In order to render 1-D nanostructures of  $\pi$ -conjugated polymers one must have the ability to template the shape of the polymer product. Templates are typically in the form of preformed channels in solid materials or organized molecules in bulk solution. Representative materials used as solid templates are “track-etched” polymeric membranes, porous aluminas, and aluminosilicates such as MCM-41. These materials all offer a narrow diameter confined channel in which 1-D structures can be synthesized. In 1989, Cai and Martin showed that the mesoscopic channels of “track-etched” membranes could be used to control the growth of 1-D structures of polyheterocyclics.<sup>[10]</sup> Oxidation can be carried out either chemically or electrochemically by this method. In electrochemical synthesis the support must first be coated with a thin layer of metal to act as the anode. For chemical oxidation, the membrane is first saturated with monomer

**Fig. 1** Schematic representation of the controlled 1-D synthesis of polymeric nanostructures using “hard” templates.

and then exposed to a solution containing an oxidizing agent. A general schematic for this process is shown in Fig. 1. Wires produced by the method exhibit enhanced conductivities in comparison to macroscale equivalent bulk materials. The reason for an elevation in conductivity was found to be due to a superior molecular ordering of polymer chains owing to synthesis taking place in a confined environment.<sup>[11]</sup>

Since the discovery that the pores of membranes could be used to morphologically control the growth of 1-D polymer structures, polymeric nanotubes/fibers with controllable diameters have been synthesized using nanoporous membranes<sup>[11–15]</sup> and mesoporous zeolites<sup>[16]</sup> as templates. In the case of mesoporous zeolites, polyaniline (PAni) nanofibers with diameters as small as 3 nm have been prepared within the pores of aluminosilicate MCM-41 templates.<sup>[16]</sup> Martin observed that when synthesizing PAni and polypyrrole (PPy) using the pores of track-etched polycarbonate membranes, the polymer preferentially nucleates and grows on the pore walls (Fig. 2).<sup>[12]</sup> This phenomenon can be explained in part by the polycationic forms of these polymers being solvophobically driven to the walls of the pores. This driving force is coupled with electrostatic forces between the cationic polymer and the anionic sites on the pore wall. In general, when a “molecular anchor” exists for the material being deposited, hollow tubules are favored over solid fibers.

The dimensions and pore shape of track-etched membranes have been investigated by several research groups with the conclusion that the pores are not always cylindrical and may not be of the reported diameter.<sup>[17–19]</sup> To this end, a novel method to produce reproducibly sized and shaped pores in membranes has been developed.<sup>[18]</sup> With this technique, track-etched membranes can be fabricated with perfectly cylindrical

pores with defined diameters in the range of 15–1000 nm. These membranes have been used to produce nanostructures of conjugated polymers with controllable diameters.<sup>[19,20]</sup>

Templates of aluminum oxide have also been used to electrochemically fabricate nanowires and nanotubes of PPy, PAni, and poly(3,4-ethylenedioxythiophene) with diameters of 200 nm and lengths of 10 to ~40  $\mu\text{m}$ .<sup>[21]</sup> It has been shown that the wall thickness

**Fig. 2** TEM image of polypyrrole nanotubules, synthesized within the pores of polycarbonate “track-etched” membranes. Source: From Ref.<sup>[12]</sup>.

of the polymer product can be controlled by the counterion and that the conductivity is influenced by the outer diameter of the tube. These nanostructures have field emission characteristics and therefore may find use as field emission displays. Anodic aluminum oxide templates have also been used to form PANi nanofibril array films that have shown interesting field emission properties.<sup>[22]</sup> Although membranes offer a route to 1-D nanostructures of conjugated polymers, a limitation inherent to the membrane synthesis technique is that post-synthesis steps are necessary to remove the polymer from the template. This process usually entails dissolving the template thereby releasing the polymer, which can unfortunately lead to damage or undesirable bundling of the product.<sup>[19]</sup>

In a similar technique, composite materials of conjugated polymer and silicas have been synthesized using a sol-gel-based method. In this approach polymerizable diacetylenic surfactants are used as template molecules for the fabrication of conjugated nanofibers in the form of a polymer/silica nanocomposite material.<sup>[23–26]</sup> In this approach silica channels are formed and packed with monomer simultaneously which in turn gives better filling of the channels as compared to post-loading approaches. More recently, this same technique has been employed using pyrrole-containing surfactants which self-organize and are then polymerized to form PPy/silica nanocomposites.<sup>[27]</sup>

### 1-D $\pi$ -CONJUGATED POLYMER NANOSTRUCTURES USING MOLECULAR INTERACTIONS AS “SOFT” TEMPLATES

In a contrasting technique in which no solid support is required, 1-D polymer nanostructures can be fabricated using a self-assembly technique. In this technique, monomer aggregates with another molecule (usually a “surfactant-like” amphiphilic molecule) to form a fiber-like assembly which is subsequently polymerized retaining the fibril morphology in the polymer product. In 1999, Huang and Wan developed a “template-free”<sup>a</sup> method to synthesize microtubes of PANi<sup>[28]</sup> and PPy<sup>[29]</sup> using  $\beta$ -naphthalene sulfonic acid ( $\beta$ -NSA) to control the polymer morphology and act as a dopant molecule. Subsequently, nanotubes of PANi with diameters in the range of 76–650 nm have been produced by this same technique and the formation mechanism has been attributed to a reaction between the basic aniline and acidic  $\beta$ -NSA to form an insoluble 1-D salt.<sup>[30]</sup> This salt then acts as a

template in the formation of the PANi nanotubes/fibers (Fig. 3). Interestingly, in this work it was found that the diameter of the PANi structures could be controlled by the ratio of  $\beta$ -NSA to aniline. When the ratio was around 2, microtubules (diameter > 100 nm) were formed but when the ratio was reduced to  $1/2$  or  $1/4$ , nanotubes (diameter < 100 nm) were favored. Since then many other organic acids have been used to fabricate 1-D nanostructures of PANi. PANi nanotubes have been synthesized in the presence of D-10-camphorsulfonic acid,<sup>[31]</sup> (4- $\{n$ -[4-(4-Nitrophenylazo)-phenoxy]alkyl}aminobenzene sulfonic acid),<sup>[32]</sup> azobenzenesulfonic acid,<sup>[33]</sup> 5-aminonaphthalene-2-sulfonic acid,<sup>[34]</sup> a sulfonated dendrimer PAMAM4.0-[naphthyl(SO<sub>3</sub>H)<sub>2</sub>]<sub>24</sub>, and hydrogensulfated fullereneol C<sub>60</sub>(OSO<sub>3</sub>H)<sub>6</sub>.<sup>[35]</sup> In all cases the chosen molecule acts as a protonic acid dopant and templating agent.

In other work, surfactants along with various inorganic acids were used to form PANi nanostructures in which the morphology, size, and electrical properties were dependent on the reaction conditions and dopant.<sup>[36]</sup> PANi nanofibers with diameters of 30–50 nm and lengths from 500 nm to several microns have been synthesized using camphorsulfonic acid at the interface between an organic and aqueous phase.<sup>[37]</sup> The dedoped nanofibers were shown to have much faster response to doping/dedoping than conventional undoped PANi films. In other work, organic acids such as  $\beta$ -NSA or *p*-toluenesulfonic acid have been used to prepare Ppy micro/nanotubes with diameters of 50–2000 nm and high conductivities.<sup>[38]</sup> Once again the properties of the polymer can be controlled by the polymerization method and conditions, or by the dopant. In a surfactant-based method, PPy nanotubes with diameters < 100 nm have been successfully

**Fig. 3** SEM image of polyaniline nanotubes (92 nm average diameter), synthesized in the presence of  $\beta$ -naphthalene sulfonic acid. Source: From Ref.<sup>[30]</sup>.

<sup>a</sup>The term “template free” is a misnomer, as described below. A more precise term would be “hard-template free.”

**Fig. 4** FE-SEM image of polypyrrole nanotubes (95 nm diameter), synthesized by reverse microemulsion polymerization using surfactant molecules as templates. Source: From Ref.<sup>[39]</sup>.

fabricated by a technique that uses a reverse microemulsion (Fig. 4).<sup>[39]</sup> This method employs reverse micelles that form in apolar solvents with surfactant headgroups oriented away from the solvent. Upon

addition of iron chloride, the morphology of the reverse micelles is transitioned into cylindrical micelles which can then be used as nanoreactors to carry out the controlled synthesis of a partitioned monomer (Fig. 5). All of the aforementioned studies incorporate a polymerization step in the formation of the 1-D structure.

Preformed polymers have also been shown to self-assemble into hierarchical structures, including nano-scale polymeric cylindrical structures due to molecular interactions such as hydrogen bonding and recognition.<sup>[40]</sup> Comb-shaped polymers are a class of polymers that consists of amphiphilic molecules that are either covalently or physically bonded to the polymer backbone. Interactions between the polymer backbone and appendage molecules control the self-assembled structure. Conjugated polymers, or rigid polymers, can be decorated with amphiphiles to form so-called “hairy rod” polymers, which in turn form self-organized structures. For example, high molecular weight dedoped PANi has been doped with camphorsulfonic acid (CSA) and then mixed with 4-hexylresorcinol (Hres). Hydrogen bonding between all three molecules induces self-organization into PANi cylinders with a repeat distance of 3.5 nm.<sup>[41–43]</sup> The conductivity of this material has been investigated

**Fig. 5** A schematic of the reverse microemulsion technique identifying four stages. In the first stage, reverse micelles form in an apolar solvent. These spherical micelles are then transitioned into cylindrical micelles by the addition of iron chloride in a second stage. Pyrrole then partitions around the cylindrical structure before being polymerized in the third step. Finally, the surfactant is removed, leaving Ppy nanotubes.

**Fig. 6** A schematic representation of a three-stage “template-free” technique in which oriented arrays of polyaniline nanotubes synthesize directly on surfaces. In stage one a large current density is applied to create nucleation sites on the substrate. In stages two and three, deposition takes place in which a reduced current density is applied forming arrays of nanowires.

and found to increase by 2 orders of magnitude when cylindrical structures were present. Once again this elevation in conductivity has been attributed to the confinement of PANi chains within the cylinders.

### 1-D $\pi$ -CONJUGATED POLYMER NANOSTRUCTURES SYNTHESIZED ON SURFACES

Because of the desire for smaller circuitry in microelectronics, new methods for depositing  $\pi$ -conjugated polymers with special resolution on surfaces are required.<sup>[44]</sup> One significant challenge to constructing microelectronic devices composed of polymeric sub-units is that the properties of the polymer remain intact after the procedure is complete. To this end a number of techniques to fabricate 1-D nanostructures of conducting polymers on surfaces have been developed.

In 2001, nanowires of a polydiacetylene compound were polymerized on the surface of graphite by using the probe tip of a scanning tunneling microscope.<sup>[45]</sup> In this work, a diacetylene compound was first adsorbed onto graphite and then a 6-nm defect site was produced on the surface. A negatively biased STM tip was then passed over the substrate, toward the defect site, leaving a line of polymer ending at the defect site. Lines of the conducting polymer were rendered with spatial resolution of around 1 nm by this method. In another similar process termed electrochemical dip-pen nanolithography (E-DPN), 3,4-ethylenedioxythiophene (EDOT) was polymerized on both semiconducting and insulating surfaces to form sub-100-nm wires.<sup>[46]</sup> In this work the tip of an atomic force microscope was coated with a thiophene derivative by immersion in a monomer/solvent solution. A negative bias was applied between the tip and substrate as it was traversed in a preprogrammed pattern above the surface of the substrate, leaving a line of poly-EDOT. Condensation facilitates the transport of material to the surface and a chemical process

immobilizes the material. Nanostructures of organic,<sup>[47,48]</sup> semiconducting,<sup>[49]</sup> and metallic materials<sup>[49,50]</sup> have also been fabricated using this process.

Recently, large arrays of oriented PANi nanowires have been grown on various substrates by a template-free method.<sup>[51]</sup> In this entry, PANi nanowires have been synthesized electrochemically on platinum, silicon, titanium, gold, carbon, and silica in a three-step procedure (Fig. 6). In the first step, a large current density is applied to create nucleation sites on the substrate followed by a second and third deposition step in which a reduced current density is applied. The PANi nanowires are mostly oriented perpendicular to the surface when flat substrates are used and grow radially in the case of colloidal particles. Such nanowires have diameters in the range of 50–70 nm and lengths of around 0.8  $\mu\text{m}$  and have been shown to be effective as sensors for peroxide detection (Fig. 7).<sup>[52]</sup>

Electrochemically synthesized conducting polymer nanowires have also been prepared by several research groups. In one such study, PPy nanowires have been synthesized on gold electrodes using self-assembled

**Fig. 7** Tilted SEM image of an array of oriented polyaniline nanotubes (50–70 nm), synthesized electrochemically by a “template-free” method on a platinum surface. *Source:* From Ref.<sup>[52]</sup>.

**Fig. 8** A schematic representation of a technique in which arrays of polyaniline nanowires can be synthesized parallel to the surface of graphite. The sketch may not be truly accurate as it is not clear whether surfactant aggregates form before or simultaneously with monomer-filled surfactant aggregates as both reagents are added simultaneously.

monolayers of cyclodextrins as templates.<sup>[53]</sup> These SAMs form cavities on the gold that serve as initiation points for the electrochemical polymerization of adsorbed monomers. Interestingly, when the cavities are far apart, wires are favored over dots, which form when the cavities are close together. Wires with diameters of 70 nm and lengths of 1.5  $\mu\text{m}$  have been made by this technique.

In other work, PANi nanowires have been synthesized and aligned parallel to the surface of graphite by a one-step procedure using surfactant molecules as templates.<sup>[54]</sup> Surfactants are known to adsorb onto some crystalline surfaces in aligned arrays of either hemicylindrical or cylindrical morphologies.<sup>[55]</sup> In this

technique, adsorbed arrays of surfactant are used as nanoscale reaction environments for the synthesis of aligned PANi nanowires (Fig. 8). The wires have been shown to have dimensions of around 17 and 40 nm depending on polymerization conditions and surface chemistry and will only change orientation at grain boundaries or steps on the graphite (Fig. 9). Coadsorbing molecules are known to change the morphology of adsorbed surfactant aggregates.<sup>[56–58]</sup> Similarly, manipulation of the polymer morphology between spheres and wires has been shown to occur by the incorporation of long-chain alcohols into the surfactant/monomer aggregate.

## CONCLUSION

Here we have endeavored to give an overview of techniques currently available to synthesize 1-D nanostructures of electrically conducting polymers. The drive for the fabrication of 1-D nanostructures of conjugated polymers continues to thrive with many approaches being reported recently in the literature. There is still the need for simple techniques that not only produce high-quality nanomaterials with controllable dimensions and therefore properties, but also arrange these building blocks into architectures to make viable components or products. The field of nanotechnology is still in its infancy although it has made huge strides over the last few years. The opportunities are endless for making exhilarating discoveries and inventing new devices and technologies based on materials having these dimensions.

## INTRODUCTION

Molecules (and supermolecules)<sup>[1,2]</sup> form the smaller size range of nano-objects, especially those that allow a degree of rational design including control of size or other properties and those that possess some useful function. This article puts the spotlight on molecules whose usefulness stems from the human comprehensibility of light signals. When a molecule is empowered with light absorption/emission, its small size can be an advantage to operate in tiny spaces but yet remain under a degree of human remote control. Most of these are sensing and switching devices,<sup>[3–5]</sup> the latter including some logic capabilities. Some of the design principles governing these will be outlined below. These are classified in terms of the formatting of chromophore/fluorophore and receptor components.<sup>[6]</sup> Chromophores and fluorophores are dyes that give light absorption signals and in the latter case, light emission signals as well. As their name suggests, receptors serve to receive species which are chemical in our cases. Thus chromo/fluorophores and receptors allow physical and chemical transactions, respectively.

## “CHROMOPHORE–RECEPTOR” SYSTEMS

The most famous optical molecular devices of this kind are the pH indicators<sup>[7]</sup> known to every student of high school chemistry. Occupation of the receptor by a proton disturbs the electron distribution of the former. Because of the direct coupling between the chromophore and the receptor, it is therefore natural that the electron distribution of the chromophore itself is disturbed (Fig. 1). The consequence is a significant change of the absorption spectrum of the chromophore. Such acid-induced color changes have brightened up many a chemistry class around the world. A common example would be **1**. In general, such  $\pi$ -electron systems have electron donor and electron acceptor terminals, which leads to charge separation in the excited state. Such fractionally charged

regions in these internal charge transfer (ICT) excited states can easily lead to observation of spectral wavelength shifts as a result of electrostatic interactions with the newly arrived target ion.

As simple as these indicators are, from a chemical standpoint, they also show a logic activity that has hitherto gone unnoticed. For instance, **2**<sup>[8]</sup> shows a simple blue shift of its absorption spectrum upon interaction with  $\text{Ca}^{2+}$ . However, this blue shift can be examined as a series of optical transmittance values obtained at different wavelengths of observation. As Fig. 2 shows, four wavelengths can be picked out to show clear  $\text{Ca}^{2+}$ -induced transmittance changes of the “low–high,” “high–low,” “low–low,” and “high–high” variety. When “high” is coded as binary 1 and “low” is coded as binary 0, these digital input–output patterns can be identified as arising from single-input logic devices of the YES, NOT, PASS 0, and PASS 1 types, respectively. Furthermore, all of these logic behaviors can be simultaneously observed because light signals are readily multiplexed. So it is clear that humble ion indicators can show superposed logic behavior, which is unknown in the semiconductor device world.

## “RECEPTOR<sub>1</sub>–CHROMOPHORE–RECEPTOR<sub>2</sub>” SYSTEMS

It is only logical to add another receptor to a “chromophore–receptor” system to develop more sophisticated formats (Fig. 3). This can be particularly productive when the two receptors are chosen to be selective, each to its own target species. For instance, **3**<sup>[8]</sup> takes in  $\text{H}^+$  and  $\text{Ca}^{2+}$  at its quinoline nitrogen and amino acid receptors, respectively. The  $\pi$ -electron system again develops a dipole in the excited state with the positive pole being near the amino acid nitrogen and the negative end being close to the quinoline nitrogen. Thus admission of  $\text{Ca}^{2+}$  causes a destabilization of the excited state and hence a blue shift of the absorption spectrum (Fig. 4). On the other hand, the

**Fig. 1** The general format of a “Chromophore (C)–Receptor (R)” system.

entry of  $H^+$  causes a stabilization of the excited state and hence a red shift of the absorption spectrum. Of course, the simultaneous treatment of **2** with  $H^+$  and  $Ca^{2+}$  gives a near cancellation of these spectral shifts. So an interesting situation arises, where the spectral effect caused by two target ions is nearly the same as what is seen in their absence. Hence we can choose a monitoring wavelength where the transmittance of light is low (coded as binary 0) when the input target species are both low ( $H^+$  and  $Ca^{2+}$  both coded as 0) or both high ( $H^+$  and  $Ca^{2+}$  both coded as 1). Furthermore, each target ion on its own causes an absorption spectral shift away from the ion-free position. So now the transmittance of light is high (coded as binary 1) when the one input target species is low and the other high ( $H^+$  coded as 1 and  $Ca^{2+}$  coded as 0 or its permutation). When these results are cast into a logic truth table (Fig. 3), we see that **3** behaves as a two-input XOR gate.

### “FLUOROPHORE–RECEPTOR” SYSTEMS

Fluorescent versions of ion indicators<sup>[9]</sup> also have a long history and their mode of action borrows extensively from their absorption-based cousins. One of

**Fig. 2** Simultaneous observation of all four single-input logic types from a single experiment with a  $Ca^{2+}$  indicator.

the significant deviations of “fluorophore–receptor” systems arises as a result of the relative temporal delay before fluorescence emerges from an excited molecule (Fig. 5). Electrostatic repulsion between the photo-produced charge separations and the receptor-incumbent target species during this time period can cause decoordination of the target. Thus the target-induced spectral change will also dissolve away. Fluorescence emission spectra are therefore weakly influenced by target binding in many “fluorophore–receptor” systems known so far, although several exceptions are available. Of course, the target-induced changes survive in the fluorescence excitation spectra, which are related to the absorption spectra anyway. Gryniewicz, Poenie, and Tsien<sup>[10]</sup> excellent  $Ca^{2+}$  sensor **4** illustrates this very well. Here is an iconic optical molecular device that has served the cellular

physiology community for nearly two decades now by imaging  $\text{Ca}^{2+}$  populations within living cells.

### “FLUOROPHORE–SPACER–RECEPTOR” SYSTEMS

The apparently trivial addition of a spacer between a fluorophore and a receptor (Fig. 6) can completely change the device characteristics of the system. The spacer brings with it the ability to isolate components from the influence of short-range forces that normally abound in the chemical world. So the fluorophore and the receptor are forced to communicate via long-range interactions alone. These are few, and in many cases, can be reduced to one. Photoinduced electron transfer (PET), the celebrated mechanism of green plant photosynthesis, is the commonest controller of optical molecular devices of the “fluorophore–spacer–receptor” type. The fluorescence emission capability of the fluorophore is arrested by PET successfully competing for the energy of the excited state. Thus the device output is initially held in the “low” state (coded as 0). However, PET can be electrostatically stamped out,

**Fig. 4** The realization of general XOR logic behavior in the transmittance output at 390 nm of the UV-Vis absorption spectra set of **3**.

**Fig. 5.** The general format of a “Fluorophore (F)–Receptor (R)” system.

especially by charged target species when they take up residence in the receptor. Now excitation of the system will lead to no competition for the energy of the excited state. Consequently, the excited state returns to ground by emitting fluorescence as most fluorophores do. The device output is now “high” (coded as 1). Such target-induced fluorescence switching is logically a single-input YES gate. An example is the fluorescent sensor **5**<sup>[11]</sup> for  $\text{Na}^+$ , which is marketed by Roche Diagnostics for blood analysis in hospital critical care units. Cases such as **5** use more than electrostatics to enhance the fluorescence switching. The receptor within **5** is a *N*-(2-methoxyphenyl)monoaza-15-crown-5 ether, which suffers a major change in conformation upon capturing  $\text{Na}^+$ . This act reduces the electron delocalization within  $\pi$ -system of the receptor, which, in turn, makes the PET process more difficult and the fluorescence emission stronger. An extra feature within systems such as **5** is the ease with which components can be substituted for, in order to change the species being targeted or even its concentration range. So  $\text{K}^+$ -selective sensors with the same optical parameters found in **5** become available by simply replacing the receptor. Similarly, the  $\text{Na}^+$ -selective relatives of **5** such as **6**,<sup>[12]</sup> which communicate with different colors, of absorption and emission, are obtained by changing the fluorophore. Of course, the feasibility of PET must be conserved during such module replacements.

### “FLUOROPHORE–SPACER<sub>1</sub>–RECEPTOR<sub>1</sub>–SPACER<sub>2</sub>–RECEPTOR<sub>2</sub>” SYSTEMS

As observed above, a spacer ensures a high degree of modularity of systems so that individual components

**Fig. 6** The general format of a “Fluorophore (F)–Spacer (S)–Receptor (R)” system.

are somewhat autonomous. This not only makes PET switch system design a predictive activity but also makes PET system expansion thoroughly logical. Addition of new modules will bring with them possibilities of PET, which are each predictable (provided that electron transfer data are available). Then it becomes possible to arrange situations in which two target species arrive at suitable receptors, either alone or together. Of course, we need to have adequate selectivity within the chosen receptors so that cross-talk of target species will be minimized. Now we have two-input, one-output devices that employ the same foundations as discussed above for one-input, one-output systems. In the simplest cases, “fluorophore–spacer<sub>1</sub>–receptor<sub>1</sub>–spacer<sub>2</sub>–receptor<sub>2</sub>” systems will have two possible PET paths originating from each receptor and finishing at the fluorophore, unless each is blocked by the correct target species. So fluorescence emerges unchallenged only if both receptors are blocked by the two target species being applied as inputs. The condition of Input<sub>1</sub> = 1 and Input<sub>2</sub> = 1 is required before a “fluorophore–spacer<sub>1</sub>–receptor<sub>1</sub>–spacer<sub>2</sub>–receptor<sub>2</sub>” PET system will pass an output = 1. This

is clearly AND logic (Fig. 7). The first example of this, and the first molecular logic gate of any kind in the primary literature, was **7**.<sup>[13]</sup> This uses H<sup>+</sup> and Na<sup>+</sup> as the two inputs. There are several excellent ways of arriving at molecular AND gates now,<sup>[14–18]</sup> some of which have led to more complex logical behavior.<sup>[14,19–21]</sup>

“Fluorophore–spacer<sub>1</sub>–receptor<sub>1</sub>–spacer<sub>2</sub>–receptor<sub>2</sub>” systems can also be put to uses that do not depend on binary logic. For instance, receptor<sub>1</sub> can be chosen as an electron donor amine, whereas receptor<sub>2</sub> can be chosen to be poorly electroactive. A pyridine is the choice for practical reasons, where the fluorophore is an anthracene unit within **8**.<sup>[22]</sup> Naturally, amines lose their electron donor activity upon binding to a proton. PET processes are suppressed. On the other hand, pyridines become good electron acceptors upon proton binding. PET processes are created. So the proton target species has opposite effects upon arrival at the two receptors, each with its own concentration threshold for reception. We note that a single-input species causes a single fluorescence output to be controlled in a relatively complex way. At low proton concentrations, both receptors are free and the amine launches a PET process to destroy fluorescence. At midrange proton concentrations, the more avid amine receptor picks up a proton, thereby closing its PET channel. Fluorescence flares up as a consequence. At high proton concentrations, both receptors are protonated. The

**Fig. 7** The general format of a “Fluorophore (F)–Spacer<sub>1</sub> (S<sub>1</sub>)–Receptor<sub>1</sub> (R<sub>1</sub>)–Spacer<sub>2</sub> (S<sub>2</sub>)–Receptor<sub>2</sub> (R<sub>2</sub>)” system and the logic truth table for the corresponding AND gate.

**8**

protonated amine remains PET-disabled, but the newly formed pyridinium launches its own PET channel and extinguishes the fluorescence. Thus the fluorescence output follows a “off-on-off” pattern in response to monotonically ramping proton concentrations (Fig. 8).<sup>[22–24]</sup> Such systems are useful in being direct optical indicators of pH conditions of enzyme activity or even cellular activity. After all, the principle of “the happy medium” or “the middle way” affects everyone.

**Fig. 8** The ‘off-on-off’ fluorescence–pH profile of **8**.

**Fig. 9** The general format of a “Receptor<sub>1</sub> (R<sub>1</sub>)–Spacer<sub>1</sub> (S<sub>1</sub>)–Fluorophore (F)–Spacer<sub>2</sub> (S<sub>2</sub>)–Receptor<sub>2</sub> (R<sub>2</sub>)” system.

### “RECEPTOR<sub>1</sub>–SPACER<sub>1</sub>–FLUOROPHORE–SPACER<sub>2</sub>–RECEPTOR<sub>2</sub>” SYSTEMS

Realizable permutations arise when a sufficiently large number of modules are contained in a system.

**9**

**10**

This is the case with “fluorophore–spacer<sub>1</sub>–receptor<sub>1</sub>–spacer<sub>2</sub>–receptor<sub>2</sub>” systems. A realizable permutation is to shift the fluorophore to the center of the system (Fig. 9). This act has an advantage for chemical design, because fluorescence switching efficiencies can be improved via accelerated PET processes arising from the shorter fluorophore–receptor distances involved. An example is **9**.<sup>[25]</sup> Even “receptor<sub>1</sub>–spacer<sub>1</sub>–fluorophore–spacer<sub>2</sub>–receptor<sub>2</sub>–spacer<sub>3</sub>–receptor<sub>3</sub>” systems are now in the hands of designers<sup>[26]</sup> to perform increasingly complex tasks with deceptively small molecules such as **10**.

The cases discussed above involved separate target species such as Na<sup>+</sup> and H<sup>+</sup> arriving essentially simultaneously at their respective receptors. Of course, these target species can be independently controlled to test all the input combinations for setting up truth tables to assign logic behavior. It is also feasible to build, say, two target species into separate sites of a bifunctional molecule. Now the real target becomes the bifunctional molecule itself. Naturally, such bifunctional reception can lead to enhanced selectivity of binding and detection. For example, **11**<sup>[27,28]</sup> selectively

targets amino acid zwitterions with a specified number of carbon atoms in between the ammonium and carboxylate functionalities. While the binding is enhanced, the fluorescence signaling suffers from a weakness. Indeed, the binding of the ammonium group leads to PET suppression and fluorescence enhancement. However, the capture of the carboxylate moiety reaps no such fluorescence reward owing to the lack of sufficient PET activity in the guanidinium group. Nevertheless, a nice case with two PET-active receptors is available in the form of **12** from Cooper and James.<sup>[29]</sup> Protonated glucosamine is the valuable target. The aza-18-crown-6 ether receives an ammonium group as in the case of **11**. Additionally, a diol feature is held by the aminomethylboronic acid receptor, which leads to PET suppression. So now both PET channels are blocked upon arrival of the glucosamine species in an AND logical manner. This application of AND logic systems for the enhanced binding and optical signaling is a very promising avenue of research.

## CONCLUSION

Dyes (fluorescent or not), receptors, and spacers are the building blocks that designers of optical molecular devices can play with. Combinations, or even some permutations, of these blocks can lead us to sensors, logic gates, and “off-on-off” systems already. Considering that at least some of these are demonstrably useful here and now, the number of players is bound to increase. The result will be even more interesting systems in the future.

# Optical Nanosensors and Nanobiosensors

**Brian M. Cullum**

*Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, Baltimore, Maryland, U.S.A.*

## INTRODUCTION

Advances in nanotechnology and nanofabrication have begun to have profound effects on many different scientific fields in recent years. In the field of chemical and biological sensing, one of the most significant advances in the last several decades has been the development of nanosensors, for the probing of microscopic environments. Simply stated, nanosensors are devices with dimensions on the nanometer scale that are capable of monitoring the presence of a specific chemical or class of chemicals. Although many different types of nanosensors (i.e., optical, electrochemical, etc.)<sup>[1–6]</sup> have been reported in the literature over the last two decades, this chapter will focus on nanosensors employing optical transduction methods.

As with larger optical sensors, optical nanosensors can generally be classified into one of two different classes: 1) chemical nanosensors, or 2) nanobiosensors, depending on the type of recognition element (i.e., chemical or biochemical) used to provide specificity to the sensor.<sup>[7–10]</sup> Although both of these classes of optical nanosensors are capable of obtaining quantitative measurements in many different microscopic environments, they have found an ideal application in the analysis of chemical and biochemical species present within living cells. Their small sizes allow them to be inserted and precisely positioned within individual cells to obtain spatially localized measurements of chemical species in real time.

## OVERVIEW

Prior to the development of optical nanosensors, chemical analyses inside individual living cells were limited almost entirely to the field of fluorescence microscopy, wherein a fluorescent indicator dye is introduced into a cell and allowed to diffuse throughout. When the dye comes in contact with the analyte of interest, a change in the fluorescence properties (e.g., intensity, spectral shift, etc.) of the dye occurs and fluorescence images of the entire cell are obtained. From these images, it is possible to monitor the presence of the analyte at various locations. However,

because this technique relies on imaging of the fluorescent dye, its homogenous dispersion throughout the cell is required. Unfortunately, homogeneous dispersion of dyes is often limited by intracellular conditions (i.e., pH, etc.), or prevented entirely by compartmentalization of the dye by the cell.<sup>[11]</sup> Therefore nanosensors offer significant improvements over such analyses in many cases, as they allow the user to obtain measurements at whatever location is desired without the need for homogenous dispersion of a fluorescent indicator dye.

Because of their potential for providing an enhanced understanding of cellular responses to various stimuli, several reviews have already been devoted to the subject of optical nanosensors, despite their short existence.<sup>[5,12–16]</sup> This chapter will look at the evolution of optical nanosensors from their beginning (near-field optical microscopy) to the present (biosensors capable of probing subcellular compartments of individual cells) and discuss their application to biological measurements, as well as future directions in optical nanosensing.

## EVOLUTION OF OPTICAL NANOSENSORS

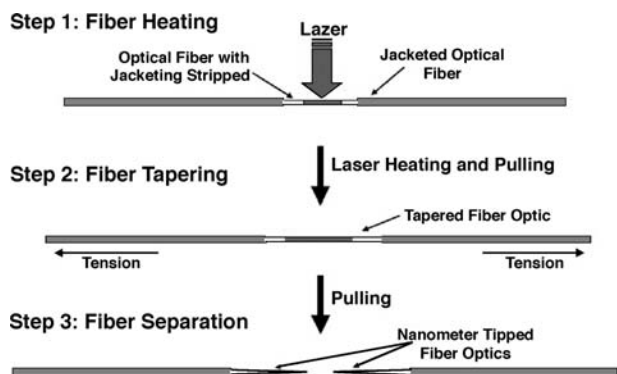

Presently, the most widely reported class of optical nanosensors is fiber optic nanosensors. These sensors employ fiber optics that have been tapered on one end to diameters typically ranging between 20 and 100 nm. Although such sensors are based on the same principles as larger, conventional fiber optic sensors, their excitation process is quite different. Because the diameter of the tapered end of a fiber optic nanosensor is significantly smaller than the wavelength of light used for excitation, photons cannot escape from the tip of the fiber to be absorbed by the species of interest, as is the case in larger fiber optic sensors. Instead, excitons or evanescent fields continue to travel through the remainder of the tapered fiber's tip, providing the necessary excitation energy. Because of the weak nature of these phenomena, excitation using such a sensor is highly localized, allowing only species close to the fiber's tip to be excited. The use of tapered fiber optics to produce highly localized excitation processes (i.e., near-field excitation) arose from an area of research known as near-field optical scanning microscopy (NSOM).

## Near-Field Scanning Optical Microscopy

Near-field optical scanning microscopy is a relatively recent field of research, employing light sources and/or detectors that are smaller than the wavelength of light used for imaging.<sup>[17–20]</sup> By using such small excitation sources or detectors, images of a sample can be obtained with nanometer-scale (i.e., 10–50 nm) spatial resolution. One common method for performing such experiments is to place a pinhole in front of the detector, effectively reducing the detector's size to nanometer dimensions.<sup>[20,21]</sup> However, a variation of this technique that is growing more and more popular is to construct an excitation probe with dimensions that are smaller than the wavelength of light that is being used for sample interrogation, thereby providing a light source with sub-wavelength dimensions.<sup>[22,23]</sup> The first such excitation probe was developed by Betzig et al.<sup>[22]</sup> by tapering a single-mode optical fiber to dimensions of approximately 20 nm, thereby confining the excitation radiation to the fiber tip. Using this nanometer-scale tapered optical fiber, NSOM images of a known pattern were reconstructed with signal enhancements of greater than  $10^4$ <sup>[22,23]</sup> over previous NSOM analyses.<sup>[18,19,24,25]</sup>

### Fiber tapering methods

To construct tapered fiber optic probes for NSOM, two different processes have been developed: heated pulling and chemical etching, each capable of creating fibers with various tip diameters, taper angles, and smoothness. The first and most commonly employed of these procedures uses a heated pulling instrument, such as a laser-based micropipette puller. In this procedure, a fiber optic is placed in the micropipette puller, and a CO<sub>2</sub> laser heats the fiber while it is stretched along its major axis by a tension device (Fig. 1). As the fiber is pulled, the heated region begins to taper until, finally, the fiber is pulled into two pieces, each having one large end and one end with

**Fig. 1** Cartoon depicting the heated pulling process used for nanofiber fabrication.

**Fig. 2** A SEM of a tapered fiber optic probe. The diameter of the tapered tip is approximately 40 nm.

nanometer-scale dimensions. By varying the heating temperature as well as the tension applied during the pulling process, tip diameters ranging in size from less than 20 nm to greater than 1000 nm have been reported.<sup>[22,26–29]</sup> A scanning electron micrograph (SEM) of an optical fiber that has been pulled with such an instrument is shown in Fig. 2. Using this technique, it is possible to produce optical fibers with highly reproducible nanometer-scale tips in just seconds.

In addition to the heated pulling process, optical fibers with nanometer-scale tips can also be produced via chemical etching. Two different variations of chemical etching have been reported in the literature: 1) Turner etching,<sup>[30,31]</sup> and 2) tube etching.<sup>[32]</sup> In both processes, hydrofluoric acid (HF) is used to etch the silica core of a fiber optic to a point. In the Turner method, the fiber is placed in the meniscus between HF and an organic overlayer, causing the HF to etch the silica and the organic overlayer to protect it. This process creates fibers with larger taper angles than those produced via the heated pulling method. These larger taper angles allow excitation light to travel closer to the tip of the fiber before being trapped, providing a more efficient excitation process. Unfortunately, because of the dual chemical nature of the etchant solution, environmental parameters such as temperature fluctuations and vibrations can cause significant batch-to-batch variations in the characteristics of the fiber tips.

Unlike Turner etching, the second chemical etching process, tube etching, employs a single-phase solution,

**Fig. 3** Cartoon depicting the tube etching process used for nanofiber fabrication.

thereby reducing the potential batch-to-batch variability induced by two phases. In this process, a silica core fiber having a polymer cladding is polished optically flat and one end is placed into a solution of HF. After being inserted into the HF, the silica core of the fiber begins to dissolve without affecting the cladding. Over time, the silica core continues to be etched away until it is no longer below the surface of the HF solution. When this occurs, capillary action draws HF up the walls of the polymer cladding. This HF then reaches the silica core of the fiber, where it drains back into the solution below, forming a smooth tip with a large taper angle (Fig. 3) within approximately 2 hr. To remove the surrounding polymer cladding and to expose the silica tip, the fiber is then simply placed in a suitable organic solvent. By varying the diameter of the fiber used and the depth at which it is inserted into the etching solution, accurate control over the fiber tip diameter and its taper angle can be achieved. Although this process can produce more reproducible tapered fiber optic probes than Turner etching, difficulties associated with submerging multiple fibers to the exact same depth in the HF solution make it less reproducible than the heated pulling process.

#### Application of fiber optic nanoprobes to near-field optical microscopy

One of the most significant applications of fiber optic nanoprobes to NSOM analyses of biological samples occurred when a single dye-labeled DNA molecule was detected using near-field surface-enhanced resonance Raman spectroscopy (NFSERRS).<sup>[33,34]</sup> In that work, dye-labeled DNA strands were spotted onto a surface-enhanced Raman spectroscopy (SERS) substrate that was prepared by evaporating silver on

a nanoparticle-coated surface.<sup>[33,34]</sup> Following preparation of the sample, a fiber optic nanoprobe was raster-scanned over the sample's surface, illuminating it point by point, while the resulting Raman signals were measured with a charge-coupled device (CCD). Based on the intensity of the Raman signals measured at every location, a two-dimensional image of the DNA molecules was reconstructed and normalized for surface topography based on the intensity of the Rayleigh scatter.

With the advent of fiber optic nanoprobes, NSOM promises to be an area of research that holds a great deal of promise for biological analyses. Because many biological compounds produce luminescent signals following excitation, which are typically much stronger than Raman signals, it may be possible to map out the location of individual molecules of specific chemicals in human tissues (e.g., neurotransmitters in the brain) using NSOM. Such analyses could open new horizons in the investigation of complex chemical reactions and pathways of biological systems.

#### FIBER OPTIC CHEMICAL NANOSENSORS

Shortly after the development of fiber optic nanoprobes for NSOM, they were applied to the field of chemical sensing, making it possible to obtain spatially localized measurements (i.e., less than 50 nm away from the fiber's tip) of specific chemicals in three-dimensional structures.<sup>[26]</sup> Unlike simple NSOM probes, these fiber optic chemical nanosensors have chemical recognition elements (e.g., fluorescent indicator dyes, etc.) bound to the tapered tip of the fiber to provide a degree of specificity. Because of this specificity and their ability to obtain spatially localized measurements, the monitoring of concentration gradients and spatial inhomogeneities in submicroscopic environments (e.g., cells, etc.) with chemical nanosensors is possible. However, because of the small sampling volume probed by such fiber optic chemical nanosensors, the amount of analytes present in the excitation volume at any given time is very small, making it important to use a sensitive spectroscopic analysis technique (e.g., fluorescence, etc.).

In addition to employing a sensitive spectroscopic technique, it is also important to employ a sensitive detection system, such as the one shown in Fig. 4. In such a system, the sample is excited by launching an intense light source (e.g., laser) into the proximal end of the fiber optic nanosensor. The nanosensor is then positioned in the desired location using an  $x$ - $y$ - $z$  micromanipulator or piezoelectric positioning system mounted on a microscope. Once in place, the fluorescent indicator dye immobilized on the tip of the fiber is excited, and the resulting fluorescence emission

**Fig. 4** Schematic diagram depicting a typical measurement system for fiber optic nanosensor-based analyses. The nanosensor is manipulated to the location of interest using an  $x$ - $y$ - $z$  micromanipulator.

is collected and filtered by the microscope before being detected with either a photomultiplier tube (PMT) or a CCD.

### Ion-Sensitive Fiber Optic Nanosensors

The first fiber optic-based chemical nanosensors were reported in 1992 for the monitoring of pH.<sup>[26]</sup> In that original work, multimode fibers and single-mode fibers were tapered via a heated pulling process to produce tip diameters ranging from 100 to 1000 nm.<sup>[26,27]</sup> These tapered fibers were then used to fabricate pH-sensitive nanosensors via a three-step process. Immediately following the tapering process, a thick layer of aluminum was applied to the walls of the fibers using a vacuum evaporation system. This aluminum layer ensured that total internal reflection occurred over the tapered region of the fibers, where the cladding was stretched too thin. To prevent aluminum from depositing on the tips of the fibers, where the receptor molecules (i.e., fluorescent indicator dye molecules) were to be bound, the fibers were placed in an evaporator system with their tapered tips facing away from the source of the evaporating aluminum. This allowed the sides of the fibers to shadow the tips from the evaporating metal. This is illustrated in Fig. 5. Once the walls of the fibers were coated with aluminum, the silica tips were silanized to allow cross-linking to a polymer coating. The third and final step in the fabrication of these pH nanosensors consisted of attaching a pH-sensitive dye, acrylofluoresceinamine, to the silanized fiber tips through a variation of a photo-polymerization process that has been used in

**Fig. 5** Cartoon depicting the thermal evaporation procedure used to coat the sides of the tapered fiber optic probes with metal.

the construction of larger chemical sensors.<sup>[35,36]</sup> However, unlike the larger nontapered fiber optic chemical sensors, the near-field excitation provided by these small fiber probes restricted the cross-linking of the polymer solution to the near-field of the fiber, providing a small sensing volume.

Following fabrication, the response characteristics of the pH nanosensors were evaluated. During this evaluation, the sampling volume of the nanosensors was determined to be more than six orders of magnitude smaller than conventional fiber optic chemical sensors, making them ideal for biological analyses. In addition, these nanosensors were found to be both stable and reversible to pH changes, and have response times of approximately 300 msec, which is approximately 100-fold faster than conventional fiber optic chemical sensors.

The application of fiber optic chemical nanosensors to a biologically relevant analysis was first performed by monitoring the pH of the extraembryonic space of rat conceptuses in an attempt to understand the role environmental factors play on embryonic growth.<sup>[26]</sup> In this study, pH nanosensors similar to the ones described above were inserted into the extraembryonic space of rat conceptuses, with minimal damage to the surrounding visceral yolk sac, and pH measurements were obtained. In a similar study using the same pH-sensitive nanosensors, indirect analyses of nitrite and chloride levels in the yolk sac of rat conceptuses were also performed.<sup>[37]</sup>

Since the construction of the first fiber optic nanosensors, additional fiber optic-based chemical nanosensors have been reported for the measurement

of pH,<sup>[38–41]</sup> various metal ions,<sup>[42,43]</sup> as well as nitric oxide.<sup>[44]</sup> In addition, the size of the environments in which they probe continues to become smaller. In fact, the measurement of chemical species inside individual living cells has even been reported using fiber optic chemical nanosensors. The first such intracellular measurements with fiber optic chemical nanosensors employed sodium ion (Na<sup>+</sup>)-sensitive indicator dyes immobilized onto the tips of tapered fiber optics through a process similar to that described for the pH nanosensors. These sensors were then used to measure sodium ion (Na<sup>+</sup>) concentrations in the cytoplasmic space of a single mouse oocyte, one of the largest mammalian cells (ca. 100 μm in diameter), while ion channels were opened and closed by external stimulation.<sup>[15]</sup> In addition to intracellular analyses of Na<sup>+</sup> ions, fiber optic chemical nanosensors have also been used to monitor intracellular calcium (Ca<sup>2+</sup>) ion fluctuations in vascular smooth muscle cells, following stimulation.<sup>[45]</sup> Because of the large number of cellular reactions that are signaled by fluctuations in the concentration of ionic species, and the demonstrated ability of fiber optic nanosensors to perform intracellular measurements of those ionic species, these sensors should prove to be valuable tools for future discoveries in cellular dynamics.

## FIBER OPTIC NANOBIOSENSORS

Because of the complexity of biological systems and the number of possible interference to chemical nanosensors, the need for added specificity in cellular analyses can arise. To achieve this added specificity, fiber optic nanobiosensors are often employed. Like their larger counterparts, conventional fiber optic biosensors, biological receptor molecules (i.e., antibodies, enzymes, etc.) are used to provide added specificity. The different types of bioreceptor molecules that have been used for the fabrication of fiber optic nanobiosensors include antibodies, oligonucleotides, and enzymes, thereby allowing for the detection of a wide array of analytes.

### Antibody-Based Fiber Optic Nanobiosensors

The first fiber optic nanobiosensor was reported by Alarie and VoDinh<sup>[28]</sup> in 1996. In this work, antibody-based nanobiosensors for the DNA adduct, benzo[*a*]pyrene tetrol (BPT), were developed and characterized. The fabrication of these first nanobiosensors was performed in a process very similar to that used in the development of fiber optic chemical sensors. Initially, a 600-μm-diameter multimode fiber optic was tapered down to 40 nm at the tip. After tapering, a thick layer

of silver was applied to the sides of the fiber in such a way as to prevent the coating of the fiber's tip. Next, the uncoated fiber tip was silanized, and antibodies were attached via a covalent-binding procedure.<sup>[28]</sup> Following attachment of the antibodies, the fiber optic nanobiosensors were characterized in terms of antibody binding affinity as well as sensitivity and absolute detection limits. From these measurements, it was found that the antibodies had retained greater than 95% of their native binding affinity for BPT after being bound and that the absolute detection limit for BPT using these nanobiosensors was approximately 300 zmol (i.e.,  $300 \times 10^{-21}$  mol).

Shortly after the development of this first antibody-based fiber optic nanobiosensor, several others were developed and applied to *in vitro* measurements within individual living cells.<sup>[5,29,46–48]</sup> In one such study, nanobiosensors for BPT were prepared as described above and used to obtain quantitative measurements of intracellular concentrations of BPT in the cytosol of two different cell lines: 1) rat liver epithelial cells, and 2) human mammary carcinoma cells.<sup>[29]</sup> Unlike previous intracellular analyses that employed relatively large cells (i.e., mouse oocytes and neurons), the cells analyzed in this study were spherical in shape and had diameters of approximately 10 μm, thereby demonstrating that fiber optic nanosensors and nanobiosensors could be used to analyze cells the size of typical mammalian somatic cells (i.e., 10–15 μm) without destroying them. In fact, this study also demonstrated that the insertion of a fiber optic nanosensor or fiber optic nanobiosensor into such a cell and the subsequent measurement seemed to have little effect on the cell's normal function. This was demonstrated by inserting the fiber optic nanobiosensor into the cytoplasm of a cell beginning to undergo mitosis and monitoring cell division following incubation of the nanofiber in the cell for 5 min. Fig. 6 contains an image of the fiber optic nanosensor being inserted into this cell, as well as a second image showing the two daughter cells that it divided into after approximately 2 hr.

