>

## BIOMEDICAL APPLICATIONS OF LAYER-BY-LAYER FILMS

Primary biomaterial applications of planar layers involve the use as matrix materials for functional or biological molecular entities, e.g., sensors, tissue engineering scaffolds, membranes, or for surface modification of other materials. The range of potential applications is even broader when considering uses of multilayer-coated functional colloidal particles including novel sensors and reactor systems. Further expansion of applicability is given by removal of the solid colloidal core to produce stable, hollow polymeric shell structures. Such hollow, thin-walled microcapsules have attracted particular interest from the viewpoint of applications in encapsulation, for example, as drug carrier systems or microreactors.

### Surface Modification

Recent examples of how LbL is being used to modify surfaces of real systems for improving properties are found in both industrial use and envisioned potential in the scientific literature. To begin with, Ciba-Vision has patented use of the LbL process to modify contact lenses,<sup>[128]</sup> and this method continues to be studied as an approach for applying several novel, multifunctional coatings. This is believed to be the first commercial use of the process. A second example is found in functionalized food wrapping, recently released by the Japanese company Shiratori NanoTechnology in Kawasaki. Its “Yasa-sheet” coating is a multilayer coating comprising chitosan, a major sugar-based ingredient of crab shells, and an enzyme-containing liquid extracted from bamboo. The protective wrapper designed to preserve fruit and vegetables works by suppressing the food’s emission of ethylene gas, a naturally produced ripening agent that eventually makes fruits and vegetables rot.<sup>[129]</sup>

Several additional useful applications of coatings are envisioned based on solid laboratory demonstrations recently reported in the scientific literature. Corrosion control is particularly promising, as suggested by recent experiments using ultrathin (70 nm) polymer coatings deposited on stainless steel wires. When the coated wires were immersed in saltwater and biased with an electrical potential, they exhibited considerably less corrosion for all potentials when compared to untreated wires.<sup>[130]</sup> These coatings could improve the longevity of implanted devices as well as enhance environmental stability of pipes and other metal-based

systems. Optical coatings have also been proposed, including antireflection coatings, demonstrated to enhance the throughput of optical elements, offering a cost-effective alternative to current coating methods,<sup>[131]</sup> and designed profiles of silver nanoparticles and organic layers generate ideal reflection because of the refractive index gradient.<sup>[132]</sup>

As a complement to surface coatings designed to impart specific chemical or optical properties, transport barriers have been assembled on porous surfaces to assess the potential for depositing selectively permeable films for separation via controlled diffusion or filtration. Control over charge and composition in polyelectrolyte “skin” has been shown to allow highly selective separation of ions according to charge, size, or hydration energy.<sup>[133]</sup> Additionally, using “template” ions to control fixed charge density has been shown to further enhance anion-transport selectivity.<sup>[105]</sup> Deposition of polyelectrolyte nanofilms on porous supports can also yield nanofiltration membranes that allow high selectivities, water fluxes, and ion rejections, making them potentially attractive for applications in water and salt purification.

### Cell/Tissue Scaffolds

Nanostructured polyelectrolyte multilayer thin films has recently been applied as novel substrates for growth of cells in culture. This new class of biomaterial allows precise control over the cellular microenvironment, which dynamically interacts with cells to determine *in vitro* behavior, and may lead to biological test beds that more exactly match *in vivo* conditions. Fibroblasts have been shown to attach to multilayer combinations in which strong interactions dominate, whereas weakly ionically cross-linked multilayers which present hydrated surfaces resisted fibroblast attachment.<sup>[134]</sup> By controlling the multilayer assembly conditions (pH, ionic strength), a single multilayer combination may be either cell-adhesive or cell-resistant. Hydrogen-bonded multilayers were also found to exhibit high resistance to the fibroblast adhesion, even with only a single bilayer coating.<sup>[135]</sup> More recent work with protein-coated patterned polymer multilayers has shown the ability to deposit precise micropatterns of nanofilms, and the underlying architecture of these profoundly influences cell morphology.<sup>[136,137]</sup> These recent findings are likely to lay the foundation for a large effort to investigate biomaterial interactions with LbL nanoassemblies. Examples of the exciting potential of these systems are given in Fig. 7. These microscopic images of patterned LbL nanofilms demonstrate the feasibility of using especially designed multilayer structures to control and manipulate cell adhesion.<sup>[136]</sup>

**Fig. 7** Examples of controlled cell–material interactions enabled by LbL nanofilm assembly and patterning. (A) Conceptual rendering of multifunctional substrate with four regions of different composition and structure; (B) Fluorescence micrographs for experimental demonstration of two-region pattern comprising PSS {PAH/PSS}<sub>5</sub> {PAH/FITC-secreted phospholipase A<sub>2</sub>}<sub>5</sub> (green) and PSS {PAH/PSS}<sub>5</sub> {TRITC-poly(lysine)/PSS}<sub>5</sub> {TRITC-poly(lysine)} (red) patterned on a background of PDDA on glass; (C) and (D) examples of spatially controlled cell–material interactions using rat aortic smooth muscle cells (RSMCs) grown on fibronectin-coated LbL films of PDDA/PSS patterned against a cytophobic PDDA background.