### Molecular Beacon-Based Fiber Optic Nanobiosensors

To detect the presence of oligonucleotides (i.e., RNA, DNA, etc.) in intracellular environments, a class of fiber optic nanobiosensors that employ a relatively new type of bioreceptor molecules known as a molecular beacon has been developed.<sup>[49]</sup> Molecular beacons are hairpin-shaped oligonucleotide probes that rely on the complementarity of nucleic acids (i.e., adenine:thymine, cytosine:guanosine, etc.) to form the basis for the molecular recognition of a specific oligonucleotide sequence. As shown in Fig. 7, molecular beacons form a stem-loop structure in the absence of the target

120 minutes  
after probing  
with a fiber optic  
optic

**Fig. 6** Photograph of an individual cell that is probed with a fiber optic nanosensor as it begins to undergo mitosis, and a second photograph of that same cell approximately 2 hr later, having divided into two daughter cells.

sequence, in which a fluorophore [e.g., fluorescein isothiocyanate (FITC), etc.] on one end of the stem is in close proximity to a nonfluorescing, quenching moiety [e.g., dimethylaminophenylazobenzoic acid (DABCYL), etc.] on the other end.<sup>[50]</sup> In this state, when the fluorophore on the molecular beacon is excited, an energy transfer takes place between the excited fluorophore and the quencher, either by direct energy transfer or fluorescence resonance energy transfer (FRET), and minimal fluorescence emission occurs. However, when the loop sequence of the molecular beacon comes into contact with its complementary sequence, the stem begins to unzip, creating a spatial separation between the fluorophore and the quencher. This spatial separation in turn causes a dramatic increase in the fluorescence intensity of the molecular beacon, with some reports stating enhancements exceeding 200-fold.<sup>[51]</sup>

**Fig. 7** Cartoon depicting the mechanism of action of a molecular beacon.

Because of their inherent sensitivity and specificity, molecular beacons have recently been used as bioreceptor molecules in the fabrication of fiber optic nanobiosensors for single-stranded DNA and RNA.<sup>[52,53]</sup> In these works, Liu and Tan and Liu et al. attached molecular beacons to the silica core of a fiber optic nanosensor through biotin–avidin linkages. By binding the molecular beacons to the tapered tip of the fiber optic in this method, a strong attachment was achieved, while not degrading the activity of the beacon.

### Enzyme-Based Fiber Optic Nanobiosensors

In addition to the use of molecular beacons and antibodies as bioreceptor molecules, fiber optic nanobiosensors that employ enzymes for molecular recognition have also been developed.<sup>[54,55]</sup> Using enzymes as bioreceptors not only provides nanobiosensors with a high degree of specificity, but their catalytic activity can amplify the species being measured, allowing for sensitive analyses. One such enzymatic-based fiber optic nanobiosensor was developed for the indirect detection of glucose.<sup>[55]</sup> In this work, Rosenzweig and Kopelman immobilized the enzyme, glucose oxidase, and the oxygen-sensitive indicator, tris(1,10-phenanthroline) ruthenium chloride, in an acrylamide polymer on the tapered end of a nanofiber via a photopolymerization process. Therefore when the nanobiosensor is in the presence of glucose, the enzyme catalyzes the oxidation of glucose into gluconic acid, consuming oxygen. The resulting changes in oxygen levels are then measured via the oxygen-sensitive indicator dye. By using an enzymatic receptor, these nanobiosensors were capable of absolute detection limits of approximately  $10^{-15}$  mol and a sensitivity five to six orders of magnitude greater than current glucose optodes.<sup>[55]</sup>

Another example of an enzymatic nanobiosensor was developed by Tan et al. for the indirect measurement of the neurotransmitter, glutamate. In this work, glutamate dehydrogenase is bound to the tip of the fiber optic nanobiosensor to achieve molecular recognition. When the sensor is in the presence of glutamate, the nonfluorescent species, NAD, is reduced into the autofluorescent species, NADH, which can then be monitored via fluorescence spectroscopy. By relating the intensity of the NADH fluorescence to glutamate concentration, sensitive analyses were performed. Following the construction of these nanobiosensors, their usefulness was evaluated by continuously monitoring the release of glutamate from individual neurons during stimulation.

### FIBER OPTIC NANOIMAGING SENSORS

Although fiber optic nanosensors and nanobiosensors have proven to be useful tools for the spatially localized, quantitative analysis of chemical species in cells, only one sensor can be inserted into a typical mammalian somatic cell at a time, without causing significant damage.<sup>[56]</sup> This inability to monitor multiple locations simultaneously can dramatically limit the applicability of fiber optic nanosensors and nanobiosensors to many types of cellular analyses. To overcome this limitation, a couple of research groups have recently begun to develop nanoscale fiber optic imaging probes and sensors comprised of thousands of individual fibers arranged in a coherent bundle.<sup>[57,58]</sup> These nanoimaging sensors represent the latest advance in fiber optic-based nanosensors, and are capable of obtaining measurements at thousands of different locations simultaneously with nanometer-scale spatial resolution.

#### Fiber Optic Nanoimaging Probe Fabrication

Similar to single-fiber-based nanosensors and nanobiosensors, nanoimaging probes can be fabricated either through a chemical etching process, or a heated pulling process. In the chemical etching process, commercially available coherent imaging bundles with 30,000 individual fibers are etched in HF to form an array of silicon tips.<sup>[58]</sup> Following formation of the array of silicon tips, a layer of gold is sputtered over the entire surface to prevent light from escaping from the tapered sides of each fiber element. After deposition of the gold overlayer, a polymer is electrochemically deposited over the gold and heat-cured to expose the gold at the tips of the individual fiber elements. Finally, the exposed gold surface on each of the individual fiber

**Fig. 8** Photographs of a fiber optic nanoimaging probe that has been tapered using a heated pulling process. Panel A shows a side-on view of the fiber demonstrating the flat tip after pulling. Panels B and C are end-on views of the tapered end and the nontapered end of the fiber, respectively.

element tips is dissolved to produce free silica surfaces for spectroscopic probing.

In addition to chemical etching, nanoimaging probes have also been fabricated using a heated pulling process.<sup>[57]</sup> However, unlike the nanoimaging array created via chemical etching, the heated pulling process produces an array having a flat surface. This can be seen in Fig. 8A, which shows a side-on view of a fiber optic imaging bundle that has been tapered in a micropipette puller. To produce this flat surface, which is necessary for imaging, the delay between the final pull in the micropipette puller and the time at which the heating laser turned off is increased, thus allowing the fiber to cool off slightly and be broken, with all of the individual fiber elements being of the same length and diameter. By changing the heating temperature and the initial pull strength of the micropipette puller, fibers can be accurately and reproducibly tapered to all different diameters. Fig. 8 shows a fiber that has been tapered to have individual fiber element diameters of 800 nm on one end (Fig. 8B) and 4- $\mu$ m diameters on the untapered end (Fig. 8C).

Using these two different fabrication techniques, fiber optic nanoimaging probes and sensors that will not only allow for the quantitative measurement of individual chemical species, but also the simultaneous measurement at many different locations are being developed. Although these fiber optic imaging bundles

are too large to be inserted into individual living cells, they can be used to monitor cellular membranes without damage.

## NANOPARTICLE-BASED OPTICAL NANOSENSORS

Although fiber optic-based nanosensors have had a large impact on the fields of cellular biology and biochemistry, significant advances and variations in optical nanosensors are constantly being made, from the use of more selective bioreceptors to the development of different types of optical-based nanobiosensors. One such advance in the last several years has been the development of nanoparticle-based optochemical sensors, with nanometer-scale sizes in all three dimensions. Because of the small sizes of these sensors, a large number of them can be implanted within an individual cell at one time, allowing for the monitoring of many locations simultaneously. Although many different nanoparticle-based sensors are currently being developed, three main classes have already shown a great deal of promise for intracellular analyses. These three classes are quantum dot-based nanobiosensors, polymer-encapsulated nanosensors known as PEBBLEs, and phospholipid-based nanosensors. Each of these different classes of nanoparticle-based sensors is described in more detail below.

### Quantum Dot-Based Nanosensors

The first class of nanoparticle-based optical nanosensor that was developed involved attaching nanometer-scale semiconductor particles, known as quantum dots, to various biological receptor molecules including antibodies, oligonucleotides, and enzymes.<sup>[59–63]</sup> The quantum dots used in these nanosensors comprised ZnS particles capped with Cd–Se. By using quantum dots instead of conventional fluorescent dyes, these sensors exhibit much more intense emission as well as a much greater degree of photostability. These properties are very important when trying to monitor changes in chemical or biochemical species concentrations over time because most fluorescent dyes exhibit rapid and significant photobleaching with the small amount used in cellular analyses. Unfortunately, because quantum dot-based nanobiosensors exhibit luminescence emission whether bound to the analyte or not, there are limits to their applicability to cellular analyses. Additionally, a biocompatibility issue also exists for these sensors because the materials used to fabricate the quantum dots (e.g., Cd–Se, etc.) are toxic to cells. Because of their toxicity, there is a significant effort currently underway in many research groups to develop more biocompatible

quantum dot-based nanobiosensors to perform long-term monitoring of cellular reactions or processes.

### PEBBLEs Sensors

A second class of nanoparticle-based optical nanosensors that has already had a large impact on the fields of cellular biology and biochemistry was developed by Sasaki et al.,<sup>[64]</sup> Clark et al.,<sup>[65,66,67]</sup> Sumner et al.,<sup>[68]</sup> and Xu et al.<sup>[69,70]</sup> in the last several years. These sensors, known as PEBBLEs (probes encapsulated by biologically localized embedding), are comprised of fluorescent indicator dyes sensitive to ionic species (i.e.,  $H^+$ ,  $Ca^{2+}$ , etc.) that are embedded in 20-nm-diameter or 200-nm-diameter polymer or sol–gel spheres.<sup>[65,66]</sup> By encapsulating the fluorescent indicator dyes in a polymer matrix, they are protected from cellular degradation by proteins, while still allowing ions to pass and react with them. In addition, this polymer coating also protects the cell from the toxic effects of the dye.

Since they were first developed in 1996, PEBBLEs have been applied to the measurement of many different species (pH,  $Ca^{2+}$ , NO,  $O_2$ , and  $Zn^{2+}$ ) within individual cells.<sup>[65–70]</sup> In these analyses, large quantities of PEBBLEs are inserted in a cell, either by a gene gun or a similar device, to ensure that sensors are present at every location in which a measurement might be desired. Once the sensors have been injected into the cell, the entire cell is illuminated and the fluorescence signal from the indicator dye is measured over the autofluorescent background of the cell.

Because of the potential for intense autofluorescence from the cell, depending on the excitation wavelength used, the detection limits of such analyses can be relatively high. To overcome this problem, Anker, Behrend, and Kopelman<sup>[71]</sup> and Anker and Kopelman<sup>[72]</sup> have recently developed magnetically modulated variations of these sensors, known as MagMOONs (magnetically modulated optical nanoprobes). These MagMOONs are created around aspheric magnetic nanoparticles that can be rotated in the presence of a rotating magnetic field. As the particles begin to rotate, the optical emission from the sensor is modulated. During demodulation, the emission from the sensors can be separated from the continuous autofluorescence background signals, thereby dramatically improving the detection limit of such sensors.

### Phospholipid Sensors

The third major class of nanoparticle-based sensors that has already demonstrated a significant impact on cellular analyses is phospholipid-based sensors. Like the PEBBLEs described above, these nanosensors also

employ an encapsulation technique to ensure biocompatibility with the cell being investigated.<sup>[73–78]</sup> Within this class of nanosensors, two distinct subclasses exist: liposome sensors,<sup>[77,78]</sup> and lipobead sensors.<sup>[73,75]</sup> The first of these subclasses, liposome-based nanosensors, employs fluorescent indicator dyes encapsulated in the internal aqueous compartment of a liposome. This allows the dye, which is sensitive to a particular analyte, to retain its solution-based characteristics (i.e., spectral emission profile, Stokes shift, response time, etc.) while preventing toxic dye molecules from diffusing throughout the cell. Currently, liposome nanosensors have been developed and applied to the measurement of molecular oxygen<sup>[78]</sup> and pH<sup>[77]</sup> in various cellular environments, demonstrating a high degree of sensitivity as well as specificity.

Recently, a variation of these liposome-encapsulated nanosensors was developed by Ji et al.,<sup>[73]</sup> McNamara et al.,<sup>[75]</sup> McNamara and Rosenzweig,<sup>[79]</sup> and DeCoster et al.<sup>[80]</sup> in which the fluorescent indicator dye molecules were immobilized onto a polystyrene nanoparticle prior to being encapsulated in a phospholipid membrane. This second subclass of phospholipid-based nanosensors, known as lipobead nanosensors, is more stable and less susceptible to biological degradation than liposome-based sensors. An additional advantage of these lipobead nanosensors over liposome nanosensors or PEBBLEs is that the fluorescent indicator dyes can be partially embedded in the phospholipid membrane, allowing the measurement of a much larger number of chemical species, because the analyte does not need to diffuse through a protective coating before interacting with the dye.<sup>[73,75]</sup>

## CONCLUSION

With interest in nanotechnology and its practical use rising, the development of optical nanosensors for microscopic analyses has increased dramatically over the last decade. Since the development of the first fiber optic nanoprobe for near-field scanning optical microscopy, optical nanosensors have evolved into many different forms, each having its own distinct advantages for a particular type of analysis. Furthermore, these optical nanosensors and nanobiosensors have begun to demonstrate their ability to obtain reliable and useful measurements of chemical species within cellular and even subcellular environments. Based on the rapid impact that optical nanosensor and nanobiosensor technologies have already had on cellular biology and biomedical diagnostics, future developments (i.e., smaller, less invasive sensors; more biocompatible sensors; etc.) should revolutionize the fields of healthcare and pharmaceutical development by providing a much greater understanding of basic

cellular reaction pathways for various biological functions and diseases.

## ACKNOWLEDGMENTS

This work was supported, in part, by the University of Maryland Baltimore County. In addition, I would like to acknowledge the generous assistance of Dr. Dimitra Stratis-Cullum with the graphics.

# Ordered Vesicles at the Silicon–Water Interface

Duncan J. McGillivray

Physical and Theoretical Chemistry Laboratory,  
Oxford University, Oxford, U.K.

## INTRODUCTION

The purpose of this entry is to examine the stable, ordered near-surface phase of dichain cationic surfactants, which has been recently reported,<sup>[1]</sup> and to determine whether this phase can be unambiguously assigned as a vesicular phase. Such a phase would be a remarkable example of an aligned near-surface phase, extending hundreds of nanometers into solution, which exists in equilibrium with the bulk aqueous phase, and may explain the superspreading characteristics of these surfactants,<sup>[2]</sup> providing a reservoir of surfactant near the surface.

These surfactants are also widely used as fabric softeners and are the subjects of keen interest for pharmaceutical applications. They have been shown to form vesicles in dilute solutions. This is particularly significant as it extends the range of standard vesicle-forming compounds beyond phospholipids, long the gold standard of the field. Furthermore, the vesicles formed by these cationic surfactants are generally smaller than those formed from phospholipids, ranging from as small as 30 nm. These cationic vesicles are the subjects of biomedical research, where they are highly regarded as effective gene transfer agents in gene therapy.<sup>[3]</sup> Part of the success of this technique depends on the interaction between the cationic vesicle–DNA complex and the target cell membrane, which enables the DNA to cross undegraded,<sup>[4]</sup> and thus it is of interest to know how the surfactant vesicles behave near a surface.

## VESICLES

The vesicle morphology is a common motif in surfactant self-arrangement. Favored by surfactants whose packing parameter falls in the typically lamellar range ( $0.5 < pp < 1$ ), it often coexists in solution with other lamellar-type structures such as lamellar fragments or sponge phases. The precise morphology chosen for a given surfactant depends critically on the precise nature of the surfactant and its counterion and the solution conditions of the system.

The most well-studied and common vesicle-forming surfactants are phospholipids.<sup>[5]</sup> These vesicles have

been used as cell-membrane analogs<sup>[6,7]</sup> and have a great deal in common with ordinary biological cells. They do not form spontaneously, requiring significant energy input to form typically through sonication, and produce large, metastable vesicles which can grow as large as micrometers. Phospholipid vesicles are not generally monodisperse and can be both unilamellar and multilamellar. Monodispersity is often achieved by forming vesicles using a fixed-size extrusion technique.

Phospholipid vesicles are not, however, found to be stable when interacting with a solid surface. This enables them to be widely used to deposit phospholipid bilayers on surfaces for use as model membranes, where the vesicle collapses on contact to produce a lamellar bilayer at the surface.<sup>[8–10]</sup>

The range of vesicle-forming surfactant systems has recently been enlarged through the use of combinations of oppositely charged surfactants,<sup>[11–14]</sup> non-ionic surfactants,<sup>[15,16]</sup> and dichain cationic surfactants.<sup>[17–20]</sup> The vesicle-forming dichain cationic surfactants, which are the dialkyldimethylammonium bromide (DAB) family, are the focus of the work referred to as the basis of this article.

## SURFACE MEASUREMENTS

Neutron reflectometry provides the unique ability to probe the surface and near-surface region of a solid–liquid interface *non-intrusively*, an important condition for the study of such fragile systems. Neutrons of 1–10 Å wavelengths, which are typically used for surface measurements, penetrate a single crystal of silicon with greater than 70% transmittance over a path length of around 15 cm and are then reflected from the solid–liquid interface (see Fig. 1 for the standard geometry of a solid–liquid experiment). Neutron reflectometry also gives information about the near-surface structure in solution. The neutron penetration length in D<sub>2</sub>O is of the order of microns for 10-Å neutrons, although, experimentally, it is found that it is difficult to detect species which are highly disperse or rough below the surface.

The reflection experiment measures the number of neutrons reflected as a function of the wave vector

**Fig. 1** The geometry of a specular neutron reflection experiment at the solid–liquid interface, where  $\theta_i = \theta_r$  and  $Q_z$  is the vertical momentum transfer.

change on reflection (normally referred to as the momentum transfer)  $Q_z$ , which itself is a function of the wavelength of the neutrons and the angle of reflection

$$Q_z = \frac{4\pi \sin \theta}{\lambda} \quad (1.1)$$

The reflection depends on the interaction of the neutrons with the nuclei present at the surface. The extent of nuclear interaction with a neutron is described by an experimentally well-determined quantity known as the coherent scattering length  $b_{\text{coh}}$ , which varies non-systematically across the periodic table (see Table 1 for values of this parameter for a few biologically significant isotopes). In contrast to the X-ray scattering equivalent, it can be seen that hydrogen isotopes have large  $b_{\text{coh}}$ , which significantly takes a negative value for  $^1\text{H}$ . This allows simple isotopic substitution to adjust the contrast of hydrogen-containing molecules; indeed, for water, the scattering length density (SLD) can range from  $-0.58$  up to  $6.35 \text{ \AA}^{-2}$ , enabling it to be contrast-matched to many common interfaces [ $\text{SLD}(\text{Si}) = 2.07 \text{ \AA}^{-2}$ ,  $\text{SLD}(\text{Air}) = 0.0 \text{ \AA}^{-2}$ ] so that the only scattering arises from material found at the interfacial region.

**Table 1** Bound coherent scattering lengths ( $b_{\text{coh}}$ ) for biologically significant isotopes

Element	$b_{\text{coh}} (10^{-5} \text{ \AA})$	Element	$b_{\text{coh}} (10^{-5} \text{ \AA})$
$^1\text{H}$	$-3.74$	$^{12}\text{C}$	$6.65$
$^2\text{H}$ (D)	$6.67$	$^{13}\text{C}$	$6.20$
$^{16}\text{O}$	$5.81$	$^{14}\text{N}$	$9.37$

## Modeling

Data analysis is normally performed using optical matrix methods, in which the interface region is modeled as a series of homogenous layers. The layers are each characterized by a thickness [ $\tau$  ( $\text{\AA}$ )], SLD [ $\rho$  ( $\text{\AA}^{-2}$ )], and an interfacial roughness between adjacent layers [ $\sigma$  ( $\text{\AA}^{-1}$ )]. The exact reflectivity can be calculated from such a model; this can be compared with the data, and the model is then refined using least-squares minimization routines. For a more detailed discussion of the analysis of neutron reflectometry data in general, refer to Li et al.<sup>[22]</sup>

## Off-Specular Scattering

If the interface between two regions is rough on a length scale appropriate to the wavelength of the scattering neutrons, then it is possible for some reflection to occur at angles that do not equal the incident angle. In this situation, the scattering, known as off-specular scattering, contains momentum transfer in both the perpendicular ( $Q_z$ ) and horizontal ( $Q_x$ ) directions (see Fig. 2 below showing the geometry of the off-specular scattering experiment). It is therefore theoretically possible to determine, from the pattern of this scattering, information about the horizontal structure in a surface layer.

In practice, the determination of horizontal order is far from a routine procedure. Current instruments are not optimized for the detection of off-specular scattering, particularly at the small dispersive angles

**Fig. 2** The geometry of an off-specular reflection experiment. Here the angle of the reflected beam  $\theta_r \neq \theta_i$ , and there are two components to the total momentum transfer  $Q_{\text{tot}}$ , a vertical ( $Q_z$ ) and a horizontal ( $Q_x$ ) component.

**Fig. 3** Specular reflectivity profile and simple modeled fit to data for C12C12DAB 1% w/w solution in D<sub>2</sub>O at 65°C.

necessary for these DAB measurements, and there have been few measurements making use of this ability. The most notable exceptions are in the field of magnetic thin films, where the ability of polarized neutrons to interact with magnetic fields is employed.<sup>[23]</sup>

### Bulk Solution Measurements

As an aid to modeling the surface conditions, bulk solution measurements are often used as a guide. Small-angle scattering is a well-established technique for determining bulk solution structures of surfactant solutions, which involves measuring the scattering of X-rays or neutrons from solutions in a transmission geometry. This technique is also non-perturbing, and neutron small-angle scattering shares many of the benefits of reflectometry in relation to the ability to alter contrast through the use of isotope labeling. X-ray small-angle scattering has the advantage of being able to make use of the extremely high flux available at modern synchrotron sources, enabling low-contrast (e.g., dilute) solutions to be measured, or measurements with high temporal resolution.

Cryo-transmission electron microscopy (cryo-TEM) is a much more recent technique, which involves taking a thin-film of a surfactant solution and flash-freezing it in near-freezing ethane. The freezing happens so rapidly that the water does not have time to crystallize

and is considered to be much faster than what surfactant rearrangement would be, preserving the room-temperature surfactant structure.<sup>[24]</sup> However, it has been reported that the process of thinning the surfactant solution to an appropriate thickness for flash freezing (100–200 nm) may cause changes to the surfactant structure,<sup>[25]</sup> so that the evidence from cryo-TEM images must always be considered carefully.

## RESULTS

Fig. 3 shows a typical specular reflectivity profile for a sample of C12C12DAB (didodecyldimethylammonium bromide) at 1% w/w in solution, together with a simple modeled fit to the data. The parameters of this optical matrix model can be found in Table 2. Several features are immediately clear. The primary feature is the appearance of strong quasi-Bragg peaks in the specular reflectivity profile. These peaks are indicative of a periodic structure extending into solution perpendicular to the surface. The relatively poor definition of the peaks, and the appearance of subsidiary peaks, implies that the structure consists of a limited number of repeats into the solution. In this case, it appears that the pattern is adequately fit through the use of only two layers, but more detailed modeling<sup>[1]</sup> suggests up to four may be partially complete for this sample. Samples of other DABs show very similar behavior across the same temperature range.

The modeling implies a lamellar structure aligned with the surface, consisting of broad lamellar sheets separated by large solvent-filled voids of the order of 1000 Å. Such a pattern may be observed for several morphologies at the surface, which are illustrated in Fig. 4.

It is difficult to determine from a perpendicular density profile which of these options is the one occurring at the surface. Each could give rise to a periodic density modulation, as seen in the diagram (where the characteristic repeat distance is marked), and the vertical walls in the sponge and vesicle phases would contribute negligibly to the average SLD across the voids in the structure. A significant point that arises from the fitting is that the periodic repeat layer is of low density (approximately 90% solvent content) and much thicker

**Table 2** Parameters of the optical matrix Fit to the Scattering from a C12C12DAB 1% w/w solution in D<sub>2</sub>O at 65°C

Layer	Silicon	SiO <sub>2</sub> layer	Void 1	Layer 1	Void 2	Layer 2
SLD (Å <sup>-2</sup> )	2.07	3.4	−0.2	−0.2	−0.2	−0.2
Thickness/(Å)	n/a	12.0	690	170	630	165
Roughness/(Å)	5.0	5.0	40	30	40	30
Solvent/(%)	n/a	0	100	90	100	93

**Fig. 4** Possible morphologies giving rise to lamellar layers at the surface. (A) Vesicles aligning at the surface; (B) a sponge phase; (C) lamellar sheets, with the characteristic repeat distance  $d$  marked.

than the typical bilayer thickness for a bilayer of a C12-surfactant sheet (ca. 20 Å). The interlayer spacing is also smaller than that calculated for a simple space-filling lamellar bilayer structure at similar concentrations (ca. 2000 Å), implying that this phase does not extend throughout the solution. This coincides with surface force measurements, which do not show any evidence of this phase,<sup>[26]</sup> implying that the layering detected in reflectometry is either too diffuse, too fragile, or both to be detected by a contact method.

These facts can be rationalized differently for each of possible morphologies. For a lamellar system, this observation would be consistent with an undulating bilayer, such that the density of the layer is averaged over the undulation period. This implies undulations of a 100-Å amplitude, which is reasonable for a lamellar sheet at this temperature unconstrained by near neighbors. Conversely, for a vesicular system, the low density and thick layers could be explained by a low horizontal packing density of vesicles, as would be expected given their surface charges and the fact that the curved surface of the vesicle is being projected into a planar averaging. Similar arguments could be used for the sponge phase.

### Comparison with Bulk Structure

Some guidance can perhaps be gained from a knowledge of the bulk behavior of these surfactants. Phase diagrams have been produced for dichain cationic surfactants of these types,<sup>[17,20,27]</sup> which show some general features in common. The first is that they all form a vesicular phase at low concentrations (approximately those of the systems described here, namely, of the order of 1% w/w). The stability of these vesicles has been questioned, it being suggested that they do not form spontaneously (requiring some form of energy input to form, such as sonication or shaking)<sup>[14]</sup> and will spontaneously collapse to a lamellar phase with time.<sup>[17]</sup> The solutions reported here were indeed sonicated on dissolution, but the structuring at the surface is stable over a period of hours, with no visible changes. Another marked difference between the bulk and the surface is that the vesicles imaged in the bulk phase (e.g., through freeze-fracture electron microscopy) are polydisperse, with radii of  $1300 \pm 600$  Å for a solution of C11C12DAB imaged by freeze-fracture TEM.<sup>[20]</sup> The degree of polydispersity would need to be much lower to give rise to the quasi-Bragg peaks

seen in the specular reflectivity profiles measured for these systems.

However, it is also seen that either lamellar or sponge phases can coexist with this vesicle phase. Each of these phases is quite consistent with the simple geometric rationale of surfactant morphologies proposed by Tanford<sup>[28]</sup> and developed by Israelachvili, Mitchell, and Ninham<sup>[29]</sup> as the packing parameter for the dichain surfactants, ca. 0.6 (varying  $\pm 0.01$  depending on the chain length), lies in the middle of the range of lamellar-based structures. It appears that the bulk phase of the dichain surfactants is therefore quite complex and appears to be dependent on the precise history of the sample.

As a result, small-angle scattering and cryo-TEM experiments can be useful to determine the particular nature of these solution phases. Two representative cryo-TEM images are shown below (Fig. 5). These images clearly show that for the same sample, regions of vesicle and lamellar-like structures can be found. Indeed, other images also show that the vesicles and the lamellae were capable of coexisting in the same region. There is no evidence, however, of sponge phase structures found in any of the exposures. The lamellar structures imaged also show that the lamellae seen are not isolated lamellar sheets, but rather appear to be elongated microtubules—connected with a definite interior and exterior (as marked in Fig. 5).

Although the lack of sponge phase observed in the cryo-TEM does not of itself exclude the possibility of sponge phase being found at the surface (particularly given the nature of cryo-TEM discussed above), it seems that this phase is the least likely of the postulated options. The inherently three-dimensional continuous structure of the sponge phase does not pack well into the highly asymmetric and constrained near-surface region and, as such, would need to show some form of transition from a free bulk sponge phase to a surface phase.

In any case, the small-angle scattering experiments provide evidence that the bulk phase behaves significantly differently to the near-surface phase—direct evidence for the limited nature of the surface-induced structural alterations. Although there is some evidence of a lamellar layering in the small-angle X-ray scattering, the structure is not as pronounced as that found at the surface (see Fig. 6 for a comparison of the structuring found for C12C12DAB, 1% w/w solution, for example) nor does bulk spacing (when observed) correspond to the surface spacing.

The differences between the bulk and the near-surface are also seen in the temperature response of the two systems. The interlayer spacing of the near-surface phase is highly sensitive to the temperature, generally decreasing with increasing temperature, as seen by the shift in the quasi-Bragg peaks in the

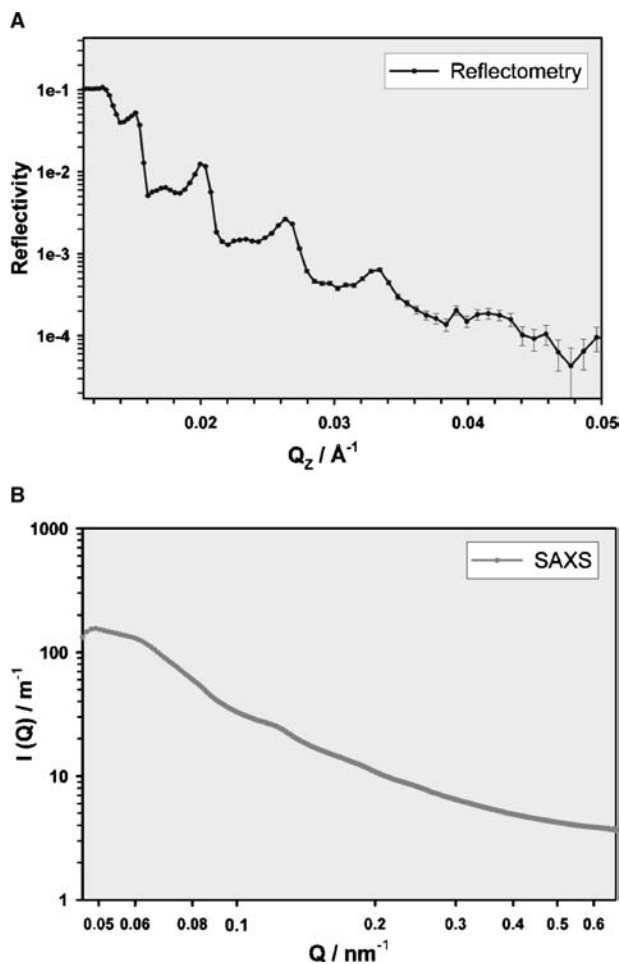

**Fig. 5** Cryo-TEM images of C12C12DAB 2% w/w solution flash-frozen from ca. 25°C; (A) showing polydisperse unilamellar vesicles in the solution; (B) showing the “extended vesicle” or microtubules. The closure is marked with an arrow. Both images are taken from different areas of the same sample, scale as marked.

scattering (Fig. 7). This type of temperature dependence at the surface has previously been reported for the lamellar phase of a 2% solution of NaAOT (sodium bis(2-ethylhexyl)sulfosuccinate) at the silicon–water interface, where the spacing changes from 270 Å at 5°C to 165 Å at 35°C.<sup>[30]</sup> In that system, the change in spacing was attributed to a change in an equilibrium between a micellar and a lamellar phase, where the surface structure was unambiguously lamellar extending thousands of layers into solution.

This change of spacing is reversible over at least a 30°C temperature range, which is also in contrast to the bulk solution, which is shown by small-angle

**Fig. 6** Comparison of structuring for C12C12DAB 1% w/w solution at 45°C at the surface and in the bulk solution from (A) reflectometry and (B) small-angle scattering.

scattering to be only broadly reversible (Fig. 7). This implies that the surface layer is in equilibrium at the surface and also that the time taken for the surface phase to reach this stable position is less than the equilibration time allowed after temperature changes (< 1 hr).

The temperature dependence can again be justified in terms of both the vesicular and lamellar morphologies at the surface. As the temperature increases, the solvation shell of headgroups will decrease, and the degree of ionization of the bilayer will increase—effects which will tend to increase the rigidity of the bilayer and hence decrease the degree of fluctuation–repulsion. However, this effect will be offset by the increased thermal energy of the bilayer and the increased electrostatic repulsion of the more highly charged layers, and the net effect is difficult to predict.

In the case of the vesicular morphology, in particular, attention needs to be given to the manner of how exactly the interlayer spacing might change. The direct implication is that the vesicles themselves change

**Fig. 7** The change in the d-spacing of the surfactant solution as determined from neutron reflectivity and small-angle scattering. The arrows indicate the direction of the temperature cycles in testing the reversibility of changes.

size, achieved either through the smooth aggregation of smaller vesicles to form larger vesicles (equivalently budding material on warming) or the loss of material to free surfactant as the solubility increases with temperature. Simple calculations for C12C12DAB show, for a unilamellar spherical surfactant vesicle, that the decrease in the volume of the bilayer in going from 1100 to 600 Å (between 40°C and 70°C) is approximately 70% of the original volume, equivalent to an increase of solubility of the order of 100 times. This is much greater than the predicted change in solubility, which means the former mechanism must be dominant to explain the behavior seen here for spherical vesicles.

### Off-Specular Scattering

The samples exhibit significant off-specular scattering associated with the quasi-Bragg peaks, indicative of a degree of lateral ordering. Unfortunately, the length scale of the lateral resolution of the measurements is much larger than the equivalent vertical dimension (micrometers rather than angstroms), which means that any interference patterns on the same length scale as those found in the specular scattering, as might be envisioned from a horizontally ordered vesicular layer, would not be seen.

The scattering which is seen consists of bands of scattering across a range of  $Q_x$  at constant  $Q_z$  (Fig. 8). The question of whether this is true near-surface scattering, or instead derives from the bulk, can be answered by reference to two features of the scattering—namely, the centering of the off-specular intensity decay on the specular ridge and the appearance of curvature in the bands as a result of refraction in the  $\text{D}_2\text{O}$  sample, which is absent in the sample

**Fig. 8** Off-specular scattering from C12C12DAB 1% w/w in (A) D<sub>2</sub>O and (B) CMSi, a mixture of H<sub>2</sub>O and D<sub>2</sub>O with a SLD equal to that of silicon crystal ( $\rho = 2.07 \times 10^{-6} \text{ \AA}^{-2}$ ).

contrast-matched to silicon (CMSi). This is also similar to the pattern seen for NaAOT and is believed to arise from correlated undulations between layers such as might be seen from the natural layer undulations.<sup>[31]</sup> These undulations might arise from either vesicular or lamellar membranes, but in the case of lamellar sheets, the large distance between the layers begs the question of the source of the correlation between the layers, failing connection between the sheets.

## CONCLUSION

While it is clear that the system in question exhibits unusual surface properties, and that there is indeed a

near-surface phase which differs from the bulk, it is extremely difficult to distinguish the possibilities that make up the structure. It is known that sponge, lamellar, and vesicular phases can exist in the solution, depending on the individual route of the preparation of the sample, but it is clear from small-angle scattering measurements that the surface is not exhibiting the same characteristics as the bulk. The exact surface density distribution, the temperature dependence of the structure, and the off-specular scattering all provide constraints on the possibilities at the surface, but none of these specifically excludes any of the candidates. A sponge phase seems the least likely because of the complexity of the phase in the dimensionally constrained near-surface region and necessity for the phase to align with the surface. Simplicity suggests that the best candidate for the surface might be a lamellar phase; this, however, represents extremely large spacing for a lamellar phase, and it is difficult then to explain the correlated nature of the undulations seen from the off-specular scattering.

The third choice, vesicles, has its own complications—in particular, that the vesicles would be more monodisperse than the bulk solution, and that the mechanism for the change in the size of the vesicles with temperature is unclear. Perhaps the most reasonable compromise is suggested by the cryo-TEM images, which show the existence of an intermediary phase between vesicular and lamellar, equivalent to extended vesicles (microtubules). However, it does not seem possible to distinguish these possibilities based on the evidence now available.

## ACKNOWLEDGMENTS

I would like to acknowledge the assistance in preparing this manuscript received from Dr. R.K. Thomas (University of Oxford, Oxford, United Kingdom) and the many useful conversations with Prof. J. Penfold (ISIS Facility, Rutherford-Appleton Lab, Didcot, United Kingdom) and Prof. A. Rennie (Studsвик, Uppsala University, Sweden). I would also like to acknowledge the assistance of Hanna Vacklin (University of Oxford) and Dr. Gunnel Karlsson at the University of Lund, Sweden, for assistance in obtaining the cryo-TEM images, and the Rhodes Trust, Oxford, for financial support through a scholarship.

# Organofullerenes in Water

Eiichi Nakamura

Hiroyuki Isobe

Department of Chemistry, University of Tokyo, Tokyo, Japan

## INTRODUCTION

Fullerenes<sup>[1–4]</sup> are entirely insoluble in water and by themselves do not show appreciable biological activity. However, suitable chemical modification allows the molecules to dissolve in aqueous solution to exhibit significant activity. In 1993, three papers reported simultaneously on the biological activities of fullerene carboxylic acids **1** and **2** (Fig. 1).<sup>[5–8]</sup> Studies ensued afterward revealed various interesting biological activities of organofullerenes owing to their photoactivity, radical quenching activity, and hydrophobicity.<sup>[9–11]</sup> The interests in biology stimulated the studies on the behavior of fullerenes in water and led to new discoveries on the formation of one- to three-dimensional supramolecular objects, including vesicle, rod, globule, membrane, and linear assemblies. Several fundamental properties of fullerenes form the background of such interest in fullerenes in water: extremely high hydrophobicity, high cohesive force between fullerene molecules,<sup>[12,13]</sup> photoactivity,<sup>[14]</sup> ability to accept and release electrons,<sup>[15]</sup> and relatively high reactivity that allows structural modifications.<sup>[16,17]</sup> This article highlights the behaviors of organofunctionalized fullerenes in water.

## BIOLOGICAL EFFECTS OF WATER-SOLUBLE FULLERENES

An obvious obstacle for the studies of fullerenes in water is the lack of solubility of fullerenes in water.<sup>[18–22]</sup> One approach to solve the issue utilizes a solubilizing agent such as polyvinylpyridone<sup>[23]</sup> or cyclodextrin,<sup>[24]</sup> and the other relies on introduction of hydrophilic function(s) by chemical modification of the molecule. Attachment of amino or hydroxyl groups<sup>[25]</sup> is straightforward but affords an inseparable mixture comprising many products of similar properties. Carbon–carbon bond forming modifications of fullerenes is more selective. The compounds **1** and **2** represent the compounds in this category (Fig. 1).

Nakamura et al.<sup>[26]</sup> synthesized the compound **1** and discovered that the compound shows significant

biological activities.<sup>[5]</sup> The compound **1** (and later its C<sub>70</sub> analog)<sup>[27]</sup> suppresses growth of mammalian cells, inhibits activity of various enzymes (including HIV protease, which they found later; Fig. 3),<sup>[28]</sup> and cuts DNA upon visible light irradiation. Later studies indicated that the cleavage is caused by active oxygen species generated by fullerene-sensitized activation of molecular oxygen in the medium (Fig. 2).<sup>[29,30]</sup> The carboxylic acid **1** does not bind to DNA.<sup>[31]</sup>

Papers from 1993<sup>[6–8]</sup> described inhibition of HIV protease by the compound **2**. The dicarboxylic acid **2** acts as a reversible inhibitor of the enzyme through binding to the cleft-like active site of the enzyme in competition with the natural peptide substrate. This shape-recognition binding is illustrated in Fig. 3 for the carboxylic acid **1**.<sup>[28]</sup> A dendritic variation of the fullerene inhibitor is studied for treatment of drug-resistant HIV.<sup>[32,33]</sup>

## Pharmacokinetics and Toxicity of Water-Soluble Fullerenes

Toxicity is the primary concern for people working on fullerenes on the bench. Although earlier studies on C<sub>60</sub> itself suggested low toxicity,<sup>[34–36]</sup> it was unclear if water-soluble fullerenes are also innocuous molecules. For the studies of the pharmacokinetic behavior of water-soluble organofullerenes, Nakamura et al.<sup>[37–40]</sup> synthesized the compounds **1** and **1-C14** starting with an alkoxy-substituted methylenecyclopropane by the use of radiolabeled trimethylenemethane chemistry as shown in Fig. 4.

The radiolabeled water-soluble fullerene **1-C14** quickly migrates through the body and accumulates mainly in the liver after a few hours. Importantly, the study also suggested that the fullerene molecule can pass through the blood–brain barrier, which was later confirmed by others.<sup>[41,42]</sup> The behavior stands in sharp contrast to the parent fullerene, which was absorbed by serum protein in blood quickly after injection.<sup>[34–36]</sup> The pharmacokinetic studies have shown that organofullerenes are excreted either slowly or rapidly depending on the substituents, which may be suitably modified under the capacity of medicinal chemists.<sup>[43]</sup>

**Fig. 1** Monocarboxylic and dicarboxylic acids **1** and **2**.

The toxicity studies on the carboxylic acid **3** showed that the molecule does not show serious acute toxicity. Thus upon injection of up to 500 mg/kg quantity of the compound **3** to female mice, all mice survived for 1 week. Later studies<sup>[44-46]</sup> also indicated that the fullerene molecules do not show appreciable short-term toxicity. Long-term toxicity has so far not been reported, and little has yet been known for degradation of fullerenes in the environment.<sup>[47,48]</sup>

### Selective Binding to DNA

The initial discoveries made for the two simple molecules **1** and **2** quickly led to the studies on further application using more complex molecules. A fullerene molecule was connected to a 14-mer oligonucleotide that is complementary to single and double helix.

The fullerene/DNA conjugate **4** was found to bind to the target DNA site (Fig. 5),<sup>[49]</sup> cleaving the guanine bases in the position expected on the basis of complementary of triple helix formation. A similar result was reported for a fullerene conjugate bearing a 31-mer DNA recognition site.<sup>[50]</sup> The binding ability of such DNA/fullerene conjugates has been assessed.<sup>[51]</sup> Fullerene molecules bearing an intercalating group have been shown also to bind to double-strand DNA.<sup>[52]</sup>

One application of the above study is the photodynamic therapy of cancer. A C<sub>60</sub> derivative bearing polyether side chains was found to shrink skin cancer in mice.<sup>[53]</sup> In vivo ultrasound irradiation of fullerene-containing tissue may also suppress tumor growth.<sup>[54,55]</sup> Inactivation of virus has also been reported.<sup>[56]</sup> The actual biological targets of these approaches still remain unclear, although DNA may be a possible candidate.

**Fig. 2** DNA cleavage by fullerene carboxylic acid **1**.

**Fig. 4** Pharmacokinetics of radiolabeled fullerene carboxylic acid **1-C14**.

## Gene Delivery

Delivery of gene into living cells through encapsulation of the gene in a “vector” is a fundamental technology in modern biology.<sup>[57]</sup> This process called “transfection” (transfer + infection) allows the production of the protein encoded in the delivered DNA within the cell. Recent studies indicated that suitably modified fullerene molecules are effective for the gene delivery.

A series of fullerenes bearing amino side chain(s) has been synthesized and was examined for their DNA binding ability as well as their transfection capability.<sup>[58]</sup> The  $C_{2}$ -chiral two-handed fullerene **5** was synthesized by double [3 + 2] cycloaddition of a bis-cyclopropenone acetal that took place with complete regioselectivity to give the desired compound.<sup>[59]</sup>

Some representative examples of the DNA-binding fullerenes (**5–8**) are shown in Chart 1.<sup>[58,60–63]</sup> As a solution of a 4.5-kbp plasmid DNA with a reporter gene

**Fig. 5** Triple helix forming fullerene/DNA conjugate **4** (CPK model), its three-dimensional binding model, and site-selective photo-cleavage of DNA (as indicated by arrows).

Chart 1 Representative DNA binding fullerenes examined for transfection.

was mixed together with a solution of the two-handed tetraminofullerene **5** in buffer, particles of 0.5–3  $\mu\text{m}$  diameter form as observed by optical microscope (Fig. 6). When this mixture was incubated with dividing mammalian cells, the dark-colored fullerene/DNA particles were taken into the cells, and protein production occurred. Screening of various cell lines indicated that the efficiency of this first-generation

fullerene vector is comparable to or better than the commercially available lipid-based vectors.

When a double-strand DNA is treated with an aminofullerene **7**, the fullerene molecules stick to the DNA strand without much changing the linear outline of the DNA as studied by TEM.<sup>[62,63]</sup> In spite of its binding ability, aminofullerene **7** is not effective for gene delivery.

Fig. 6 Delivery of green fluorescent protein (GFP) plasmid into COS-1 cells with **5**. Bars show 100  $\mu\text{m}$ . (A) Differential interference contrast microscopy (DIC) micrograph of COS-1 cells and small black particles (1–10  $\mu\text{m}$ ) of the fullerene/DNA complex after 1-hr transfection time. (B) DIC micrograph of COS-1 cells after 2-day incubation time. (C) Fluorescence image of the area same as (B). (D) Superimposed photograph of (B) and (C). Round black clumps of 0.5–3  $\mu\text{m}$  size observed in the fluorescent cells contain fullerene materials. *Source:* Adapted from “Functionalized fullerene as a new artificial vector for transfection,” in *Angew. Chem.*<sup>[31]</sup>.

## Neuron Protection

In 1997, it was reported that the fullerene hexacarboxylic acid **9** acts as a drug for neurodegenerative diseases such as Alzheimer's, Parkinson's, or amyotrophic lateral sclerosis (ALS).<sup>[41]</sup> The activity is considered to arise from trapping of hydroxy radicals by the fullerene molecule.<sup>[64]</sup> The finding is currently developed for clinical trials.

## Endohedral Metal Complexes

Metal-containing fullerenes are attracting people's attention for their clinical applications. Biodistribution studies of <sup>166</sup>Ho<sub>x</sub>@C<sub>82</sub>(OH)<sub>y</sub> showed the uptake of the polyhydroxylated fullerene by bone without clearance and may be used as in vivo radiotracer.<sup>[42]</sup> The use of metallofullerenes as a magnetic resonance imaging (MRI) contrast agent is another area of extensive current studies. Gd@C<sub>82</sub>(OH)<sub>n</sub> was found to be a much better contrast agent than the conventional agents (i.e., a nitrogen-ligand coordinated to the metal).<sup>[65,66]</sup> The metal-containing fullerene accelerates spin relaxation (*T*<sub>1</sub>) of water protons that surrounds the fullerene molecule. The water proton relaxivity *R*<sub>1</sub> is much higher (20-folds) than that of the MRI contrast agent currently in use (e.g., Magnevist®, gadolinium-diethylenetri-aminepentaacetic acid). Polycarboxylic acid derivatives of Gd@C<sub>82</sub> also serve as an excellent contrast agent.<sup>[67]</sup>

## MOLECULAR ASSEMBLY OF WATER-SOLUBLE FULLERENES

Many of "water-soluble" fullerenes do not simply dissolve in water, but form various intriguing supramolecular structures, some of which have been unknown for conventional surfactants and lipid molecules. Various new discoveries have been made in recent years with respect to the formation of one- to three-dimensional supramolecular objects, including vesicle, rod, globule, membrane, and linear assemblies.

Fig. 7 Molecular model of LB film of **1**.

## Langmuir-Blodgett Film

Formation of molecular layers of fullerene and their derivatives has attracted the attention of scientists for a long time, yet earlier attempts to make uniform monolayer of C<sub>60</sub> were rather unsatisfactory.<sup>[68]</sup> The amphiphilic fullerene carboxylic acid **1** was reported in 1995 to form a uniform Langmuir-Blodgett (LB) film at the water-air interface.<sup>[69]</sup> The average area per molecule determined by the  $\pi$ -A plot was 0.78 nm<sup>2</sup>, and the distance between the neighboring C<sub>60</sub> was 0.95 nm, which is close to (but slightly smaller than) the distance of 1.0 nm determined in the crystal structure of C<sub>60</sub>. Atomic force microscopic (AFM) analysis indicated that the surface contains far less defects than the LB film made from unmodified C<sub>60</sub> under similar conditions (Fig. 7).

## Nanorod and Nanoparticles

Rod-like assembly of fullerene forms when a DMSO solution of a cationic amphiphile **7** is dispersed in benzene.<sup>[62,63]</sup> The nanorods measure a diameter of 14–120 nm and a length of over 70  $\mu$ m. When the dispersion is sonicated, vesicles of various sizes and shapes form. The thickness of the vesicle wall (3–6 nm) suggests a multilamellar structure.<sup>[70]</sup> Georgakilas et al.<sup>[71]</sup> also reported that cationic amphiphiles form nanospheres and nanorods.

## Bilayer Vesicles

Ph<sub>5</sub>C<sub>60</sub>H (**10**) is an interesting hydrocarbon<sup>[72–74]</sup> in that its anion, Ph<sub>5</sub>C<sub>60</sub>K (**11**), dissolves freely in water (Scheme 1). It dissolves in water not as unimer, but as spherical aggregates.<sup>[75]</sup> Atomic force microscopy

Scheme 1

and laser light scattering (LLS) studies of the solution of **11** indicated that the solution contains bilayer vesicles and that the size distribution is quite narrow.<sup>[76]</sup> Thus upon slow addition of a THF solution to water,  $\text{Ph}_5\text{C}_{60}\text{K}$  forms spherical bilayer aggregates of 34-nm average diameter composed of about 13,000 fullerene molecules as determined by LLS (Fig. 8). This ability of  $\text{Ph}_5\text{C}_{60}\text{K}$  to form vesicles in water is the most intriguing. The  $\text{Ph}_5\text{C}_{60}$  anion amphiphile is noteworthy for its virtually all- $\text{sp}^2$  carbon framework, high structural rigidity, spherical hydrophobic moiety, and the lack of heteroatom hydrophilic sites.<sup>[77]</sup> In addition, the fullerene moiety is unique because it is highly hydrophobic but not lipophilic.

Penta-arylated  $\text{C}_{60}$  bears large aryl groups to form a cavity that can recognize another  $\text{C}_{60}$  molecule. Such a

molecule **12** looks like a badminton shuttlecock and stacks with each other to form a one-dimensional array of both in crystals and in liquid crystals (Fig. 9).<sup>[78]</sup> One may expect that, with suitable modifications, such “nanoshuttlecock” would also be useful for the formation of supramolecular structures in aqueous solutions.

### DNA/Fullerene Nanoparticles

The aforementioned experiments of gene delivery demonstrated the ability of the fullerene **5** to condense and to release DNA, and the molecular nature of the DNA condensation/release process was probed in test-tube experiments with AFM.<sup>[79]</sup> When half an equivalent/base pair of the fullerene **5** was mixed with 4-kbp plasmid DNA (Fig. 10A), the DNA molecule was condensed into a globular object seen in Fig. 10B as a flat disc of 3-nm thickness and 50-nm diameter. This condensate comprises one molecule of the plasmid DNA and about 2000 molecules of the fullerene derivative. Upon further addition of fullerene **5**, many single-molecule DNA condensates gather together to

**Fig. 8** Atomic force microscopic image of bilayer vesicle of **11** and the molecular model obtained by LLS study. *Source:* Adapted from “Spherical bilayer vesicles of fullerene based surfactants in water: A laser light scattering study,” in *Science*.<sup>[76]</sup>

**Fig. 9** Nanoshuttlecock molecule **12** and a three-dimensional model of the stack-of-five molecules.

**Fig. 10** Condensation of 4-kbp plasmid DNA (A) into globules with increasing amount of **5** (B and C) and its release upon removal of fullerene (D). *Source:* Adapted from “Atomic force microscope studies on condensation of plasmid DNA with functionalized fullerene,” in *Angew. Chem.*<sup>[79]</sup>.

form the micrometer-sized object (Fig. 10c). Release of the DNA molecules from these large particles was achieved (Fig. 10d) by extractive removal of the fullerene with  $\text{CHCl}_3$ .

The formation of globular condensates composed of a single to a few DNA molecules is unique among other DNA-condensation studies based on lipid and dendrimeric molecules, which create much larger and less structurally defined DNA condensates.<sup>[80]</sup> Studies on a series of DNA-binding aminofullerenes recently showed that DNA condensation is required, but not sufficient for successful transfection.<sup>[60,61]</sup>

### Fullerene-Binding Antibody

A fullerene binding protein has been elicited purposely.<sup>[81]</sup> Immunization of mice with a  $\text{C}_{60}$ -bovine thyroglobulin (>600 kDa) conjugate elicited the desired IgG isotype antibody. Crystal structure of Fab fragment of the antifullerene antibody revealed that a shape-complementary clustering of hydrophobic amino acids forms a fullerene binding site.<sup>[82]</sup> Modeling study shows participation of the induced fit mechanism in the binding process. Interestingly, a subpopulation of the antibodies also recognizes  $\text{C}_{70}$  and even carbon nanotubes.<sup>[83–85]</sup>

### CONCLUSION

The development of the science of water-soluble fullerenes has been very rapid. The molecular design starting

from the compounds **1** and **2** has become much more elaborate and the synthesis has become more sophisticated, leading recently to the synthesis of the most complex compounds in high yield and on a large scale. Practical applications to clinical and materials uses are therefore just ahead. The science of water-soluble fullerene stimulated the studies to dissolve also carbon nanotubes in water and organic solvent.<sup>[86,87]</sup> The high cost of fullerenes has been the biggest barrier toward practical applications of any fullerene derivative, and this problem is now resolved by a large-scale production achieved by a Japanese company.<sup>[88]</sup> The cost problem is still a big issue in the use of metal-containing fullerenes, but may be resolved in the not-too-distant future.

# Organosilanes: Molecular Assembly

Atsushi Takahara

*Institute for Fundamental Research of Organic Chemistry, Kyushu University, Fukuoka, Japan*

## INTRODUCTION

Ultrathin films of organosilane have been identified as promising nanocoating for micro- and nanoscale technologies such as electronic devices and micromachines.<sup>[1–3]</sup> As the silanol groups of organosilane monolayer prepared from organotrichlorosilane or organotrialkoxysilane strongly interact with the substrate surface, the monolayer is thermally and chemically robust compared with conventional amphiphilic monolayers. Because the chain length of organosilane is approximately 1–3 nm, the organosilane forms a uniform ultrathin film on the substrate surface.

Two methods have been proposed for the preparation of organosilane monolayers. One is chemisorption from organosilane solution,<sup>[4–7]</sup> and the other is the Langmuir–Blodgett (LB) method.<sup>[8–22]</sup> Fig. 1 shows the film-formation mechanisms of the organosilane by the LB method (A) and the chemisorption method (B). In the case of the LB method Fig. 1A, the toluene solution of organotrichlorosilane was spread on the water surface (pH = 5.8) at a controlled subphase temperature. To attain the quasi-equilibrium state of the monolayer, the monolayer was kept on the water subphase under a given constant surface pressure for 15 min. The monolayer was transferred and immobilized onto the Si-wafer substrate surface by the LB method. In the case of chemisorption Fig. 1B, organosilane molecules were deposited either from the solution or from the vapor phase. It has been clarified that the aggregation state of the organosilane monolayers prepared by the LB method shows a higher packing density than the chemisorbed monolayers.<sup>[15,22]</sup>

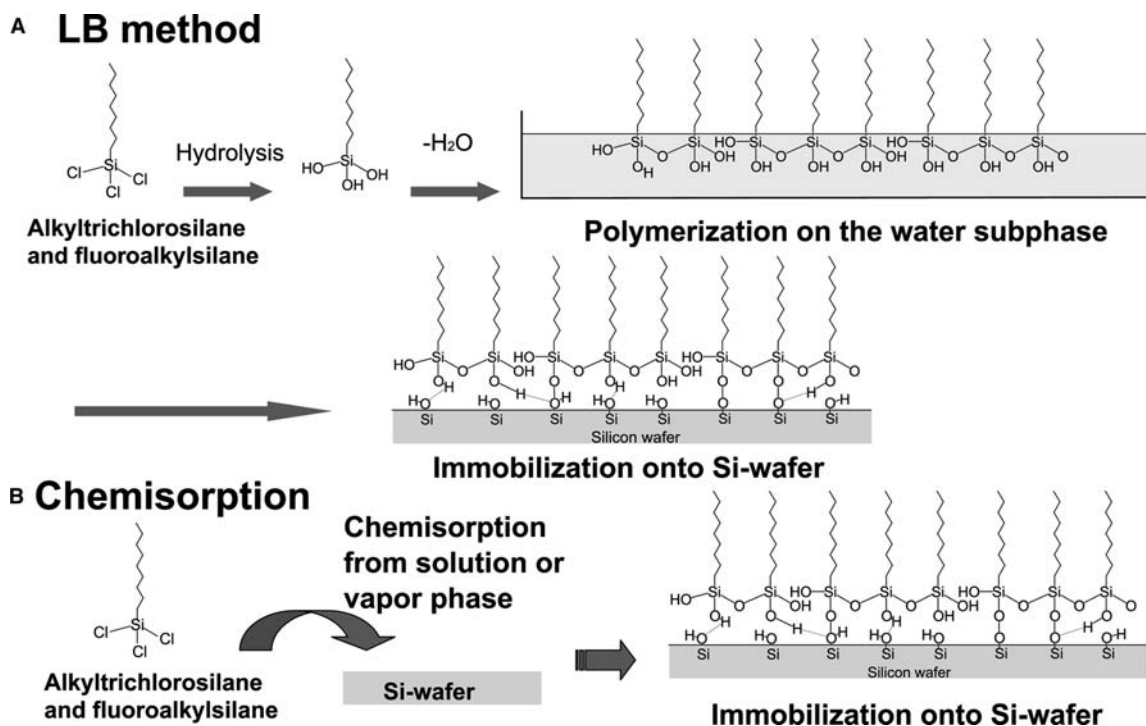

Organosilane monolayers, which have surfaces terminated by various functional groups, are useful for manipulation of the physicochemical properties of solid surfaces such as wettability, nanotribology, and protein adsorption behavior. A key to fabricating functional organosilane monolayers is controlling the distribution of surface functional groups. Fabricating micro- and nanodevices using a bottom-up approach requires building blocks with a precisely controlled and tunable chemical composition, morphology, and size that can be fabricated virtually at will. The

organosilane monolayer is a candidate for such a building block because of its stability and ease of fabrication. Patterned microfeatures of organosilane monolayers can be fabricated on the substrate, allowing surface physicochemical properties to be area-selectively controlled. Two methods will be discussed in this article. One of them utilizes crystallization of organosilane of the binary component monolayer at the air/water interface.<sup>[8–11]</sup> Because the diffusion of organosilane molecules at the air/water interface is slow, macroscopic phase separation is inhibited, even with the alkylsilane and fluoroalkylsilane mixed monolayers. The phase-separated monolayer is transferred to the Si-wafer substrate by the LB method. Another method utilizes photolithography by a vacuum ultraviolet (VUV) ray source.<sup>[23,24]</sup> In the case of a VUV source with  $\lambda = 172$  nm, photodecomposition of the organic moiety occurs because of the higher photon energy of the VUV ray compared with the bond energy of a typical C–C linkage. Using photolithography, one can prepare a micropatterned surface with various organosilane monolayers by repeating the photodecomposition and chemisorption processes. By changing the shape and area ratio of the patterns of the photomask, this technique enables one to control the area ratio and the wettability gap of different organosilane monolayers.

## PATTERNING OF ORGANOSILANE MONOLAYERS VIA CRYSTALLIZATION AT THE AIR/WATER INTERFACE

### Formation of Organosilane Monolayers at the Air/Water Interface

Fig. 2 shows the chemical structure of organosilanes used for monolayer preparation. Organotrichlorosilane is primarily used for monolayer preparation at the air/water interface. Lignoseric acid [LA,  $\text{CH}_3(\text{CH}_2)_{22}\text{COOH}$ ] is also used to prepare the mixed monolayers. LA is not polymerized and is also non-reactive against the silicon substrate. The chlorine groups of organosilane on the water surface were found to be substituted by hydroxyl groups. At a

**Fig. 1** Film formation mechanism of organosilane by Langmuir–Blodgett (LB) method (A) and chemisorption method (B).

surface pressure of  $10\text{--}30\text{ mN m}^{-1}$ , the hydroxyl groups in organosilane molecules reacted with those in adjacent molecules in the case of the highly condensed monolayer, resulting in formation of a polymerized monolayer. The polymerized monolayer was easily transferred onto a Si wafer by the LB method,

and the residual hydroxyl groups could be covalently bonded with silanol groups on the Si wafer surface.

**Fig. 3** shows the surface pressure–area ( $\pi$ – $A$ ) isotherms for the *n*-octadecyltrichlorosilane (OTS), *n*-dodecyltrichlorosilane (DDTS), [1H,1H,2H,2H-perfluorododecyloxy]propyltriethoxysilane (FDOPTES), and [2-perfluorooctyl]ethyltrichlorosilane (FOETS) monolayers on the water surface at a subphase temperature of 293 K, as well as electron diffraction (ED) patterns of the monolayers transferred onto the hydrophilic SiO substrate on the EM grid at a surface pressure of approximately  $20\text{ mN m}^{-1}$ . The  $\pi$ – $A$  isotherms of the OTS and FDOPTES monolayers showed a steep increase in surface pressure with decreases in the surface area. The molecular occupied areas were determined to be  $0.24$  and  $0.29\text{ nm}^2\text{ molecule}^{-1}$  for the OTS and FDOPTES monolayers, respectively. Electron diffraction patterns of both the OTS and the FDOPTES monolayers showed hexagonal crystalline arcs at 293 K. The (10) spacings of the OTS and the FDOPTES monolayers were calculated to be ca.  $0.42$  and  $0.50\text{ nm}$  based on ED patterns, respectively.<sup>[18]</sup> These ED results make it clear that the hydrophobic alkyl and fluoroalkyl chains in the crystalline OTS and FDOPTES monolayers were closely packed in the hexagonal crystal lattice at 293 K.

High-resolution atomic force microscopy (AFM) was applied to observe the molecular arrangement of both the crystalline OTS-C18 and FDOPTES monolayers. **Fig. 3** also displays AFM images on a molecular

**Fig. 3**  $\pi$ - $A$  isotherms for the OTS, DDTS, FDOPTES, and FOETS monolayers on the water surface at a subphase temperature of 293 K, as well as the AFM images and ED patterns of the monolayers transferred onto the substrate at the surface pressure of around  $20 \text{ mN m}^{-1}$ .

scale for the crystalline OTS-C18 and FDOPTES monolayers transferred onto a Si wafer at a surface pressure of  $15 \text{ mN m}^{-1}$  at 293 K.<sup>[18]</sup> The (10) spacing was evaluated to be ca. 0.42 and 0.50 nm by two-dimensional fast Fourier transform (2-D-FFT). These values are in good agreement with the (10) spacings determined from the ED patterns for the crystalline OTS and FDOPTES monolayers. Thus, it is conceivable that the higher portions (the brighter dots) in the AFM images of Fig. 3 correspond to the individual methyl group of the OTS molecule and the fluoromethyl group of the FDOPTES molecule in the monolayers, respectively. In contrast, the  $\pi$ - $A$  isotherms for the DDTS monolayer and the FOETS monolayer with a shorter alkyl chain showed a gradual increase in surface pressure with decreasing surface area. In general, this can be interpreted as an indication that the monolayer is in a liquid-condensed or liquid-expanded state. In addition, the ED patterns of the DDTS and the FOETS monolayers showed an amorphous halo at 293 K. Hence, it can be envisaged that the chain lengths of hydrophobic groups of the DDTS and the FOETS molecules were not long enough to crystallize on the water subphase at 293 K.

### Phase Separation of Mixed Monolayers at the Air/Water Interface

Phase separation is expected to occur in the binary component monolayer of crystalline OTS and amorphous FOETS because of the incompatibility of OTS and FOETS. Fig. 4 shows the  $\pi$ - $A$  isotherm and the AFM

image of the scanned area  $10 \times 10 \mu\text{m}^2$  for the OTS/FOETS (50/50 mol/mol) mixed monolayer, which was transferred onto the Si wafer substrate by the LB method at a surface pressure of  $25 \text{ mN m}^{-1}$ . The height profile along the line shown in the AFM image revealed that the brighter and darker portions in the AFM image correspond to the higher and the lower

**Fig. 4**  $\pi$ - $A$  isotherm and AFM image of the scanned area  $10 \times 10 \mu\text{m}^2$  for the OTS/FOETS (50/50) mixed monolayer, which was transferred onto the Si wafer substrate by the LB method at the surface pressure of  $25 \text{ mN m}^{-1}$ .

regions of the monolayer surface, respectively. The molecular occupied area (the limiting area) of  $0.28 \text{ nm}^2 \text{ molecule}^{-1}$  for the OTS/FOETS (50/50) mixed monolayer appears to be almost equal to the average of the molecular occupied area for the OTS ( $0.24 \text{ nm}^2 \text{ molecule}^{-1}$ ) monolayer and the FOETS ( $0.31 \text{ nm}^2 \text{ molecule}^{-1}$ ) monolayer based on the molar fraction of OTS and FOETS. The OTS/FOETS mixed monolayer can be transferred onto the Si wafer substrate over a wide range of surface pressure. The transfer ratio of the OTS/FOETS mixed monolayer was ca. 1.0 at a surface pressure of  $25 \text{ mN m}^{-1}$ , indicating that the substrate surface is almost completely covered with the immobilized mixed monolayer. Also, the transfer of the OTS/FOETS mixed monolayer on the silicon substrate was confirmed by using attenuated total reflection Fourier transform infrared (ATR-FT-IR) spectroscopy and X-ray photoelectron spectroscopy (XPS). Because the area occupied by the circular flat-topped domains increases with increases in the OTS content, it is expected that the circular domains correspond to the OTS domain. The AFM line profile revealed that the circular domains were 1.1–1.3 nm higher than the surrounding area. Because the difference in molecular lengths between OTS and FOETS was ca. 1.3 nm, it can be concluded that the higher circular domains and the surrounding flat matrix regions were composed of OTS and FOETS molecules, respectively. OTS molecules formed circular domains even if the molar percent of OTS molecules was 75%. It is apparent from the ED pattern of the OTS/FOETS (75/25) mixed monolayer that the OTS domain is in a crystalline state, as the ED pattern showed a Debye ring and the magnitude of spacing corresponds to the (10) spacing of the OTS monolayer. In the case of the mixture of fluoroalkane and alkane, macroscopic phase separation was observed. However, in the case of organosilanes at the air/water interface, macroscopic phase separation such as that occurring with coalescence of the crystalline domain is inhibited because of the limited diffusion at the air/water interface.

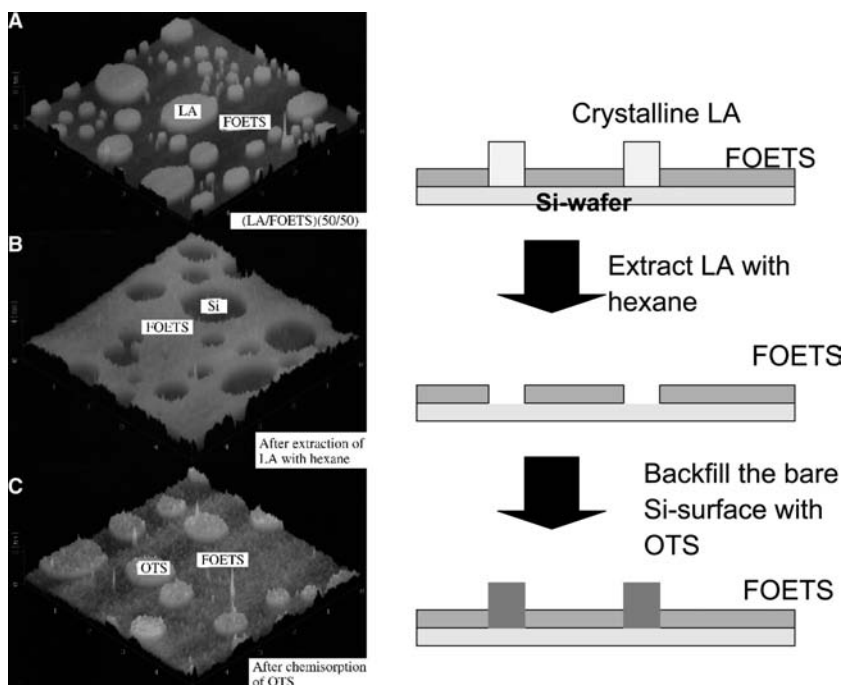

A similar phase-separated structure was also expected for the mixed monolayer of the crystalline NTS and amorphous FOETS. Crystallization of the *n*-non-adeceyltrichlorosilane (NTS) phase was confirmed by ED.<sup>[17]</sup> Fig. 5 shows the AFM images of the mixed NTS/FOETS and carboxylated NTS (NTS<sub>COOH</sub>)/FOETS monolayers. It was clarified that the NTS/FOETS mixed monolayers were in a phase-separated state, and that circular flat-topped domains ca. 1–2 μm in diameter were surrounded by a sealike flat region. The phase separation in the mixed NTS/FOETS can also arise from crystallization of the NTS component. The NTS<sub>COOH</sub>/FOETS mixed monolayer was prepared through oxidation of the vinyl end groups of the NTS phase in the NTS/FOETS

**Fig. 5** AFM images of the mixed NTS/FOETS and carboxylated NTS (NTS<sub>COOH</sub>)/FOETS monolayers.

mixed monolayer.<sup>[17]</sup> The NTS<sub>COOH</sub> monolayer showed high surface free energy, with the magnitude being comparable to that of water. The surface morphology of the NTS/FOETS mixed monolayer was not changed even after oxidation because of the presence of a strong interaction between silanol groups of NTS and the Si wafer. The height difference between the NTS<sub>COOH</sub> domain and the FOETS matrix phase in the NTS<sub>COOH</sub>/FOETS mixed monolayer was almost the same as that for the NTS/FOETS mixed monolayer. In addition, an XPS measurement was performed for the NTS/FOETS and the NTS<sub>COOH</sub>/FOETS mixed monolayers to confirm oxidation of the NTS phase. The larger ratio of oxygen/carbon atoms for the (NTS<sub>COOH</sub>/FOETS) mixed monolayer than that for the NTS/FOETS monolayer suggests that the vinyl end groups of the NTS molecules were oxidized to carboxyl groups. The magnitude of the lateral force of the NTS<sub>COOH</sub> phase was higher than that of the FOETS phase in the case of the NTS<sub>COOH</sub>/FOETS mixed monolayer in contrast to the case of the NTS/FOETS mixed monolayer. As the NTS<sub>COOH</sub> phase had hydrophilic carboxyl end groups at the surface, these end groups can presumably form intermolecular hydrogen bonds with neighboring NTS<sub>COOH</sub> molecules. Therefore, the surface of the outermost NTS<sub>COOH</sub> phase is expected to show a higher shear strength than that of the NTS phase because of a difficulty in surface deformation. Also, there is a significant contribution of adhesion force between the sample surface and the tip with regard to lateral force. Because the surface free energy of the NTS<sub>COOH</sub> phase is comparable to that of water, the water capillary force interacting between the NTS<sub>COOH</sub> monolayer surface and the hydrophilic Si<sub>3</sub>N<sub>4</sub> tip could strongly

**Fig. 6** AFM images of the LA/FOETS (50/50 mol/mol) mixed monolayer (A), ghost monolayer after extraction of LA with hexane (B), and after backfill of ghost monolayer with OTS (C). *Source:* Reproduced from Ref.<sup>[13]</sup>.

contribute to the adhesion force of the  $\text{NTS}_{\text{COOH}}$  phase. It is therefore conceivable that the  $\text{NTS}_{\text{COOH}}$  phase exhibited higher lateral force than the FOETS phase because of the formation of intermolecular hydrogen bonding and a thicker adsorbed water layer as discussed above. Lateral force microscopic (LFM) and XPS measurements revealed that the phase-separated monolayer with a large surface energy gap was successfully prepared.

To investigate the various types of mixed monolayers, a novel mixed-monolayer system was designed using reactive organosilanes and a non-reactive fatty acid. A phase-separated monolayer can also be prepared from both FOETS and non-polymerizable and crystallizable amphiphiles such as stearic acid (SA) and lignoceric acid (LA). Fig. 6 shows the AFM images of the LA/FOETS (50/50 mol/mol) mixed monolayer Fig. 6A and after extraction of LA with hexane Fig. 6B. The LA/FOETS mixed monolayer was in a phase-separated state similar to the OTS/FOETS mixed monolayer as shown in Fig. 4. It is reasonable to conclude from Fig. 6A and B that the circular domains are composed of LA molecules, as the circular flat-topped domains were preferentially extracted with hexane. In addition, the FOETS matrix was not extracted with hexane because FOETS molecules were immobilized on the Si wafer surface by the Si–O–Si covalent bond and multiple hydrogen bonding. The electron diffraction of the LA/FOETS mixed monolayer showed a crystalline diffraction from LA domains. In addition, the circular domain of LA is

higher than that of FOETS by 2 nm. Because the bare Si surface with Si–OH groups was exposed to the surface, the Si phase can easily be backfilled by another organosilane through chemisorption from its solution. Thus, various types of surface modification are possible by chemisorption of various organosilanes to the FOETS monolayer with holes shown in Fig. 6B. Fig. 6C shows the AFM topographic image of the OTS/FOETS mixed monolayer prepared by the chemisorption of OTS onto the Si part of the FOETS monolayer. The surface structure of Fig. 6C was very similar to the phase-separated structure observed for the OTS/FOETS mixed monolayer directly prepared by the LB method. The OTS phase is mechanically and chemically very stable because of the polymerization and anchoring to the Si wafer. However, the domain height of the OTS phase in Fig. 6C was less than that observed for the OTS/FOETS mixed monolayer prepared by the LB method in Fig. 6C. In addition, the surface roughness of the OTS domains prepared by chemisorption was more distinct than that of the OTS domains prepared by the LB method. These results indicate that the OTS monolayer prepared by chemisorption is less ordered than that prepared by the LB method. This was also confirmed by grazing incidence X-ray diffraction (GIXD).<sup>[15,22]</sup> However, the abovementioned procedure to backfill the Si portion of the FOETS monolayer by the chemisorption of organosilane could be applicable to the preparation of two-phase monolayers in which the constituents have different surface free energies or surface chemistries.

**Fig. 7** Schematic representation of surface patterning, site-specific polymerization, and site-specific immobilization of microparticles.

### FABRICATION OF MULTIPHASE ORGANOSILANE MONOLAYERS THROUGH CHEMISORPTION AND PHOTOLITHOGRAPHY

A structural surface that exhibits patterns of varying wettability can be produced by chemisorption and local photodecomposition of organosilanes. Using such patterns as templates for 3-D structures with various topographic and surface properties appears very promising. Site-specific adsorption of microparticles can be achieved by specific interactions between microparticles and a monolayer surface. Immobilization of a polymerization initiator on a functional monolayer enables site-specific polymerization, which can result in a large topography change. Fig. 7 summarizes the scheme of fabrication of micropatterned organosilane monolayers, site-specific polymerization, and immobilization of microparticles on patterned organosilane monolayers. These three processes are described in this section.

#### Preparation of a Three Component Patterned Organosilane Monolayer

Fig. 8 outlines the essential steps for fabrication of micropatterned organosilane monolayers. The first step was the preparation of organosilane-grafted Si substrates. The chemical vapor adsorption (CVA) method was used to fabricate the monolayers from organotrialkoxysilane.<sup>[25]</sup> Uniform monolayer formation was confirmed by AFM observations. Removal of the monolayer in selected areas by photodecomposition was the next step in the process. In photolithography, irradiation with VUV rays ( $\lambda = 172$  nm) leads to excitation cleavage of covalent bonds such as

C–C, C–H, and Si–C bonds, and formation of surface Si–OH residues.<sup>[25]</sup> The magnitude of water contact angle on OTES and FHETES monolayers was measured as a function of irradiation time of VUV light generated from an excimer lamp ( $\lambda = 172$  nm). VUV irradiation was done under 0.8 mm Hg of pressure. Initially, OTES and FHETES monolayers gave water contact angles larger than  $100^\circ$ . However, within 15 min, the angles approached  $0^\circ$ , which indicates that

**Fig. 8** Schematic representation of site-specific photodecomposition by irradiation with VUV rays and chemisorption. *Source:* Reproduced from Ref.<sup>[24]</sup>.

almost complete removal of a monolayer can be achieved with 15-min irradiation of VUV light. The monolayer removal was also confirmed by XPS measurements. Using a photomask, one can prepare a pattern with the desired shape and a precisely controlled arrangement of surface functional groups. As an example, the preparation and characterization of an *n*-octadecyltriethoxysilane (OTES), [2-perfluorohexyl]ethyltriethoxysilane (FHETES), [2-aminoethyl]-3-aminopropylmethyldimethoxysilane (AEAPDMS) patterned surface is introduced in this section. The OTES-grafted Si wafer was irradiated for 15 min with VUV light. The second organosilane monolayer, FHETES (molecular length ca. 1.0 nm), was then introduced onto the first patterned surfaces by a similar method with alkylsilane. Formation of a ternary component monolayer requires another photodecomposition and chemisorption process, with the photomask rotated 90° from its position in the first patterning step. The OTES/FHETES sample was then irradiated with VUV, resulting in crossline micropatterns on the substrate surfaces. The third organosilane monolayer, AEAPDMS (molecular length ca. 0.9 nm), was finally introduced onto the second patterned substrate surfaces, again by the CVA method.

XPS and contact angle measurements were used to characterize the changes in the surface chemical compositions of the micropatterned organosilane monolayers. Fig. 9 shows the XPS survey scan spectra of the changes in the surface chemical compositions through the micropatterning process. The OTES monolayer showed C<sub>1s</sub>, O<sub>1s</sub>, Si<sub>2s</sub>, and Si<sub>2p</sub> peaks at 285, 533, 151, and 100 eV, respectively. The OTES/FHETES patterned Si substrate clearly showed an additional F<sub>1s</sub> peak at 690 eV, whereas the OTES/FHETES/AEAPDMS grafted Si substrates showed another N<sub>1s</sub> peak at 400 eV. Decomposition of the FHETES monolayer was revealed by the decreased intensity of the F<sub>1s</sub> peak. The grafting of organosilane monolayers was also confirmed from C<sub>1s</sub> and N<sub>1s</sub> XPS narrow-scan spectra. These results indicate that the three kinds of organosilane molecules were subsequently grafted on the substrate surfaces.

Fabrication of a micropattern with three kinds of surface functional groups was confirmed by Scanning force microscopy (SFM) observation. Fig. 10A and B shows AFM and LFM images of an OTES/FHETES/AEAPDMS three-component micropatterned organosilane monolayer, respectively. Fig. 10C and D shows the line profiles of the white lines in Fig. 10A. These figures show crossline microstructures fabricated on Si-wafer substrates. The widths of the fabricated FHETES and AEAPDMS lines were consistent with the widths of slits in the photomask. In the line profile of the AFM image as shown in Fig. 10C, the height difference between the OTES

**Fig. 9** XPS survey scan spectra of the OTES, OTES/FHETES, and OTES/FHETES/AEAPDMS micropatterned Si substrates (emission angle 45°).

and FHETES surfaces was ca. 1.4 nm. The height difference corresponds to the difference in the molecular length (ca. 1.3 nm) between OTES and FHETES. In contrast, the height difference between the OTES and AEAPDMS surfaces was ca. 1.5 nm Fig. 10D, corresponding to the difference in the molecular length (ca. 1.4 nm) between OTES and AEAPDMS. The origin of the contrast in the LFM image can be explained by the difference in the surface properties of the three components, i.e., the chain rigidity, crystallinity, and chemistry of terminal functional groups of the organosilane molecules.<sup>[22]</sup> AEAPDMS-grafted areas are the brightest of the three components because the terminal amino groups exerted high lateral force due to the strong interaction between the hydrophilic amino group and the Si-OH group of the cantilever tip. The area ratio of the prepared micropatterned monolayer is in accord with that of the target value; that is, the estimated area ratio of OTES/FHETES/AEAPDMS was 4/2/3.

The introduction of a different organosilane component was also confirmed by the measurement of surface free energy. Table 1 shows the surface free energies of uniform or micropatterned organosilane monolayers. The surface free energy was calculated from the contact angles of water and methylene iodide based on Owens and Wendt's method.<sup>[26]</sup> In Table 1,  $\gamma_s^d$  and  $\gamma_s^p$  denote the dispersion and polar components of surface

**Fig. 10** AFM and LFM images of three-component micropatterned organosilane monolayers. (A) AFM image of an OTES/FHETES/AEAPDMS micropatterned surface; (B) LFM image of an OTES/FHETES/AEAPDMS micropatterned surface; (C), (D) line profiles of white line parts in (A). Source: Reproduced from Ref.<sup>[37]</sup>.

free energy, respectively. The surface free energy of the OTES/FHETES micropatterned surface is smaller than that of the OTES monolayer surface; the decrease can be attributed to the fluoroalkyl groups of FHETES, which are known to decrease surface free energy. On the other hand, the surface free energy, especially the hydrogen-bonding component  $\gamma_s^h$ , extensively increased after the grafting of AEAPDMS; this increase can likely be attributed to the relatively high polarity of amino groups introduced in the grafted AEAPDMS monolayers.<sup>[24]</sup> Taken together with the SFM observation, this stepwise change in surface free energy confirms that the three-component organosilane surfaces had been micropatterned with highly hydrophobic and hydrophilic areas. Our patterning of three-component organosilane monolayers is expected to be a useful template for immobilizing various organic or inorganic materials on Si surfaces.

A laterally structured surface with different wetting properties may be produced by various techniques such as microcontact printing,<sup>[27]</sup> micromachining,<sup>[28]</sup> photolithography,<sup>[29]</sup> and vapor deposition.<sup>[30]</sup> If one

phase of a micropatterned surface has an affinity toward a certain liquid, the surface can be used as a template for local liquid condensation. A line-patterned high-wettability contrast surface was prepared via the local photodecomposition of an FHETMS monolayer. The advantage of this method is that the height difference of the two phases is less than 2 nm and the topographic effect on wettability can be ignored. The water-droplet formation on the micropatterned surface was directly observed with an environmental scanning electron microscope. First, the Environmental scanning electron microscope (ESEM) sample chamber was evacuated below the saturated vapor pressure (612 Pa) of water at 273 K. The sample surface was then cooled to 273 K and the vapor pressure of the ESEM sample chamber was increased to 700 Pa. Fig. 11 shows the ESEM image of the water droplet on the surface of the FHETMS/Si-OH patterned monolayer during the initial condensation process. The water began to condense on the Si-OH portion of the patterned surface. The size of the water droplet and the number of water droplets increased until the droplets coalesced in a line. Because water has a large surface free energy compared with the FHETMS phase, it is more likely to condense on the higher surface free energy region. After the vapor pressure of the ESEM sample chamber was raised to 1050 Pa, the water droplet began to bridge with droplets on the adjacent line. Because the micropatterning surface can confine liquid in distinct micropatterned regions, the surface can be used for local growth of a crystal of functional molecules<sup>[31]</sup> or as a substrate for ink-jet printing with functional molecules.<sup>[32]</sup>

**Table 1** Surface free energy of micropatterned organosilane monolayers

Organosilanes	$\gamma_{sv}$ (mJ m <sup>-2</sup> )	$\gamma_{sv}^d$ (mJ m <sup>-2</sup> )	$\gamma_{sv}^h$ (mJ m <sup>-2</sup> )

### Site-Specific Polymerization of Methacrylate Monomers

The patterned organosilane monolayers introducing an organosilane molecule with a polymerization-initiating unit are useful as template surfaces for site-specific polymerization. An atom transfer radical polymerization (ATRP) unit was immobilized as a monolayer component. Because ATRP is one of the most successful methods for polymerizing a variety of monomers in a controlled fashion,<sup>[33,34]</sup> tailor-made surface topography is possible. Several reports have described the formation of polymer thin film by radical polymerization from the immobilized ATRP initiator.<sup>[35,36]</sup>

Fig. 12 shows a schematic representation of a site-specific ATRP from a micropatterned monolayer surface.<sup>[37]</sup> Before introducing the initiator for ATRP into the organosilane monolayer system, an AEAPDMS monolayer was prepared on a Si wafer substrate surface. The prepared surface terminated by amino groups was treated with 2-bromoisobutyric acid in

the presence of a condensation agent. After the modification, the water contact angle of the obtained surface increased from 63° to 69° because of the change in the surface functional groups. Introduction of the initiating unit was further confirmed by an XPS measurement, in which the peaks attributed to Br and carbonyl carbon were observed at 68 and 287.9 eV, respectively. The resulting surface was irradiated by VUV light through a photomask. The LFM image of the patterned surface shows the presence of a pattern corresponding to the line width of the photomask used.

Surface-initiated radical polymerization of methyl methacrylate (MMA) was done in the presence of CuBr(I) and 4,4'-di-*n*-heptyl-2,2'-bipyridine in anisole. To control the polymerization process, the corresponding initiator, ethyl 2-bromoisobutyrate, was also added for bulk polymerization. The mixture was degassed, and argon was bubbled through the mixture for 20 min to ensure that oxygen was removed completely. The mixture was heated to 363 K. After several hours, the polymerization solution was cooled to room temperature to terminate the polymerization. The Si wafer was immersed in THF and rinsed with toluene to remove the adsorbed free poly(methyl methacrylate) (PMMA). The PMMA micropattern was observed by AFM.

Fig. 12 also shows the AFM image of the line-patterned PMMA ultrathin film. An AFM image revealed that the site-specific polymerization of methacrylate monomer occurred on the micropatterned surface of the ATRP initiator. The height and width of the PMMA layer is ca. 6–10 nm and ca. 5 μm, respectively. The width estimated from the AFM image is in good agreement with the line width of micropatterns of surface immobilized initiator. The formation of a PMMA layer was further confirmed by an XPS measurement, in which the characteristic

**Fig. 12** Schematic representation of the site-specific atom transfer living radical polymerization from a micropatterned monolayer surface and AFM image of line-patterned PMMA ultrathin film.

peaks attributed to the aliphatic ether and carbonyl carbons were observed at 285, 286.5, and 288.8 eV, respectively.

### Site-Specific Adsorption of Charged Microparticles

Two-dimensional alignment of micro- and nanoparticles on a substrate surface might be a promising method for fabricating functional materials, as properties of micro- and nanoparticles can be adjusted by controlling the size and surface chemistry. Various attempts have been made at the site-specific immobilization of micro- and nanoparticles.<sup>[38,39]</sup> In this study, the micropatterned organosilane monolayer with an aminosilane/fluoroalkylsilane line pattern was applied as a template surface for site-specific immobilization of negatively charged microparticles.

FHETMS and AEAPDMS were used as surface modifiers for a Si wafer substrate. The AEAPDMS/FHETMS micropattern (line width, AEAPDMS//FHETMS = 2/4  $\mu\text{m}/\mu\text{m}$ ) was fabricated by a method similar to that used to yield the multicomponent organosilane monolayer. The Si wafer substrate with a micropatterned surface was then exposed to the aqueous dispersed solution of sulfonated polystyrene (PS) microparticles at pH = ca. 6.0 for 30 min. As shown in Fig. 13, the site-specific immobilization of PS particles was successfully achieved on the micropatterned substrate surface.<sup>[40]</sup> An AFM image shows that the layers consisting of adsorbed PS microparticles are ca. 200 nm high and ca. 2  $\mu\text{m}$  wide. The height and width estimated from the AFM image is in good agreement with the diameter of PS microparticles and the line width of AEAPDMS micropatterns, respectively.

**Fig. 13** AFM image of the AEAPDMS/FHETMS monolayer after exposure to the aqueous dispersion of sulfonated PS microparticles. *Source:* Reproduced from Ref.<sup>[37]</sup>.

This result suggests that the sulfonated PS particles were adsorbed on the surface as a monolayer. The site-specific adsorption of PS particles onto the AEAPDMS grafted surfaces can be ascribed to the electrostatic interaction between negatively charged sulfonic acid groups of PS particles and positively charged amino groups of AEAPDMS-grafted surfaces.

### CONCLUSION

Patterned microfeatures of organosilane monolayers were fabricated on the substrate by two different methods. One method utilizes the crystallization of a binary component organosilane monolayer at the air/water interface. Another method utilizes the local photodecomposition by VUV light and backfilling of the decomposed area by chemisorption of organosilane monolayers. It was also revealed that micropatterned organosilane monolayers can be used as model surfaces with controlled, area-selective surface nature such as free energy, nanostructure, and chemical composition.

## INTRODUCTION

Although intensively studied in a variety of fields such as catalysis, magnetism, and optics, oxide nanoparticles have just been modestly considered within the field of energy storage until these last few years that have witnessed intense developments, mainly regarding Li-ion battery technology as devoted herein.

For the last 20 years, it was a common and well-accepted belief that highly divided materials could not be suitable for extended reversible redox reaction with metallic lithium. This seems quite astonishing because most primary and secondary lithium electrochemical cell devices are based on redox reactions involving interfacial reactions between a liquid organic-based electrolyte and a solid electrode material. In fact, this idea was rooted on the belief that electrochemically driven irreversible decomposition of the organic-based electrolyte occurs at the surface of the active particles while the cell is cycled, together with possible dissolution of the solids. Thus, the higher the surface of contact between the particles and the electrolyte, the higher would be the extent of this capacity loss, hence the requirement of large particles with low surface area. Along that line, the BET surface areas of powders presently used in commercial Li-ion cells do not exceed  $2 \text{ m}^2/\text{g}$ . Recently, these prevailing ideas were seriously contradicted by several findings linked to the recent interest in nanopowders, as we will discuss in this paper. Owing to the present staggering trend toward nano objects in various research fields, too often driven by funding opportunities rather than true science, much confusion has surged about the real meaning of “nano.” Undoubtedly, the world of the so-called nanosciences is still waiting for a concrete and universal definition or at least an accurate, related size scale. Thus, we talk about nanopowders, nanostructures/nanocomposites, nanotextures, and nanoarchitected electrodes by reference to materials having a single component, two or more components intimately mixed at the nanometric scale, a porous electrode having pores and components in the nanometric scale, and finally a well-designed (either by

template deposition or by lithography) two-component system at the nanometric scale. Basically, we are prone to think that a given object, observed for a given property with a specific characterization mean, enters the “nanoworld” as soon as its size reaches a value below which the studied property starts to drastically differ from that of bulk. For instance, the significant decrease in Au particles’ melting point as their particle size becomes smaller than  $50 \text{ \AA}$  perfectly illustrates this point,<sup>[1]</sup> and for such a phenomenon  $50 \text{ \AA}$  will be the threshold value delimiting the nano/macro worlds. It is therefore unfortunate that we do not have such an equivalent to Plank’s constant that neatly separates classical mechanics from quantum mechanics.

As we march from bulk materials toward systems with small particles, new electrochemical effects are recently observed and these require the formulation of a new theoretical foundation on which to base our interpretation and understanding of the experimental data. A theoretical approach was recently undertaken and the effect of surface, particle size toward the evolution of electrochemical reactions considered. A profound effect on the chemical potential–composition curves and energy sites was demonstrated.<sup>[2]</sup> Moreover, a decrease in domain size results in a dramatic increase in grain boundaries<sup>[3]</sup> that were shown, by acting as space charge regions, to be beneficial to ionic conductivity. However, the particle size is not the only parameter that can account for the modification of properties. Indeed, the size of the crystallized reacting domains (crystallites), the specific surface area of the powder, the porosity, and the possible confinement of the matter can have a drastic influence as well.

It is surprising that the effect of the size of the reacting domains on the electrochemical properties remains almost uninvestigated, while most of the scientific fields are now, as a whole, turning toward the nanomaterials. Given the implications of the energy storage in our evolving modern society (communication, biocompatible devices), we definitively have to consider this rich domain of opportunities that lies beyond the use of nanomaterials in this field, as illustrated by the following examples.

## LITHIUM REACTIVITY THROUGH INSERTION PROCESSES

Although the principle of a Li-based secondary cell dates back to the 70s, we had to wait until the 90s for the first commercialization of reliable and safe rechargeable batteries. This impressive delay originates from numerous scientific and technological problems whose step-by-step resolution lasted decades and required sustained and crossed endeavor from physicists, chemists, and theorists. Aside from the formulation of stable electrolytes within a wide electrochemical potential window, the search for suitable electrode materials is still a major issue. The main difficulty encountered along this quest for the “ideal” insertion material is nested in the numerous criteria they have to meet all in one. They have to show high insertion capacity without undergoing drastic structural changes, low toxicity and low cost, highly separated redox potential between the cathode and anode, enhanced thermal/chemical stability toward the electrolyte, high electronic/ionic conductivities for power rate capabilities, and, finally, easy synthesis with scale-up possibilities.

Such “ideal” materials do not exist and to date only very few compounds were isolated as coming close to these requirements: ternary  $\text{LiCoO}_2$ ,  $\text{LiNiO}_2$ ,  $\text{LiMn}_2\text{O}_4$  oxides for the cathode,<sup>[4,5]</sup> and carbonaceous materials for the anode. To bypass the identified drawbacks of these materials, present studies dealing with anionic and cationic substitutions,<sup>[6]</sup> surface treatments,<sup>[7]</sup> or the making of composite materials are exploring new compromises rather than innovative and creative approaches, with the exception of a few that are exploiting lithium chemical reactivity at the nanometric scale.

Below, we give some examples showing how nanomaterials, either as electrodes or as part of the electrolyte composition, could greatly benefit the field of rechargeable Li batteries.

*LiMn<sub>2</sub>O<sub>4</sub> spinel oxide* is the first example selected to illustrate how Li-driven phase transitions associated to drastic electrode volume changes and leading to poor electrochemical performances can turn to our advantage when using small reacting domains. It has long been well known that Li insertion in this spinel framework results in a cooperative Jahn–Teller distortion together with the formation of a tetragonal phase showing a volume expansion of about 16% as compared to its cubic precursor with the overall result being very poor retention capacity upon cycling.<sup>[4,5]</sup> In contrast, when very small internal crystallites are formed by intense mechanical milling performed on crystallized powders or by precipitation techniques, this reaction appears to be very reversible.<sup>[8,9]</sup> This unexpected behavior was attributed to an isotropic

and benign expansion of the small domains as compared to the highly anisotropic and strain-inducing expansion of large ones, when the material is made by the “bake and shake” method. Because of the plasticity of the ball-milled powders, the electrode maintains its integrity upon insertion–removal of lithium ions with limited resulting loss of electrical contact.

By acting on the particle size, aside from the possibility of modifying the side effects associated to an intercalation phenomenon, one can modify the insertion mechanism by itself. This has been recently achieved for several compounds by acting on the size of the reacting domains as demonstrated through a few studies on carbonaceous materials.

*Carbonaceous materials*, owing to their both faradic and capacitive properties, are now widely implemented in Li-ion batteries and supercondensators. Their electrochemical properties are highly dependent on their texture, composition, and synthetic history. Although capacitor technology has long recognized the benefits of high-surface-area materials, it was quite recently that Li insertion in disordered and highly divided carbons turned out to be a promising approach. Such disordered/divided carbonaceous materials were, for instance, elaborated by direct preparation through pyrolysis of organic precursors or by postgrinding treatment under various conditions (atmosphere, grinding time, miller type) of crystallized carbons previously prepared at high temperatures.<sup>[10]</sup> Following the latter approach after an early appraisal of various ball-milling key parameters, carbonaceous materials having reversible specific electrochemical capacity that can reach 720 mA hr/g, which is about twice that of graphite, and low irreversible loss in the first cycle (200 mA hr/g) were fabricated. More importantly, such performance gains were not limited to one specific carbon precursor because ball milling, once the experimental parameters optimized, was shown to lead to identical texture whatever the carbonaceous precursor, stressing the universal effect of this mechanical treatment.<sup>[11]</sup> Several models have been proposed to explain this behavior, but despite this controversy, there is no doubt the origin of this increase in capacity is nested in the extremely small domains (30 Å) created by the milling.

*Hematite  $\alpha\text{-Fe}_2\text{O}_3$* <sup>[12,13]</sup> and *M<sub>3</sub>O<sub>4</sub>* (*M* = Fe, Co, Mn)<sup>[15]</sup> will be used as pedagogical examples to illustrate the effect of particle size on the electrochemical reaction path itself upon reaction with metallic lithium.