### Building Living Tissues/Organs

It may be possible to employ the exquisitely simple LbL approach to nanoassembly as an aid in wound healing and repair of damaged tissue using films containing natural materials with specific bioactivity. A tremendous possibility proposed recently is to directly deposit multilayers onto arterial walls to provide protection for the damaged blood vessels and to avoid restenosis.<sup>[138]</sup> LbL self-assembly of two polysaccharides, hyaluronan (HA) and chitosan (CH), known to have anti-inflammatory properties, was recently reported for modifying the arterial wall in *ex vivo* models. The polyanionic chitosan apparently adheres strongly to the negatively charged surfaces presented by damaged blood vessels, providing a surface for HA deposition, which can be immobilized within the films at concentrations much higher than is possible by infusion. In addition, doping of multilayers with L-arginine showed increased thromboresistance.

A second example, less remarkable yet still significant, was used to show the potential for LbL to modify implantable materials for improved biocompatibility and controlled release of substances to facilitate healing. In this case, assembly of HA and CH was used to modify endovascular stents.<sup>[139]</sup> Multilayer-coated

NiTi disks presented enhanced antifouling properties, compared to unmodified NiTi disks, as evidenced by decreased platelet adhesion in an *in vitro* assay, although *ex vivo* assay on a porcine model indicated that the coating did not prevent fouling by neutrophils. The multilayers were also used as *in situ* drug delivery systems by incorporating the nitric oxide donor sodium nitroprusside (SNP), which further reduced platelet adhesion.

### Enzyme Assemblies—Nanoreactors

The LbL deposition of organized enzyme multilayered shells on nanoscale cores is a promising approach for creating tiny reactors for biocatalysts applications, as has recently been demonstrated for glucose oxidase, peroxidase, urease, luciferase, and  $\beta$ -glucosidase.<sup>[13,14,140]</sup> Such organized enzyme/polyion multilayers, with enzymes arranged in a predetermined order within semipermeable polymeric shells, present a new class of bio/nanoreactors. The degree of order and complexity that can be imparted to these systems via the flexible LbL technique makes them distinct from the more traditional liposome- or copolymer-shelled enzymatic reactors. Additionally, an expansion of capabilities for bio/nanoreactors through inclusion of inorganic and magnetic nanoparticles within multilayer polymer/enzyme films was demonstrated. Enhanced functionality, such as catalytic activity and manipulation, may be produced by higher surface area and magnetic shells.<sup>[14]</sup> This is part of an overall strategy to create unique and complex biocolloids, with emphasis on tailored enzyme self-assembly using nanoparticle layers on latex microcores. Examples of potential applications of these general technologies include therapeutic devices, reactors for efficient catalysis, and biosensors.

### Sensors

Building upon the possibilities afforded by coating micro/nanoscale templates with functional materials such as enzymes and dyes, sensors for chemicals and biochemicals are being developed as tools for biological research, medical diagnostics and monitoring, and biodefense applications. Using nanoparticles coated with fluorescent materials that respond selectively to specific species by binding or other interactions, ratiometric nanoscale probes have been developed for intracellular and extracellular measurements of ions and oxygen.<sup>[141–145]</sup> These nanodevices have advantages over standard liquid-phase small-molecule indicators in that they provide a protective package for the chemistry, separating the dyes from the biological environment and, in doing so, reducing nonspecific

responses, dye–protein binding, and toxic effects. In addition, the immobilization of the indicators within the nanofilms provides physical linkage with reference fluorophores, allowing constant ratiometric monitoring without large shifts in calibrations otherwise seen. By coupling the chemical nanosensors with an enzyme nanoreactor, a second class of sensors may be realized, using direct monitoring of coreactants or products as an indirect means of determining the concentration of other substrates.<sup>[14,146,147]</sup>

### Therapeutic Agents

A promising use for microcapsules and therapeutic agents modified directly with multilayer coatings is in controlled release. A variety of demonstrations for protein and drug encapsulation suggest a bright future for applications in controlled delivery of therapeutic agents.<sup>[19,148–150]</sup> In an effort to exploit these possibilities toward commercial use, Capsulation GmbH (Berlin, Germany) is offering several products based on LbL coatings for drug delivery (LBL-Flash<sup>®</sup>—enhanced dissolution for poorly soluble drugs; LBL-Solv<sup>®</sup>—enhanced bioavailability for drug candidates; LBL-Intra<sup>®</sup>—prolonged circulation and enhanced intracellular uptake) and a variety of diagnostic products for improving fluorescence-based assays.<sup>[151]</sup>

### CONCLUSION

Layer-by-layer nanofabrication is a simple yet versatile means of precisely modifying any charge substrate by sequential deposition of complementary materials. The choice of molecules available is wide, the dimensional precision is high, and the potential application areas are broad. Over the past 10 years, significant progress has been made toward understanding fundamental structural, chemical, and physical properties of multilayer ultrathin films, and this work is beginning to enable creation of novel coatings tailored to realize desired properties. As a result, nanoassembly is now finding some commercial applications, and many more are expected to arise in the near future. Because of the amazing flexibility and precision allowed, this technique of self-assembly will lead to useful nanoscale devices, and the impact will likely be large.