The reaction of lithium with hematite  $\alpha\text{-Fe}_2\text{O}_3$  entails a very limited solid solution domain up to a lithium critical concentration of about 0.03 lithium per formula unit, and then an irreversible transition leading to a  $\text{Li}_2\text{Fe}_2\text{O}_3$  rock-salt-type phase. It is

surprising that when using very small hematite particles, this reactivity scheme appears to be drastically different. More specifically, two batches of hematite were compared: micron-sized ( $M\text{-Fe}_2\text{O}_3$ ,  $2\text{ m}^2/\text{g}$ ,  $0.5\text{ }\mu\text{m}$  mean particle size, commercial) and nanosized ( $n\text{-Fe}_2\text{O}_3$ ,  $60\text{ m}^2/\text{g}$ ,  $200\text{ }\text{\AA}$  mean particle size, home-made) samples (Figs. 1 and 2). Quasi-equilibrium voltage evolutions along the reaction with lithium [open circuit voltage (OCV) measurements] confirm that the reduction of  $M\text{-Fe}_2\text{O}_3$  proceeds through a biphasic process ( $2.20\text{ V}$  vs.  $\text{Li}^+/\text{Li}$ ) after a very small solid solution domain. In contrast, a much longer single-phase solid solution domain (up to about one Li) is observed for  $n\text{-Fe}_2\text{O}_3$ , followed by a biphasic domain characterized by an OCV value of  $1.85\text{ V}$  vs.  $\text{Li}^+/\text{Li}^\circ$  (Fig. 3). In situ X-ray diffraction experiments (Fig. 4) further confirm these differences in reactivity when the particle size is modified. For a maximum lithium amount of one per formula unit ( $x = 1$ ),  $M\text{-Fe}_2\text{O}_3$  irreversibly transforms into a cubic rock-salt-type  $\text{Li}_2\text{Fe}_2\text{O}_3$  phase, although the  $n\text{-Fe}_2\text{O}_3$  Bragg reflections progressively and reversibly shift without any evidence for extra phase. The cell volume expansion linked to this topotactic insertion is evaluated to be 1% from  $\alpha\text{-Fe}_2\text{O}_3$  to  $\alpha\text{-Li}_1\text{Fe}_2\text{O}_3$ . As expected for such benign cationic insertion associated with small volume changes, the nanometric material exhibits higher reversible capacity and improved cycling behavior when compared to the  $M\text{-Fe}_2\text{O}_3$  batch (Fig. 5). Aside from these electrochemical aspects and the possibility of forming the  $\alpha\text{-Li}_1\text{Fe}_2\text{O}_3$  phase, recent Mössbauer and EXAFS measurements indicate that

Fig. 2 TEM and SEM pictures of nanosized ( $n\text{-Fe}_2\text{O}_3$ ) and micron-sized ( $M\text{-Fe}_2\text{O}_3$ ) samples.

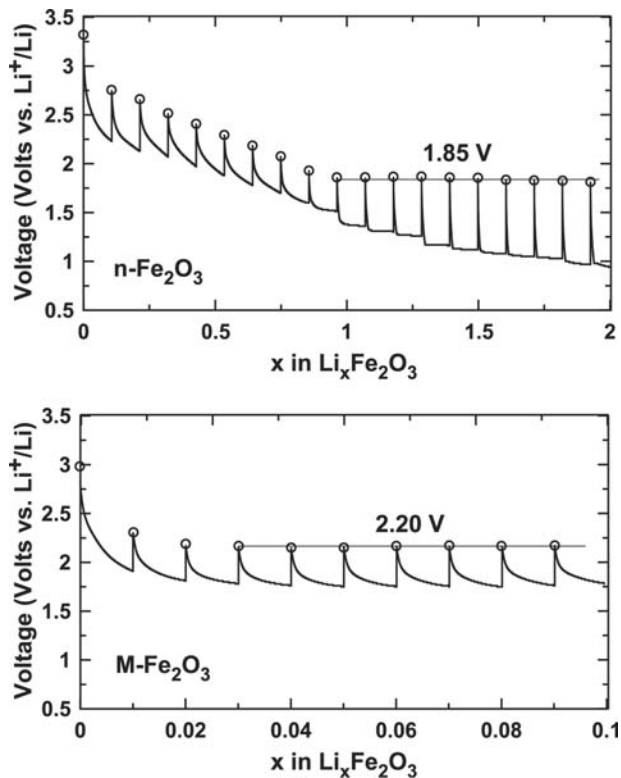

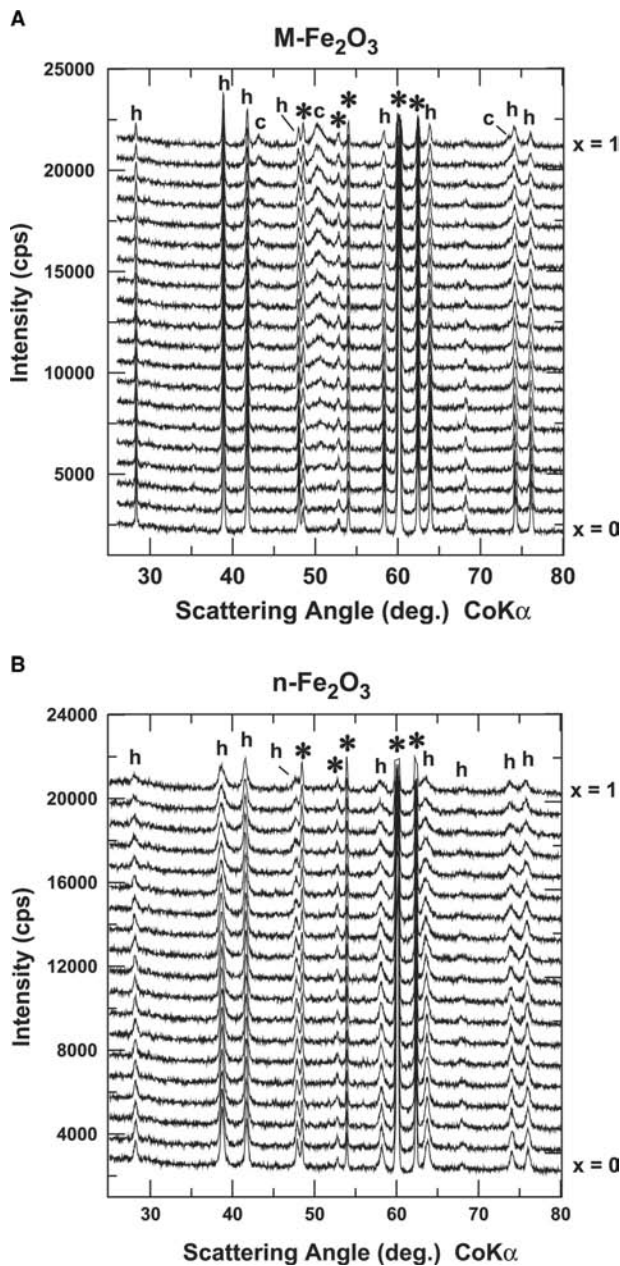

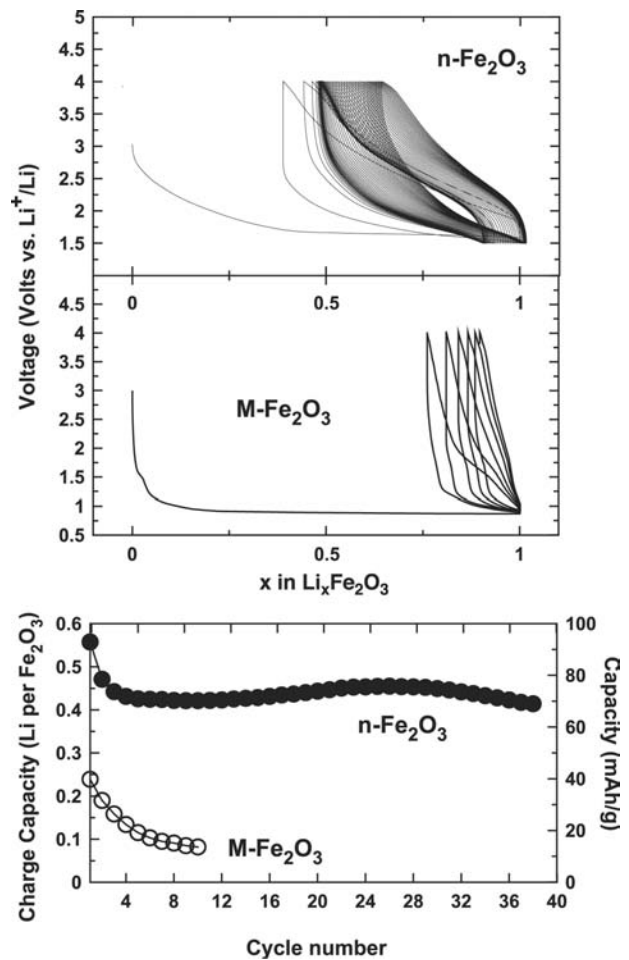

Fig. 3 Voltage–composition curves for  $n\text{-Fe}_2\text{O}_3$  and  $M\text{-Fe}_2\text{O}_3$  in Potentiostatic Intermittent Titration Technique mode. Open circles indicate the quasi-equilibrium OCVs.

**Fig. 4** In situ X-ray diffraction patterns collected on (A) Li/M-Fe<sub>2</sub>O<sub>3</sub> and (B) Li/n-Fe<sub>2</sub>O<sub>3</sub> cells discharged at C/5 rate. The “h” and “c” labels indicate the hexagonal  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and the cubic Li<sub>2</sub>Fe<sub>2</sub>O<sub>3</sub> phases, respectively. Asterisks indicate the peaks due to apparatus (Be, BeO).

**Fig. 5** Voltage–composition curves and capacity evolution upon cycling for Li/n-Fe<sub>2</sub>O<sub>3</sub> and Li/M-Fe<sub>2</sub>O<sub>3</sub> cells (1 Li/5 hr, 25°C).

the intimate reaction path beyond  $x = 1$  is also dependent on the particle size. For instance, we could unambiguously demonstrate a disproportionation ( $3\text{Fe}^{2+} \rightarrow 2\text{Fe}^{3+} + \text{Fe}^{\circ}$ ) mechanism along the n-Fe<sub>2</sub>O<sub>3</sub> reduction beyond  $x = 1$ , whereas it is not observed for M-Fe<sub>2</sub>O<sub>3</sub>.<sup>[13]</sup>

Finally, the overall alternative paths observed depending on the domains size could be summarized as follows:

**Fig. 6** In situ X-ray diffraction patterns collected during the electrochemical reduction of Low Surface Area-Co<sub>3</sub>O<sub>4</sub> (A) and High Surface Area-Co<sub>3</sub>O<sub>4</sub> (B) at constant current (1 Li/12 hr) at 25°C. The top patterns correspond to the initial Co<sub>3</sub>O<sub>4</sub> and the bottom ones to  $x = 2.0$  Li per Co<sub>3</sub>O<sub>4</sub> (CuK<sub>α</sub>).

Similar extension of the solid solution domain by using small particles/crystallites was also recently demonstrated for compact structures such as anatase TiO<sub>2</sub>,<sup>[14]</sup> and we believe that numerous host materials disregarded for reversible lithium intercalation behave in a similar way. Thus, a completely new area is ahead of us in the search for new valuable insertion materials.

Besides hematite, numerous other materials with empty available sites are reported to irreversibly react with lithium. Among them, 3d-metal spinel materials M<sub>3</sub>O<sub>4</sub> (M = Co, Mn, Fe) are also known to transform into lithiated rock-salt type Li<sub>x</sub>M<sub>3</sub>O<sub>4</sub> structures. This is illustrated in Fig. 6. Low-surface-area Co<sub>3</sub>O<sub>4</sub> (3 m<sup>2</sup>/g) reacts with metallic lithium at constant C/12 rate (one Li in 12 hr) through a two-phase Li insertion process leading to a cubic rock-salt-type phase with the approximate composition Li<sub>~1.5</sub>Co<sub>3</sub>O<sub>4</sub> (Fig. 6A). In contrast, high-surface-area Co<sub>3</sub>O<sub>4</sub> materials (66 m<sup>2</sup>/g) behave differently because they transform into rock-salt α-CoO (Fig. 6B). The same CoO formation was observed when (3 m<sup>2</sup>/g) Co<sub>3</sub>O<sub>4</sub> powders were slowly reduced (C/100) or reacted with lithium in an intermittent mode consisting of short discharge steps followed by 2-hr relaxation periods. Note that similar current-density-driven observations were also made on

Mn<sub>3</sub>O<sub>4</sub> materials of different surface area. Such behavior fully contrasts with that of Fe<sub>3</sub>O<sub>4</sub>, as Li<sub>x</sub>Fe<sub>3</sub>O<sub>4</sub> phases are always formed whatever the reduction rate or the texture of the starting Fe<sub>3</sub>O<sub>4</sub> powders, suggesting an effect of the crystallographic nature of the spinel (normal for Co<sub>3</sub>O<sub>4</sub> as compared to inverse for Fe<sub>3</sub>O<sub>4</sub>). For Co<sub>3</sub>O<sub>4</sub> and Mn<sub>3</sub>O<sub>4</sub>, the key parameter governing the reduction reaction is therefore not the particle size but the applied current density (current/specific surface area ratio). Therefore, through these examples we demonstrate that by varying either the cycling rate or the specific surface area of the active material one can control the Li reacting path as summarized below.

## LITHIUM REACTIVITY THROUGH CONVERSION PROCESSES

Because the division state and texture of oxides used as electrode materials can drastically alter the initial intercalation process, one wonders whether the full reduction of 3d-metal oxides into metal can be affected as well. Although the size of the metallic clusters so formed are not significantly dependent on the initial oxide particle size, it was astonishing to observe, as demonstrated for various oxides such  $\text{Cu}_2\text{O}$ ,  $\text{CuO}$ ,  $\text{CoO}$ ,  $\text{NiO}$ ,  $\text{MnO}$ ,  $\text{FeO}$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{Fe}_3\text{O}_4$ , and  $\text{Co}_3\text{O}_4$ ,<sup>[16–18]</sup> a very high reversibility of these oxides toward Li according to the following reaction:

The reversibility of these conversion reactions was attributed to the in situ formation of nanometric metallic clusters embedded in a lithia matrix with, therefore, a very high metal/ $\text{Li}_2\text{O}$  surface of contact. Upon reoxidation of these nanocomposites, very small clusters of oxides are formed back. This is shown in Figs. 7–9 for  $\text{CoO}/\text{Li}$  cells. However, the formation of such nanocomposites is not the only key parameter

**Fig. 7** Composition–voltage curve for a  $\text{CoO}/\text{Li}$  cell (top) and evolution of the capacity as a function of the cycle number (bottom).

required for high reversibility. Indeed, when ex situ formed highly divided oxides are cycled vs. lithium, the overall cell capacity drops very quickly. This is linked to the growing of an organic gel at the surface of the particles (resulting from the decomposition/reduction of the electrolyte) that tends to electrically isolate the active particles from the current collector. The criteria for good long-term cycling behavior are twofold: 1) low surface area of the initial oxide particles and 2) in situ formed nanodomains insuring high internal contact. Note that this need of in situ nanostructure was already demonstrated in aqueous electrochemical storage using nickel hydroxide as active material.<sup>[19]</sup> These reversible conversion reactions were not only limited to oxides but were found to occur for various classes of compounds such as nitrides, fluorides, and sulfides with formation of metal/ $\text{Li}_3\text{N}$ , metal/ $\text{LiF}$ , and metal/ $\text{Li}_2\text{S}$  nanocomposites, respectively.<sup>[20–24]</sup> Thanks to the universality of these reactions, to their appealing electrochemical performances, to their intrinsic simplicity from a thermodynamic point of view, and to the large panel of materials available, it clearly appears that they represent a main opportunity for future development in the field of electrode materials. Because they involve two to three electrons per 3d metal as compared to 1, and high voltages as well (3 V for  $\text{CoF}_3$ ), such nanodriven reversible conversion reactions, owing to their staggering capacity gains over classical insertion reactions, could revolutionize the way the world stores and uses power.

## ALLOYING REACTIONS

Lithium-alloying reaction with metal such as Al, Sn, Si, Ge, Cd, Pb, and Sb is one of the most attractive alternatives to intercalation reactions.<sup>[25–29]</sup> About 25 metals or semimetals are known to form alloys with lithium and most of their combinations are active toward lithium.<sup>[30–33]</sup> These reactions offer very high capacities (Si: 4200 mA hr/g, Ge: 1600 mA hr/g, Al and Sn: 990 mA hr/g) at relatively low voltages (< 1 V vs.  $\text{Li}^+/\text{Li}^0$ ) but their cycling behavior is very poor. This detrimental characteristic is attributed to the pulverization of the material, and hence the loss of electrical contact, due to the large volume expansion of the active domains and high strain-inducing phase transitions together with the Li incorporation. Although these structural changes are intrinsic to the reactions, several attempts have been made to limit their side effects on the electrode integrity. Among them, the active/inactive nanocomposite concept represents one of the most promising exploratory routes in the field. Such composites consist of two intimately mixed materials, one reacting with lithium

**Fig. 8** HRTEM images (A) and corresponding selected-area electron diffraction (SAED) diagram of a CoO electrode after reaction with 2 Li per CoO.

while the other acts as an inactive confining buffer. In addition, the use of small-sized metallic clusters as Li hosts considerably suppress the associated strains and therefore improve their textural response to the alloying reaction.<sup>[34,35]</sup> Several recent examples can illustrate this concept through different systems such as Sn–O based glasses,<sup>[36–39]</sup> Si–C,<sup>[40–42]</sup> Sn–Fe–C<sup>[43–45]</sup> and Sn–Mn–C.<sup>[46,47]</sup> The best experimental proof of the beneficial aspect of the buffer matrix arises from the ability to obtain several hundreds of cycles on a composite made by precipitating Sn metal at the grain boundaries of an electrochemically inactive SnFe<sub>3</sub>C matrix. However, the retention capacity was improved at the expense of a decrease in the material electrochemical capacity. Undoubtedly, alloy performance can also benefit from nanostructuring, but further developments are needed in the search for elaboration techniques to develop tailor-made nanostructure alloys.

## ELECTROLYTE

Small particles are not only involved in electrode redox mechanisms but can also be of great implications for the electrolyte conduction properties. For instance, the addition of nanometric inorganic fillers (TiO<sub>2</sub>, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>) into various types of dry or hybrid polymer systems has proved effective in improving their ionic conduction properties to a large extent without affecting their interfacial and mechanical stabilities, in the whole temperature range.<sup>[48–50]</sup> This enhancement of the conductivity was explained both in chemical terms through the introduction of a Lewis acid–base concept that considers the effect of fillers in ion–ion and ion–polymer interactions in polymeric electrolytes and in theoretical terms through a modification of diffusion and transport coefficient in space charge regions created at the nanoceramic/polymer

**Fig. 9** HRTEM images (A) and corresponding SAED diagram of a CoO electrode after one discharge/charge cycle.

interfaces. Present trends are devoted toward searching for new nanostructured polymers loaded with functionalized ceramic nanomaterials (e.g., nanoceramics having acid or basic surface groups). Such an approach was shown to be quite beneficial in developing highly performing protonic membranes for fuel cell applications.

## CONCLUSION

It is now evident that the entire energy storage field is moving toward nanostructures and nanoparticles. So far, only the capacitor technology was apparently concerned by this aspect and it is probably not purely coincidental that recent works have demonstrated the feasibility of hybrid capacitive/faradic

lithium cells.<sup>[51]</sup> Through this simple example, it is clear that a completely new area of opportunities is now open within the field of energy storage, both at the fundamental and applied levels. As we march from bulk materials toward systems with small particles, new electrochemical phenomena are observed and these require the formulation of a new theoretical foundation on which to base our interpretation and understanding of the experimental data. Regarding the applications, several foreseen benefits associated to nanomaterial-based Li batteries are the following: 1) an easier accommodation of structural strains for better calendar life, 2) a shorter diffusion path for enhanced electrode power capabilities, 3) an increase of the surface vs. core volume for larger double-layer capacitance contribution, and 4) an enhanced solid state reactivity to bypass

kinetics limitations so that novel reactions showing staggering electrochemical capacity gains and involving low-cost materials are becoming feasible. Such cumulated effects should translate into tremendous gain costs while preserving safety. However, although quite exciting, enthusiasm should not prevail over reality, and a few critical problems that will require cooperative endeavor and cross-sharing of knowledge accumulated for the last decades in fields such as catalysis and others remain to be solved.

## ACKNOWLEDGMENTS

## INTRODUCTION

The chemistry of polynuclear metal clusters in the nanometer scale has become a central issue in materials science because of their unique functions as electronic, optical, magnetic, and catalytic devices, which bring new technologies in many industrial areas.<sup>[1–5]</sup> At present, there is some progress being made in the preparation of metal nanoclusters.<sup>[6–15]</sup> They have been synthesized by the chemical reduction of metal salts in the presence of stabilizing ligands such as surfactants,<sup>[6,7]</sup> organic polymers,<sup>[8–10]</sup> and organic bases,<sup>[11–13]</sup> which preserve the metal clusters from the agglomeration of the clusters themselves. However, the above methods hardly produce metal nanoclusters with a high degree of size dispersity.

Transition metals have been extensively used as catalysts for many organic reactions, where the oxidation state of the metal plays an important role in attaining highly selective reactions.<sup>[16–19]</sup> A multiple interaction of substrate molecules with surface metal atoms of transition metal nanoclusters would offer the possibility of unprecedented catalytic reactions. Furthermore, a creation of specific surface ensemble sites consisting of zero-valent metals and metal cations is a promising strategy for designing highly functionalized nanocluster catalysts based on cooperative action among the multiple metal species.

The purpose of this entry is to develop a new synthetic protocol of monodispersed palladium (Pd) nanoclusters at the nanometer-scale precision as high-performance catalysts. We describe here the novel synthesis of Pd nanoclusters with a high degree of size dispersity, where the standard deviation of the mean diameter ( $\sigma/d$ ) is less than 10%, by treatment of the small Pd cluster with metal nitrates such as  $\text{Cu}(\text{NO}_3)_2$  under an  $\text{O}_2$  atmosphere. This method also yielded mixed-valence states with  $\text{Pd}^0$  and cationic Pd species on the cluster surface.<sup>[20]</sup> An advantage of this synthetic method is that the particle size and the surface oxidation state of monodispersed Pd nanoclusters can be controlled by selecting the amount of the metal

nitrates and by varying the preparation time of the clusters. Furthermore, the above Pd nanoclusters are applicable to highly efficient and selective heterogeneous catalysts for liquid-phase oxidations such as acetoxylation of toluene, alcohol oxidation, and the Wacker oxidation under an atmospheric pressure of  $\text{O}_2$ .<sup>[20–22]</sup> The unique catalyses of the Pd nanoclusters are attributed to the cooperative action between zero-valent Pd and Pd cations on the surface ensemble Pd sites.

## PREPARATION OF NANOCCLUSERS

A representative example is the synthesis of the monodispersed Pd nanocluster with a mean diameter of 38 Å. A solution of  $\text{Pd}(\text{OAc})_2$  (0.20 g, 0.89 mmol) in AcOH (20 mL) was stirred at 50°C for 2 hr under continuous CO flow, yielding 0.12 g of  $\text{Pd}_4(\text{CO})_4(\text{OAc})_4 \cdot 2\text{AcOH}$  (PCA) as a yellow precipitate.<sup>[23]</sup> The obtained PCA (0.12 g, 0.155 mmol, Pd 0.62 mmol) was stirred in AcOH (2.5 mL) in the presence of 1,10-phenanthroline (phen) (0.0614 g, 0.31 mmol) at room temperature for 30 min in air to give a dark brown solution of  $\text{Pd}_4\text{phen}_2(\text{CO})_2(\text{OAc})_4$ <sup>[24]</sup> [anal. calc. for  $\text{Pd}_4\text{C}_{34}\text{H}_{28}\text{N}_4\text{O}_{10}$  (%): C, 37.9; H, 2.6; N, 5.2; found (%): C, 34.1; H, 2.7; N, 5.2].<sup>a</sup> Then, 0.0038 g of  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  (0.0155 mmol) was added to the above solution and heated at 90°C under an atmospheric  $\text{O}_2$ . After 15 min, a black solid was precipitated with the consumption of 0.067 mmol  $\text{O}_2$  ( $\text{O}_2/\text{Pd} = 0.108$  mol/mol).<sup>b</sup> The precipitate was washed with AcOH for several times and dried in vacuo to yield the Pd

<sup>a</sup>An optimum mole ratio of Pd to phen in the synthesis of giant Pd clusters was found to be 2. The use of  $\text{Pd}_4\text{phen}_4(\text{CO})_2(\text{OAc})_4$  instead of  $\text{Pd}_4\text{phen}_2(\text{CO})_2(\text{OAc})_4$  did not afford giant Pd clusters.

<sup>b</sup>The amount of  $\text{O}_2$  uptake during the preparation of the Pd nanoclusters was volumetrically measured using a gas buret by trapping evolved  $\text{CO}_2$  in a cold trap at  $-120^\circ\text{C}$ .

**Scheme 1** Formation of the  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$  cluster.

nanoclusters (0.032 g, ca. 30% yield based on Pd) [anal. calc. for  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$  (%): C, 3.28; H, 0.41; N, 1.91; found (%): C, 3.21; H, 0.23; N, 1.34; X-ray photon spectroscopy (XPS): Pd  $3d_{5/2} = 334.5\text{--}335.2\text{ eV}$ , O  $1s = 531.5\text{ eV}$ , N  $1s = 399.4\text{ eV}$ . The XPS peak positions are referred to C  $1s$  at  $284.6\text{ eV}$  (atomic ratio by XPS: C/Pd = 0.6, N/Pd = 0.12). Copper signals were not appreciable on the clusters.]<sup>c</sup> Scheme 1 represents the formation of the Pd nanoclusters. During the preparation of the Pd nanoclusters, molecular oxygen was consumed to form  $\text{CO}_2$  and  $\text{H}_2\text{O}$ , and the oxygen species on the cluster surface.

A typical example for the immobilization of the Pd clusters on the metal oxides is described for the Pd nanocluster/ $\text{TiO}_2$ .  $\text{TiO}_2$  (JRC-TIO-2, 1.30 g) was added into the acetic acid solution of the  $\text{Pd}_4\text{phen}_2(\text{CO})_2(\text{OAc})_4$  and  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ , and then stirred at  $90^\circ\text{C}$  under an atmospheric  $\text{O}_2$  (3 wt.% as Pd cluster).<sup>d</sup> The solid compound of 1.4 g was obtained after filtration, washing with acetic acid and drying under a vacuum.

In the X-ray diffraction (XRD) pattern of the Pd nanoclusters, the three peaks are observed at  $40^\circ$ ,  $46^\circ$ , and  $68^\circ$ , which correspond to the  $\{111\}$ ,  $\{200\}$ , and  $\{220\}$  planes of a face-centered cubic (fcc) lattice, respectively. The mean crystalline size of the Pd nanoclusters, calculated from the line broadening of the peak at  $40^\circ$  using the Scherrer equation, is ca.  $35\text{ \AA}$ . The particle size distribution and the ordering of Pd atoms of the Pd clusters were estimated by field emission scanning electron microscopy (FE-SEM) and high-resolution transmission electron microscopy (HR-TEM) of the Pd clusters immobilized on the  $\text{TiO}_2$  surface because the Pd nanoclusters could be immobilized on a surface of  $\text{TiO}_2$  without a change in their original cluster size and the local ordering of the Pd atoms on the cluster surface. As shown in Fig. 1A, the FE-SEM image of the Pd clusters on the  $\text{TiO}_2$  surface reveals that the Pd nanoclusters are well dispersed with a quite narrow size distribution throughout the  $\text{TiO}_2$  surface. The mean diameter ( $d$ )

of the Pd clusters is  $38\text{ \AA}$  with a standard deviation ( $\sigma$ ) of  $2.1\text{ \AA}$ , where the  $\sigma/d$  value is 6%. This particle size corresponds to that of the giant eight-shell metal cluster composed of 2060 Pd atoms as the magic number.<sup>[25]</sup> To the best of our knowledge, the Pd nanoclusters prepared by our method using metal nitrates have the narrowest size distribution of Pd nanoparticles obtained by chemical and electrochemical methods.<sup>[6–15]</sup>

Figure 2 represents the HR-TEM image of the Pd nanocluster immobilized on the  $\text{TiO}_2$  surface. A regular arrangement of Pd atoms on the Pd nanocluster surface can be clearly observed, with 17 Pd atoms along the  $\{111\}$  planes. The Pd K-edge X-ray absorption fine structure (XAFS) measurement of the Pd nanoclusters indicated that the inner part is composed of a metallic Pd atom. However, the surface analysis of the above Pd nanoclusters by XPS proved the presence of both cationic and metallic Pd species. Furthermore, the treatment of the Pd nanoclusters with a CO molecule at  $0^\circ\text{C}$  led to both  $\text{CO}_2$  evolution and CO adsorption on metallic Pd; the cationic Pd species are reduced to  $\text{Pd}^0$  during exposure to CO. The evolution of  $\text{CO}_2$  ascertains the presence of oxygen species on the surface of the Pd nanoclusters. Because the reactivity of the surface oxygen species was high enough to oxidize a CO molecule even at  $0^\circ\text{C}$ , the Pd sites responsible for the above CO oxidation would be  $\text{Pd}_2\text{O}$  species on the cluster surface.<sup>e</sup> The ratio of the  $\text{Pd}_2\text{O}$  species to the surface Pd atoms of the monodispersed Pd nanoclusters with a diameter of  $38\text{ \AA}$ , evaluated from the amounts of the formed  $\text{CO}_2$  and the CO uptake, is 23%.

A possible arrangement of the Pd atoms of the eight-shell Pd cluster with an fcc cuboctahedral shape is illustrated in Scheme 2A, where the  $\text{Pd}^0$  and  $\text{Pd}^+$  cation species are situated on the face of the nanocluster. The fraction of  $\text{Pd}^+$  ( $\text{Pd}_2\text{O}$ ) species of the surface Pd atoms was 23%, whereas those of  $\text{Pd}^{2+}$  and  $\text{Pd}^0$  species were 56% and 20%, respectively.<sup>[20]</sup> This accords with the composition of the Pd nanoclusters,  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$ ; the surface-divalent Pd cations were preserved at corner/edge sites by anions of  $\text{NO}_3^-$  and  $\text{OAc}^-$ , where oxygen species were bound to the two monovalent Pd ions on the face of the nanocluster.

The use of  $\text{Fe}(\text{NO}_3)_3$  instead of  $\text{Cu}(\text{NO}_3)_2$  could also afford the Pd nanoclusters having a narrow size distribution with a mean diameter and standard deviation ( $d \pm \sigma$ ) of  $38 \pm 4.4\text{ \AA}$  ( $\sigma/d = 11\%$ ), where the fraction of the surface  $\text{Pd}_2\text{O}$  species exhibited the maximum of 22%. The composition of the eight-shell

<sup>c</sup>The  $\text{Pd}(\text{phen})(\text{OAc})_2$  complex was formed in the residual solution.

<sup>d</sup> $\text{TiO}_2$  (JRC-TIO-2) was supplied from the Catalysis Society of Japan (anatase, BET surface area:  $14\text{ m}^2\text{ g}^{-1}$ ), and is characterized by its low acidity and basicity compared with other  $\text{TiO}_2$  reference samples.

<sup>e</sup>A  $\text{Pd}^+$  species has been already reported on palladium-loaded silicoaluminophosphate molecular sieves. (See Ref.<sup>[26]</sup>)

**Fig. 1** The FE-SEM photograph and the particle size distribution of the Pd nanoclusters prepared with the  $\text{Cu}(\text{NO}_3)_2/\text{PCA}$  molar ratio of (A) 0.10 (15 min), (B) 0.05 (8 min), and (C) 0.10 (10 min). The values in parentheses are the preparation times of the cluster.

Pd nanoclusters was  $\text{Pd}_{2060}(\text{NO}_3)_{250}(\text{OAc})_{470}\text{O}_{80}$ . The ratio of  $\text{OAc}^-$  to  $\text{NO}_3^-$  anions was different from that obtained for the eight-shell Pd clusters using  $\text{Cu}(\text{NO}_3)_2$ . However, the total number of anionic species situated on the cluster surface was constant, irrespective of the metal nitrates.

Furthermore, we found that the selection of the  $\text{Cu}(\text{NO}_3)_2/\text{PCA}$  molar ratio can control the particle size of the Pd nanoclusters.<sup>[20]</sup> When the  $\text{Cu}(\text{NO}_3)_2/\text{PCA}$  molar ratio was 0.05, the five-shell Pd

nanoclusters with the  $\sigma/d$  value of 9% ( $\sigma = 2.5 \text{ \AA}$ ,  $d = 27 \text{ \AA}$ ) were obtained. A typical FE-SEM image and the particle size distribution are shown in Fig. 1B. The fraction of the  $\text{Pd}^+$  species of the surface Pd atoms became 7% when the  $\text{Cu}(\text{NO}_3)_2/\text{PCA}$  molar ratio was 0.05. Scheme 2B shows a proposed structure of the five-shell Pd nanocluster composed of 560 Pd atoms whose composition is  $\text{Pd}_{560}(\text{NO}_3)_{100}(\text{OAc})_{250}\text{O}_{10}$ . It is notable that the treatment of  $\text{Pd}_4\text{phen}_2(\text{CO})_2(\text{OAc})_4$  with  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  in a shorter preparation time (e.g.,  $\sim 10$  min) afforded Pd nanoclusters with a  $\sigma/d$  value of 9% ( $\sigma = 2.8 \text{ \AA}$ ,  $d = 32 \text{ \AA}$ ), as depicted in Fig. 1C. This particle size might correspond with six-shell or seven-shell clusters.<sup>[12]</sup>

The above shell-selective synthesis of monodispersed Pd clusters allows us to consider the feature

**Fig. 2** The HR-TEM image of the eight-shell Pd nanocluster immobilized on the  $\text{TiO}_2$  surface.

**Scheme 2** Possible structure models of (A) the eight-shell Pd nanocluster,  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$ , and (B) the five-shell Pd nanocluster,  $\text{Pd}_{560}(\text{NO}_3)_{100}(\text{OAc})_{250}\text{O}_{10}$ , with an fcc cuboctahedral shape.

of nanocluster formation as follows. The metal nitrates promote the disproportionation of monovalent Pd ions of  $\text{Pd}_4\text{phen}_2(\text{CO})_2(\text{OAc})_4$  complex to yield  $\text{Pd}^0$  and  $\text{Pd}^{2+}$  cation species. The  $\text{Pd}^0$  species aggregate to form relatively small Pd assemblies. Because the amounts of  $\text{Pd}^0$  and  $\text{Pd}^{2+}$  species increase with increasing amount of the metal nitrates and duration of the treatment, the small assembly of  $\text{Pd}^0$  species is overspread with generated  $\text{Pd}^0$  species, which lead to the growth of a larger  $\text{Pd}^0$  nanocluster. Subsequently, the  $\text{Pd}^0$  atoms located at corner/edge sites of the larger cluster surface are oxidized by the metal nitrate to give  $\text{Pd}^{2+}$  cations, which are stabilized by anionic ligands such as  $\text{OAc}^-$  and  $\text{NO}_3^-$ . On the other hand, the  $\text{Pd}_2\text{O}$  surface species might be formed by the oxidation of the  $\text{Pd}^0$  ions by  $\text{O}_2$ . An additional increase in the amount of the metal nitrates resulted in a deep oxidation of the surface Pd species and also an exfoliation of  $\text{Pd}^{2+}$  ions from the cluster surface, which resulted in the formation of smaller metallic clusters together with decomposition into the monomeric  $\text{Pd}^{2+}$  complex. Indeed, both the particle size and the surface oxidation state of the Pd cluster exhibited maxima at a  $\text{Cu}(\text{NO}_3)_2/\text{PCA}$  molar ratio of 0.10.<sup>[20]</sup>

The quite narrow size distribution of the present Pd nanoclusters could be ascribed to the strong ability of the metal nitrate for the disproportionation of monovalent Pd ions of the  $\text{Pd}_4\text{phen}_2(\text{CO})_2(\text{OAc})_4$  complex that leads to a formation of a relatively small Pd assembly through a fast nucleation step of the  $\text{Pd}^0$  species. Furthermore, the partial oxidation of surface  $\text{Pd}^0$  species at the larger cluster surface with metal nitrate retards the successive growth of the nanoclusters.

Conclusively, the treatment of palladium carbonyl acetate (PCA) cluster with  $\text{Cu}(\text{NO}_3)_2$  in the presence of phen under an  $\text{O}_2$  atmosphere afforded monodispersed Pd nanoclusters containing both  $\text{Pd}^0$  and cationic Pd species on the surface. The novel preparation method described here enables a “shell-selective” synthesis of Pd nanoclusters, keeping the high monodispersity as well as a tuning of the surface fraction of  $\text{Pd}^0$ ,  $\text{Pd}^+$ , and  $\text{Pd}^{2+}$  species. Unique catalyses of

**Scheme 3** Oxidative acetoxylation of toluene in the presence of molecular oxygen catalyzed by the eight-shell Pd nanoclusters.

the Pd nanoclusters in the acetoxylation of toluene, alcohol oxidation, and the Wacker oxidation are described below.

## APPLICATION

Palladium is among the most important catalysts in organic synthesis.<sup>[17,18,27,28]</sup> Our monodispersed Pd nanoclusters will offer the possibility of unprecedented catalytic reactions based on specific surface ensemble Pd sites within a regular arrangement of multiple Pd species. We applied the monodispersed Pd nanoclusters to heterogeneous catalysts for oxidative functional transformations in liquid phase under an atmospheric  $\text{O}_2$  pressure.

### Acetoxylation of Toluene

Acetoxylation is one of the powerful methods to functionalize various kinds of C–H bonds in hydrocarbons; the acetoxy group can be facilely transformed into other functional ones. Generally, the acetoxylation of toluene occurs by using a homogeneous  $\text{Pd}(\text{OAc})_2$  complex in an acetic acid under an  $\text{O}_2$  atmosphere to give benzyl acetates, where additives of KOAc and  $\text{Sn}(\text{OAc})_2$  are indispensable.<sup>[29]</sup> In heterogeneous Pd catalysts, Pd particles on charcoal or  $\text{SiO}_2$ , as a support interacting with excess amounts of  $\text{Sn}(\text{2-ethyl-hexanoate})_2$  and KOAc, exhibit catalytic activity.<sup>[30,31]</sup> It is said that the efficient acetoxylation by Pd catalysts cannot be attained without any additives.

Our monodispersed Pd nanoclusters acted as heterogeneous catalysts for the oxidative acetoxylation of

<sup>d</sup>Fifteen percent of 2-hexenyl acetate was formed.

toluene to benzyl acetates using molecular oxygen (Scheme 3).<sup>[20]</sup> Among the Pd nanoclusters prepared using Cu(NO<sub>3</sub>)<sub>2</sub>, the maximum catalytic activity was obtained in the case of the eight-shell Pd nanoclusters having the highest fraction of Pd<sub>2</sub>O and the divalent Pd species. It is interesting to note that the monodispersed Pd nanoclusters can efficiently catalyze the oxidative acetoxylation of toluene without any additives such as Sn(II) compounds, KOAc, and reoxidizing reagents. Furthermore, the eight-shell Pd nanoclusters showed much higher catalytic activity than conventional Pd catalysts [e.g. Pd/carbon, Pd/Al<sub>2</sub>O<sub>3</sub>, and Pd(OAc)<sub>2</sub>]. The eight-shell Pd nanoclusters immobilized on the TiO<sub>2</sub> surface

also had high catalytic activity for the acetoxylation of toluene.<sup>f</sup> These results are summarized in Table 1.

The high catalytic activity of the Pd nanoclusters is ascribed to an ensemble of the cationic Pd species and Pd<sup>0</sup> on the cluster surface. Vide supra, in the conventional oxidative acetoxylation catalyzed by Pd catalyst systems, an addition of potassium and tin compounds is indispensable. The Sn<sup>2+</sup> additives promote the

<sup>f</sup>The particle size of the Pd clusters did not change appreciably after the acetoxylation reaction. During the acetoxylation, no Pd leaching was observed by the ICP method, whose detection limit is 24 ppb.

reduction step of  $\text{Pd}^{2+}$  to  $\text{Pd}^0$ , and the resulting  $\text{Sn}^{4+}$  oxide may serve as an oxygen reservoir in oxygen-poor regimes. The potassium renders Pd particles more electropositive, which becomes susceptible to interaction with an electron-donating substrate (e.g., toluene). Because the cationic Pd atoms already exist on the surface of the Pd cluster in the present catalyst system, the addition of potassium compounds is not required to facilitate the interaction with toluene. Furthermore, tin compound is also unnecessary because the  $\text{Pd}_2\text{O}$  species acted as an oxygen reservoir through an easy interconversion between  $\text{Pd}^+$  and  $\text{Pd}^0$  species.

## Alcohol Oxidation

Recently, much attention has focused on Pd-catalyzed oxidation of alcohols into the corresponding carbonyl compounds using molecular oxygen as an environment-friendly oxidant.<sup>[32–37]</sup> In this section, we explore the catalytic potential of the monodispersed Pd nanoclusters in the aerobic oxidation of alcohols.<sup>[21]</sup>

Results of the aerobic oxidation of various alcohols catalyzed by the  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$  nanoclusters are displayed in Table 2 together with those using the  $\text{Pd}_{561}\text{phen}_{60}(\text{OAc})_{180}$  cluster<sup>[38]</sup> and  $\text{Pd}(\text{OAc})_2$ -pyridine<sup>[35]</sup> catalytic systems. Our Pd nanoclusters efficiently catalyzed the oxidation of *primary* aromatic allylic alcohols to the corresponding aldehydes using molecular oxygen (entries 1, 4, and 5). It should be noted that the present Pd nanoclusters showed higher reactivity for *primary* aromatic allylic alcohols than for aliphatic ones (e.g., 3-methyl-2-buten-1-ol and 2-hexen-1-ol, entries 6 and 8). Furthermore, the oxidation of *secondary* aromatic allylic alcohols proceeded

slowly (entry 10). Interestingly, benzylic alcohols were oxidized more slowly than allylic alcohols (entries 14 and 17). This high reactivity for allylic alcohols was also exemplified in a competitive reaction of an equimolar mixture of cinnamyl alcohol and benzyl alcohol; cinnamaldehyde was selectively obtained in 92% yield, together with only 1% of benzaldehyde for 3 hr (Fig. 3).

Generally, divalent Pd catalysts are prone to oxidize benzyl alcohols, but are not suitable for the oxidation of allylic alcohols because of an irreversible coordination of allylic alcohols to the Pd species (entry 3 vs. entry 16).<sup>[35,39]</sup> The difference between the present Pd nanoclusters and conventional  $\text{Pd}^{2+}$  complexes lies in the high reactivity for allylic alcohols over benzylic alcohols. As compared with the  $\text{Pd}_{561}\text{phen}_{60}(\text{OAc})_{180}$  cluster, having  $\text{Pd}^+$  cation species throughout the surface,<sup>[38]</sup> the present Pd nanoclusters preferred aromatic allylic alcohols to aliphatic ones. Cinnamyl alcohol was completely oxidized only for 1 hr, whereas the oxidation of 3-methyl-2-buten-1-ol required 5 hr (entry 1 vs. entry 6). In contrast, using the  $\text{Pd}_{561}\text{phen}_{60}(\text{OAc})_{180}$  catalyst, the oxidation of both allylic alcohols proceeded in a similar rate (entry 2 vs. entry 7).

The highest catalytic activity was obtained for the  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$  nanoclusters, which have the highest percentage of the  $\text{Pd}^+$  species among the surface Pd atoms.<sup>[21]</sup> Therefore, in a similar fashion of the above acetoxylation, we considered that the highly selective oxidation of aromatic alcohols by the Pd nanoclusters could be explained by the unique surface ensemble Pd sites; a  $\pi$ -bond interaction between aromatic allylic alcohols and the cationic  $\text{Pd}^{2+}$  species. The high selectivity for the oxidation of allylic alcohols when compared with benzyl alcohol might be related to a coordination of the C=C bond with a Pd cation (e.g.,  $\text{Pd}^{2+}$ ). Correspondingly, the distance between the Pd cation and Pd<sup>0</sup> fits with that found for the distance between a terminal  $\beta$ -carbon of a C=C bond and an oxygen atom of the OH of allylic alcohols.<sup>g</sup>

## Wacker Oxidation

The Wacker oxidation is a powerful method to synthesize methyl ketones from terminal olefins, catalyzed by an aqueous solution of  $\text{Pd}^{2+}$  salt combined with  $\text{Cu}^{2+}$  and HCl under aerobic conditions.<sup>[27]</sup> The HCl is required to achieve a favorable reoxidation of  $\text{Pd}^0$  by  $\text{Cu}^{2+}$  ions, and to prevent the aggregation of transient

**Fig. 3** Competitive oxidation of an equimolar mixture of cinnamyl alcohol and benzyl alcohol. Reaction conditions:  $\text{Pd}_{2060}(\text{NO}_3)_{360}(\text{OAc})_{360}\text{O}_{80}$  0.0063 g (Pd; 0.05 mmol), cinnamyl alcohol 2 mmol, benzyl alcohol 2 mmol, AcOH 5 ml, 60°C,  $\text{O}_2$  atmosphere.

<sup>g</sup>The EXAFS measurement of the Pd nanoclusters showed that the average distance between the Pd species was 2.75 Å. The distance between a terminal  $\beta$ -carbon of the C=C bond and oxygen atom of the OH function of cinnamyl alcohol was ca. 3 Å, calculated by the PM3 semiempirical method as implemented in MOPAC.

**Scheme 4** The Wacker oxidation of terminal olefins catalyzed by eight-shell Pd nanoclusters immobilized on the TiO<sub>2</sub> surface.

atomic Pd<sup>0</sup> species to inactive Pd precipitates. An acidic chloride medium not only corrodes the reactor wall, but also leads to the formation of chlorinated by-products. Hence much effort has been devoted to the development of HCl-free Wacker systems.<sup>[40–42]</sup> However, there are few heterogeneous catalysts for the Wacker oxidation of unreactive higher terminal olefins in liquid phase.<sup>[43–46]</sup> We found that the Pd nanoclusters immobilized on a TiO<sub>2</sub> surface acted as a highly active and recyclable catalyst for the liquid-phase Wacker oxidation of higher terminal olefins in *N,N*-dimethylacetamide (DMA) solvent without acid additives (Scheme 4).<sup>[22]</sup>

The eight-shell Pd nanoclusters showed high catalytic activity for the oxidation of 1-decene in the presence of water and CuCl<sub>2</sub> · 2H<sub>2</sub>O under O<sub>2</sub> at atmospheric pressure to afford 2-decanone selectively. The catalytic activity of the eight-shell Pd nanoclusters was higher than that of the five-shell Pd<sub>560</sub>(NO<sub>3</sub>)<sub>100</sub>(OAc)<sub>250</sub>O<sub>10</sub> clusters. In the present oxidation, the Pd nanoclusters immobilized on the TiO<sub>2</sub> could maintain the high catalytic activity and selectivity that make the workup procedure strikingly simple. Water, O<sub>2</sub>, and CuCl<sub>2</sub> · 2H<sub>2</sub>O were necessary to obtain high yields of 2-decanone. Only three equivalents of CuCl<sub>2</sub> to Pd were sufficient for achieving high catalytic activity. It is notable that the Pd nanocluster catalysts enable the Wacker oxidation in liquid phase under acid-free conditions.

**Table 3** The wacker oxidation of various terminal olefins catalyzed by eight-shell Pd nanoclusters/TiO<sub>2</sub><sup>a</sup>

Substrate	Yield (%) <sup>b</sup>	Selectivity (%)
1-Hexane	94 <sup>c</sup>	98
1-Octene	84	98
1-Decene	88	97
1-Dodecene	83	98
<i>n</i> -Butyl vinyl ether	91	100
Vinylcyclohexane	92 <sup>d</sup>	100

<sup>a</sup>Reaction conditions: Pd 0.01 mmol, substrate 1 mmol, CuCl<sub>2</sub> · 2H<sub>2</sub>O 0.03 mmol, *N,N*-dimethylacetamide 4 mL, H<sub>2</sub>O 0.5 mL, 80°C, 2 hr, O<sub>2</sub> atmosphere.

<sup>b</sup>Yields of products were determined by GC analysis using an internal standard technique.

<sup>c</sup>50°C.

<sup>d</sup>60°C, 3 hr.

Terminal olefins such as 1-hexene, 1-octene, 1-decene, 1-dodecene, vinylcyclohexane, and *n*-butyl vinyl ether were selectively oxidized by the immobilized Pd nanocluster catalysts to give the corresponding methyl ketones and *n*-butyl acetate, respectively, in high yields within 3 hr (Table 3). Furthermore, the spent catalyst was easily separated from the reaction mixture by filtration and could be reused with retention of high activity and selectivity. However, no oxidation occurred when the filtrate was further reacted. The present Wacker oxidation proceeds via the Pd<sup>2+</sup> species on the Pd nanocluster surface. The use of even small amounts of CuCl<sub>2</sub> efficiently promoted the reoxidation of Pd<sup>0</sup> to Pd<sup>2+</sup> species, which might be ascribed to a cooperative action of Pd<sup>2+</sup>, Pd<sup>+</sup>, and Pd<sup>0</sup> species on the nanocluster surface.

## CONCLUSION

This study demonstrated the “shell-selective” synthesis and characterization of monodispersed Pd nanoclusters containing Pd<sup>0</sup>, Pd<sup>+</sup>, and Pd<sup>2+</sup> species on the surface. Each surface Pd species (e.g., Pd<sup>0</sup>, Pd<sup>+</sup>, and Pd<sup>2+</sup>) does not act individually as a catalytic site, but works cooperatively as a “trio” on the same cluster surface to attain unique catalytic performances for functional transformations under an O<sub>2</sub> atmosphere. Furthermore, the Pd nanoclusters could be immobilized on a neutral TiO<sub>2</sub> surface with retention of their original size and unique catalysis. The monodispersed Pd nanoclusters provides a new strategy to design highly *selective* Pd catalysts in many organic syntheses aiming at “green and sustainable chemistry”.<sup>[47]</sup>

# Patents and Inventions

Jeffrey A. Lindeman

*Nixon Peabody LLP, Washington, District of Columbia, U.S.A.*

## INTRODUCTION

Invention is only the first step in the process of obtaining a patent. Preparing and filing a patent application is the required second step; yet, though it describes the invention, a patent application is as much a legal document as it is a technical document. In a patent application, the language of science comes under legal scrutiny. For new technology, the language of science may not easily fit into a legal document, yet it is the words used to describe and claim the invention that determine the scope of the intellectual property right deeded by the patent grant. For emerging technologies, such as nanotechnology, choosing the right words to describe and claim an invention presents a particularly unique challenge. This entry looks at the legal framework used to interpret the language of patent claims and considers how best to navigate the legal landscape to obtain robust and effective patents for nanotechnology.

This entry is written in a legal memorandum style. Citations for and references to portions of the statutes and the legal decisions discussed are included in the text rather than as endnotes.

## DEFINITIONS OF NANOTECHNOLOGY

Although still an emerging science, nanotechnology is already spanning and combining many diverse technologies, from biotechnology to circuits and machines to molecules. Despite its broad technological range, nanotechnology inventions are all characterized in terms of their small scale, their very small scale. To say size is important in nanotechnology is to understate its scientific premise. Size is everything in nanotechnology. Therefore, to patent nanotechnology, the patentable nanoscale features of the invention should be the focus of the patent specification and the patent claims.

Nanotechnology has been defined as research and technology development on the atomic, molecular, or macromolecular scale, where dimensions range from approximately 1–100 nm. Research and development efforts in nanotechnology seek to provide not only a fundamental understanding of phenomena and

materials at the nanoscale but also to create and use structures, devices, and systems that have unique properties and functions because of their very small size. These unique properties and functions include mechanisms, operation and control at the nanoscale, as well as integration of nanoscale structure and processes into larger material components, systems, and architectures. Within these larger scale assemblies, the control and construction of their structures and components remains at the nanometer scale.<sup>[1]</sup>

For patent applicants, another important definition of nanotechnology comes from the United States Patent and Trademark Office (USPTO). The USPTO arranges technology by what it terms classes and subclasses. Although this serves an administrative function, each class of technology is uniquely defined. At the USPTO, Class 977 covers nanotechnology and has the following class definition:<sup>[2]</sup>

This class provides for disclosures

- a. related to research and technology development at the atomic, molecular or macromolecular levels, in the length of scale of approximately 1–100 nm range in at least one dimension, and
- b. that provides a fundamental understanding of phenomena and materials at the nanoscale and to create and use structures, devices, and systems that have novel properties and functions because of their small and/or intermediate size.

In addition, disclosures in this class may be defined by one or more of the following statements.

- a. The novel and differentiating properties and functions of disclosures in this class are developed at a critical length scale of matter, typically under 100 nm.
- b. Nanotechnology research and development includes manipulation, processing, and fabrication under control of the nanoscale structures and their integration into larger material components, systems and architectures. Within these larger scale assemblies, the control and construction of their structures and components remains at the nanometer scale.

- c. In some particular cases, the critical length scale for novel properties and phenomena may be less than 1 nm or be slightly larger than 100 nm.
- d. The novel properties or functions, e.g., special effects, are attributed to and are intrinsic at the nanoscale.

Such nanoscale materials are infinitesimally minute arrangements of matter (i.e., nano-structural assemblages) have particularly shaped configurations formed during manufacture and are distinct from both naturally occurring and chemically produced chemical or biological arrangements composed of similar matter.

- a. Also, encompassed within this collection are disclosures related to the controlled analysis, measurement, manufacture or treatment of such nano-structural assemblages and their associated processes or apparatus specially adapted for performing at least one step in such processes.
- b. Novel and differentiating properties and functions relate to the altering of basic chemical or physical properties of the nano-structural assemblage attributed at the nanoscale.

Obviously, numerous nanotechnology inventions come within this definition.

Almost any invention can be thought of as a new and nonobvious solution to a problem. A nanoscale invention, likewise, solves problems, but in spaces of about 1–100 nm. Certainly working at the nanoscale presents unique technical problems to be solved. In the same way, preparing patent applications to adequately and appropriately protect nanotechnology inventions presents its own unique challenges.

## PATENTING NANOTECHNOLOGY

The claims of a patent define the scope of the patented invention. To claim nanotechnology, at least some word or term in the patent claim typically indicates that at least some aspect of the invention is at the nanoscale. Words, as everyone knows, are not necessarily precise. This is particularly true when words are used to describe and define technology, especially nanotechnology. Unfortunately, the nature of language makes it impossible to capture the essence of a thing in a patent application. *See Festo Corp. v. Shoketsu Kinzoku Kogyo Kabushi Co. Ltd.*, 535 U.S. 722, 731 (2002) (discussing the imprecision of language and patent infringement under the doctrine of equivalents).

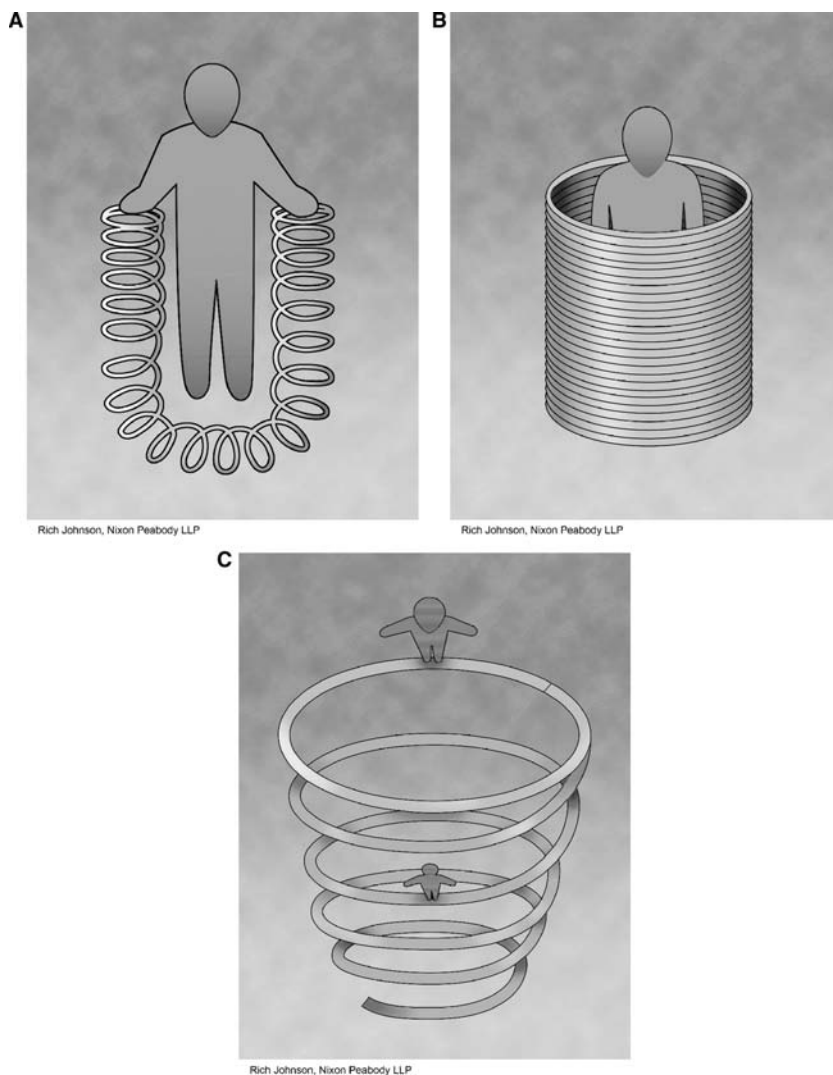

The scope of a patent claim is determined by the words used to describe and claim the invention. The everyday words we often use to describe technology

or an invention do not necessarily change with a change in size, for example when one moves from the macroscale to the nanoscale. The only change is in the size of what we are describing and what the words define. If the words of a patent claim carry their everyday meaning, they may be too big for nanotechnology. The typical meaning of words in patent claims may not be sufficient to describe a nanotechnology invention, but we cannot, and we do not, simply add the prefix *nano* to every word as we discuss or write about nanotechnology. The common meaning of a word can often be acceptable for ordinary inventions—those in more established areas of technology—but patenting nanotechnology involves more careful diction. This article gives an overview of how words in patent claims are interpreted and discusses considerations for drafting patent claims to nanotechnology. As nanotechnology continues to develop, so do nanotechnology patent practice and court decisions concerning nanotechnology patents. With that in mind, we may see unique applications of patent law and practice to nanotechnology.

## The Beginning

As mentioned, inventions most often involve a new solution to a particular problem. Nanotechnology inventions involve solving problems with nanoscale technology. Simply creating a nanoscale device or performing a nanoscale process can be the new solution that is invention. Not all devices or processes can be readily manufactured or accomplished on the nanoscale. Just moving from the macroscale or from the microscale to the nanoscale can present the very problem that needs to be solved. Fig. 1A–C illustrate such a change in perspective as one moves from the macroscale to contemplating the nanoscale. There can also be new devices or processes that simply could not have existed before the advent of nanotechnology. This can provide the basis for an invention. Under U.S. law, whoever invents or discovers any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof, may obtain a patent therefore. *See* 35 U.S.C. § 101.

To obtain a patent, an applicant first files a patent application with the U.S. Patent and Trademark Office. The patent application then undergoes examination by a patent examiner. The patent application must describe the invention and then conclude with one or more patent claims where the patent applicant sets out the invention to be patented. *See* 35 U.S.C. §§ 111 and 112. During examination, the patent examiner focuses on the claimed invention to ensure that it meets the statutory requirements of novelty (35 U.S.C. § 102) and unobviousness (35 U.S.C. § 103) and that

**Fig. 1** (A) The macroscale view; (B) The microscale view; (C) The nanoscale view.

the patent specification describes the claimed invention as required by statute (35 U.S.C. § 112). A patent is issued only after the patent examiner concludes that these requirements are fully met.

### Patent Claims

Patent claims define the scope of technology property rights granted in the form of a patent. A patent claim must, by statute, particularly point out and distinctly claim the subject matter that the applicant regards as his invention. 35 U.S.C. § 112, second paragraph. This is essentially a requirement for precision and definiteness of claim language. The language of the claims must make clear what they encompass. *PPG Industries, Inc. v. Guardian Industries Corp.*, 75 F.3d 1558, 1562 (Fed. Cir. 1996) (citations omitted). The standard for assessing whether a patent claim meets the statutory requirement has been stated as

follows: “If one skilled in the art would understand the bounds of the claim when read in light of the specification, then the claim satisfies section 112 paragraph 2.” *Exxon Research and Engineering Corp. v. U.S.*, 265 F.3d 1371, 1375 (Fed. Cir. 2001) citing *Miles Labs., Inc. v. Shandon, Inc.*, 997 F.2d 870, 875 (Fed. Cir. 1993). This standard has also been stated in somewhat different terms: whether “the claims at issue [are] sufficiently precise to permit a potential competitor to determine whether or not he is infringing.” *Exxon Research*, 265 F.3d at 1375 quoting *Morton Int’l, Inc. v. Cardinal Chem, Co.*, 5 F.3d 1464, 1470. (Fed. Cir. 1993).

Although patent claims are first presented by the patent applicant and then examined by the patent examiner, patent claims are often not fully tested until a patent is litigated. While being examined for patentability, patent claims are given their broadest reasonable interpretation, consistent with the specification. During examination, the patent applicant and the

patent examiner often carry on a discussion of what the terms in a patent claim mean and the scope of the invention the claims define. From the USPTO's perspective, a patent applicant always has the opportunity to amend the claims and broad interpretation by the examiner reduces the possibility that the claim, once issued in a patent, will be interpreted more broadly than is justified. Manual of Patent Examining Procedure (MPEP) § 2111.

In patent litigation, the interpretation of a patent claim, (claim construction), is a question of law for the court (the judge) to decide, not one of fact for the jury to decide. *Markman v. Westview Instruments, Inc.*, 517 U.S. 370, 384 (1996); *Gechter v. Davidson*, 116 F.3d 1454, 1457 (Fed. Cir. 1997); *Vitronics Corp. v. Conceptoronic, Inc.*, 90 F.3d 1576, 1582 (Fed. Cir. 1996). In litigation, claim language should be interpreted as one reasonably skilled in the art would have interpreted the claim at the time of invention. *Specialty Composites v. Cabot Corp.*, 845 F.2d 981, 986 (Fed. Cir. 1988) (quoting *Loctite Corp. v. Ultraseal Ltd.*, 781 F.2d 861, 867 (Fed. Cir. 1985)).

Claim construction, the determination of the meaning and scope of patent claims, begins with the language of the claims. *Vitronics Corp.*, 90 F.3d at 1582. The words of a claim are generally to be accorded their *ordinary and customary meaning*, *id.* at 1582, which is "the meaning that term would have to a person of ordinary skill in the art in question at the time of invention." *Phillips v. AWH Corp.*, 415 F.3d 1303, 1313 (Fed. Cir. 2005) (en banc). It is presumed that the person of ordinary skill in the art read the claim in the context of the entire patent, including the specification, not confining his understanding to the claim at issue. *Id.* at 1314; see also *V-Formation, Inc. v. Bennetton Group SpA*, 401 F.3d 1307, 1310 (Fed. Cir. 2005) (noting that the intrinsic record [the patent file history], "usually provides the technological and temporal context to enable the court to ascertain the meaning of the claim to one of ordinary skill in the art at the time of the invention"). Further, claim terms are presumed to be used consistently throughout the patent, such that the usage of a term in one claim can often illuminate the meaning of the same term in other claims. *Phillips*, 415 F.3d, at 1314; see also *Rexnord Corp. v. Laitram Corp.*, 274 F.3d 1336, 1342 (Fed. Cir. 2001).

For inventions in nanotechnology, *ordinary and customary meaning* may be a poor fit if an inventor intends a word to define the nanoscale aspect of the invention, particularly when its ordinary meaning does not define size or, for example, differentiate between the nanoscale or the macroscale. To effectively draft nanotechnology patent applications, especially patent claims, one should understand the legal contours of patent claim constitution, its role in defining claim

language, and, thereby, in delineating the scope of patent claims. Employing appropriate claim terminology can mean the difference between a patent claim that successfully captures the inventive nanotechnology, or one that unintentionally and unfortunately overlaps macroscale technology. Overlapping the macroscale may cause a patent claim to be invalid because it unwittingly encompasses prior art or because it fails to particularly point out and distinctly claim the subject matter of applicant's invention. See 35 U.S.C. § 112, second paragraph.

## CONSTRUING PATENT CLAIM LANGUAGE

Construing, or defining the scope of, a patent claim, a court first examines the intrinsic evidence associated with the patent, i.e., the patent claims, the patent specification, and often the patent's prosecution history. See *Gart v. Logitech, Inc.*, 115 F.3d 1334, 1339–1340 (Fed. Cir. 1997); and *O.I. Corp. v. Tekmar Co. Inc.*, 115 F.3d 1576, 1581 (Fed. Cir. 1997). The patent claims, specification, and drawings/Figs. (if present) embody the patent application an inventor files. Patent prosecution is the back and forth exchange of documents and the discussion that the patent applicant has with the patent examiner when a patent application is undergoing examination. The patent application and the patent's prosecution history provide ample opportunities (and perhaps ample pitfalls) for words to be explained or further defined. When interpreting patent claims, a court will hold a patent applicant to the definitions established in this intrinsic evidence. If the intrinsic evidence fails to clarify the meaning and scope of a claim term, extrinsic evidence (e.g., expert testimony, inventor testimony, scientific articles, treatises) may be used. *Spectrum Int'l, Inc. v. Sterillite Corp.*, 164 F.3d 1372, 1378 (Fed. Cir. 1998); *Kegel Co., Inc. v. AMF Bolwing, Inc.*, 127 F.3d 1420, 1426 (Fed. Cir. 1997). Extrinsic evidence should not be used to rebut the definition of claim meaning that is unambiguous in light of the intrinsic evidence. *Phillips*, 415 F.3d, at 1324.

In the context of those established claim construction principles, a heavy presumption nonetheless exists that a word carries its ordinary or customary meaning in the relevant art. The words used in the claims are presumed to mean what they say. The words have the full, ordinary meaning that would be attributed to those words by persons skilled in the relevant art. See *CCS Fitness, Inc. v. Brunswick Corp.*, 288 F.3d 1359, 1366, (Fed. Cir. 2002); *K-2 Corp. v. Salomon S.A.*, 191 F.3d 1356, 1362–1363 (Fed. Cir. 1999); *Johnson Worldwide Assocs., Inc. v. Zebco Corp.*, 175 F.3d 985, 989 (Fed. Cir. 1999); and *Specialty Composites v. Cabot Corp.*, 845 F.2d 981, 986 (Fed. Cir. 1988). It is the language

of the claims that frames and ultimately resolves all issues of claim interpretation. *AbTox, Inc. v. Exitron Corp.*, 122 F.3d 1019, 1023 (Fed. Cir. 1997). The resulting claim interpretation must, in the end, accord with the words chosen by the patentee to stake out the boundaries of the claimed intellectual property. See *Renishaw PLC, v. Marposs Societa' per Azioni*, 158 F.3d 1243, 1248 (Fed. Cir. 1998) citing *Thermalloy, Inc. v. Aavid Eng'g, Inc.*, 121 F.3d 691, 693 (Fed. Cir. 1997) (“Throughout the interpretation process, the focus remains on the meaning of the claim language”).

### No “Importing” Limitations into Patent Claims

While intrinsic evidence, such as the patent specification and prosecution history, must be consulted to ensure consistency of the selected meaning of a claim term, courts must take care not to import limitations into the claims. It is axiomatic that limitations must not be imported from the specification into the claims. Importing a limitation into the claims can seize the meaning of a term and push the claim construction in a different direction than the patent applicant intended. In other words, if a patent claim does not set out nanoscale limitations, a court may refuse to construe the patent claim as defining a nanoscale invention. Particular embodiments from the patent specification will not be read into patent claims when the language is broader than the particular embodiments. See *Electro Med. Sys. S.S. v. Cooper Life Sci.*, 34 F.3d 1048, 1054 (Fed. Cir. 1994). In *Specialty Composites* the court refused to limit the term plasticizer in the claims to external plasticizers when the specification and prosecution showed the term to include both external and internal plasticizers. *Specialty Composites*, 845 F.3d at 986–987. See also, *Virginia Panel Corp. v. MAC Panel Co.*, 133 F.3d 860, 865–866 (Fed. Cir. 1997) (the term “reciprocating” given its ordinary meaning and not limited to linear reciprocation); *Sojland v. Musland*, 847 F.2d 1573, 1581–1582 (Fed. Cir. 1988) (term baffle not limited to only rigid baffles and panel not limited to only panels of lattice construction).

### RELEVANT ART

A claim term takes its ordinary meaning as understood by persons skilled in the relevant art. *Rexnord Corp. v. Laitram Corp.*, 274 F.3d 1336, 1342 (Fed. Cir. 2001). It is interesting to consider what the relevant art may be for nanotechnology. Is it the particular area of technology, electrical circuits, or devices, for example? Or, is the relevant art determined only by the nanoscale aspects? Certainly, if it is not now, it will be a combination of these as distinct areas of nanotechnology continue to develop.

Patent applicants will always use common language and parlance when discussing their inventions. An entirely new language will not develop exclusively for nanotechnology. Even as areas of nanotechnology develop their own lexicons, patent applicants will use their own thoughts and words to describe their inventions. Variation in the ordinary meaning of common words as well as in accepted or customary nanotechnology terms will certainly occur and persist. Understanding that, there are four common situations when a court may constrict or restrict the ordinary meaning of a claim term:

1. the patentee acted as his or her own lexicographer;
2. the patentee distinguished the invention from the prior art;
3. the term chosen by the patentee deprives the claim of clarity; and
4. the patentee phrased the claim in means-plus-function format.

*CCS Fitness*, 288 F.3d at 1366–1367. In each of these situations the patentee actively applies a particular definition to the term in question; the term’s ordinary meaning is not necessarily any longer presumed. This is true for all areas of technology. It is likely to be particularly true for nanotechnology—now as the language of nanotechnology is developing and later once it has its own fully established lexicon and jargon.

### The Patentee as His or Her Own Lexicographer

A patentee may choose to define a term in the patent specification. If so, that defined meaning controls the meaning of that term in the patent, particularly in the patent claims. Acting as his or her own lexicographer overcomes the presumption favoring ordinary and customary meaning where the patentee has clearly set forth an explicit definition of the term different from its ordinary meaning. See *Johnson Worldwide*, 175 F.3d at 990 and *Abbott Labs. v. Novopharm*, 323 F.3d 1324 (Fed. Cir. 2003). Often a patent applicant, an inventor, will want a word in a patent claim to take its ordinary meaning. When focusing on the nanoscale aspects of a nanotechnology invention, an applicant may, however, want to avoid any uncertainty in meaning and firmly establish patentability based on the nanoscale aspects.

An illustration of where, by acting as their own lexicographer, a patent applicant controlled the meaning of a claim term is found in *Abbott Labs v. Novopharm*. The patented invention involved micronized pharmaceutical formulations of fenofibrate, which is used to treat hyperlipidemia and hypercholesterolemia.

The micronized formulation improved the bioavailability of fenofibrate. The Abbott Labs case turned on the construction of the terms *co-micronized mixture* and *co-micronization*. During prosecution, Abbott amended its claims, changing the phrase “the said composition containing fenofibrate and a solid surfactant, which have been co-micronized” to “said composition containing a co-micronized mixture of particles of fenofibrate and a solid surfactant, wherein the mean particle size of the co-micronized mixture is less than 15 μm.” *Abbott Labs*, 323 F.3d at 1327. The dispute was whether co-micronization required micronization of fenofibrate and a solid surfactant “in the absence of other excipients.” The term *co-micronization* was not known in the prior art before Abbott’s patent application, although the terms *micronization* and *co-* did have well known meanings understood by those of ordinary skill in the art. The Federal Circuit observed that the specification explicitly defined the phrase “co-micronization of fenofibrate and a solid surfactant” as “micronization of an intimate mixture of fenofibrate and a solid surfactant.” Based on this definition, the court held that Abbott had acted as its own lexicographer and concluded accordingly that the definition from the specification could be read into the claims. *Abbott Labs*, 323 F.3d at 1330. Focusing on the intimate mixture defined in the specification, the *Abbott Labs* court construed the co-micronization of fenofibrate and solid surfactant term in the claims to mean co-micronization of a mixture consisting essentially of fenofibrate and solid surfactant but not excluding minor impurities. Because the Novopharm formulation mixed fenofibrate and a solid surfactant in the presence of other significant ingredients, the Abbott patent was not infringed.

Defining your own terms as in *Abbott Labs*, acting as your own lexicographer, is not then without risk to the patent claim’s scope. For nanotechnology, however, it may be a necessity. The defined term is likely to be narrowly construed to the specific definition employed. Yet, neglecting to consider or even relying on a term’s ordinary meaning itself carries risk that the term may not be sufficiently precise to describe and distinguish the invention. Here is the true risk for nanotechnology. Simply put, care should be taken when choosing a particular word or combination of words to describe and claim the invention. Once made, that choice must be respected throughout prosecution of the patent.

### Distinguishing the Invention from the Prior Art

A term will not carry its common meaning if the patentee used a different or specific meaning of the term to distinguish the patented invention from the prior art. This can occur where the patentee distinguished the

prior art on the basis of a particular embodiment of the invention, expressly disclaimed subject matter, or described a particular embodiment as important to the invention. See *CCS Fitness*, 288 F.3d at 1366–1367. In other words, the presumption favoring ordinary meaning will be rebutted if the inventor has disavowed or disclaimed scope of coverage, by using words or expressions of manifest exclusion or restriction, representing a clear disavowal of claim scope. See *Teleflex*, 299 F.3d at 1324. *Spectrum Int’l*, 164 F.3d at 1378 (narrowing a claim term’s ordinary meaning based on statements in intrinsic evidence that distinguished the claimed invention from the prior art); *Scimed Life Sys, Inc. v. Adv. Cardiovascular Sys., Inc.*, 242 F.3d 1337, 1343–1344 (Fed. Cir. 2001) (limiting a claim term based in part on statements in the specification indicating the “all embodiments” of the claimed invention used a particular structure); *Toro Co. v. White Consol. Indus., Inc.*, 199 F.3d 1295, 1301 (Fed. Cir. 1999) (limiting claim term based in part on statements made in the specification describing a particular structure as “important to the invention”); *General Am. Transp. Corp. v. Cryo-Trans, Inc.*, 93 F.3d 766, 770 (Fed. Cir. 1996) (holding that claim language and specification made clear that openings “adjacent each of said side walls and end walls” of a rail car required the openings to be adjacent to all four walls of the railcar.); and *Modine Mfg. Co. v. United States Int’l Trade Comm’n*, 75 F.3d 1545, 1551 (Fed. Cir. 1996) (claim limited to a particular numerical range when broader range was surrendered during prosecution by amendment of the specification).

Without intending to over generalize, it is likely that much of the prior art that patent applicants will face when seeking patents for nanotechnology will be prior work done on a larger scale. Successful and patentable nanotechnology may be a patentable advance over technology previously done, for example, at the microscale. Since size may often be the touchstone for patenting nanotechnology, a patent applicant should anticipate making arguments to the patent examiner concerning the invention’s nanoscale features and the advantages those nanoscale features provide. Those arguments can constrict or restrict the meaning of claim terms to the nanoscale. This may be entirely appropriate in the context of the invention. It may or may not adversely affect claim scope, but one should consider the potential adverse impact such arguments may have on the breadth of patent protection. As has been the common theme of this article, it is best to build into patent claims the nanoscale aspect of the invention. This will often provide the opportunity to argue from the original language of the claims themselves without having to impart a particular meaning to a claim term in order to define over the prior art.

## Depriving the Patent Claim of Clarity

A claim term will not be given its ordinary meaning when doing so deprives the patent claim of clarity and requires resort to other intrinsic evidence for a definite meaning. See *Johnson Worldwide*, 175 F.3d at 990; *Gart*, 254 F.3d at 1341. *CCS Fitness*, 288 F.3d at 1367. Patents concerning nanotechnology may actually compel a court to go beyond the ordinary meaning of a term used in a patent to understand and define the nanotechnology aspects of the invention. The claim construction analysis may turn to the dictionary definition, but available dictionaries may simply not be current enough to keep pace with nanotechnology developments. A common meaning, even one expressed in a relevant dictionary, which flies in the face of the patent disclosure, is undeserving of fealty. Where there are several common meanings for a claim term, the patent disclosure often does and should serve to point away from the improper meaning and toward the proper meaning. Ultimately, the interpretation to be given a term can only be determined and confirmed with a full understanding of what the inventors actually invented and intended to claim. The construction that stays true to the claim language and most naturally aligns with the patent's discussion will be, in the end, the correct construction. See *Renishaw PLC*, 158 F.3d at 1250.

In *Renishaw PLC*, the question of infringement actually turned on the meaning of the word *when*. The patented invention involved improved touch probes used in automated manufacturing to measure the dimensions of machined parts. According to the patent claims, the touch probe generated “a trigger signal *when* said sensing tip contacts an object and said stylus holder is thereby deflected relative to said housing” (emphasis added) if *when*, applying its dictionary definitions, meant “at or after the time that”, “in the event that,” or “on the condition that” the patent was infringed. If, as the District Court construed it, *when* meant “as soon as contact was made and deflection occurred,” there was no infringement. In the patent specification, the patentee was preeminently generating a trigger signal as soon as possible. The patent specification made abundantly clear that *when* meant at the time of and not some appreciable time thereafter. *Renishaw PLC*, 158 F.3d at 1252. The *Renishaw PLC* Court applied the meaning set out in the specification, not the full range of ordinary meanings for the term *when*. The operation of the allegedly infringing probe sent a signal appreciably after contact with the workpiece and initial deflection. There was, therefore, no infringement.

In *Altiris* the Federal Circuit relied on *CCS Fitness* in affirming the District Court's claim construction of the claim term *automation code*—“means the code in the

automation partition which loads an operating system, LAN drivers for the resident NIC, and a program for reading a database on the network server to ascertain the automation commands to be executed.” See *Altiris, Inc. v. Symantec Corp.*, 318 F.3d 1363, 1374 (Fed. Cir. 2003). When interpreting the phrase, the District Court had relied in part on the specification definition because “this phrase is not commonly used in the industry and the claim language is not clear.” *Id.* The Federal Circuit tried to apply an ordinary meaning and concluded that there was not a clear definition. The Federal Circuit ultimately agreed with the District Court that the specification definition controlled, stating “the patentee chose a phrase that ‘so deprives the claim of clarity as to require resort to other intrinsic evidence for a definite meaning,’” citing *CCS Fitness*, 288 F.3d at 1366–1367 (citations and internal quotation marks omitted).

As illustrated by *Renishaw PLC* and *Altiris*, when construing the words of a patent claim one seeks to find meanings that fit with the discussion in the patent specification. Moreover, words such as *when* in *Renishaw PLC* imply time but do not by themselves define the time scale. The possible definitions of *when* discussed above demonstrate the variability inherent in language. This can lead an inventor to select a particular word and a particular meaning of that word to describe the invention. Words, however, must be used in the same way in both the claims and the specification. See *Autogiro Co. of America v. United States*, 384 F.2d 391, 397 (Ct. Cl. 1967). Consistency, then, can play a crucial role in establishing the scope of patent claims.

## Means-Plus-Function Format

An element of a patent claim may be expressed as a means or step for performing a specialized function without reciting the structure, material, or acts supporting the means or step of that function. This language is most often employed in claims to apparatus to define a portion of the apparatus in terms of its function, rather than reciting a list of possible structural elements. If means-plus-function language is used, the patent claim is construed to cover the corresponding structure, material, or acts described in the patent specification and their equivalents. For example, a volume control means for a stereo could include a knob, a sliding switch, or a remote control, if they were described in the patent specification. These claim elements are known as means-plus-function (or step-plus-function in method claims) terms. The means-plus-function language is specifically governed by statute, 35 U.S.C. § 112, ¶ 6. In fact, “a claim

limitation that employs the language ‘means...for’ invokes a rebuttable presumption that § 112, ¶ 6 applies.’ See *Gemstar-TV Guide Int’l, Inc. v. ITC*, 383 F.3d 1352, 1369 (2004) (citing *CCS Fitness, Inc. v. Brunswick Corp.*, 288 F.3d 1359, 1369 (Fed. Cir. 2002)).

To construe a means-plus-function term a court first identifies the function of the means-plus-function term. The second step is to identify the corresponding structure disclosed in the specification. See *Micro-Chem, Inc. v. Great Plains Chem. Co.*, 194 F.3d 1250, 1258 (Fed. Cir. 1999). “Structure disclosed in the specification is ‘corresponding’ structure only if the specification or prosecution history clearly links or associates that structure to the function recited in the claim.” *B. Braun Med. Inc. v. Abbot Labs*, 124 F.3d 1419, 1424 (Fed. Cir. 1997).

Means-plus-function or step-plus-function language in patent claims, while permitted by 35 U.S.C. § 112, sixth paragraph, is a convenience for the patentee. Using this language allows a patentee to define the claim term and the opportunity to identify a wide variety of structures, materials, or acts that correspond to the function. The patentee is then not necessarily limited to the *ordinary* meaning of the words in the means-plus-function or step-plus-function language. The price that must be paid for that convenience is the limiting of the claim to the means specified in the specification and their equivalents. See, *O.I. Corp.*, 115 F.3d at 1583 and *B. Braun*, 124 F.3d at 1424.

## TERMINOLOGY IN NANOTECHNOLOGY PATENT CLAIMS

The words of a claim are generally given their ordinary and customary meaning, which is the meaning that the term would have to a person of ordinary skill in the art in question at the time of the invention. *NTP, Inc. v. Research In Motion, Ltp.*, 418 F.3d 1282, 1293 (Fed. Cir. 2005). Without encountering any of the situations that narrow a claim term as discussed above, this definition can be quite broad. Certainly a patentee wants the scope of its patent claims to be construed as broadly as possible. Breadth of patent protection, however, does not always follow from broad or imprecise claim language. For nanotechnology inventions, the words used to describe the technology are quite often words that do not themselves indicate any particular size, much less the nanoscale. Yet, with nanotechnology, patentability often lies in the size of the invention. To those in traditional technologies, it may seem somewhat ironic that a patent applicant’s own actions (acting as a lexicographer, distinguishing the prior art, using means-plus-function, or defining a term such that it undermines the claim’s clarity) may constrict the

meaning of a claim term. But, for nanotechnology, a more strategic approach suggests itself—to view these traditional limitations on claim language as tools and to use them to uniquely define the patentable, nanoscale aspects of the invention. This strategic approach points to three additional considerations for patenting nanotechnology that have not been discussed above.

## Clarity of Language Does Not Mean Narrow Patent Claims

By statute, the claims of a patent must particularly point out and distinctly claim applicant’s invention. 35 U.S.C. § 112, second paragraph. Clearly defining the important aspects of the invention provides distinctness that strengthens patentability and clarity in claim scope for patent infringement. This does not mean that every aspect of an invention should be defined with the utmost detail. Using clear, appropriate technical language to describe technology does not necessarily narrow claim scope. Narrow patent claims result from overloading the claim with unnecessary details (referred to as elements or limitations of the claim)—ones that may be impossible to prove for infringement. Robust patent claims come from appropriately defining the technical features of the invention that give patentability and must be present in an infringing device. For nanotechnology, this will often mean clearly stating the nanoscale features of the invention. Other more general features, those not necessary for patentability but which describe or give context to the invention, may be included in the claim but without all their particulars.

Breadth in patent claims comes from having fewer limitations or elements in the patent claim. A patent claim having elements A, B, and C is broader than a patent claim having elements A, B, C, D, and E. The former recites only three elements necessary for infringement while the latter requires the presence of five. Well chosen claim language provides clarity as to what the claim elements are and does not necessarily sacrifice claim scope.

Related to the need for clearly defined terms, one can structure patent claims based on the inventive concept, not just the nanoscale structure. For nanotechnology, the inventive concept may be constructing a device that functions at the nanoscale. To write effective patent claims to cover that nanoscale device, focus not only on the structure and components of the device but also on its size and function. Consider how to get the key, patentable concept or function into the patent claims. For example, a *nanomotor*, such as in Fig. 2, may have turn based on the rotation of atom groups about a chemical bond. A patent claim that showed the chemical structure would be appropriate

Components of molecular motor design

Fig. 2 Molecular motor design. Courtesy of the University of Nevada-Reno. Patent application pending.

for that nanomotor but could be limited to the specific chemical structure shown in the patent claim. Adding another patent claim where the nanomotor has rotation about a carbon-carbon single bond, for example, to provide mechanical drive provides a broader, functional scope in contrast to the claim limited to the specific chemical structure. This latter claim identifies the nanoscale in terms of the carbon-carbon bond and gives the function of the motor, “to provide mechanical drive.”

### Choosing to Define a Term

If an inventor chooses another, more limited, meaning for a claim term, then the inventor should choose deliberately and wisely. Being conscious of this choice and why it was made results in better patent application and claim drafting, as well as in potentially simplifying examination of the application and determining infringement of the eventual patent. For nanotechnology, specifically defining a term may be done not just to have clarity and certainty but also to focus on the patentable feature(s) of the invention, to exclude previously known macroscale devices. For example, Fig. 3 shows a cantilever device. Cantilevers are well known and come in all different sizes. The cantilever device in Fig. 3, however, is a nanoscale cantilever, a *nano-cantilever*. *Nano-cantilever* defines the scale of the cantilever. But, it is the uniquely defined nano-scale wires forming the cantilever that are the focus on the invention and carry the weight of patentability.

If a term is uniquely defined, a patent applicant should consider including a definition of the term in the specification. As a patent application evolves during preparation, the usage and definition of key terms should be checked to determine whether the claim terms still match their original, defined meaning or if

Fig. 3 Schematic of nano-cantilever using nano-scale wires and with built-in and bottom electrodes arrangement. Courtesy of Nano-Horizons, Inc., State College, PA, [www.nanohorizons.com](http://www.nanohorizons.com) Patent application pending.

editing or redefinitions is needed. It is important that the inventor(s) review both the specification and the patent claims to be satisfied with the claim language and its meaning.

### The Need for Consistency from Beginning to End

Whether a claim term is specifically defined in the patent specification or simply occurs in the patent specification and the patent claims, another key to preserving its fullest and intended meaning is consistency. This has been mentioned above, but further comment is warranted. To the extent possible, all words used in a patent claim should be used consistently, not only in the patent specification, but also in all correspondence with the USPTO. One should avoid the temptation to restate a term or limitation using different words to vary writing style (whether in drafting the application or corresponding with the USPTO). Variation in wording does not necessarily add breadth to a defined term, but it often adds ambiguity. Avoid using synonyms just for the sake of variety. Broadly, but clearly, defining a term is the appropriate way to add breadth. With the exception of identifying structures, materials, steps, etc. in the context of means-plus-function claims, listing or using alternative language for claim terms can limit the terms such that they will not reach the fullest intended meaning. It is the language of the patent claims that controls the scope of patent protection. It is that language that should be used consistently throughout the patent application and patent examination process.

### PATENTING NANOTECHNOLOGY— CONCLUSION

Nanotechnology seeks to take advantage of the unique structures, the unique properties, and the unique processes that can occur in the space of 1–100 nm. As nanotechnology advances on these nanoscale frontiers, barriers will be overcome and inventions will, undoubtedly, result, and nanotechnology patent applications will be filed. Patents are intellectual property rights in technology. In a patent, the inventive technology must

be described and then the boundaries of the intellectual property right set out in the patent claims. Thus, in a patent, the precision of science and technology takes on the imprecision of language and defines a legal property right. Using language to describe any technology then presents a challenge. Using language to describe nanotechnology, as it continues to emerge and become established, presents an even greater challenge. Yet, to obtain a patent, nanotechnology inventions must be described and claimed. Language is the only means to do this.

In patent claims, the words used are presumed to take on their full meaning. Often the common meaning of a word is just what is intended. For nanotechnology, however, the meaning of a word may not carry the needed or intended nanoscale aspects. The meaning may simply be too big for the nanotechnology invention. This requires one to consider the meaning of the words one uses to describe and claim nanotechnology inventions. An inventor should expect to be held to the words in the patent application. An inventor is not, however, left without tools to describe and claim the invention. Acting as his own lexicographer, an inventor can define the terms necessary for the invention. For nanotechnology, words can be chosen and defined to reflect the nanoscale aspects of the invention and its patentability. Choosing and defining appropriate terms for inventions in nanotechnology, and using them consistently in the patent specification, claims, and during examination, will yield strong, clear patents—ones that will provide the necessary foundation to not only patent but to also commercialize nanotechnology.

Ljubljana, Slovenia*

## Abstract

Permanent magnets are vital components in many technologies, ranging from computers and domestic appliances, to many automotive, medical, and industrial applications. In simple terms, a stronger permanent-magnet material will make it possible to produce a smaller device that is capable of carrying out the same task; this is true for both static, holding applications and applications where the magnet is used in combination with electricity to produce movement. Since the development of the first steel magnets at the beginning of the 20th century, the improvements in permanent-magnet materials have been astonishing. The figure of merit used to describe the strength of a magnet, the  $BH_{\max}$ , has increased from around 4 MGOe to over 50 MGOe.

These tremendous improvements have come about as a result of discovering better materials and better methods of processing. The most recent generations of permanent magnets, which are based on a combination of one or more rare earths and transition metals like iron and cobalt, can be produced using a wide variety of methods, such as sintering, melt spinning, deposition techniques, chemical techniques, gas atomization and mechanical alloying, and result in materials with a wide range of properties. In this overview we will look at permanent magnets based on nanostructured intermetallic alloys, their properties, and their methods of production.

## HISTORICAL INTRODUCTION TO PERMANENT MAGNETS

Before the invention of the electromagnet by Sturgeon in 1925, the only permanent-magnet materials were the naturally occurring lodestone, a form of magnetite  $Fe_3O_4$ , and various forms of iron-carbon alloys. Many of these early magnets were built up from wires or strips, since these were easily magnetized by stroking them with another magnet.

The development of modern permanent magnets can be said to have begun around the end of the 19<sup>th</sup> century, with the introduction of the steel magnet.<sup>[1]</sup> The next step forward in the story of permanent magnets was made when it was realized that larger values of magnetic anisotropy were needed to produce higher coercivities. The coercivity of a permanent magnet is its ability to withstand the effects of an opposing magnetic field. These high anisotropies were found in materials that had highly anisotropic crystal structures and hexagonal or tetragonal symmetries.<sup>[2]</sup> A good example of a material with this type of structure is the common, household ferrite magnet. This is the type of magnet you will often find stuck to the door of a fridge, but is also the workhorse magnet for thousands of industrial, automotive, and domestic applications.

There were few developments in permanent magnets until the 1960s. The Second World War had seen advances in the separation and purification of rare earths, and with these metals now available, researchers began to look at combinations of rare earths and transition metals. The year 1967 saw the first reports of  $RCO_5$  (R = rare earth) materials with  $CaCu_5$ -type structures, which soon led to the commercial availability of  $SmCo_5$  magnets with properties that literally dwarfed those of ferrites,  $AlNiCos$ , and the steel magnets that had come before – albeit at a price.<sup>[3]</sup> Within a short time, it was realized that the magnetic properties of these  $SmCo_5$  magnets were being limited by the magnetization of the cobalt sub-lattice, and so a new type of magnet, based on  $R_2Co_{17}$ , quickly followed.<sup>[4]</sup> These Sm-Co magnets made possible a wide range of new applications and presented tremendous possibilities for miniaturization because of their enormous energy densities, but the high—and perhaps more importantly, the variable—price of cobalt was a problem. This situation became even worse with the cobalt crisis of 1979–1981.<sup>[5]</sup> The crisis was due to a rebellion in Zaire, source of about half of the world's cobalt, when many of the mines were flooded. The price of cobalt increased sixfold as a result, and this intensified the search for high-energy cobalt-free permanent-magnet materials. The first announcements

Fig. 1 Progress in permanent magnets, in terms of energy product.

of the successful production of magnets based on neodymium, iron, and boron were made at a meeting in Pittsburgh, PA, in 1983. At the same meeting, there were reports from Sumitomo Special Metals of Japan<sup>[6]</sup> and General Motors of the USA<sup>[7]</sup> of a new generation of permanent magnets based on a material with the chemical formula  $\text{Nd}_2\text{Fe}_{14}\text{B}$ . This Nd–Fe–B-type magnet was an improvement in many ways over the existing Sm–Co materials, and could be produced using a number of different techniques. The Japanese produced their Nd–Fe–B magnets via a relatively conventional powder-metallurgy sintering route, whereas the Americans had used a novel method called melt spinning. Within a few years, there were to be more reports of good magnetic properties from groups working with techniques such as mechanical alloying,<sup>[8]</sup> screen-printing,<sup>[9]</sup> sputtering,<sup>[10]</sup> ablation,<sup>[11]</sup> and techniques based on hydriding.<sup>[12]</sup>

One more major discovery has been made since the arrival of Nd–Fe–B, and that occurred in 1990, when a group in Ireland reported hard magnetic properties in nitrided Sm–Fe-based materials.<sup>[13]</sup> The  $\text{Sm}_2\text{Fe}_{17}\text{N}_3$  magnet had excellent properties, comparable in many ways to the market-leading Nd–Fe–B-based magnets, but difficulties associated with nitriding bulk samples have kept them from anything other than a niche market. A summary of the improvements made in permanent-magnet materials over the past 100 years can be seen in Fig. 1.

## PERMANENT-MAGNET PROPERTIES

To describe a permanent magnet quantitatively, we need to measure its magnetic properties. To do this, we subject the magnet to a large positive magnetic field, to saturate the magnet, and then we apply a large negative field to assess its ability to withstand a reverse magnetic field. This form of measurement

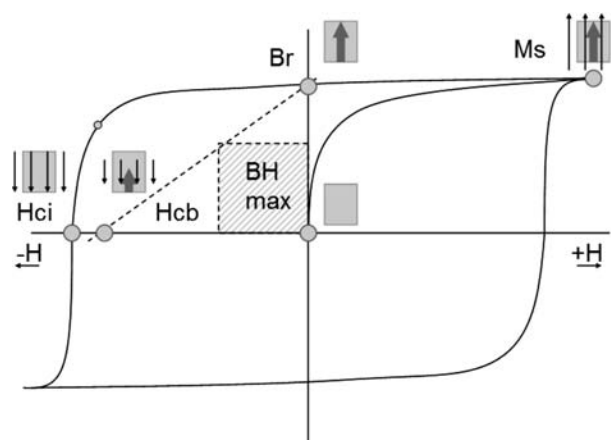

Fig. 2 Hysteresis loop of a permanent magnet.

is shown schematically in Fig. 2 and described in more detail later.

The measurement of the permanent magnet's properties begins with a completely demagnetized magnet in a zero magnetic field at the crossing point of the  $X$ -axis (the applied field) and the  $Y$ -axis (the magnetization of the sample). The state of the magnet is illustrated by the empty rectangle, i.e., the magnet is unmagnetized. The first part of the measurement involves applying a large positive magnet field ( $+H$ ). At this point, the magnet becomes fully saturated (note the arrow) while it exists in a large positive field. The next stage is to remove the applied field and look at the magnetization state of the magnet while there is no external field. With a good-quality magnet, the internal magnetization (the arrow) will remain, even in the absence of the applied field. This point on the  $Y$ -axis,  $B_r$ , is referred to as the remanence. This is followed by a demagnetization stage, where a negative field ( $-H$ ) is applied to the sample. With a sufficiently high field, the magnetization of the sample will be reduced to nothing (no arrow), and this field is referred to as the intrinsic coercivity,  $H_{ci}$ , of the magnet. For most permanent-magnet applications, we are looking for magnets with a high remanence and a high coercivity, although there are some applications when a very high coercivity would be disadvantageous. There is one other point that is important from the applications point of view, the normal coercivity,  $H_{cb}$ . This is the point where the external demagnetizing field is equal and opposite to the internal magnetization; the system, in effect, is equal to zero. This measurement is of more interest to electrical engineers than to material scientists, who are more interested in the material's performance than the performance of the system. In order that we can have a single quantity to describe the quality of a magnet, the term energy product (or  $BH_{max}$ ) has been introduced. To calculate the energy

product of a magnet, we draw a straight line from the remanence point to the normal coercivity and then measure the area of the largest rectangle that we can fit under this line. The best Nd–Fe–B magnets have energy products in excess of 50 MGOe (mega Gauss Oersted), typical Sm–Co magnets are in the range 25–30 MGOe, and ferrites are about 4 MGOe.

### COERCIVITY AND MICROSTRUCTURE IN NANOSTRUCTURED PERMANENT MAGNETS

The origin of the coercivity in all rare-earth–transition-metal permanent magnets is their high easy-axis magnetocrystalline anisotropy. However, since the coercivity remains well below the value of the anisotropy field, by a factor of about 4, the coercivity is clearly also very dependent on the nano/microstructure, with magnetization reversal being the result of the nucleation and growth of reverse magnetic domains. Sintered Nd–Fe–B magnets show two main coercivity characteristics that suggest that the coercivity mechanism is one of nucleation and growth rather than a pinning-type mechanism: unmagnetized magnets have many domains per grain, and the coercivity increases with the size of the field used to magnetize the magnet.<sup>[14]</sup> To generate high coercivities under such conditions, it is important to produce materials with a small grain size, thereby limiting the surface areas of individual grains. This is in stark contrast to permanent-magnet materials like the Sm<sub>2</sub>Co<sub>17</sub>-type magnets, where large coercivities can be generated in cast-and-annealed ingots with very large grains, and where the mechanism of the coercivity is related to the pinning of domains within the volume of the grains by precipitates.<sup>[15]</sup>

### PROCESSING INTERMETALLIC PERMANENT MAGNETS

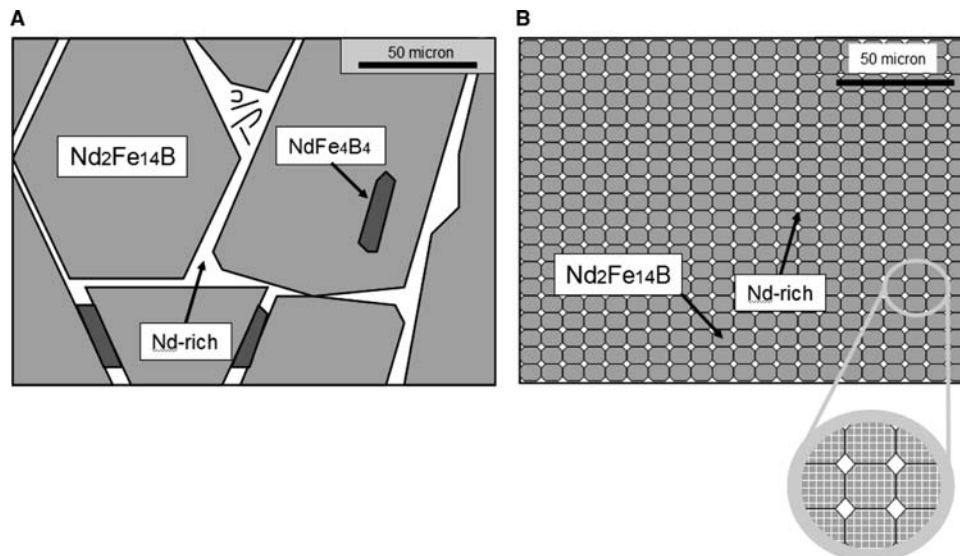

Nd–Fe–B permanent magnets are multiphase metallic structures. Irrespective of the processing route employed to produce them, the starting point is nearly always an as-cast alloy with a composition in the region of Nd<sub>15</sub>Fe<sub>77</sub>B<sub>8</sub>. The aim when processing Nd–Fe–B magnets is twofold:

- First, reducing the grain size down to micro/nano-sizes, thereby maximizing the potential coercivity of the sample.
- Second, orienting the grains as much as possible so that the *c*-axes (which are the easy magnetic axes) of the grains are pointing in the same direction, thereby maximizing the potential remanence of the sample.

This is shown in Fig. 3, where Fig. 3A shows schematically a typical as-cast microstructure for a Nd–Fe–B alloy with a composition of Nd<sub>15</sub>Fe<sub>77</sub>B<sub>8</sub>, cast into a mold containing about 10–15 kg of material, and Fig. 3B shows schematically an idealized magnet nano/microstructure with grains in the range of 100–1000 nm.

### PROCESSING Nd–Fe–B MAGNETS VIA THE SINTERING ROUTE

From the commercial point of view, sintering is the most important method for producing Nd–Fe–B magnets; however, these magnets are better described as “micro” rather than nanostructured, and so we will not discuss them in any detail here. The reader is

**Fig. 3** (A) Schematic microstructure of Nd<sub>15</sub>Fe<sub>77</sub>B<sub>8</sub> cast alloy. (B) Schematic micro/nanostructure of idealized permanent magnet.

referred to the extensive literature for more information on sintered Nd–Fe–B magnets.<sup>[16–18]</sup>

## PROCESSING Nd–Fe–B MAGNETS VIA THE MELT-SPINNING ROUTE

The melt-spinning production route, unlike the powder-metallurgy sintering route, was not used for previous generations of permanent magnets. The combination of melt spinning and Nd–Fe–B-type magnets was pioneered by General Motors in the USA, a development that ran in parallel with Sumitomo Special Metals' research on the sintered route for Nd–Fe–B.

In the melt-spinning process, a jet of molten alloy comes from material in an induction-melting crucible and hits a rapidly rotating water-cooled copper wheel. Under such conditions, cooling rates can be as high as  $10^6$  K/s. The Nd–Fe–B alloy tends to form in the shape of ribbons, a few centimeters long and about  $30\ \mu\text{m}$  thick, which are then thrown from the copper wheel and collected a meter or so away in a hopper. As with the sintering process, everything is carried out in a protective, inert atmosphere. A schematic diagram of the melt-spinner and some crushed Nd–Fe–B ribbons are shown in Fig. 4A and 4B.

The usual procedure involves over-quenching the ribbons to produce a largely amorphous structure, and then heat treating them at  $600\text{--}700^\circ\text{C}$  to produce  $\text{Nd}_2\text{Fe}_{14}\text{B}$  grains that are  $100\text{--}500\ \text{nm}$  in size. The grain size of melt-spun magnets tends to be smaller than with sintered magnets, but this is a consequence of many factors, not least of which is the radically different processing route. The most important feature of Nd–Fe–B melt-spun ribbons is that they are completely isotropic, i.e., there is no preferred orientation of the  $c$ -axes in the material, leading to relatively low values for the remanence. Nevertheless, the simplicity of the ribbon-production process, the intrinsic stability of the

ribbons in the atmosphere, and the ease with which these materials can be mixed with polymers and other binders and molded into intricate shapes makes them a very attractive material.<sup>[19]</sup>

## HOT PRESSING MELT-SPUN RIBBONS

These Nd–Fe–B melt-spun ribbons are also suitable for hot pressing. In such a process, the ribbon pieces are placed in a die and compacted under high loads and temperatures in the range  $700\text{--}800^\circ\text{C}$  to form 100%-dense solids. Of course, since there is no possibility of aligning the grains in a magnetic field, these materials are still isotropic, but their high density gives them an advantage over the polymer-bonded variants.<sup>[20]</sup>

## DIE-UPSET FORGING OF MELT-SPUN RIBBONS

A third possibility is to die-upset forge the compacted melt-spin ribbons.<sup>[21,22]</sup> This rather expensive process involves first of all producing a straightforward 100%-dense solid from the ribbons as described earlier, and then re-pressing the dense compact in an over-sized die, causing the material to flow in a direction perpendicular to the direction of pressing. The two hot-pressing techniques are illustrated in Fig. 5A and 5B.

This flow under pressure at high temperatures causes the material to become highly oriented along the pressing direction. This reorientation is the result of the growth of favorably oriented nanostructured grains in combination with grain-boundary sliding, boundary diffusion, and diffusion slip. The process can be enhanced by small additions of elements such as gallium,<sup>[23]</sup> although die-upsetting ratios of about 4, i.e., the compact must be reduced to a quarter of its original height, are required.

**Fig. 4** (A) Schematic diagram of melt-spinner. (B) Crushed melt-spun ribbons of Nd–Fe–B.

**Fig. 5** (A) Hot pressing of melt-spun powder to produce a fully dense isotropic magnet. (B) Die-upset forging of a fully dense isotropic magnet to produce an anisotropic magnet.

### PROCESSING Nd–Fe–B AND Sm–Fe–N MAGNETS VIA THE HYDROGENATION–DISPROPORTIONATION–DESORPTION–RECOMBINATION ROUTE

A third method for producing nanostructured permanent magnets from a starting material of as-cast alloy is called the hydrogenation–disproportionation–desorption–recombination process, or HDDR process.<sup>[24–31]</sup> The process involves heating the as-cast alloy in an atmosphere of hydrogen to about 700–750°C, holding for a period of minutes to hours, and then cooling the material to room temperature in vacuum. During the first stage of the process, the material reacts with hydrogen to form interstitial hydrides and a lot of cracks form in the material due to the expansion of the crystal lattice with the formation of the hydrides. However, as the temperature increases, these hydrides become unstable and the material disproportionates to form iron, ferroboron, and neodymium hydride. The disproportionation reaction can be represented as:

where  $\Delta H$  is the heat of reaction. The value of  $x$  is dependent on the hydrogen pressure used and the exact composition of the starting alloy.

The disproportionated mixture consists of a nano-dispersed mixture of iron, neodymium hydride, and ferroboron. During the second stage of the process, when the material is subjected to vacuum conditions at high temperature, the neodymium hydride desorbs to form neodymium metal, which then leads to the neodymium, iron, and ferroboron recombining to form large amounts of nanostructured  $\text{Nd}_2\text{Fe}_{14}\text{B}$  phase, together with some Nd–Fe intergranular material, only now the grain size of the  $\text{Nd}_2\text{Fe}_{14}\text{B}$  phase is in the 100–500 nm range. In simple terms, the HDDR process converts a coarse-grained as-cast material into a powdered nanostructured material via a reversible chemical reaction involving hydrogen. The process is shown schematically in Fig. 6.

As with melt-spinning, the process is intrinsically isotropic, and the resulting nanostructured HDDR powders tend to have remanences close to about half of the saturation magnetization; however, in the case of the HDDR process, it is possible to produce anisotropic material with the use of additives like zirconium,<sup>[32]</sup> hafnium,<sup>[33]</sup> and gallium,<sup>[34]</sup> and closely

**Fig. 6** Schematic representation of the hydrogenation–disproportionation–desorption–recombination (HDDR) process.

controlled processing conditions.<sup>[35]</sup> HDDR-processed powder is also very suitable for hot pressing fully dense magnets in a procedure similar to that used for the melt-spun ribbons.<sup>[36]</sup>

## OTHER PROCESSING TECHNIQUES

Nd–Fe–B materials are remarkable in many ways, but perhaps their most remarkable characteristic is the number of different methods that can be used to produce high-coercivity permanent magnets from basically the same starting material. From the commercial point of view, the three techniques already discussed – sintering, melt-spinning, and HDDR – are the most important, but from the research perspective techniques like rapid casting,<sup>[37]</sup> hot working,<sup>[38]</sup> mechanical alloying,<sup>[39]</sup> laser ablation,<sup>[40]</sup> pulsed-laser deposition,<sup>[41]</sup> rotary forging,<sup>[42]</sup> gas atomization,<sup>[43]</sup> and explosive compaction,<sup>[44]</sup> have provided valuable insights into the capabilities and limitations of nanostructured magnets produced from the Nd–Fe–B system. From the purely scientific aspect, the most interesting nanostructured magnets produced from rare-earth–transition-metal intermetallics are exchange-coupled magnets.<sup>[45]</sup> These magnets will be described in the next section.

## EXCHANGE-COUPLED MAGNETS

Nanocomposite exchange-coupled magnets consisting of a fine mixture of magnetically hard (to provide high coercivity) and soft (to provide high magnetization) phases have attracted a lot of attention because of their remarkable magnetic properties. The exchange coupling between the two phases causes the magnetization vector of the soft phase to align with that of the hard phase, leading to a remanent magnetization of more than half of the saturation magnetization in a crystallographically isotropic structure, and this high remanence is combined with a good coercivity. Because of this, it is possible to achieve a higher  $BH_{\max}$  than with conventional isotropic uncoupled magnets.

## THE NANOSTRUCTURE–PROPERTY RELATIONSHIP IN EXCHANGE-COUPLED MAGNETS

It has been demonstrated by theory and with micro-magnetic modelling simulations<sup>[46]</sup> that the magnetic properties of nanocomposite magnets depend strongly on the intrinsic magnetic properties of the phases present and on the nano/microstructural features. Earlier studies<sup>[47]</sup> showed that in such a microstructure,

the hard and the soft phase would be exchange-coupled if the sizes of both the soft and the hard phases are of the order of twice the domain wall-width of the hard phase, which is less than 10 nm for most hard phases. Fischer et al.<sup>[48]</sup> predicted that  $M_r$  and  $H_c$  would decrease with increasing grain size and that the magnetic properties are degraded by a non-uniform nano/microstructure. Therefore, it is very important to develop a uniform nano/microstructure with very fine soft-phase grains, which are uniformly distributed in the nanocomposite magnets to obtain optimum coupling. This can be achieved by optimizing both the composition and the processing parameters.

The magnetization-reversal process in nanocomposite magnets is more complicated than with conventional magnets owing to the coexistence of the exchange-coupled hard and soft phases. The overall anisotropy constant is reduced by the soft phase, and so the coercivity is controlled by the nucleation of the reversed domains in the soft phase. This nucleation field would be very low if there was no exchange coupling between the hard and the soft phases. But, in fact, the exchange coupling significantly increases the nucleation field and thus preserves a reasonably high coercivity. This effect is generally known as exchange hardening.

## NANOPHASE MAGNETS BASED ON COBALT OR IRON AND PLATINUM

CoPt and FePt have emerged as candidates for high-performance exchange-coupled magnets with enhanced magnetic properties. Both materials have high anisotropies ( $4.9 \times 10^6 \text{ J/m}^3$  and  $6.6 \times 10^6 \text{ J/m}^3$ , respectively). However, the FePt system has the advantage of complete solid solubility at higher temperatures, and at lower temperatures the crystal structure transforms from FCC to a face-centered tetragonal structure, which has improved hard magnetic properties due to the increased anisotropy.

Zhou et al.<sup>[49]</sup> investigated improvements in the properties of FePt through exchange-coupled FePt–Fe layered films prepared by magnetron sputtering. In FePt thin films, a maximum energy product of up to  $BH_{\max} = 15 \text{ MGOe}$ , was obtained, and with CoPt thin films a maximum energy product of up to  $BH_{\max} = 50 \text{ MGOe}$  was observed.

Huang et al.<sup>[50]</sup> investigated the fabrication and magnetic properties of FePt/C films containing FePt nanoparticles to increase the coercivity when compared with normal FePt thin films. The films were produced with FePt particle sizes in the range 3–20 nm. For the films with the smallest particle sizes, the blocking temperature, which marks the boundary between hysteretic and non-hysteretic behaviour, was found to

be 200 K. For films with larger particle sizes, the blocking temperature is higher. Once the particle sizes were such that the blocking temperature was above room temperature, it was found that the coercivities were greater for the films with larger particles. A coercivity of  $1.84 \times 10^6$  A/m (23 kOe) was obtained for the 8 nm diameter particles and a coercivity of  $2.72 \times 10^6$  A/m (34 kOe) for the 15-nm diameter particles. It was also found that by depositing FePt simultaneously with carbon, the structure of the films could be controlled so that a strong perpendicular anisotropy can be produced in the films, suitable for magnetic recording-media applications.

## SUMMARY

This has been a brief overview of the processing of permanent magnets based on nanostructured alloys and the relationships between processing, nano/microstructure, and magnetic properties. We have looked mainly at the Nd-Fe-B ternary material because it is the most flexible in terms of processing – sintering, melt-spinning, and the HDDR process – and produces high-quality nanostructured magnets with useful properties for many applications.

## INTRODUCTION

Permanent magnets (PMs) are one of the key materials that support modern electronic technologies and the society that is built upon them. The basic function of a PM is to provide a static magnetic field in a limited space in which electric energy is converted into mechanical energy or vice versa. The quest for PM materials that can generate a larger magnetic flux with a given volume, or that can generate a given magnetic flux with a smaller volume, still exists even after the advent of the Nd-Fe-B anisotropic magnets.<sup>[1]</sup> The maximum magnetic energy product  $(BH)_{\max}$  exceeding  $450 \text{ kJ/m}^3$ , a magnificent record that was only a dream 20 years before, has been achieved in the Nd-Fe-B magnets prepared by controlled powder-metallurgical route.<sup>[2]</sup> An ideal permanent magnet having a rectangular hysteresis loop with the remanence value of  $B_r$  will have a  $(BH)_{\max}$  value of  $1/4\mu_0 \times B_r^2$  provided that the intrinsic coercivity is greater than one half of  $B_r/\mu_0$ .<sup>[3]</sup> As a remanence cannot exceed the saturation polarization ( $J_s$ ) of the PM material, the maximal value of  $B_r$  is  $\mu_0 J_s$ . Therefore when one reminds that  $B = J + \mu_0 H$  and that  $H < 0$  for the case under consideration, the theoretical limit of  $(BH)_{\max}$  is  $1/4 \times \mu_0 J_s^2$ , namely, a product of  $1/2 \times \mu_0 J_s$  and  $1/2 \times J_s$ . Therefore a search for a more powerful PM involves, as its principal element, a search for ferromagnetic materials that have  $J_s$  larger than that of  $\text{Nd}_2\text{Fe}_{14}\text{B}$ ,<sup>[4]</sup> the main hard magnetic component of the Nd-Fe-B magnets.

Nanocomposite PM (NPM) is a PM consisting of a combination of a hard magnetic phase (HP) and a relatively soft magnetic phase (SP) having a large  $J_s$ .<sup>[5]</sup> The concept of NPM has attracted considerable attention because of the possibility that a larger  $B_r$  than the  $J_s$  value of the currently most powerful PM (Nd-Fe-B) can be realized by combining an SP of a larger  $J_s$  than that of  $\text{Nd}_2\text{Fe}_{14}\text{B}$  (1.6 T at room temperature) as was pointed out by Skomski and Coey.<sup>[5]</sup>

The first NPM was probably  $\text{Nd}_4\text{Fe}_{81}\text{B}_{19}$  ribbons obtained by rapid solidification and a subsequent annealing treatment.<sup>[6]</sup> This material consisted of  $\text{Fe}_3\text{B}$ ,  $\text{Nd}_2\text{Fe}_{14}\text{B}$ , and a small amount of  $\alpha\text{-Fe}$ . Its  $B_r$  was approximately 1.2 T at room temperature. Because

of the isotropic nature of the material, i.e., no orientation of crystallographic axes was present, this value of  $B_r$  is smaller than the  $J_s$  of both  $\text{Fe}_3\text{B}$  and  $\text{Nd}_2\text{Fe}_{14}\text{B}$  phases. However, it is significantly larger than the expected value, which is one half of  $J_s$ ,<sup>[7]</sup> for noninteracting ensemble of hard magnetic particles of uniaxial magnetic anisotropy. This type of materials, which we classify as the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type hereafter, have been constantly improved with respect to their magnetic performance by several research groups including ourselves,<sup>[8]</sup> and form a class of commercial products that are used as a hard magnetic component of resin-bonded PM. A variety of combinations of hard magnetic and soft magnetic phases have been tried, and mechanisms of formation of nanostructures have been investigated in the past years as presented in this entry.

## PRINCIPLES

### Exchange Coupling and Critical Sizes

A composite material consisting of an HP and an SP, which are coupled via mere magnetostatic interactions or dipolar field interactions, cannot have a good hysteresis loop for practical PM applications. The reason is that the magnetization of HP, which is typically a soft magnetic phase such as  $\alpha\text{-Fe}$  or  $\text{Fe}_3\text{B}$ , easily responds to a demagnetization field. To prevent a sizable response of the SP magnetization from occurring, it is necessary to lock it by a strong coupling between SP and HP magnetic moments. Kneller and Hawig<sup>[9]</sup> discussed the role of exchange couplings in such a composite and argued that the composite can behave as if it were a single-phase PM if SP and HP are coupled via the exchange interactions between spins at the grain boundaries and if the grain sizes are smaller than the following critical values:

$$\text{for soft magnetic phase : } b_{\text{cS}} = \pi(A_{\text{S}}/2K_{\text{H}})^{1/2} \quad (1)$$

$$\text{for hard magnetic phase : } b_{\text{cH}} = b_{\text{cH}} \quad (2)$$

where  $A_S$  stands for the exchange stiffness constant of SP and  $K_H$  stands for the magnetocrystalline anisotropy constant of HP. With typical values for  $A_S$  and  $K_H$ ,  $10^{-11}$  J/m and  $2 \times 10^6$  J/m<sup>3</sup>, respectively, one obtains  $b_{cS} = b_{cH} = 5$  nm.<sup>[9]</sup>

### Remanence

Kneller and Hawig<sup>[9]</sup> further discussed about remanence and coercivity expected for a nanocomposite permanent magnet. If the saturation magnetization of HP and SP are  $J_{sH}$  and  $J_{sS}$ , respectively, and the volume ratio of HP is  $v_H$ , the saturation magnetization  $J_s$  of the composite magnet is given by

$$J_s = v_H J_{sH} + (1 - v_H) J_{sS} \quad (3)$$

The remanence  $B_r$  of the composite magnet is given by

$$B_r = v_H m_{rH} J_{sH} + (1 - v_H) m_{rS} J_{sS} \quad (4)$$

where  $m_{rH}$  and  $m_{rS}$  represent relative ratio of remanence of each component phase given by

$$m_r = B_r / J_s = \langle \cos \theta \rangle \quad (5)$$

where  $\theta$  represents the angle between the direction of the previous saturation field  $H$  and the direction of magnetization of a grain.  $\langle \cos \theta \rangle$  represents the average of  $\cos \theta$  over the entire composite. For an HP with a uniaxial magnetic anisotropy,  $\langle \cos \theta \rangle = 0.5$ , if there exists no magnetic coupling among grains. However, in the nanocomposite permanent magnet, the magnetization of SP is exchange-coupled with the magnetization of HP along their mutual grain boundaries. Therefore the resulting remanence of SP will be parallel to the magnetization of HP. If the easy direction of magnetization of the HP grains are distributed throughout the composite, the resulting magnetization state after saturation along  $H$  is inhomogeneous and numerical estimation of the values of  $m_r$  will require knowledge of space distribution of magnetization in the sample.

### Coercivity

For the optimal microstructure with  $b_{cH} = b_{cF}$ , the upper limit of the nucleation field  $H_{n0}$  is  $2K_H/J_{sS}$  for a completely aligned microstructure,<sup>[9]</sup> and it is about one half of this for isotropic polycrystallites;

$$H_{n0} = K_H / J_{sS} \quad (6)$$

which yields a coercivity value of the order of 1 MA/m for the case  $K_H = 2 \times 10^6$  J/m<sup>3</sup> and  $J_{sS} = 1.8$  T.

### The Maximum Energy Product

Skomski and Coey<sup>[5]</sup> analytically considered a case of an ideally soft magnetic inclusion of diameter  $D$  embedded in a hard magnetic matrix. The nucleation field  $H_{n0}$  reaches a plateau for  $D$  values below the Bloch wall width of HP,  $4(A_H K_H)^{1/2}$ . For larger inclusions,  $H_{n0}$  decreases as  $D^{-2}$ . The plateau value was estimated to be about 20 T for the case of  $J_{sS} = 2.15$  T,  $J_{sH} = 1.55$  T,  $A_F/A_H = 1.5$ ,  $K_F = 0$ , and  $K_H = 12$  MJ/m<sup>3</sup>, the case of  $\alpha$ -Fe inclusion in the Sm<sub>2</sub>Fe<sub>17</sub>N<sub>3</sub> matrix. For a fully aligned microstructure with rectangular hysteresis loop, they obtained an estimation for  $(BH)_{\max}$  as

$$(BH)_{\max} = 1/4 \mu_0 J_{sS}^2 \left\{ 1 - \mu_0 (J_{sS} - J_{sH}) J_{sS} / (2K_H) \right\} \quad (7)$$

and corresponding volume fraction of HP as

$$v_H = \mu_0 J_{sS}^2 / (4K_H) \quad (8)$$

For the case of  $\alpha$ -Fe inclusions in Sm<sub>2</sub>Fe<sub>17</sub>N<sub>3</sub> matrix, Eq. (7) yields  $(BH)_{\max}$  of 880 kJ/m<sup>3</sup> with only 7 vol.% of Sm<sub>2</sub>Fe<sub>17</sub>N<sub>3</sub>. However, this treatment may be oversimplified because of the assumption of the completeness in alignment and the squareness of the hysteresis loop.

### Micromagnetically Assessed Magnetic Properties

Micromagnetic calculation of inhomogeneously distributed magnetization states in exchange-coupled isotropic polycrystalline composite magnets have been performed for realistic microstructural models. Fukunaga, Kitajima, and Kanai<sup>[10]</sup> considered a model magnet composed of cubic grains of the edge length of  $L$ . Each grain is either an SP or an HP grain, the crystallographic axis of which is randomly oriented from grain to grain, namely, the magnet is an isotropic polycrystalline material. From the necessity that functional derivative of the total magnetic energy  $W$  with respect to magnetization vector of each grain to be null, a set of nonlinear equation is derived and a set of solutions is numerically obtained so that magnetic torque acting on magnetization of each grain diminishes. The solution thus obtained is not unique. When the fraction of SP is specified, the hysteresis loop depends on seven parameters; three intergranular exchange coupling constants, two intragranular exchange coupling constants, and two magnetocrystalline anisotropy constants for SP and HP. Fig. 1 shows the relationship between reduced coercivity ( $h_c$ ) and reduced remanence ( $m_r$ ) calculated with varying grain size  $L$ . Each curve corresponds to a specific value of fraction of SP (expressed as “soft” in Fig. 1). With decreasing  $L$ ,

**Fig. 1** Relationship between reduced coercivity ( $h_c$ ) and reduced remanence ( $m_r$ ) calculated with varying grain size  $L$ .

the corresponding point on the curve moves from lower right to upper left, passing through a maximum of  $h_c$  when the fraction of SP is not zero. The maximum of  $h_c$  occurs because the hysteresis loop has a characteristic two-phase behavior when  $L$  is much larger than  $b_{cs}$  while the hysteresis loop becomes extremely narrow as the anisotropy energy begins to be averaged out when  $L$  is much smaller than the ferromagnetic correlation length  $(AK)^{1/2}$  as shown in Fig. 2.

The inhomogeneous distribution of directions of magnetization vectors in isotropic nanocomposite permanent magnets can be calculated by using finite-element micromagnetic calculation approach.<sup>[11]</sup> Very recently, progress in electron holography technology of transmission electron microscopy (TEM) has made observation of magnetic force lines in a nanocomposite

**Fig. 2** Hysteresis loops of an isotropic nanocomposite permanent magnet calculated for various fractions of soft magnetic phase (“soft” in the figure). *Source:* From Ref.<sup>[8]</sup>.

**Fig. 3** Magnetic force lines in a nanocomposite permanent magnet composed of  $\text{Fe}_3\text{B}$  and  $\text{Nd}_2\text{Fe}_{14}\text{B}$ . *Source:* Courtesy of Professor Daisuke Shindo, from Ref.<sup>[12]</sup>.

permanent magnet possible,<sup>[12]</sup> as shown in Fig. 3 for the case of SP =  $\text{Fe}_3\text{B}$  and HP =  $\text{Nd}_2\text{Fe}_{14}\text{B}$ . The white lines in Fig. 3 correspond to magnetic force lines and the net drawn by solid black lines correspond to grain boundaries. The arrows indicate the easy directions of magnetization of the  $\text{Nd}_2\text{Fe}_{14}\text{B}$  grains. Grains identified to be  $\text{Fe}_3\text{B}$  via nanobeam electron probe X-ray spectroscopy (EDX) are indicated as S.

### “Exchange-Spring” Behavior

The response of magnetization of a permanent magnet to a varying demagnetizing field is called a recoil curve. The recoil curve of an NPM has a characteristic nearly reversible response to the demagnetization field because magnetization of SP rotates in a reversible manner as long as magnetization of HP does not reverse its direction irreversibly. The reversible rotation of magnetization of SP occurs because the exchange field counteracts applied demagnetization. This characteristic recoil behavior is frequently referred to as exchange-spring, as termed by Kneller and Hawig.<sup>[9]</sup> An example of recoil curves of an  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type isotropic nanocomposite magnet is shown in Fig. 4.

### POSSIBLE COMBINATIONS OF SOFT MAGNETIC AND HARD MAGNETIC PHASES

In principle, any combination of SP and HP is possible provided that they coexist in a stable or quasi stable state. Typical HP phases of interest are listed in Table 1 together with their room temperature magnetic properties. Large magnetocrystalline anisotropy in the rare-earth-based intermetallic compounds such as  $\text{SmCo}_5$  arises from the single-ion anisotropy of the rare-earth ions. On the other hand, the magnetocrystalline anisotropy in the ordered ( $L1_0$  structure) CoPt and FePt alloys is due to Pt

**Fig. 4** An example of recoil curves of an  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type isotropic nanocomposite magnet.

atoms. For economic reasons, bulk magnets produced in industrial scales are iron-based materials, typically Nd-Fe-B. Soft magnetic phases with large  $J_s$ 's are listed in Table 2 together with their room temperature magnetic properties. For the iron-based HP,  $\alpha$ -Fe and bcc-(Fe-Co) alloys are the most promising candidates for SP. In the following, a type of a nanocomposite is designated by the SP and HP combination as SP/HP.

Because of the large  $J_s$  of  $\text{Nd}_2\text{Fe}_{14}\text{B}$ , the Fe-rich region of the Fe-Nd-B system is of a particular interest in conjunction with NPM. The volume fraction of SP can be chosen to be any value for the  $\alpha$ -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$  or  $\alpha$ -Fe/ $\text{Sm}_2\text{Fe}_{17}\text{N}_3$  type in terms of metallurgy. In contrast, available volume fraction of the metastable  $\text{Fe}_3\text{B}$  phase is limited in the case of the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$  type because other metastable compounds are formed in a certain composition range.<sup>[14]</sup>

## FABRICATION TECHNIQUES FOR NANOCRYSTALLINE STRUCTURES

A nanocrystalline structure can be fabricated through rapid solidification and crystallization. The technique

**Table 1** Hard magnetic phases for nanocomposite permanent magnets and their magnetic properties at room temperature

$\text{Nd}_2\text{Fe}_{14}\text{B}$	1.61	4.9	[13]
$\text{Sm}_2\text{Fe}_{17}\text{N}_3$	1.54	8.6	[13]
CoPt	1.00	4.9	[13]
FePt	1.43	6.6	[14]

**Table 2** Ferromagnetic phases of interest as the high-magnetization component for nanocomposite permanent magnets and their magnetic properties at room temperature

Material	$J_s$ (T)	$K$ (MJ/m <sup>3</sup> )	Reference
$\alpha$ -Fe	2.15	0.05	[13]
hcp-Co	1.81	0.53	[13]
$\text{Fe}_3\text{B}$	1.62	-0.32	[11]

most commonly used for rapid solidification of hard magnetic alloys is the melt spinning (MS) technique. In the MS technique, a melt is ejected through a small orifice onto a surface of a rotating chill wheel or roll. The surface velocity of the wheel is typically 20–50 m/sec and the cooling rate is around  $10^6$  K/sec. The crystallization process may occur either during the solidification process or during an annealing heat treatment after the alloy is quenched into an amorphous state and subsequently heated to a temperature at which atomic diffusion can take place (i.e., around 600–700°C). Empirically determined critical cooling rates for amorphous formation ( $R_c$ ) in the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type alloys are approximately  $2 \times 10^5$  K/sec. For the  $\alpha$ -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ -type alloys,  $R_c$  is several times larger than this value if no additive elements that retard the crystallization process are used.

Alternative methods to fabricate a nanocrystalline structure include mechanical alloying (MA) or mechanical grinding (MG) followed by a suitable annealing treatment, vapor deposition (VD) techniques such as sputtering followed by suitable annealing treatments. Except for the VD techniques, only an isotropic nanocrystalline structure is obtained. Anisotropic or oriented films can be fabricated by sputter- or pulsed-laser-deposition (PLD) techniques.

## EXAMPLES OF NANOCOMPOSITE PERMANENT MAGNETS

Examples of nanocomposite permanent magnets are briefly discussed in this section. Their magnetic properties are summarized in Table 3.

### Isotropic Nanocomposite Permanent Magnets Based on $\alpha$ -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$

The fabrication of  $\text{Nd}_2\text{Fe}_{14}\text{B}$ -based permanent magnets with trace of  $\alpha$ -Fe was fabricated via MS by Yajima et al.<sup>[15]</sup> in as early as 1988.  $\text{Nd}_{10}\text{Fe}_{82}\text{B}_8$  showed a distinct indication of coarse  $\alpha$ -Fe precipitation in as-spun ribbon. Partial replacement of Fe with Zr resulted to a significant improvement of magnetic properties, but with a significant reduction of the amount of the  $\alpha$ -Fe phase resulting in a nearly single-phase  $\text{Nd}_2\text{Fe}_{14}\text{B}$ -type magnet in melt-spun  $\text{Nd}_9\text{Fe}_{72.5}$ .

**Table 3** Typical magnetic properties of isotropic nanocomposite permanent magnets

Preparation methods: MS = melt-spinning; MA = mechanical alloying; A = annealing; N = nitrogeation; SANP = self-assembly of nanoparticles.

Co<sub>10</sub>Zr<sub>2.5</sub>B<sub>6</sub>. Manaf, Buckley, and Davies<sup>[16]</sup> prepared Nd<sub>8</sub>Fe<sub>86</sub>B<sub>6</sub> melt-spun ribbons of a high remanence, 1.12 T, which was attributed to the existence of  $\alpha$ -Fe. They investigated the microstructure of melt-spun Nd<sub>10</sub>Fe<sub>84</sub>B<sub>6</sub> by TEM and showed existence of a nanometer-sized  $\alpha$ -Fe particle at a grain junction of  $\alpha$ -Fe grains.<sup>[17]</sup> Ribbons with significant amounts of  $\alpha$ -Fe were prepared by Manaf et al.<sup>[17]</sup> One of the best energy densities achieved (185 kJ/m<sup>3</sup>) was obtained by Bauer, Seeger, and Kronmuller<sup>[18]</sup> on Nd<sub>8</sub>Fe<sub>87.5</sub>B<sub>4.5</sub> via MS under an He atmosphere. On the other hand, Inoue et al.<sup>[20]</sup> showed that an  $\alpha$ -Fe/Nd<sub>2</sub>Fe<sub>14</sub>B-type nanocomposite with a remaining amorphous phase exhibit a superior magnetic properties to fully crystalline materials. More recent micromagnetic calculation by Fukunaga, Kuma, and Kanai<sup>[21]</sup> suggested that

softening of exchange coupling in a grain boundary phase should be beneficial to increase coercivity.

Recent improvements of magnetic properties of the  $\alpha$ -Fe/Nd<sub>2</sub>Fe<sub>14</sub>B-type nanocomposite permanent magnets are based on structural refinement by use of refractory metallic elements such as Nb, Hf, Mo, and Zr.<sup>[22]</sup> These elements affect the solidification and crystallization kinetics in the  $\alpha$ -Fe/Nd<sub>2</sub>Fe<sub>14</sub>B-type nanocomposite alloys. Nb is one of the most effective elements in this sense.<sup>[22]</sup> Growth kinetics in undercooled Nd<sub>2</sub>Fe<sub>14</sub>B alloys with C and Ti or Mo addition was recently studied by Hermann and Bächer<sup>[23]</sup> using the electromagnetic levitation technique. The growth velocity of the Nd<sub>2</sub>Fe<sub>14</sub>B phase was estimated to be from 1.1 to 6.4 mm/sec, depending on the degree of supercooling, in Nd<sub>2</sub>Fe<sub>14</sub>B melt, whereas it was

reduced to 0.3–2.5 mm/sec in  $(\text{Nd}_2\text{Fe}_{14}\text{B})_{0.94}(\text{TiC})_{0.03}$  alloy. The considerable slowing down of the growth kinetics resulted in refinement of grain sizes.

One approach toward a nanocomposite permanent magnet with an improved coercivity is to increase the magnetocrystalline anisotropy of HP. Partial replacement of rare-earth ions such as Pr, Tb, and Dy for Nd in the  $\text{Nd}_2\text{Fe}_{14}\text{B}$ -type compounds results in an increase in  $K_H$  of the compound. Hadjipanayis, Withanawasam, and Krause<sup>[22]</sup> prepared melt-spun ribbons of  $\text{Nd}_6\text{Fe}_{87}\text{Nb}_1\text{B}_6$  and  $\text{Nd}_4\text{Tb}_2\text{Fe}_{86}\text{Nb}_2\text{B}_6$  and obtained  $H_{cJ}$  values of 302 and 358 kA/m, respectively. Chang et al.<sup>[24]</sup> studied effects of Co substitution for Fe and obtained good magnetic properties of  $(BH)_{\text{max}} = 143 \text{ kJ/m}^3$  for  $\text{Nd}_8\text{Fe}_{76}\text{Co}_8\text{Nb}_2\text{B}_6$ . More recently, Arai et al.<sup>[25]</sup> achieved an energy density of  $166 \text{ kJ/m}^3$  for  $(\text{Nd}_{0.9}\text{Dy}_{0.1})_9(\text{Fe}_{0.9}\text{Co}_{0.1})_{84.5}\text{B}_{5.5}\text{Nb}_1$  via the melt-spinning method, with grooved TiN-coated roll under an He atmosphere. It was rationalized that the TiN-coating layer lowered the heat transfer at the roll-ribbon interface, resulting in uniform cooling rate through the thickness of the ribbon. Better combinations of  $H_{cJ}$  and  $(BH)_{\text{max}}$  have been obtained for Pr-Fe-B nanocrystalline magnets than for the Nd-Fe-B, resulting from the higher magnetocrystalline anisotropy of  $\text{Pr}_2\text{Fe}_{14}\text{B}$  than  $\text{Nd}_2\text{Fe}_{14}\text{B}$ .<sup>[26]</sup> In a systematic study of  $\alpha$ -Fe/ $\text{Pr}_2\text{Fe}_{14}\text{B}$  melt-spun magnets, a large  $(BH)_{\text{max}}$  of  $180.7 \text{ kJ/m}^3$  was obtained for 30.4 vol.% of  $\alpha$ -Fe.<sup>[27]</sup>

### Isotropic Nanocomposite Permanent Magnets Based on Fe-B/ $\text{Nd}_2\text{Fe}_{14}\text{B}$

The first nanocomposite permanent magnet was the melt-spun  $\text{Nd}_4\text{Fe}_{80}\text{B}_{20}$ , which was of the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$  type, composed of 73%  $\text{Fe}_3\text{B}$ , 15%  $\text{Nd}_2\text{Fe}_{14}\text{B}$ , and 12%  $\alpha$ -Fe.<sup>[4]</sup> This material had relatively large  $B_r$  of 1.2 T, but  $H_{cJ}$  was not large enough for most applications. Among various elements that have been tried to improve magnetic properties of the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -based nanocomposites, Cr is one of the most effective elements to improve the intrinsic coercivity,  $H_{cJ}$ .<sup>[28]</sup> Because of the strong affinity of Cr with B, Cr is enriched in  $\text{Fe}_3\text{B}$  upon crystallization and stabilizes this phase.<sup>[29]</sup> This leads to formation of the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$  composite even in the concentration range where formation of  $\text{Nd}_2\text{Fe}_{23}\text{B}_3$  prevails (namely for  $\text{Nd} > \sim 5 \text{ at.}\%$ ) in the ternary alloys. Accordingly, Cr addition helps to realize nanocomposites with a larger volume fraction of  $\text{Nd}_2\text{Fe}_{14}\text{B}$  and hence a large coercivity. Suzuki and Cadogan<sup>[30]</sup> pointed out that Cr has a significant effect on kinetics of phase formation and decomposition, and that it allows a reaction path in which the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$  composite is formed as a metastable intermediate structure instead of the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{23}\text{B}_3$  combination.

$\text{Fe}_{23}\text{B}_6$  has spontaneous magnetization of approximately 1.7 T at room temperature,<sup>[9]</sup> which is larger than that of  $\text{Fe}_3\text{B}$  (1.6 T) and  $\text{Nd}_2\text{Fe}_{14}\text{B}$  (1.6 T). Therefore the presence of this phase may be beneficial.  $\text{Fe}_{23}\text{B}_6$  crystallizes from residual amorphous phase nearly simultaneously with  $\text{Nd}_2\text{Fe}_{14}\text{B}$  at a slightly higher temperature than the crystallization temperature of  $\text{Fe}_3\text{B}$  when Nb is microalloyed in  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type alloys.<sup>[31]</sup> Cu also has a prominent effect on the kinetics of  $\text{Fe}_3\text{B}$  crystallization. Three-dimensional atom probe microanalysis (3-D APM) has revealed that Cu-enriched clusters are formed upon annealing of an amorphous  $\text{Nd}_{4.5}\text{Fe}_{76.8}\text{B}_{18.5}\text{Cu}_{0.2}$  alloy well below the crystallization temperature of  $\text{Fe}_3\text{B}$ .<sup>[31]</sup> Nd is also enriched in these clusters, leaving Nd-depleted and B-enriched region around them. This region provides a chemically favored crystallization site for  $\text{Fe}_3\text{B}$ . Interestingly, simultaneous addition of very small amount of Cu and Nb resulted to significant improvement of the magnetic properties through refinement of the grain sizes.<sup>[31]</sup> The small amount of addition is sometimes referred to as “microalloying.” The impacts of microalloying of Cu and Nb on demagnetization curves and microstructure of an  $\text{Nd}_{4.5}\text{Fe}_{77}\text{B}_{18.5}$   $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type NPM are shown in Figs. 5 and 6.<sup>[31]</sup>

Zr is also effective in refining grain sizes in the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$  nanocomposites. Addition of 0.1–0.5 at.% of Zr increases the crystallization temperature of particularly  $\text{Nd}_2\text{Fe}_{14}\text{B}$ . The effect of microalloying Zr is greater than that of Nb.<sup>[32]</sup> According to a recent 3-D APM analysis of Zr-Cu-doped magnets, Zr is rejected from  $\text{Fe}_3\text{B}$  and thus suppresses grain growth of this phase. Zr concentrates along grain boundaries between  $\text{Fe}_3\text{B}$  and  $\text{Nd}_2\text{Fe}_{14}\text{B}$  in the fully crystallized stage.<sup>[33]</sup>

**Fig. 5** Demagnetization curves of  $\text{Nd}_{4.5}\text{Fe}_{77}\text{B}_{18.5}\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type nanocomposites showing the impact of microalloying Cu and Nb. Source: From Ref.<sup>[31]</sup>.

**Fig. 6** Transmission electron microscope images of (A)  $\text{Nd}_{4.5}\text{Fe}_{75.8}\text{B}_{18.5}$ , (B)  $\text{Nd}_{4.5}\text{Fe}_{76.8}\text{B}_{18.5}\text{Cu}_{0.2}$ , (C)  $\text{Nd}_{4.5}\text{Fe}_{75.8}\text{B}_{18.5}\text{Cu}_{0.2}\text{Nb}_1$ , and (D)  $\text{Nd}_{4.5}\text{Fe}_{76}\text{B}_{18.5}\text{Nb}_1$ , showing the impact of simultaneous microalloying of Cu and Nb. The average grain size is about 30, 17, 12, and 43 nm, respectively. Source: From Ref.<sup>[31]</sup>.

Compositional adjustment has yielded a relatively high coercivity material on the basis of Nd–Fe–B–Cr–Co, namely  $\text{Nd}_{4.5}\text{Fe}_{73}\text{B}_{18.5}\text{Cr}_2\text{Co}_2$ , which has  $B_r$  of 1.05 T,  $H_{cJ}$  of 378 kA/m, and  $(BH)_{\text{max}}$  of 108 kJ/m<sup>3</sup>. Simultaneous addition of small amounts of Cu and Nb to this material has been successfully carried out to improve  $(BH)_{\text{max}}$  with a slight sacrifice in  $H_{cJ}$  to yield  $\text{Nd}_{4.5}\text{Fe}_{72.3}\text{B}_{18.5}\text{Cr}_2\text{Co}_2\text{Cu}_{0.2}\text{Nb}_{0.5}$  with  $B_r$  of 1.10 T,  $H_{cJ}$  of 336 kA/m, and  $(BH)_{\text{max}}$  of 123 kJ/m<sup>3</sup>.<sup>[32]</sup> Manipulation of crystallization behavior, especially that of  $\text{Nd}_2\text{Fe}_{14}\text{B}$ , can be carried out by readjusting Cu content. An example of such compositional modifications to yield higher coercivity magnets is  $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{71.3}\text{B}_{18.5}\text{Cr}_{2.4}\text{Co}_{2.4}\text{Cu}_{0.4}\text{Nb}_{0.5}$ , which has  $B_r$  of 0.93 T,  $H_{cJ}$  of 468 kA/m, and  $(BH)_{\text{max}}$  of 100 kJ/m<sup>3</sup>.<sup>[34]</sup> Utilizing the stronger effect of Zr to prevent grain growth, better magnetic properties have been obtained in  $\text{Nd}_{3.4}\text{Dy}_1\text{Fe}_{71.7}\text{B}_{18.5}\text{Cr}_{2.4}\text{Co}_{2.4}\text{Cu}_{0.4}\text{Zr}_{0.2}$ , which has  $B_r$  of 0.97 T,  $H_{cJ}$  of 465 kA/m, and  $(BH)_{\text{max}}$  of 105 kJ/m<sup>3</sup>.

Gallium (Ga) is another important element for improving magnetic properties of the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$  nanocomposite.<sup>[35]</sup> One of the best  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type nanocomposite is  $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$  with  $(BH)_{\text{max}}$  of 136 kJ/m<sup>3</sup>,  $B_r$  of 1.18 T, and  $H_{cJ}$  of 390 kA/m.<sup>[36]</sup> Mishra and Panchanathan<sup>[37]</sup> studied  $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$  by TEM–EDX, and observed that Ga additives were all detected in the  $\text{Nd}_2\text{Fe}_{14}\text{B}$  phase with Ga concentrations mostly near grain boundaries. More recently, a 3-D APM analysis revealed that Co and Ga atoms are partitioned to the  $\text{Nd}_2\text{Fe}_{14}\text{B}$  phase. Moreover, evidence for a slight enrichment of Ga

atoms at the  $\text{Nd}_2\text{Fe}_{14}\text{B}/\text{Fe}_3\text{B}$  interface has been found.<sup>[38]</sup>

The effects of Cr, Ti, Nb, Zr, Hf, Ta, and W on microstructure and magnetic properties of nanocomposites composed mainly of  $\text{Nd}_2\text{Fe}_{14}\text{B}$ , with minor amounts of ferromagnetic borides such as  $\text{Nd}_2\text{Fe}_{23}\text{B}_3$ , have been studied by Chang et al.<sup>[39]</sup> The formation of metastable  $\text{Nd}_2\text{Fe}_{23}\text{B}_3$  was found to be suppressed by the addition of Cr, Ti, Nb, and V in  $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{78}\text{M}_2\text{B}_{10.5}$ . Thermal magnetic analysis indicated existence of  $\alpha$ -Fe and an  $\text{Nd}_2\text{Fe}_{14}\text{B}$ -type phase. Considerable refinement of grain sizes was observed by TEM in  $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{78}\text{Cr}_2\text{B}_{10.5}$  and in  $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{78}\text{Ti}_2\text{B}_{10.5}$ . In a similar composition range, Chiriac et al.<sup>[40]</sup> reported that relatively good hard magnetic properties can be obtained by a chill disk melt spinning technique with a small surface velocity of only 3 m/sec in the as-cast state of  $\text{Nd}_8\text{Fe}_{73}\text{Co}_5\text{Hf}_2\text{B}_{12}$ . Thermal magnetic analysis indicated formation of  $\text{Nd}_2\text{Fe}_{14}\text{B}$ -type phase and  $\alpha$ -(Fe, Co). However, significantly better magnetic properties are obtained in as-cast alloys for the  $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ -type alloys.<sup>[41]</sup>

### Isotropic Nanocomposite Permanent Magnets Based on $\alpha$ -Fe/Sm–Fe–C, $\alpha$ -Fe/Sm–Fe–N, and Sm–Co

An  $\alpha$ -Fe/Sm<sub>2</sub>Fe<sub>17</sub>N<sub>x</sub>-type nanocomposite permanent magnet powder, the combination of the phases that was emphasized by the theoretical study of Skomski and Coey,<sup>[5]</sup> was obtained in as early as 1993 by Ding et al.<sup>[42]</sup> by mechanical alloying of Sm<sub>7</sub>Fe<sub>93</sub> followed by annealing and nitriding. The powder was isotropic and was reported to have a very large remanence of 1.75 T and a  $(BH)_{\text{max}}$  value of 204 kJ/m<sup>3</sup> after a correction for the demagnetization field. From the melt-spinning route, Yoneyama et al.<sup>[43]</sup> prepared an  $\alpha$ -Fe/SmFe<sub>7</sub>N<sub>x</sub>-type nanocomposite powder. The SmFe<sub>7</sub>N<sub>x</sub> phase has the TbCu<sub>7</sub>-type structure, which is a disordered hexagonal structure that can be derived from the Th<sub>2</sub>Zn<sub>17</sub>-type Sm<sub>2</sub>Fe<sub>17</sub> structure but with a random arrangement of dumbbell Fe pairs at the Sm sites. The addition of Co, aiming at a higher Curie temperature and remanence, resulted in a higher coercive force.

To eliminate the gas–solid reactions, namely nitriding, preparation of NPM on the basis of the Sm<sub>2</sub>Fe<sub>17</sub>C<sub>x</sub> hard magnetic compound have been attempted. Substitution of Al, Ga, Cr, and Si for Fe stabilized Sm<sub>2</sub>Fe<sub>17</sub> with high carbon concentration.<sup>[44,45]</sup> Melt-spun and annealed ribbons of  $\alpha$ -Fe/Sm<sub>2</sub>Fe<sub>15</sub>Si<sub>2</sub>C with Cu additives showed reasonable magnetic properties of  $(BH)_{\text{max}} = 85 \text{ kJ/m}^3$ .<sup>[46]</sup>

Cobalt as an SP may coexist with Sm<sub>2</sub>Co<sub>17</sub>. Isotropic nanocomposite permanent magnets were prepared by mechanical alloying processes to exhibit relatively good magnetic properties after annealing at 900°C of

$(BH)_{\max} = 81 \text{ kJ/m}^3$  for Co/Sm<sub>2</sub>Co<sub>17</sub>.<sup>[47]</sup> Somewhat better magnetic properties were obtained by mechanically alloying Sm–Co alloys and Fe powder and subsequent annealing. The finished powder of Sm<sub>11.67</sub>Co<sub>58.33</sub>Fe<sub>30</sub> had a  $(BH)_{\max}$  of  $101 \text{ kJ/m}^3$ .<sup>[48]</sup>

### Anisotropic Nanocomposite Permanent Magnet Films

Thin films prepared by vapor deposition techniques such as Ar-sputtering normally show magnetic anisotropy or texture. Therefore epitaxially grown thin films composed of soft magnetic and hard magnetic alternate layers can potentially become anisotropic nanocomposite permanent magnets of extraordinary  $(BH)_{\max}$  values. An Fe/Nd<sub>2</sub>Fe<sub>14</sub>B/Fe trilayer grown by Parhorer et al.<sup>[49]</sup> had texture with the easy direction of magnetization perpendicular to the film plane. Fe/[NdFeB/Fe]<sub>5</sub> multilayers grown by Shindo et al.<sup>[50]</sup> (Table 4) with isotropic texture in the hard magnetic layers were used to estimate the exchange-coupling constant  $J_{\text{SH}}$  between the soft and hard magnetic layers. The estimated  $J_{\text{SH}}$  value is  $2.0 \times 10^{-3} \text{ J/m}$ , which is about 1 order of magnitude smaller than the Fe/Fe and Nd<sub>2</sub>Fe<sub>14</sub>B/Nd<sub>2</sub>Fe<sub>14</sub>B couplings. Epitaxial superlattices of [Sm–Co (45 nm)/Co (30 nm)]<sub>10</sub> grown by Fullerton et al.<sup>[51]</sup> showed a relatively large  $H_{\text{cJ}}$  value of about 400 kA/m. Textured  $\alpha$ -Fe/SmFe<sub>12</sub> films in which the composite phases are randomly dispersed have been synthesized by Kato et al.<sup>[52]</sup> The film containing 25 vol.%  $\alpha$ -Fe showed  $(BH)_{\max}$  of  $152 \text{ kJ/m}^3$ . Apart from rare-earth-based systems, Liu et al.<sup>[53]</sup> succeeded to obtain a large  $(BH)_{\max}$  value of  $420 \text{ kJ/m}^3$  along the film—normal direction in an Fe<sub>3</sub>Pt/FePt multilayer film. The preparation procedure of the film included sputter deposition of Fe/Pt multilayers on a cold substrate and subsequent rapid thermal annealing of more than one step during which the Fe<sub>3</sub>Pt phase was formed.

### UTILIZATION OF NANOCOMPOSITE PERMANENT MAGNETS

The main application area of the rapidly solidified or mechanically alloyed nanocomposite permanent

magnet powders will be the resin-bonded magnet as the nanoscopic structure is metastable and cannot be maintained in the normal densification processes such as sintering. The resin-bonded magnets may be classified in compression-molded magnets and injection-molded magnets. The compression-molded magnets normally have a higher packing fraction of the magnetic composition than the injection-molded magnets. The typical packing fraction of the magnetic powder for these two types of magnets is 80 and 60 vol.%, respectively. Therefore the  $(BH)_{\max}$  of a resin-bonded magnet is only about one half of the magnetic powder used in the magnet. However, owing to the relatively simple preparation process and good dimensional accuracy originating from the molding processes, the resin-bonded magnets are widely used in electric devices such as small high-precision motors, which are used, for instance, in hard-disk drives mounted in personal computers. Rapidly solidified Nd–Fe–B powders with a small excess amount of Nd over Nd<sub>2</sub>Fe<sub>14</sub>B stoichiometry<sup>[54]</sup> have been almost exclusively used for the resin-bonded magnets. The advent of the nanocomposite permanent magnets based on the  $\alpha$ -Fe/Nd<sub>2</sub>Fe<sub>14</sub>B or Fe<sub>3</sub>B/Nd<sub>2</sub>Fe<sub>14</sub>B nanocomposite powders have added alternative choices for material engineers in this area of applications.

The R–Fe–B-based NPM powders (R is a rare-earth element) have several unique aspects when compared with the conventional Nd<sub>2</sub>Fe<sub>14</sub>B-based powders. First, NCM has compositions richer in Fe than the conventional powders, and consequently shows weaker susceptibility to oxygen or moisture. This is beneficial in massive handling of fine metallic powders in the production of bonded magnets. Second, because of the off-stoichiometric compositions, the R–Fe–B-based NPM alloys generally have greater formability of an amorphous phase, which allows application of rapid solidification techniques with relatively slow cooling rates. For instance, gas atomization may be used to produce spherical particles, which has beneficial characteristics for the injection-molding process.<sup>[55]</sup> The Fe<sub>3</sub>B/Nd<sub>2</sub>Fe<sub>14</sub>B-based NPM powders have similar morphological characteristics because of the relatively large thickness of the rapidly solidified alloys from

**Table 4** Magnetic properties of anisotropic nanocomposite permanent magnet films

Type (SP/HP)	Composition	Preparation method	$B_r$ (T)	$H_{\text{cJ}}$ (kA/m)	$(BH)_{\max}$ (kJ/m <sup>3</sup> )	Reference
$\alpha$ -Fe/Nd <sub>2</sub> Fe <sub>14</sub> B	SiO <sub>2</sub> /NdFeB/Fe/NdFeB/Cr	S	1.2	380	N/A	[49]
	Ti/Fe/[NdFeB/Fe] <sub>5</sub> /Ti	S	0.75	240	43	[50]
Co/Sm–Co	MgO/Cr/[Sm–Co(45 nm)/Co(30 nm)] <sub>10</sub> /Cr	S	N/A	500	N/A	[51]
$\alpha$ -Fe/SmFe <sub>12</sub>	(25 vol.% $\alpha$ -Fe)/(75 vol.% SmFe <sub>12</sub> )	S	1.3	240	151	[52]
Fe <sub>3</sub> Pt/FePt	Fe <sub>2</sub> Pt	S–A	1.4	1400	420	[53]

S and A denote sputtering and annealing, respectively.

which the powder particles are obtained by crushing.<sup>[8,56]</sup>

To exploit the large remanence of an NPM, the NPM powder needs to be fully consolidated. However, as mentioned above, normal densification processes such as liquid-phase sintering cannot be applied because if long-distance diffusion is to be allowed, the nanocomposite structure will be destroyed. To densify NMP, pressure-aided, moderate-temperature processes such as hot pressing must be used. Fully dense NPMs were prepared by Ono et al.<sup>[57]</sup> using spark plasma sintering method on the basis of  $\text{Nd}_{10}\text{Fe}_{75}\text{Co}_8\text{V}_1\text{B}_6$  to exhibit  $(BH)_{\text{max}} = 134 \text{ kJ/m}^3$ .

## CONCLUSION

We have witnessed an era of spectacular development of permanent magnetic materials in the last few decades. After the discovery of the  $\text{Nd}_2\text{Fe}_{14}\text{B}$  hard magnetic compound, no superior hard magnetic phase has been found. The concept of nanocomposite permanent magnet (NPM) remains the only concept that leads to designed experimentation toward a superior permanent magnet material. An NPM is a polycrystalline material composed of nanometer-sized hard magnetic phase and ferromagnetic phases that augment the total magnetization of the material. The nanosized microstructure is a prerequisite to obtain smooth J–H and B–H curves. A giant magnetic energy product reaching about  $0.7 \text{ MJ/m}^3$  may be expected in a textured NPM consisting of bcc Fe and hard magnetic phases such as  $\text{Nd}_2\text{Fe}_{14}\text{B}$  or  $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ , although, in reality, only nontextured, isotropic NPM have been successfully produced in a sizable mass via rapid solidification or other techniques. Attempts to fabricate textured thin films via sputtering or laser pulse deposition<sup>[58]</sup> are among the most promising approaches. Other techniques that recently appeared may include self-organized assembly of nanoparticles prepared by means of wet chemistry,<sup>[59]</sup> spark erosion,<sup>[60]</sup> repeated cold rolling of layered stack of metallic sheets,<sup>[61]</sup> and crystallization of amorphous precursor in a magnetic field.<sup>[62]</sup> One novel and promising approach utilizes wet-chemical, self-organized assembly of nanoparticles. In the approach recently proposed by Zeng et al.,<sup>[63]</sup> both FePt and  $\text{Fe}_3\text{O}_4$  particles were incorporated as nanometer-scale building blocks into binary assemblies. Subsequent annealing under a flow of a mixture of Ar and  $\text{H}_2$  converted the assembly into FePr– $\text{Fe}_3\text{Pt}$  nanocomposites (see Table 3 for magnetic properties). Many other processes may be proposed. On the other hand, currently exploited Nd–Fe–B sintered magnets have  $(BH)_{\text{max}}$  values exceeding  $400 \text{ kJ/m}^3$  in the mass-production level. The prices of these conventional high-performance

magnets are reasonably low as a result of maturing of production techniques. Therefore the process used to produce the textured nanocomposite permanent magnets must be simple and suitable for a massive operation. Moreover, soft magnetic materials used with the hard magnetic materials as cores or yokes need to be improved to fully utilize such high-remanence hard magnets. Otherwise, the application area will be limited inside a small community.

For commercial applications, isotropic NPM has entered the stage of practical utilization as a hard magnetic ingredient for resin-bonded magnets. Indeed, NPM has some characteristics superior to those of conventional materials for this application. Some of the Fe–R-based NCM alloys have inherent characteristics that allow a high-throughput operation of the rapid solidification process and, accordingly, may be produced at a lower production cost. Therefore isotropic NPM powders will replace the conventional material in many application areas of resin-bonded magnets.

# Phase Transfer of Monosaccharides through Noncovalent Interactions

Elizabeth K. Auty  
Anthony P. Davis

*Department of Chemistry, University of Bristol, Bristol, U.K.*

## INTRODUCTION

Sugars constitute one of the major classes of biological building blocks. On one hand, they are important for physical construction (e.g., as cellulose) and energy storage (e.g., as starch). On another more subtle level, they are used by nature to label cells and biomolecules and thus to mediate a variety of biological events. Thus saccharide motifs are central to cell–cell recognition, infection of cells by pathogens, and many aspects of the immune response.<sup>[1–8]</sup>

Carbohydrates are hydrophilic molecules, which are usually freely soluble in water and show little inclination to enter organic media. Nonetheless, there are good reasons why one might wish to promote phase transfer of these species. First, there is a potential large-scale technological application in the production of “high-fructose syrup.” Hydrolysis of starch and enzymatic treatment can be used to produce a mixture of fructose and glucose, which is ca. 42% of the former. Higher levels are desirable as fructose is exceptionally sweet-tasting, and there is much interest in transport processes that might be used in enrichment procedures.<sup>[9,10]</sup> Second, there are biomedical applications for carbohydrate phase transfer. The most immediate might be in the management of diabetes, where an effective, reversible extraction system could be used as the basis for a glucose sensor.<sup>[11–14]</sup> In addition, there is fundamental interest in saccharide transport across biological membranes and the possibility of delivering carbohydrate-like drugs using phase-transfer agents. Third, the study of carbohydrate recognition has become a major area of supramolecular chemistry,<sup>[15,16]</sup> and carbohydrate phase transfer has proved useful in this context. The key challenge is to bind carbohydrates in direct competition with liquid water (their natural environment). However, it is difficult to design and handle receptors that are fully soluble in water. Extraction experiments, involving aqueous and organic phases, provide a straightforward solution to the problem. The receptor, dissolved in the organic solvent, is equilibrated with an aqueous solution of the substrate. The amount of substrate

transferred to the organic phase can be measured and used as a qualitative indication of receptor efficiency. Quantification is possible in principle,<sup>[17]</sup> although to date this has not been realized for carbohydrate substrates.

Broadly speaking, two approaches have been taken toward carbohydrate recognition in general, and toward carbohydrate phase transfer in particular. One is based on the reaction of boronic acids with diols to give cyclic boronate esters.<sup>[16,18]</sup> This strategy can be highly effective but, being based on covalent B–O bond formation, lacks biological relevance. The alternative relies on non-covalent interactions, and thus may be seen as “biomimetic.”<sup>[15]</sup> This entry discusses systems belonging to the second category only, focusing on the transfer/transport of simple monosaccharide substrates into/across non-polar phases. The account is divided into three sections covering: 1) preorganized receptor molecules; 2) less organized, micellar systems; and 3) self-assembling channels.

## PHASE TRANSFER OF MONOSACCHARIDES BY PREORGANIZED RECEPTORS

Monosaccharides are relatively large as substrates for supramolecular chemistry, possessing irregular arrays of divergent functional groups. Being mostly hydroxyls, these substituents are capable of hydrogen bonding but do not form especially strong and specific interactions (unlike, for example, carboxylate or ammonium units). Thus carbohydrate recognition is a difficult undertaking, even in the absence of water. Competition from water molecules adds to the challenge, given that the receptor must distinguish the target from competitors bearing the same functional groups. Preorganization, the correct positioning of binding groups and surfaces, is the key to solving such problems.<sup>[19]</sup> Cyclization is a useful strategy for controlling the shape of large, potentially flexible frameworks, and it is not surprising that macrocycles have featured strongly in supramolecular chemistry.<sup>[20]</sup> Macrocycles composed of rigid units possess still fewer conformational options, so that the cyclophane

architecture (a macrocycle incorporating one or more aromatic rings) is especially popular.<sup>[21,22]</sup> Most of the carbohydrate receptors with demonstrated phase transfer capability belong to this family of molecules.

The first such system was the receptor **1a**, synthesized by Aoyama et al.<sup>[23,24]</sup> from resorcinol and dodecanal. This system is furnished with eight phenolic OH groups, capable of hydrogen bonding to the substrate hydroxyls, and four undecyl side chains, which maintain lipophilicity and organic solubility. **1a** was determined by <sup>1</sup>H nuclear magnetic resonance (NMR) to be the all-cis, bowl-shaped isomer shown, and did indeed prove soluble in apolar media such as benzene or CCl<sub>4</sub>. Dissolved in these solvents, it was capable of carrying 4 Eq of water or glycerol **2** into the organic phase. When an extraction was performed using an equimolar mixture of water and **2** ([**2**] = [water] = 11 M), only water was transferred into the organic medium with little coextraction of glycerol evident. However, when a 5.5-M solution of ribose **3** was used as the aqueous phase, the monosaccharide was extracted with water to form a complex of estimated stoichiometry: **1a**:**3**:H<sub>2</sub>O = 1:1:2. Interestingly, the ribose was found to be extracted exclusively in the  $\alpha$ -pyranose form shown, in which all the OH groups are cis. This point is discussed further below. When the *O*-acetylated macrocycle **1b** was used in the extraction experiments, neither **2** nor **3** was transferred to the organic phase, suggestive of OH...OH hydrogen bonding as the key binding interaction.

Aoyama et al. proceeded to study the extraction by **1a** of pentoses **4–8** and hexoses **9–13**. A summary of the results is given in Table 1.

Two factors seem to dominate extractability by **1a**. The first, unsurprisingly, is the hydrophilicity of the sugar [e.g., D-galactose **10** is barely detected in the organic phase, whereas L-fucose (6-deoxy-L-galactose, **12**) is readily extracted]. The second is the relative configuration of the substrates at C<sub>3</sub> and C<sub>4</sub>. Extraction seems to be favored by a cis arrangement in the Fischer projection (e.g., **3**, **4**, **7**, and **12**), which translates to cis in the pyranose form of the carbohydrates. The results

support a face-to-face binding geometry in which OH groups emerging from the same face of the saccharide are best able to form multiple interactions with the receptor.

Later work showed that methyl- $\beta$ -D-glucoside **14** could also be extracted by **1a** from water into CCl<sub>4</sub>, despite the absence of *cis*-1,2-diol units.<sup>[25]</sup> However, in this case, a 2:1 receptor/substrate ratio suggested

a “sandwich” structure, in which receptor molecules bind to both faces of the guest. The  $\alpha$ -anomer **15**, for which the sandwich structure is probably not possible, was very poorly extracted under the same conditions.

The second example of carbohydrate recognition by preorganized, macrocyclic receptors involved the steroid-derived “cholaphanes” **16**.<sup>[26,27]</sup> These molecules possess substantial cavities capable of fully surrounding a monosaccharide substrate. Up to six H-bonding groups ( $4 \times \text{OH}$  and  $2 \times \text{CONH}$ ) are available to interact with the carbohydrate, whereas the steroidal framework provides a lipophilic exterior compatible with organic media. A second generation of cholaphanes **17** featured externally directed alkyl groups to enhance lipophilicity. In this case, contraction of the side chain in steroidal precursors was used to vary cavity size and flexibility.<sup>[28]</sup>

Receptors **16** and **17** were studied mainly by NMR in homogeneous  $\text{CDCl}_3$  solution, employing organic-soluble glycosides such as **18** as substrates.<sup>[26–28]</sup> However, some extraction experiments were also performed by employing methyl- $\beta$ -D-glucoside **14**.<sup>[28]</sup> The NMR data were compatible with 1:1 complex formation, and allowed the estimation of binding constants ( $K_a$ ). For example, the following values were obtained for

binding to **18**: **16**,  $K_a = 3100 \text{ M}^{-1}$ ; **17a**,  $K_a = 1560 \text{ M}^{-1}$ ; **17b**,  $K_a = 600 \text{ M}^{-1}$ ; and **17c**,  $K_a = 1305 \text{ M}^{-1}$ . In the extraction experiments, solutions of the receptors in chloroform were stirred with aqueous solutions of **14** (1–to 2.5 M). Perhaps surprisingly, the order of effectiveness was **17a** > **17b** > **16** > **17c**, failing to parallel the affinities to **18**. The most efficient, **17a**, was capable of extracting  $\sim 0.2$  Eq of **14** from a 1.75-M aqueous solution, and was also shown to transport this substrate through a chloroform barrier (“U-tube” experiment). Positive results were not obtained with the more hydrophilic glucose. Although not especially effective, this system performed a useful service in relating binding constants to extraction capabilities. Broadly speaking, a  $K_a$  of roughly  $10^3 \text{ M}^{-1}$  in chloroform proved sufficient to extract a moderately hydrophilic carbohydrate (**14**) from fairly concentrated ( $\sim 2 \text{ M}$ ) aqueous solutions.

A third family of macrocycles for carbohydrate phase transfer was developed by Inouye et al. Their initial system, exemplified by **19**, was especially targeted at ribofuranosides.<sup>[29]</sup> As shown, it was designed to provide a series of H-bonding interactions with the three hydroxyl groups of these substrates. In NMR titration experiments with the organosoluble  $\beta$ -D-ribofuranoside **20** and the 2-deoxy substrate **21**, binding constants of 10,000 and  $690 \text{ M}^{-1}$  were measured, respectively. The lower value for **21** is not surprising, given that it can form fewer hydrogen bonds with the receptor. The group then converted the central alkoxy pyridine unit to a pyridone, as in **22**.<sup>[30]</sup> It was hoped that the change from H-bond acceptor to donor would make the receptor more compatible with 2-deoxyfuranosides, as shown. Indeed, the binding

**16a** R = H**16b** R =  $\text{CH}_2\text{Ph}$ **17a** n = 0**17b** n = 1**17c** n = 2**18**

constant of **22** (R = Bu<sup>i</sup>) to **21** in CDCl<sub>3</sub> was found to be 19,000 M<sup>-1</sup>.

The phase-transfer capabilities of **19** and **22** were explored through solubilization experiments employing solid carbohydrate substrates and chloroform as solvent. The results are summarized in Table 2. The data show that the affinities achieved by **19** and, especially, **22** are sufficient to solubilize a full range of monosaccharides (although not necessarily extract them from water). They also reveal genuine, receptor-based selectivity. To amplify this point, a series of figures (binding constants, extraction levels) recorded for a single receptor may not be especially informative. Differences may simply reflect the fact that some substrates are more easily bound (“stickier”) than others. However, when two receptors show distinctly different preferences, receptor

structure is shown to be a major factor. In this case, **19** extracts D-ribose **3** more effectively than 2-deoxy-D-ribose **7** and fails with pyranoses **9–11**, whereas **22** prefers **7** to **3** and succeeds quite well with **9–11**.

**Fig. 1** D-glucose **9** in  $\beta$ -pyranose form **25**, interpreted as polar and apolar binding regions. *Source:* From Ref.<sup>[31]</sup>.

Macrocyclic receptors **16**, **17**, **19**, and **22** are able to surround their substrates but not encapsulate them. A further advance was made by the macrotricyclic system **24**, which provides a preorganized, essentially enclosed binding site specifically designed for a monosaccharide.<sup>[31,32]</sup> In this case, the target was glucose **9**, in its native pyranose form. As shown in Fig. 1, the all-equatorial pattern of polar substituents in  $\beta$ -D-glucopyranose **25** allows the substrate to be viewed as a disk, with apolar surfaces top and bottom (corresponding to axial CH units) and a polar circumference. Accordingly, **24** consists of two parallel apolar units (biphenyls) connected by bridges containing H-bond donors/acceptors (amides). Modelling (Fig. 2) showed that **25** could fit in the cavity and make at least six intermolecular hydrogen bonds, as well as apolar CH- $\pi$  contacts.<sup>[31]</sup> The structure is reminiscent of that found in carbohydrate-binding proteins, where aromatic surfaces are often found in contact with lipophilic patches on saccharide substrates.<sup>[15]</sup>

Receptor **24** was initially prepared as tetraester **24a** and studied in homogeneous solution. Octyl glycosides **18**, **26**, and **27** were used as substrates. Binding constants were obtained by NMR in  $\text{CDCl}_3$ - $\text{CD}_3\text{OH}$  (92:8) and by fluorescence titration in  $\text{CHCl}_3$ . The results, summarized in Table 3, confirmed that the enclosed binding site yielded significant gains in affinity and selectivity. Thus the complex to  $\beta$ -glucoside **18** was formed with  $K_a \sim 10^3 \text{ M}^{-1}$  even in the presence of 8% by volume of competing methanol, and in pure  $\text{CHCl}_3$  (as used for previous systems), the value was raised to  $3 \times 10^5 \text{ M}^{-1}$ . In both media,  $\alpha$ -glucoside **26** was far less strongly bound.

The phase-transfer properties of **24** were first tested by stirring **24a** with D-glucose **9** in  $\text{CDCl}_3$ .<sup>[31]</sup> Analysis by NMR indicated that  $\sim 0.9$  Eq of **9** was solubilized, representing (as expected) an improvement on **22**. Remarkably, the glucose was detected as a 7:1 mixture of  $\beta$ -pyranose/ $\alpha$ -pyranose, presumably reflecting the preference for  $\beta$ -glucosyl revealed in Table 3.<sup>a</sup>

<sup>a</sup>The  $\beta$ : $\alpha$  ratio should normally be close to 1:1 in organic solvents.

For liquid-liquid extraction, it transpired that increased lipophilicity was required, so **24** was prepared as tetraamide **24b**.<sup>[32]</sup> Extraction experiments were performed in chloroform/water, with the results shown in Table 4. All the substrates were extracted from a 1-M aqueous solution including, for the first time, the hexoses **9**–**11**. Notable selectivity was shown for the “all-equatorial” saccharides glucose **9** and xylose **5**. Moreover, glucose, the specific target of **24**, was extracted from aqueous solutions as low as 0.1 M in concentration. Physiological glucose concentrations, at 0.005 M, are still out of reach, but with further development, this system could ultimately serve as the basis of a clinically relevant glucose sensor.

## PHASE TRANSFER OF MONOSACCHARIDES BY LESS ORGANIZED SYSTEMS

The essential characteristic required for carbohydrate phase transfer is an amphiphilic structure with a polar interior and an apolar exterior. Although preorganization of the polar interior should, in principle, be advantageous, it turns out that less organized structures can also be successful. One example is provided by thiosuccinate derivative **28**, studied by Greenspoon and Wachtel.<sup>[33]</sup> At a concentration of 50 mM, **28** was shown by x-ray scattering experiments to form “inverse micelles” (polar interior, apolar exterior) in a mixture of chloroform/cyclohexane, 1:1. Addition of D-glucose **9** (solid monohydrate) followed by centrifugation gave a clear solution, which was found by NMR to contain one molecule of glucose per nine molecules of **28**. It appears that the assembly of **28** can bind the glucose directly, without a solvation shell of water. When water was added, the glucose-derived NMR signals shifted, indicating a change in environment. Further NMR experiments with **29** as substrate, and electron spin resonance spectroscopy (ESR) studies employing **30**, confirmed that the monosaccharide unit was associated with the micelles.

**Fig. 2** Receptor **24**, modelled as the tetramethyl ester, binding D-glucose **9** as the  $\beta$ -pyranose. The configuration shown is the baseline conformation from a 1000-step Monte Carlo molecular mechanics study. Kobayashi et al.<sup>[34]</sup> studied **31**, a macrocyclic but flexible system best seen as a “unimolecular reversed micelle.” When **31a** dissolved in  $CCl_4$  was stirred with water, <sup>1</sup>H NMR analysis revealed the presence of ca. 40 molecules of  $H_2O$  in the organic phase. However, when 3-M solutions of D-ribose **3**, D-glucose **9**, or D-fructose **23** were substituted for water, the carbohydrate was extracted without any measurable coextraction of  $H_2O$ . In the case of D-glucose **9**, a 1 : 1 ratio of receptor/substrate was established directly by <sup>1</sup>H NMR integration, and also by reextraction of the sugar back into water. Sugar extraction, as well as water pool accommodation, were also observed with the acyclic heptakis(dihydroxyalkyl) reference host **32**, although no complexation was observed for **31b** or **33**, implying that the clustering of dihydroxyalkyl chains is essential for recognition.

Kasuga et al.<sup>[35]</sup> have shown that the lipophilic alkaline earth metal salts **34** can promote transport of monosaccharides through chloroform bulk liquid membranes. Efficiency increased with cation size, the

most effective carrier being **34** (M = Ba). A range of monosaccharides were tested as substrates, with the results shown in Table 5. Unsurprisingly, transport rates correlate to a fair degree with apparent substrate lipophilicity. However, the preference for D-ribose **3** over 2-deoxy-D-ribose **7** runs counter to this trend, and is especially interesting.

**34** M = Mg, Ca, Sr, Ba

## CHANNEL-MEDIATED TRANSPORT OF CARBOHYDRATES

Finally, in the special case of aqueous phases separated by a lipid bilayer, polar substrates may be transferred via channels in the membrane. Bong et al.<sup>[36]</sup> have studied a range of self-assembling channels formed from cyclic peptides composed of alternating D and L amino acids. The peptides stack through hydrogen bonding to form a toroidal version of a  $\beta$ -sheet. If a decapeptide is used, the resulting tube has an internal diameter of ca. 10 Å, enough to allow passage of a glucose molecule.<sup>[37]</sup> The cyclodecapeptide **35**, composed mainly of lipophilic D-leucine and L-tryptophan, was designed to concentrate in apolar environments. When added to liposome suspensions, it was shown by several spectroscopic techniques to incorporate into the bilayers to form H-bonded aggregates. If D-glucose **9** was entrapped in the liposomes, addition of **35** promoted efflux of the carbohydrate (measured using an enzyme-based assay). Kinetic studies were consistent with a channel, rather than carrier, transport mechanism. The analogous cyclooctapeptide, with an internal diameter of  $\sim 7.5$  Å, showed no activity.

**35**

## CONCLUSION

In summary, the study of carbohydrate recognition through non-covalent interactions has led to a range of phase transfer systems, effective for moderate to high concentrations of substrates. It remains difficult to transport monosaccharides into apolar media from dilute aqueous solutions. However, steady progress over the past 15 years suggests that the necessary affinities will be achieved before long. Success could have important consequences, not least in diabetes treatment where improved glucose sensors are sought with some urgency.<sup>[11–14]</sup>

## ACKNOWLEDGMENTS

A.P.D. thanks all of his coworkers, whose names appear in the references, for their contributions to date and for their ongoing efforts in this area. Funding for our program on carbohydrate recognition has been provided by the EPSRC, the European Commission, the University of Bristol, and the Enterprise Ireland.

## INTRODUCTION

In 1842, the Swiss physicist Daniel Colladon<sup>[1]</sup> demonstrated that light could be guided along a curved path within a tube of transparent material. Colladon's "light pipe" was simply a narrow stream of water issuing through a hole in the side of a tank. The underlying guidance mechanism in this case was, of course, total internal reflection (TIR)—the phenomenon by which standard single-mode fiber (SMF) guides light. A typical SMF designed for communications wavelengths (Fig. 1A) has a Ge-doped silica core (synthesized by modified chemical vapor deposition),<sup>[2]</sup> a core-cladding refractive index difference of a few percent, and a core diameter of  $\sim 10\ \mu\text{m}$ , and possesses astonishing optical clarity (0.2 dB/km at 1550 nm). Although SMF has been outstandingly successful in optical telecommunications, there is still pressure to further improve its performance. For example, optical non-linearities in the solid glass core are proving complex to understand and awkward to control, and are contributing to bit error rate deterioration over long spans in wavelength division multiplexed systems. In other fields, there is a long-standing need for fibers that can carry higher power; act as versatile sensors or hosts for rare earth ions; and have multiple cores, higher non-linearities, lower non-linearities, higher birefringence, and widely engineerable dispersion.

## Annular Fibers

In the early 1970s, another kind of structure had been proposed, in theory, as an alternative to SMF (Fig. 1B). This was a cylindrical fiber that guided light by Bragg scattering at a periodic array of annular rings of high and low refractive index arranged around a central core.<sup>[3]</sup> A team in France has recently succeeded in making a solid-core version of this structure using

modified chemical vapor deposition (MCVD).<sup>[4]</sup> Work is also underway to realize a hollow-core version of a similar structure.<sup>[5]</sup>

## Photonic Crystal Fibers

In 1991, the idea emerged<sup>[6]</sup> that light might be trapped in a hollow core by means of a two-dimensional "photonic crystal" of microscopic air capillaries running along the entire length of a fiber. Appropriately designed, this array would support a photonic band gap for incidence from air, preventing the escape of light from a hollow core into the cladding and avoiding the need for TIR. It was initially far from obvious that so many new applications and developments would emerge from the photonic crystal fiber (PCF) concept.<sup>[7–9]</sup> The two basic types—with hollow and solid cores—are illustrated in Fig. 1C and D. In this entry, we review its fabrication and guidance mechanisms, numerical modelling techniques, and the numerous and growing number of applications.

## Nomenclature

The PCF idea came from the field of photonic band gap materials, not from within fiber optics. For this reason, we prefer the name PCF. It is also sometimes referred to as "holey" fiber (P. R.'s first jocular name for it, before anyone knew whether it could be made) or "microstructure" fiber.

## FABRICATION TECHNIQUES

The first working PCF emerged from the drawing tower in late 1995.<sup>[10]</sup> Since then, structures with increasing perfection and uniformity have been produced in many laboratories, using several different

**Fig. 1** (A) Standard SMF: outer diameter, 125  $\mu\text{m}$ ; core diameter,  $\sim 9 \mu\text{m}$ ; core refractive index, a few percent higher than the silica-cladding index (1.46). (B) Annular Bragg fiber. (C) Solid-core PCF. (D) Hollow-core PCF. The black regions are hollow, and the white and grey regions denote pure and doped glass.

techniques (Fig. 2). The first stage is the production of a “preform”—a macroscopic facsimile of the nanoscopic structure in the drawn PCF. There are many ways to do this, including stacking of capillaries and rods,<sup>[11]</sup> extrusion,<sup>[12–14]</sup> sol-gel casting, injection molding, and drilling.<sup>[15]</sup>

The most widely used technique is capillary stacking (Fig. 3), a method that is especially suited to silica glass because of the ready availability of high-quality starting tubes of appropriate dimensions. Typically, meter-length capillaries with an outer diameter of around 1 mm are drawn from a starting tube of high-purity synthetic silica with a diameter of perhaps 20 mm and a length of 1 m. The inner diameter of the capillaries is largely set by the inner/outer diameter ratio of the starting tube, which might lie in the range from 0.3 up to beyond 0.9. The uniformity in diameter of the capillaries (and their circularity) should be controlled to at least 1% of the diameter, and preferably far better. When a suitable quantity of uniform capillaries is available, they are stacked horizontally by hand in a suitable jig to form a close-packed arrangement. The final stack is loosely bound with wire, before being inserted into a snug jacketing tube. It is then mounted in the preform feed assembly for drawing down to fiber.

**Fig. 2** (A) The first working PCF—the solid glass core is surrounded by a triangular array of 300-nm-diameter air channels, spaced 2.3  $\mu\text{m}$  apart. From Ref.<sup>[11]</sup>. (B) Detail of a recent low-loss solid-core PCF (interhole spacing,  $\sim 2 \mu\text{m}$ ). From Refs.<sup>[26]</sup> and<sup>[35]</sup>. (C) The first hollow-core PCF. From Ref.<sup>[19]</sup>. (D) A small-core PCF extruded from Schott SF6 glass. Source: From Ref.<sup>[13]</sup>.

Extrusion is an attractive alternative route to making PCF from bulk glass. It enables the formation of structures that are not readily achievable by stacking, and requires a minimal amount of processing. Perhaps its most important application is to non-silica glass PCFs and other materials. Fig. 2D shows the cross section of a fiber extruded, through a metal die, from a commercially available glass (Schott SF6).<sup>[13]</sup>

## CHARACTERISTICS OF PHOTONIC CRYSTAL CLADDING

The simplest photonic crystal cladding is a biaxially periodic, defect-free, composite material with its own well-defined dispersion and band structure. A good knowledge of its properties is essential for understanding the behavior of the guided modes that form at cores (or “structural defects” in the parlance of photonic crystals). A useful graphical tool is the propagation diagram—a map of the ranges of frequency and axial wavevector component where light is evanescent in all transverse directions regardless of its polarization state (Fig. 4).<sup>[16]</sup> The vertical axis is the normalized frequency  $k\Lambda = \omega\Lambda/c$  ( $\omega$  is the angular frequency,  $\Lambda$  is the inter-hole spacing, and  $c$  is the velocity of light in vacuum), and the horizontal axis is the normalized axial wavevector  $\beta\Lambda$ . Light is free to propagate in the white areas and is evanescent (due either to TIR or photonic band gaps) in the black regions. In any subregion of isotropic material (glass or air) at fixed optical frequency, the maximum possible value of  $\beta\Lambda$  is given by  $k\Lambda n$ , where  $n$  is the refractive index (at that frequency) of the region under consideration. For  $\beta < kn$ , light is free to propagate; for  $\beta > kn$ , it is evanescent; and at  $\beta = kn$ , the critical angle is reached—denoting the onset of TIR for light incident from a medium of index larger than  $n$ . Moving from left to right, the slanted guidelines (included in Fig. 4) denote the transitions from propagation to evanescence for glass, air, and the photonic crystal. The maximum value of  $\beta\Lambda$  in the photonic crystal cladding lies in the range  $k < \beta\Lambda < kn_s$  (where  $n_s$  is the index of silica) as expected of a glass/air composite

**Fig. 4** Propagation diagram for a PCF with 45% air-filling fraction. Note the different regions where light is (4) cut off completely, (3) able to propagate only in silica glass, (2) able to propagate also in the photonic crystal cladding, and (1) able to propagate in all regions. The “fingers” indicate the positions of full two-dimensional photonic band gaps. From Ref.<sup>[16]</sup>.

material. Its maximum axial refractive index depends strongly on frequency, even though neither the air nor the glass is assumed to be dispersive in the analysis. Microstructuring itself creates dispersion, through a balance between transverse energy storage and energy flow that is highly dependent on frequency. As the wavelength of the light falls, the optical fields are better able to distinguish between the glass regions and the air. The light piles up more and more in the glass or the air, causing the effective refractive index “seen” by it to change. In the limit of small wavelength  $\Lambda/\lambda \rightarrow \infty$ , the light is strongly excluded from the air holes by TIR, and the field profile freezes into a shape independent of wavelength. Treating each strand as a metallic waveguide of radius  $a = \Lambda/\sqrt{3} - d/2$  and making the approximation that the field amplitude is  $J_0(r_{z_{01}}/a)$  (where  $z_{01}$  is the first zero of the Bessel function  $J_0$ ), it may be shown that the maximum axial refractive index in the cladding is:

$$n_{\text{FSM}} \approx \sqrt{n_s^2 - \frac{z_{01}^2 \lambda^2}{4\pi^2 a^2}} \quad (1)$$

in the short wavelength limit. For a more rigorous account of this phenomenon, see Ref.<sup>[17]</sup>.

The finger-shaped regions on the diagram denote full two-dimensional photonic band gaps. Some of these extend into the region  $\beta < k$ , where light is free to propagate in vacuum, confirming the feasibility of trapping light within an empty microtube.

## CLASSES OF GUIDANCE

In SMF, guided modes form in the range of axial refractive indices  $n_{\text{cl}} < n_z < n_{\text{core}}$ , when light is evanescent in the cladding ( $n_z = \beta/k$ ). In PCF, four distinct guidance mechanisms exist: a modified form of TIR,<sup>[17,18]</sup> photonic band gap guidance,<sup>[19]</sup> a frustrated tunneling process (leading to the formation of surface states around the edge of the core),<sup>[20]</sup> and a low-leakage mechanism based on creating a low density of states in the cladding.<sup>[21]</sup>

### Modified Total Internal Reflection

This type of guidance was observed in late 1995, in the first working PCF, at a central solid core in an array of  $\sim 300$ -nm-diameter air holes, spaced  $2.3 \mu\text{m}$  apart (Fig. 2A). The striking feature of this fiber was that it was “endlessly single-mode” (i.e., the core did not ever seem to become multimode in the experiments, no matter how short the wavelength of the light).<sup>[17]</sup> Although the guidance in some respects closely resembled conventional TIR, it turned out to

have some interesting and unique features that distinguish it markedly from the standard case. These are because of the piecewise discontinuous nature of the core boundary—sections where air holes strongly block the escape of light interspersed with regions of barrier-free glass. In fact, the cladding operates in the Mie scattering regime where transverse effective wavelength (in silica) is comparable with geometrical substructures in the cladding. The zone of operation in Fig. 4 is  $n_{\text{FSM}} < n_z < n_{\text{silica}}$ .

### Photonic Band Gap: Hollow Core

Larger air-filling fractions and small interhole spacings are necessary to achieve photonic band gaps in the region  $n_z < 1$ . The relevant operating region in Fig. 4 is to the left of the vacuum line inside one of the band gap fingers. These conditions ensure that light is free to propagate—and form guided modes—within the hollow core while unable to escape into the cladding. The number  $N$  of such modes is controlled by the depth and width of the refractive index “potential well” and is given by:

$$N \approx 2\pi^2 \rho^2 (n_{\text{high}}^2 - n_{\text{low}}^2) / \lambda^2 \quad (2)$$

where  $n_{\text{high}}$  and  $n_{\text{low}}$  are the refractive indices at the edges of the photonic band gap,  $\rho$  is the core radius, and  $\lambda$  is the wavelength of light. Because the band gaps are quite narrow ( $n_{\text{high}}^2 - n_{\text{low}}^2$  is typically a few percent), the hollow core must be large if a guided mode is to exist at all. In the first working hollow-core PCF reported in 1999,<sup>[19]</sup> the core was formed by omitting

**Fig. 5** Scanning electron micrograph of a hollow-core PCF designed to guide 1064 nm light. (Transmission spectrum is plotted in Fig. 8.) Note the slightly elliptical core.

seven capillaries from the preform stack (Fig. 2C). An electron micrograph of a more recent hollow-core PCF is shown in Fig. 5.<sup>[22]</sup>

### Photonic Band Gap: Surface States

To observe unambiguous photonic band gap guidance, it is necessary to ensure that the core refractive index is lower than the cladding index. The first such PCF, demonstrated in 1998, consisted of a lattice of air holes arranged in the same way as the carbon rings in graphite. A core was formed by introducing an extra hole at the center of one of the rings, its low index precluding the possibility of TIR guidance.<sup>[20]</sup> When white light was launched into the core region, a brightly colored mode was transmitted—the colors being dependent on the absolute size to which the fiber was drawn. The modal patterns had six equally strong lobes, disposed in a flowerlike pattern around the central hole. Closer examination revealed that the light was guided not in the air holes but in the six narrow regions of glass surrounding the core. The light chose to remain in these regions, despite the close proximity of large areas of silica, full of modes. One interpretation of this behavior is that, for particular wavelengths, the phase velocity of the light in the core is not coincident with any of the phase velocities available in the transmission band created by the array of larger adjacent regions. Thus light is unable to tunnel over to them and so remains trapped in the core. This “frustrated tunneling” mechanism of photonic band gap formation can only operate in extended two-dimensional structures (similar types of behavior are seen in modes trapped within defect layers in multilayer stacks<sup>[23]</sup>). The guided modes, which can also form in hollow-core PCF, can be viewed as surface-trapped states, light being confined by TIR on the core side of a boundary and by a photonic band gap on the cladding side. The zone of operation in Fig. 4 is  $1 < n_z < n_{\text{FSM}}$ .

### Low Density-of-States Guidance

It was shown that the transmission bands can be greatly widened by fabricating a different cladding structure—a Kagomé lattice.<sup>[21]</sup> Fig. 6A shows the white-light mode emerging from such a fiber, the minimum loss being  $\sim 1$  dB/m. It turns out in this case that the density of states is greatly reduced in the cladding near the vacuum line. The consequential poor match between the core states and the greatly reduced number of cladding states slows down, but does not completely prevent, the leakage of light. The precise details of the mechanism of this case are still under study.

**Fig. 6** (A) PCF designed for guidance of white light. *Source:* From Ref.<sup>[21]</sup> (B) The “Kagomé” lattice in the cladding provides a low density of states (i.e., an incomplete band gap).

## CHARACTERISTICS OF GUIDANCE

### Controlling Number of Modes

In a solid-core PCF guiding by modified TIR, the number of modes guided at short wavelengths is approximately given by:

$$N \approx \frac{V^2}{2} = \frac{2\pi^2 \rho^2}{\lambda^2} (n_{\text{co}}^2 - n_{\text{cl}}^2) = \frac{z_{01}^2 \rho^2}{2a^2} \quad (3)$$

where Eq. (1) has been used to represent the cladding refractive index. This indicates that in the short wavelength limit, the number is determined solely by geometry. This behavior can be understood by viewing the array of holes as a modal filter or “sieve” (Fig. 7). The fundamental mode has a transverse effective wavelength (in the core)  $\lambda_{\text{eff}} \approx 4\Lambda$ . Thus it is unable to “squeeze between” the gaps between the holes (in the cladding), which are spaced  $\Lambda - d$  apart and are thus below the Rayleigh resolution limit  $\lambda_{\text{eff}}/2 = 2\Lambda$ . Provided the relative hole size  $d/\Lambda$  is small enough, higher-order modes are able to escape—their transverse effective wavelength is shorter so they have higher resolving power. As the holes are made larger, successive higher-order modes become trapped. Numerical modelling shows that if  $d/\Lambda < 0.43$ , the fiber is “endlessly single-mode” (i.e., it never supports any higher-order guided modes). The strong

**Fig. 7** Modal filtering in a solid-core PCF. (A) The fundamental mode is trapped whereas (B) higher-order modes leak away through the gaps between the air holes.

wavelength dispersion in the photonic crystal cladding causes the core-cladding index step to fall as the wavelength gets shorter.<sup>[17,18]</sup> This counteracts the usual trend toward increasingly multimode behavior at short wavelengths. In the limit of very short wavelength, the transverse single-mode profile freezes into a constant shape that does not depend on wavelength. In this regime, the light strikes the glass–air interfaces at glancing incidence, and is strongly rejected from the air holes. As a consequence, the angular divergence (numerical aperture or NA) of the emerging light is proportional to wavelength—in SMFs, it is approximately constant owing to the appearance of more and more higher-order guided modes as the frequency increases.

### Ultralarge Mode Areas

Because this sieving process is controlled only by the size and positions of the holes and the core, it does not depend strongly on wavelength. A corollary is that the behavior is quite independent of the absolute size of the structure, making possible arbitrarily large SMF cores. A PCF with a core diameter of 22  $\mu\text{m}$  at 458 nm was reported in 1998.<sup>[24]</sup> In conventional step index fibers, where  $V < 2.405$  for single-mode operation, this would require uniformity of core refractive index to  $\sim 1$  part in  $10^5$ —this is very difficult if MCVD is used to form the doped core. Large-mode areas allow much higher power to be carried before the onset of intensity-related damage. This has obvious benefits for high-power delivery, amplifiers, and lasers.

### Restricting the Guided Wavelengths

In solid-core PCF, the refractive index of the photonic crystal cladding increases with optical frequency, tending toward the index of silica glass in the short wavelength limit. Thus if the core is made from a glass with a refractive index lower than that of silica (e.g., fluorine-doped silica), guidance is lost at wavelengths shorter than a certain threshold value.<sup>[25]</sup> Such fibers have the unique ability to prevent transmission of short wavelength light—a remarkable result when one considers that conventional fibers get better and better at guiding light as the wavelength drops.

In hollow-core PCF, guidance can only occur when a photonic band gap coincides with a core resonance. This means that only restricted bands of wavelength are guided—colored light is typically transmitted when white light is launched into the core. The attenuation spectrum of a recent hollow-core PCF, designed for low-loss transmission at 1064 nm wavelength, is given in Fig. 8.<sup>[26]</sup>

**Fig. 8** Attenuation spectrum of a hollow-core PCF designed for low-loss transmission of 1064 nm light.

## Birefringence

The modes of a perfect sixfold symmetric core are not birefringent.<sup>[27]</sup> However, in practice, even slight distortions in the structure yield a degree of birefringence, and if the core is deliberately distorted so as to become twofold symmetric (e.g., by introducing capillaries with different wall thicknesses above and below the core; Fig. 9A), extremely high values of birefringence can be achieved—some 10 times larger than in conventional fibers.<sup>[28]</sup> Experiments show that the birefringence is highly insensitive to temperature, which is important in many applications. Traditional “polarization-maintaining” fibers (bow tie, elliptical core, or Panda) contain at least two different glasses, each with a different thermal expansion coefficient. The resulting temperature-dependent stresses make birefringence a strong function of temperature.

## Dispersion

Group velocity dispersion (GVD), which causes different frequencies of light to travel at different speeds, is a crucial factor in the design of telecommunications systems. The magnitude of the GVD changes with wavelength, passing through zero at  $\sim 1.3\mu\text{m}$  in

**Fig. 9** (A) Scanning electron micrograph of birefringent PCF. (B) “Cobweb” PCF with very small core and zero GVD wavelength of 560 nm. The core is only 800 nm in diameter.

conventional fiber. In PCF, the dispersion can be controlled with great freedom. For example, as the holes get larger, the core becomes more and more isolated, until it resembles an isolated strand of silica glass suspended by six thin webs of glass. If the whole structure is made very small (core diameters less than  $1\mu\text{m}$  have been made), the zero dispersion point can be shifted to wavelengths in the visible.<sup>[29,30]</sup> The “cobweb” PCF in Fig. 9B has a dispersion zero at 560 nm. By careful design, the wavelength dependence of the GVD can also be reduced. Fig. 10 shows the GVD curves of three fibers with ultraflattened low-level GVD.<sup>[31]</sup> In non-silica glasses, such as Schott SF6, the intrinsic zero dispersion wavelength is at a difference point, providing a further degree of freedom in GVD design.<sup>[13]</sup>

## Multicore

The stacking procedure makes it straightforward to produce multicore fibers. The preform stack is built up with the desired number of solid (or hollow) cores, and is drawn down to fiber in the usual manner.<sup>[33]</sup> The characteristics of coupling between the cores are unusual—the coupling strength depends on the sites chosen because the evanescent decay rate of the fields changes with azimuthal direction. Applications include curvature sensing.<sup>[34]</sup> More elaborate structures can be built up, such as fibers with inner and outer claddings designed as high-power fiber lasers.

## Attenuation Mechanisms

The optimum spacing ( $\sim 80\text{ km}$ ) between repeaters in telecommunications systems is set by the fiber attenuation, which in the best conventional fibers is limited by Rayleigh scattering to  $\sim 0.2\text{ dB/km}$  at 1550 nm wavelength. A key question is whether hollow-core or solid-core PCF can match—or perhaps improve on—this and perhaps replace rival conventional fibers in telecommunications. The answer is not yet clear, although it is easy enough to pose the questions. Are the glass–air interfaces smooth enough to avoid significant scattering out of the core or into other modes? Is Rayleigh scattering amplified by the large refractive

**Fig. 10** GVD profiles, against wavelength, for three different PCFs designed to have low-level ultraflattened GVD. Source: From Refs.<sup>[31]</sup> and<sup>[32]</sup>.

index step at the interfaces? Will the holes fill with water vapor and will huge water-related losses develop at 1.39  $\mu\text{m}$  wavelength, where an overtone of the OH bond absorption occurs?

### Absorption and scattering

The reported losses, from teams in Europe, Japan, and the United States, are steadily dropping, and the record now stands at 0.37 dB/km in a solid-core PCF.<sup>[35,36]</sup> Hollow-core PCF has the greatest potential for extremely low loss because the light is travelling predominantly in the hollow core. Although the best reported attenuation in hollow-core PCF is fairly high (13 dB/km),<sup>[37]</sup> values well below 0.2 dB/km seem at least feasible with further development of the technology. The prospect of improving on conventional fiber, at the same time greatly reducing the non-linearities associated with a solid glass core, is tantalizing.

### Bend loss

Conventional fibers suffer additional loss if bent beyond a certain critical radius  $R_{\text{crit}}$ , which depends on wavelength, core-cladding refractive index step, and, most notably, the third power of core radius  $a^3$ .<sup>[38]</sup> For wavelengths longer than a certain value (the “long wavelength bend edge”), all guidance is effectively lost. PCF does not escape this effect (large-mode area PCF in particular is highly sensitive to bend loss) and, in fact, in its endlessly single-mode form, PCF exhibits an unexpected *short* wavelength bend edge, caused by bend-induced coupling from fundamental to higher-order modes, which of course leak out of the core.<sup>[17]</sup> Experimentally, hollow-core PCF is remarkably insensitive to bend loss—in many cases, no appreciable drop in transmission is observed until the fiber breaks.

### Confinement loss

A fabricated PCF necessarily incorporates a finite number of holes in the cladding region. For a guided mode, the Bloch waves in the photonic crystal cladding are evanescent, just like the evanescent plane waves in the cladding of a conventional fiber. If the cladding is not thick enough, the evanescent fields at the cladding/coating boundary can be substantial, causing attenuation. In the solid-core case for small values of  $d/\Lambda$ , the resulting loss can be quite substantial unless a large number of periods is used.<sup>[31]</sup> Very similar losses are observed in the hollow-core fibers, where the “strength” of the photonic band gap (closely related to its width in  $\beta$ ) determines how many periods are needed to reduce confinement loss to acceptable levels. Numerical modelling is very useful for giving

an indication of how many periods are needed to reach a required loss level.

## NUMERICAL MODELING TECHNIQUES

The complex structure of PCF—in particular the large refractive index difference between glass and air and the resonant nature of the holes and inter-hole spaces—makes its electromagnetic analysis very challenging. Standard optical fiber analyses do not much help. Although—as we have seen in previous sections—a number of approximate models do exist, these are only useful as rough guidelines to the exact behavior. Maxwell’s equations must be solved numerically, using one of a number of specially developed techniques.<sup>[16,39–42]</sup>

The most popular technique uses a plane wave basis for the fields. This converts the wave equations into standard matrix eigenvalue problems suitable for numerical computation. The wave equation satisfied by the  $\mathbf{H}$  field is particularly amenable because, set up for  $(\omega^2/c^2)$  as an eigenvalue, it is Hermitian in form. For waveguiding structures, such as PCFs that incorporate a defect core into an otherwise periodic medium, a supercell is constructed. The supercell is made large enough so that, once tiled, the guided modes in different cores do not significantly interact. The plane wave expansion method suffers from its inability to accurately represent step changes in the dielectric function. The associated ringing or Gibb’s phenomenon introduces an inaccuracy in the solutions unless a very large number of plane wave components is retained. This problem can be alleviated by reexpressing the wave equation satisfied by the  $\mathbf{H}$  field in a variational form and by using a conjugate gradient minimization scheme.<sup>[43]</sup>

In most practical cases in photonics, a set of constant frequency modes is far more useful. Therefore it is convenient to set up Maxwell’s equation with  $\beta^2$  as an eigenvalue:

$$\left( \nabla_{\parallel}^2 + \frac{\omega^2}{c^2} \varepsilon(\mathbf{r}_{\parallel}) \right) \mathbf{H}_{\parallel} + [\nabla_{\parallel} \ln \varepsilon(\mathbf{r}_{\parallel})] \wedge (\nabla_{\parallel} \wedge \mathbf{H}_{\parallel}) = \beta^2 \mathbf{H}_{\parallel} \quad (4)$$

where the gradient operator within the square brackets only operates on the  $\ln \varepsilon(\mathbf{r}_{\parallel})$  term. This form also allows material dispersion to be naturally included. Fourier expansion of Eq. (4) can then be used to convert them to matrix eigenvalue forms.<sup>[40]</sup> Unfortunately, because of the non-Hermitian nature of Eq. (4), a variational approach cannot be invoked so straightforwardly, implying that the number of retained basis waves that can be considered in a plane wave expansion is more limited.

Other numerical techniques include expansion of the field in terms of Hermite–Gaussian functions,<sup>[29]</sup> the finite-difference time domain (FDTD) approach (a simple and versatile tool with which to explore waveguide geometries<sup>[44]</sup>), and the finite-element approach.<sup>[45]</sup> If the PCF structure comprises purely circular holes, the multipole or Rayleigh method is a particularly fast and efficient approach to use.<sup>[42]</sup> The method works by calculating the scattering of a field incident on each hole by the use of Mie scattering theory.

The most appropriate and efficient method to use for a given PCF structure depends on its geometry and which properties are required. The plane wave method is attractive for calculating mode properties because of the large number of basis waves that can be used. In common with most basis expansion methods, this method fails to accurately describe the discontinuities in the dielectric distribution and in the field at the dielectric interfaces; this necessitates the use of a large basis size. The multipole method overcomes this limitation by expanding the fields in various dielectric regions in local basis sets appropriate to the local symmetry and performs the boundary matching directly. For fibers comprising circular holes, the multipole method generally gives the quickest and most accurate results. Because no spatial mesh is required, the method naturally maintains the symmetry of the structure and the constructed eigenmodes show the correct symmetries also.

The confinement loss suffered by the guided modes is not directly accessible with the plane wave approach because of the Bloch boundary conditions that are applied. The leakage can be obtained from methods in which radiative boundary conditions outside the holey region can accurately be employed. This is automatic for the multipole method and can be achieved using boundary-element and finite-element approaches, although in the latter case, its accurate implementation (using, for example, perfectly matched layers) is not straightforward. The finite difference time domain approach can be invoked to calculate leakage loss if this is substantial, but losses at the level of a few decibels per kilometer or less, which are appropriate for most PCF fiber systems, are not resolved. This problem can be alleviated by reexpressing the wave equation satisfied by the  $\mathbf{H}$  field in a variational form and by using the conjugate gradient minimization scheme;<sup>[43]</sup> this allows many tens of thousands of plane waves to be retained in the expansions.

## INTRAFIBER DEVICES, CUTTING, AND JOINING

As PCF becomes more widely used, there is increasing demand for cleaving, low-loss splicing, multipoint

couplers, intrafiber devices, and mode area transformers. The air holes provide an opportunity not available in standard fibers—they collapse under surface tension when heated to the softening temperature of the glass. Thus not only can the fiber be stretched locally to reduce its cross-sectional area, but the microstructure can itself be altered.

PCF cleaves very cleanly using standard tools, showing slight end-face distortion only when the core crystal is extremely small (interhole spacing  $\sim 1\ \mu\text{m}$ ), and the air-filling fraction is very high ( $>50\%$ ). Solid-core PCF can be spliced successfully both to itself and to standard fiber using a fusion-splicing process. The two fiber ends are placed in intimate contact and heated to softening point. With careful control, they fuse together without distortion. Provided that the mode areas are well matched, splice losses of  $< 0.2\ \text{dB}$  can normally be achieved except when the core is extremely small (less than  $\sim 1.5\ \mu\text{m}$ ). Fusion splicing hollow-core fiber is feasible when there is a thick solid glass outer sheath (e.g., as depicted in the inset in Fig. 8), although very low splice losses can be obtained simply by placing the fibers end-to-end and clamping them—after all, the index matching fluid for hollow-core PCF is vacuum.

In many applications, it is important to be able to change the mode area without losing light. This is done traditionally using miniature bulk optics—tiny lenses precisely designed to match to a desired NA and spot size. In PCF, an equivalent effect can be obtained by scanning a heat source (flame or carbon dioxide laser) along the fiber. This causes the holes to collapse, with the degree of collapse depending on the dwell time of the heat. Drawing the two fiber ends apart at the same time provides additional control. Low loss graded transitions can fairly easily be made—mode diameter reductions as high as 5:1 have been realized with low loss. A further degree of freedom may be gained by pressurizing the holes during the taper process.<sup>[46]</sup>

The ability to cause large changes in the optical characteristics of PCF by heating is leading to a whole family of new intrafiber components. Microcouplers can be made in dual-core PCF—two optically isolated cores can be made to interact by collapsing the holes so as to allow the mode fields to expand and “talk” to each other.<sup>[47]</sup> Long period gratings, which couple the core light into the cladding within certain wavelength bands, can be made by periodic modulation of hole size.<sup>[48]</sup> Rocking a birefringent PCF to-and-fro, while scanning a carbon dioxide laser along it, results in so-called “rocking filters,” which transfer power from one polarization state to the other within a narrow band of wavelengths.<sup>[49]</sup> All these components have one great advantage over equivalent devices made in conventional fiber—being permanent changes in morphology, they are highly stable with temperature and over time.

## APPLICATIONS

The diversity of new or improved features, beyond what conventional fiber offers, means that PCFs are finding an increasing number of applications in every widening area of science and technology.

### Gas-Based Non-linear Optics

A long-standing challenge in photonics is how to maximize non-linear interactions between laser light and low-density media such as gases. Efficient non-linear processes require high intensities at low power, long interaction lengths, and good-quality transverse beam profiles. A structure conceptually capable of delivering all these requirements simultaneously is a perfectly guiding hollow-core waveguide supporting a single transverse mode with low attenuation losses. Although, theoretically, this could be realized using a perfect metal, the attenuation in real metals at optical frequencies is much too high. A number of conventional approaches have been used to alleviate this problem, including focusing a laser beam into the gas with suitable optics, using a  $\sim 200\text{-}\mu\text{m}$  bore fiber capillary to confine the gas and provide some degree of guidance for the light,<sup>[50]</sup> and employing a gas-filled high-finesse Fabry–Pérot cavity to increase the interaction length.<sup>[51]</sup> As explained in Ref.<sup>[21]</sup>, none of these approaches comes close to the performance offered by hollow-core PCF. At a bore diameter of  $10\text{ }\mu\text{m}$ , for example, a focused free space laser beam is marginally preferable to a capillary, whereas a hollow-core PCF with  $13\text{ dB/km}$  attenuation is an astonishing  $100,000\times$  more effective. Such huge enhancements are rare in physics, and point the way to dramatic improvements in all sorts of nonlinear laser–gas interactions. The first results are beginning to emerge: Recently stimulated Raman scattering was observed in a hydrogen-filled hollow-core PCF at threshold pulse energies  $\sim 100\times$  lower than previously reported.<sup>[21]</sup> Many other areas of nonlinear optics are likely to be revolutionized, such as x-ray generation in noble gases pumped by femtosecond Ti–sapphire laser pulses.<sup>[52]</sup> The conversion efficiency of this process was further enhanced recently by modulating the bore diameter so as to phase match the light and the x-rays.<sup>[53]</sup> This can be implemented in PCF by heat treatment with carbon dioxide laser light.<sup>[48]</sup>

### High-Power Transmission

Hollow-core fiber is also excellent for transmitting high continuous-wave power as well as ultrashort pulses with very high peak powers. A recent entry reports femtosecond solitons at  $1550\text{ nm}$  with peak powers of

$2\text{ MW}$  in hollow-core PCF.<sup>[54]</sup> For soliton formation, the sign and magnitude of the GVD are crucial. It has recently been reported that the GVD changes sign across the band gap, permitting choice of normal or anomalous dispersion depending on the application.<sup>[22]</sup>

### Rare Earth-Doped Lasers and Amplifiers

Rare earth-doped PCF lasers can be straightforwardly produced by incorporating doped canes in the preform stack. Many different structures can be fashioned, such as large-mode area cores and multicore lasers.

#### Ultrahigh power lasers

High-power rare earth-doped lasers and amplifiers can be fashioned in large-mode area PCF by incorporating a second, much larger, multimode core around the single-mode lasing core. Using microstructuring techniques, this “inner cladding waveguide” can be suspended by connecting it to an outer glass tube with very thin webs of glass (Fig. 11).<sup>[56]</sup> Very high inner cladding NA can be obtained ( $>0.9$ ), making it easy to launch and guide light from high-power diode bar pump lasers, which typically have very poor beam quality. The pump light is absorbed by the lasing core, and high-power single-mode operation can be achieved, as in recent reports for Yb-doped fiber lasers.<sup>[55,57]</sup>

#### Mode-locked fiber lasers

Mode-locked fiber lasers rely on control of the dispersion within the laser cavity to achieve ultrashort pulse

**Fig. 11** Scanning electron micrograph of a cladding-pumped PCF laser designed for high-power operation. *Source:* From Ref.<sup>[55]</sup>. The lasing core is a missing air hole close to the left-hand corner of the photonic crystal.

(subpicosecond) operation. PCF offers fine-tuning of the GVD over a wide wavelength range, making it ideal for developing a new generation of mode-locked laser systems. Laser cavities can be envisaged in which there is high local GVD but very low average dispersion over a broad wavelength range. This would allow operation in the stretched-pulse regime, or could be used simply to cancel the dispersion of other cavity components. Mode-locked fiber lasers previously were forced to operate at wavelengths beyond the 1.3- $\mu\text{m}$  zero GVD point, where the dispersion in SMF is anomalous. However, using PCF, it becomes possible to design all-fiber mode-locked systems at shorter wavelengths by shifting the zero GVD wavelength down into the visible.

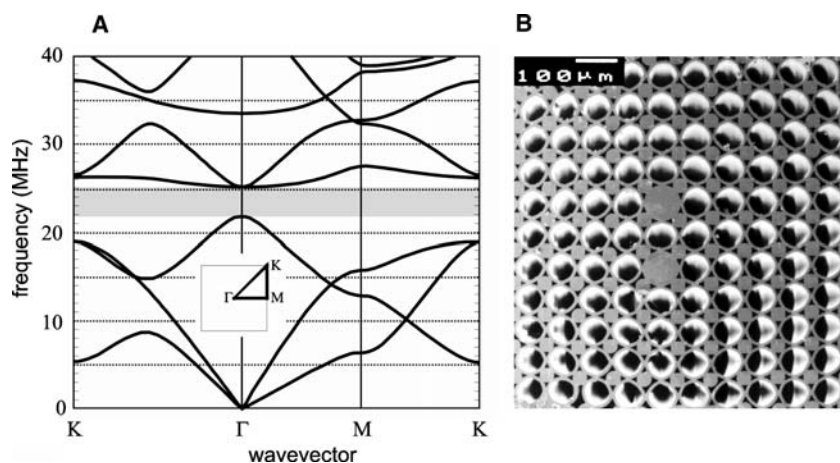

### Atom and Particle Guidance

A focused light beam produces both a longitudinal (accelerating) and a transverse (trapping) force on dielectric microparticles.<sup>[58]</sup> For maximum trapping force, the intensity gradient of the light must be as high as possible. This can be achieved by focusing a high-power laser beam with a high NA lens. The Rayleigh length for such a tightly focused beam is rather short; furthermore, the high intensity will quickly accelerate the particle out of the trapping zone. Stable trapping of a particle in free space requires the longitudinal force to be balanced either by gravity or by a second (or reflected) beam. It has long been recognized that an alternative configuration offering stability would be a non-diffracting or guided beam. To guide a dielectric particle, the beam would have to be trapped in air rather than in glass, which, until very recently, was not possible. That did not stop the demonstration of guidance of both solid particles<sup>[59]</sup> and atoms<sup>[60]</sup> along a length of hollow capillary during the past decade. Of course, use of a capillary prevented the full exploitation of the possibilities of a hollow waveguide—for

the small core sizes needed for strong transverse confinement, capillary losses are very high, even on length scales of a few millimeters. The same is not true in hollow-core PCF, where core diameters of  $\sim 10\ \mu\text{m}$  can be realized with losses as low as 50 dB/km. Such a small spot size gives a strong transverse trapping force for a given longitudinal force, so that it becomes possible to envisage guiding particles even around tightly bent fibers at reasonably high speeds. The first steps toward achieving this goal were recently taken.<sup>[61]</sup>

### Sound–Light Interactions

A perennial problem in photonics is how to force sound and light to “talk” (i.e., interact more strongly). Although in theory a single photon can be deflected by annihilation or creation of a single phonon, a fair population of phonons must be used to swamp out the effects of thermal vibrations. Even so, commercial acousto-optic Bragg cells are fantastically inefficient. Driven at 500 mW power and deflecting a laser beam of 1000 nm wavelength and a power of 1 mW, a bulk 40-MHz Bragg cell uses roughly 4 billion phonons to deflect one photon. This huge overkill is largely because of the very poor overlap between sound and light. One way of improving this is to microstructure the material so as to create a frequency band where it falls silent—an acoustic or photonic band gap.<sup>[62,63]</sup> A suitable defect volume, placed within this material, will resonate at frequencies within the band gap, with the acoustic waves being unable to escape into the surrounding silence. Very high acoustic energy densities can then be reached at small drive powers, suggesting the possibility of a new class of superefficient acousto-optic component in which both sound and light are trapped at the same time in the same place. Such components would enjoy radically enhanced performance (in terms of drive power and precision). The first steps in this direction were taken recently with

**Fig. 12** (A) Photonic band gaps of a square lattice PCF preform. (B) Full two-dimensional acoustic band gaps occur around 23 MHz, in agreement with the experiments. *Source:* From Ref.<sup>[64]</sup>.

the demonstration of intraphotonic band gap trapped resonances in the core of a square lattice PCF preform<sup>[64]</sup> (Fig. 12).

### Nonlinear Effects

The ability to enhance effective non-linearity and, at the same time, control the magnitude and wavelength dependence of the GVD makes PCF a highly versatile and complete “laboratory-in-a-fiber” for non-linear optics. Many well-known non-linear fiber optical effects (e.g., stimulated Raman scattering, four-wave mixing, self-phase modulation, modulation instability, and solitonic effects) have already been observed in short (few meters) lengths of fiber. The parameter:

$$\gamma = \omega_0 n_2 / c A_{\text{eff}} \quad (5)$$

is often used as a measure of the non-linearity of the fiber.<sup>[65]</sup> In Eq. (5),  $n_2$  is the non-linear refractive index of the fiber material ( $2.5 \times 10^{-20} \text{ m}^2 \text{ W}^{-1}$  in silica glass, and an order of magnitude or more higher for soft glasses) and  $A_{\text{eff}}$  is the effective area of the guided mode. The highest non-linearity available in conventional silica fibers is  $\gamma \sim 20 \text{ W}^{-1} \text{ km}^{-1}$  at 1550 nm wavelength<sup>[66]</sup> and  $\gamma \sim 10 \text{ W}^{-1} \text{ km}^{-1}$  at 850 nm. In comparison,  $\gamma \sim 240 \text{ W}^{-1} \text{ km}^{-1}$  at 850 nm for the PCF in Fig. 13 and non-linearities as high as  $550 \text{ W}^{-1} \text{ km}^{-1}$  at 1550 nm have been measured for PCFs based on soft glasses.<sup>[67]</sup> The fiber non-linearity is important because it sets the non-linear phase shift associated with propagation of light of a given intensity. The non-linearity can be used to calculate the nonlinear length of the fiber  $L_{\text{nl}} = (\gamma P_0)^{-1}$ , where  $P_0$

**Fig. 13** Core region of a silica/air fiber with a 1- $\mu\text{m}$  core diameter. Its unusual non-linear and dispersive properties make it a spectacular vehicle for studying non-linear fiber optics.

is the peak power. For example, for the fiber in Fig. 13, a peak power of 10 kW (easily obtained from an unamplified ultrashort pulse laser system) implies  $L_{\text{nl}} < 0.5 \text{ mm}$ . For typical values of loss (say, 100 dB/km) and dispersion (e.g., 10 psec/nm km), this non-linear length is far shorter than the fiber effective length  $L_{\text{eff}}$  and the dispersive length  $L_{\text{D}}$ .<sup>[65]</sup> Consequently, it is easy to observe extraordinary non-linear effects in such fibers. The actual non-linear processes that dominate in a particular experiment are determined by the GVD as well as the laser characteristics.

Perhaps the most dramatic application of non-linear PCF is to supercontinuum (SC) generation from picosecond and femtosecond laser pulses. When high-power pulses travel through a material their frequency spectrum can be broadened by a range of interconnected non-linear effects.<sup>[68]</sup> Until recently, the preferred pump laser was a regeneratively amplified Ti-sapphire system producing high (millijoules) energy femtosecond pulses at 800 nm wavelength and kilohertz repetition rate. Then in 2000, it was observed that highly non-linear PCF, designed with zero GVD close to 800 nm, massively broadens the spectrum of low-energy (few nanojoules) unamplified Ti-sapphire pulses launched into just a few centimeters of fiber.<sup>[69,70]</sup> Removal of the need for a power amplifier, the hugely increased 100-MHz repetition rate, and the spatial and temporal coherence of the light emerging from the core explain why this source is unique. The SC has applications in optical coherence tomography,<sup>[71]</sup> frequency metrology,<sup>[72]</sup> and all kinds of spectroscopy.

SC has been generated in different PCFs at many pump wavelengths in the range of 648 nm<sup>[73]</sup> to 1550 nm.<sup>[13]</sup> The wide range of GVD characteristics that have been demonstrated<sup>[31]</sup> in PCF in the 1550-nm wavelength band has provided a test bed<sup>[32]</sup> for non-linear fiber optics, in which the sensitivity of non-linear pulse propagation to the details of the dispersion curve can be tested. The development of conventional fiber-based optical parametric oscillators and amplifiers has been constrained by the very limited scope for engineering the GVD profile. In PCF, these constraints are lifted. The small effective mode area also offers high gain, and PCF-based oscillators based on synchronously pumped femtosecond and picosecond pump pulses have been demonstrated with relatively low powers.<sup>[74-76]</sup>

### CONCLUSION

PCFs represent a next-generation, radically improved version of a well-established and highly successful technology. In escaping from the confines of conventional fiber optics, they have created a renaissance of new

possibilities in many diverse areas of research and technology, in the process irrevocably breaking many of the tenets of received fiber optics wisdom. Over the next few years, we expect to see a gradual takeup of PCFs in many fields of application. Emerging fields of application include biotechnology, optical sensing, medical physics (imaging techniques, surgery), microparticle delivery, high-power fiber lasers, fiber-based laser delivery for manufacturing, long-haul telecommunications, and gas-based nonlinear wavelength conversion.

## INTRODUCTION

The advancement of renewable energy technology has become increasingly critical as an environmentally sustainable path to world economic and societal development. Large-scale harvesting of energy from sunlight using photovoltaic devices offers tremendous potential as a renewable energy resource. Although the field of photovoltaics has continually evolved over the last several decades, many researchers are looking beyond current device designs to what have been termed third-generation technologies. These technologies are aimed at producing significant improvements in device efficiency-to-cost ratios. This necessitates significantly improving efficiency or reducing cost or ideally both. To realize these goals, many of these technologies will need to utilize nanostructured materials and composite systems that can be tailored to have optimized electronic and optical properties.

Organic/polymeric molecule-based electronics are a promising route to meeting these needs. Organic semiconductors have emerged as a class of materials that can be specifically designed to have a wide range of chemical, optical, and electronic properties, yet they can be processed via low-cost, solution-based techniques. The field has now matured to a point where most of the fundamental photophysical and electronic phenomena of these materials are reasonably well understood. The current challenge is to fully utilize the unique properties of organic semiconductors and to specifically design and fabricate materials and devices that lead to high efficiencies. One critical aspect of these materials is the molecular morphology. It has become apparent that the particular structural arrangement of molecules in an organic semiconductor device can have a large impact on properties such as charge carrier mobility and exciton diffusion. Short-range ordering of the molecules is primarily controlled by intermolecular interactions, as well as by processing conditions such as choice of solvent. Learning how to control the morphology on longer length scales will be a necessity to produce optimized device structures.

Parallel to the development of organic semiconductors has been progress in low-cost synthetic techniques

for metal oxide semiconductors. A variety of solution-based and electrochemical routes have been developed that result in materials with well-defined, novel nanostructures that can be easily controlled by varying the fabrication conditions. This then opens up the possibility of low-cost fabrication of organic-inorganic composite structures, in which the long-range morphology of the organic molecules is determined by the three-dimensional structure of the metal oxide semiconductor. Ultimately, the development of efficient photovoltaic devices will require precise control over many parameters, including what wavelengths of light are absorbed to create excitons, the pathways available for exciton migration, the pathways and mobilities for charge carrier transport, and the alignment of energetic levels at interfaces. This entry will review existing organic photovoltaic devices and explore initial efforts at more sophisticated, yet low-cost, organic-inorganic composite structures aimed at achieving high power conversion efficiencies.

## TECHNOLOGIES FOR PHOTOVOLTAIC POWER CONVERSION

In 2001, 38.6 quads (1 quad = 1 quadrillion Btu =  $1.055 \times 10^9$  GJ) of energy, largely from fossil fuels, was consumed to produce electricity in the United States. After conversion losses, 12.7 quads of net electrical energy was output by power plants for general consumption.<sup>[1]</sup> To produce this amount of energy in 1 year would require covering a  $100 \times 100$  km square area of the Nevada desert with solar cells with a power conversion efficiency of 15%. Thus in order for photovoltaics to make a significant impact on energy production strategy, they must be produced in very large areas at low cost.

Worldwide production levels for solar cell modules have been growing rapidly over the last several years, with Japan recently taking the lead in total production volume (Table 1). Current production is dominated by single crystal and polycrystalline silicon modules, which represent a little over 82% of the market. These devices, based on silicon wafers, have been termed the “first generation” of photovoltaic technology. These

are single-junction devices, which are limited by thermodynamic considerations to a maximum theoretical power conversion efficiency of 31% under direct AM1.5 sunlight.<sup>[2]</sup> Fig. 1 shows the progress over the last two decades in single crystal silicon laboratory devices, which have achieved efficiencies close to 25%.<sup>[3]</sup> Commercially produced large-area modules have efficiencies ranging from 10% to 15%.

The highest solar cell efficiencies to date have been achieved in multijunction cells based on III–V compound semiconductors (Fig. 1).<sup>[4]</sup> These devices have multiple absorbing layers, each with different band gaps. Such a device scheme allows for higher theoretically attainable efficiencies. For devices with two, three, and

“infinite” absorbing layers, the theoretical efficiency limits are 50%, 56%, and 85%, respectively.<sup>[5,6]</sup> The current record efficiency is 36.9% for a Ga<sub>0.44</sub>In<sub>0.56</sub>P/Ga<sub>0.92</sub>In<sub>0.08</sub>As/Ge triple-junction research cell, measured under concentrated light. These devices are grown epitaxially on single crystal substrates using metal-organic chemical vapor deposition or molecular beam epitaxy. Such highly sophisticated fabrication techniques are generally considered to be too expensive for large-scale commercialization and terrestrial photovoltaic energy production. However, these devices are used commercially in space-based applications, in which high efficiency is a necessity.

Over the last decade, there has been considerable effort in advancing thin-film, “second-generation”

**Fig. 1** Progress of photovoltaic device efficiencies (under AM1.5 simulation solar illumination) for a variety of inorganic technologies. Source: From Ref.<sup>[4]</sup>.

Palladium - Platinum

technologies that do not require the use of silicon wafer substrates and can therefore be manufactured at significantly reduced cost. Steady progress has been made in laboratory efficiencies (Fig. 1) for devices based on CdS/CdTe, Cu(In,Ga)Se<sub>2</sub> (CIGS), and amorphous Si. These devices are fabricated using techniques such as sputtering, physical vapor deposition, and hot-wire chemical vapor deposition. Multijunction cells based on amorphous-Si and amorphous-SiGe alloys have been the most successful second-generation technology to date because of their ability to be fabricated at relatively low cost and be integrated into electronics and building roofing material. They currently constitute most of the remaining 18% of the market not covered by single crystal silicon. Currently, there are about a dozen companies supplying photovoltaic modules based on thin-film technologies, with efficiencies ranging from 7% to 13.4%. It is anticipated that these second-generation technologies will rapidly grow in commercial importance as manufacturing cost and lifetime issues are improved.

Nonetheless, these existing technologies will be hard-pressed to meet the efficiency and cost goals for the long-term outlook. This has led to the concept first coined by Prof. Martin Green of the University of New South Wales of “third-generation” technologies which would be able to show dramatic improvements in either efficiency or cost or both, as shown in Fig. 2. To meet these ambitious goals will require the development of radically new devices that operate on fundamentally different principles than current technologies. A number of novel approaches have been suggested that may be capable, at least theoretically, of more closely approaching the thermodynamic limit of 86.8% for the conversion efficiency of sunlight to electricity.<sup>[7]</sup> These embryonic concepts include hot carrier solar cells, cells with multiple electron-hole pairs per photon, multiband quantum

well and impurity solar cells, and thermophotovoltaic and thermophotonic devices. All of these concepts have been embedded in them major technical challenges with respect to developing new devices, establishing a realistic efficiency potential for the devices, and demonstrating that they are inherently manufacturable.

### Organic-Based Nanostructured Photovoltaics

The other approach to photovoltaic device development is to pursue technologies with moderate efficiency goals (<20%) but with significantly reduced fabrication costs (<\$20/m<sup>2</sup>). These are technologies that are potentially capable of the large-scale production necessary for a paradigm shift in global energy production. These would optimally be fabricated from solution-processible materials using low-temperature, non-vacuum techniques such as inkjet or screen printing. They would be compatible with low-cost, flexible substrates, thus allowing for high-throughput roll-to-roll processing as well as easy integration into existing building structures.

Organic molecular/polymeric semiconductors meet all of the above manufacturing process criteria. They are often soluble in common organic solvents and can be processed in a bench top laboratory setting. They have inherently low material costs and do not typically rely on the use of environmentally hazardous or elementally rare constituents. In addition, they have been proven to possess a wide range of optical, electronic, and mechanical properties that can be finely tuned through structural changes and molecular derivatization. In principle, they provide an enormous parameter space from which specific functionalities can be chosen to engineer novel, high-performance devices. These qualities make organic semiconductors strong candidates for a growing list of device applications. The area of flat-panel displays, in particular, is on the verge of a revolution because of advances in organic light-emitting diodes (OLEDs).<sup>[8,9]</sup> This technology is maturing rapidly, with first generation devices now on the market.

Using organic semiconductors in photovoltaic devices is now the subject of intense research. Organic molecules and  $\pi$ -conjugated polymers can have very high optical absorption coefficients (>10<sup>5</sup> cm<sup>-1</sup>), making them useful as the active layer in the device. Additionally, charge carrier mobilities, while generally several orders of magnitude lower than in conventional semiconductors, are sufficiently high to effectively transport charge out of the device. A multitude of organic solar cell device designs is currently being investigated. All of these use some form of heterojunction between electron-donating and electron-accepting molecules to create free charge carriers

**Fig. 2** Cost-efficiency matrix for first-, second-, and third-generation photovoltaic technologies. *Source:* From Ref.<sup>[7]</sup>.

from the bound electron–hole pairs (excitons) that are characteristic of organic semiconductors. To date, the reported power conversion efficiencies of these devices under simulated solar illumination are all less than 4%.

A great deal of basic research is needed to achieve significantly higher efficiencies in organic basic devices. Some of the key issues are:

- Exciton creation—The process of light absorption to create bound electron–hole pairs.
- Exciton diffusion—Diffusion of excitons to an interface where they can be dissociated.
- Electron transfer—Transfer of electrons to acceptor molecules.
- Charge transport—Transport of electrons and holes to the electrodes.

Many of these phenomena are determined by the morphologies of the molecular structures that occur at multiple length scales within the device. Morphologies on the length scale of a few nanometers, which affect exciton diffusion rates and charge carrier mobilities for instance, are determined by intermolecular forces and the kinetics of the growth/formation process of the material. Morphologies at longer length scales (tens to hundreds of nanometers), which affect the general direction of charge transport, are also determined by these factors, at least for an all-organic material. However, organic–inorganic composite systems allow the possibility of directly controlling the arrangement of the organic molecules at longer length scales. Inorganic materials, particularly semiconducting oxides, can be fabricated using a growing number of techniques to achieve specific three-dimensional structures. These structures can be used as a scaffolding onto which an organic material can be attached to form composite materials in which all the above photovoltaic device phenomena are optimized.

In this entry, we give a brief description of the theory of charge transport in organic materials. We then provide an overview of the existing field of all-organic-based photovoltaic devices and go on to discuss current and hypothetical organic–inorganic composite devices. Finally, we examine a variety of novel semiconducting oxide structures that can be fabricated using low-temperature, solution- and electrochemical-based techniques.

## CHARGE AND EXCITON TRANSPORT IN ORGANIC SEMICONDUCTORS

Organic semiconductors can be broadly categorized as being either small molecules (molecular weight less than a few thousand atomic mass units) or polymers

(molecular weight between a few thousand and  $\sim 1$  million amu). The distinction becomes most important in determining the processing that is required in making films and devices and for the subsequent morphologies that are obtained. However, the fundamental mechanisms that underlie light absorption, exciton diffusion, and charge carrier motion are essentially the same in the two classes of molecules. These properties are governed primarily by molecular orbitals that are built-up from  $\pi$ -electrons that are delocalized across the molecule. Examples of small molecules with extended  $\pi$ -electron delocalization and  $\pi$ -conjugated polymers commonly used in organic photovoltaic devices are depicted in Fig. 3. Highest occupied molecular orbitals (HOMOs) calculated for a sexithienyl oligomer, a fullerene, and a perylene diimide are shown in Fig. 4. Charge transfer and exciton diffusion processes are largely determined by the degree to which the orbitals of adjacent molecules and molecular subunits overlap.

Charge transfer between organic molecules can be viewed within the context of the semiclassical electron transfer theory of Marcus.<sup>[10]</sup> The rate of electron transfer between two molecules is given by

$$k_{\text{ET}} = \frac{4\pi^2}{\hbar} \frac{1}{\sqrt{4\pi k_{\text{B}} T}} t^2 \exp\left(-\frac{\lambda}{4k_{\text{B}} T}\right) \quad (1)$$

where  $\hbar$  is Planck's constant,  $k_{\text{B}}$  is Boltzmann's constant,  $T$  is the temperature,  $t$  is the transfer integral describing the strength of interaction between the two molecules, and  $\lambda$  is the reorganization energy that describes the strength of the electron–phonon interaction.<sup>[11]</sup> Thus for fast charge transfer between molecules, a large interaction strength and small reorganization energy are required. Their relative orientation and the distance between them determine the degree of interaction between two molecules. For highly ordered, single- or polycrystalline molecular films of materials such as pentacenes or perylenes, this interaction strength can be sufficiently large for band transport to be observed.<sup>[11,12]</sup> However, for  $\pi$ -conjugated polymers and amorphous small-molecule materials, the large degree of disorder results in carrier bandwidths on the order of 10 meV,<sup>[13]</sup> which is far smaller than the  $\sim 0.1$  eV required for band transport to occur.<sup>[11]</sup> Instead, carrier transport in these materials occurs via polaron hopping between sites, where each site has a defined energy and geometric (positional + orientational) disorder parameter. In small-molecule materials, a “site” is considered to be an entire molecule. In conjugated polymers, however, the  $\pi$ -electrons, in reality, are not delocalized along the entire length of a polymer chain. Structural defects (kinks and bends) and chemical defects destroy the

Fig. 3 Molecular structures of typical organic semiconductors that have been used in photovoltaic devices.

conjugation periodically; electronically, the polymer is a series of  $\pi$ -conjugated segments (typically 6–8 monomers long) that are bonded by non-conjugated sections. Fig. 5 illustrates carrier hopping between segments of a conjugated polymer.

The charge carrier mobility for a broad range of organic semiconductors, both small molecule and polymer, has been found experimentally to follow Poole–Frenkel behavior, in which the mobility  $\mu$  as a function of the electric field ( $E$ ) and temperature is given by

$$\mu(E, T) \propto \mu_0(T) \exp(\gamma(T)\sqrt{E}) \quad (2)$$

where  $\mu_0$  is the zero-field mobility and  $\gamma(T)$  is the coefficient of the stretched exponential that describes the temperature dependence of the field activation. This behavior has been successfully modeled with the “disorder formalism” originally developed by Bäessler.<sup>[14]</sup> The model assumes hopping between sites with Gaussian distributions of energies and geometric disorder parameters. A more recent version of the model developed by Novikov et al.,<sup>[15]</sup> which takes into account spatial correlations in the site energies, results in

$$\mu = \mu_\infty \exp \left[ - \left( \frac{3\hat{\sigma}_d}{5} \right)^2 + C_0 (\hat{\sigma}_d^{3/2} - \Gamma) \sqrt{\frac{eaE}{\hat{\sigma}_d}} \right] \quad (3)$$

where  $\mu_\infty$  is the mobility in the limit  $T \rightarrow \infty$ ,  $\hat{\sigma}_d$  is the width of the Gaussian distribution of site energies divided by  $k_B T$ ,  $C_0$  is an empirical constant,  $\Gamma$  describes the geometric disorder, and  $a$  is the intersite spacing. Using typical values of  $\sim 0.1$  eV and 2 for  $\hat{\sigma}_d$  and  $\Gamma$ , respectively, it becomes obvious that the mobility in these materials increases as the degree of disorder is decreased. Typical charge carrier mobilities in conjugated polymers that have been reported in the literature are in the range of  $10^{-6}$ – $10^{-3}$   $\text{cm}^2 \text{V}^{-1} \text{sec}^{-1}$ .<sup>[16]</sup>

Exciton motion/diffusion in organic semiconductors is determined by the same intermolecular interaction considerations as carrier transport, and thus exciton diffusion rates can also be described by hopping models involving Gaussian distributions of site energies. This has been demonstrated by thermally

Fig. 4 Highest occupied molecular orbitals (from semiempirical calculations) of representative organic semiconductors with extended  $\pi$ -electron delocalization.

**Fig. 5** Conceptual diagram of the mechanism of charge transport by hopping in a  $\pi$ -conjugated polymer. The rectangular sections represent regions of the polymer that are fully conjugated. Between these conjugated segments are regions of polymer that are bent or twisted, or that have chemical defects that destroy the conjugation.

stimulated photoluminescence experiments on conjugated polymer films, which have been successfully modeled using double-peak Gaussian distributions to account for regions of aggregated polymer.<sup>[17]</sup> Calculations have shown that the electronic coupling between conjugated segments that are sequentially adjacent along the backbone of the polymer (that is, physically bonded but electronically isolated by a break in the conjugation) is approximately 1 order of magnitude less than the coupling between conjugated segments on different polymer chains (or on the same chain, but far away sequentially), which are close together and aligned parallel to each other.<sup>[18]</sup> This has led to the conclusion that interchain exciton hopping is a faster process than intrachain exciton hopping.<sup>[19]</sup> Analogous to the limitations on carrier transport, poor interaction strengths between adjacent segments typically lead to short exciton diffusion lengths (the average distance the exciton moves before decaying to the ground state or becoming dissociated at a defect or interface) of the order of 6–10 nm,<sup>[20]</sup> although much large exciton diffusion lengths have been reported for highly ordered materials.<sup>[21]</sup>

The main conclusion to be drawn from this section is that molecular ordering is a critical ingredient to obtain high carrier mobilities and large exciton diffusion lengths in organic semiconductors. This point is illustrated in the polymer poly(3-hexylthiophene) (P3HT). This material (when synthesized in its regioregular, head-to-tail form) has been shown to possess a large degree of molecular ordering because of efficient interdigitation of the alkyl chains of adjacent polymer chains, leading to strong  $\pi$ -stacking of the thiophene backbones (Fig. 6). As a result, this material has shown the highest hole mobility of a conjugated polymer to

**Fig. 6** Conceptual diagram of interchain ordering in a P3HT aggregate (cyan = carbon, yellow = sulfur, hydrogen atoms are not shown).

date ( $0.1 \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$ ), when measured in a field effect transistor geometry.<sup>[22]</sup> The effect of this molecular ordering on photovoltaic device performance will be discussed in the next section.

## ORGANIC PHOTOVOLTAIC DEVICES: THE PLASTIC SOLAR CELL

Photoexcitations in organic semiconductors are inherently different than in conventional inorganic semiconductors. Whereas light absorption in an inorganic

semiconductor typically leads to the immediate production of a free electron–hole pair, light absorption in an organic semiconductor results in the formation of an exciton (bound electron–hole pairs). In order for a free carrier to be generated, this exciton must be dissociated. This can happen in the presence of very high electric fields, at a defect site in the material, or at the interface between two materials that have a sufficient mismatch of their energetic levels (band offset). In the case of dissociation at the interface between two materials, an exciton created in the material with lower (higher) electron affinity diffuses to the interface, and electron (hole) transfer occurs to the material with higher (lower) electron affinity. The higher electron affinity material is referred to as the acceptor, while the lower electron affinity material is the donor. Thus one can fabricate a photovoltaic device with the structure positive electrode/donor/acceptor/negative electrode. Tang<sup>[23]</sup> using a copper phthalocyanine layer as the donor and a perylene derivative as the acceptor first did this. This device had a power conversion efficiency of about 1% under simulated solar illumination.

There are two possible driving forces in the operation of a photovoltaic device: the electrical potential gradient (the electric field) and the chemical potential gradient.<sup>[24]</sup> In a bilayer donor–acceptor device, a chemical potential gradient is established that preferentially drives electrons away from the interface toward the negative electrode and holes away from the interface toward the positive electrode. An electric field in the device, such as one established by a difference in the work functions of the positive and negative electrodes, can assist in driving charges toward the electrodes, but may not be critical to the operation of the device. The important criteria for high efficiency in such a device are large exciton diffusion lengths in both the donor and acceptor materials, fast electron transfer and slow recombination rates at the interface, and high charge carrier mobilities in both layers. Several molecular donor–acceptor pairs have been investigated for use in bilayer photovoltaic devices, including phthalocyanine–perylene,<sup>[23,25]</sup> phthalocyanine–fullerene,<sup>[26,27]</sup> polymer–polymer,<sup>[28]</sup> polymer–perylene,<sup>[29]</sup> and polymer–fullerene.<sup>[30]</sup> As a result of the short exciton diffusion lengths in these materials, only excitons that are generated within approximately 10 nm of the interface contribute to the photocurrent. This presents a serious limitation on the possible power conversion efficiency of these devices.

To overcome this problem, researchers have developed devices in which the donor and acceptor molecules are blended together in an intimate mixture to produce a “bulk heterojunction” solar cell.<sup>[31]</sup> The donor and acceptor molecules form two “interpenetrating networks” that transport holes and electrons,

respectively. In this device, an exciton generated anywhere in the bulk has only a few nanometers to diffuse before encountering an acceptor interface. After dissociation of the exciton into a free electron and a free hole, the charge carriers are transported through the bulk of the film (along their respective transport networks) to the electrodes. Directionality of the charge transport is provided by a built-in electric field in the device, which originates from a difference in effective work functions of the electrodes, as well as possibly a chemical potential gradient, which originates from “selective” electrodes that preferentially block either holes or electrons.<sup>[32]</sup>

Bulk heterojunction solar cells based on blends of a conjugated polymer with a fullerene (Fig. 7) have been among the most successful to date.<sup>[33]</sup> Photoinduced electron transfer from a conjugated polymer to a fullerene was demonstrated to occur on an ultrafast time-scale (~45 fsec) and to produce a long-lived charge-separated state, with recombination to the ground state following a power law decay ranging from 300 nsec to 1 msec.<sup>[34,35]</sup> Thus excitons generated in the conjugated polymer, which have lifetimes of several hundred picoseconds, are quickly dissociated into free carriers when they encounter a fullerene interface. These free carriers will have sufficient time to be transported to the electrodes before recombining provided that the active layer of the device is not too thick. This produces an inherent tradeoff in the device design. As the active layer is made thicker, more light is absorbed and more excitons/charge carriers are created, but the carriers spend longer time in the device and thus have a higher probability of recombining to the ground state before they can contribute to the photocurrent. This means that high carrier mobility (for both holes and electrons) is required in the elements of the blend to allow the

**Fig. 7** Schematic diagram of a conjugated polymer–fullerene bulk heterojunction photovoltaic device.

active layer to be thick enough to have significant optical density.

As discussed above, morphology is an important factor in determining a material's carrier mobility. Thus a critical area for development of high efficiency devices is to develop approaches that lead to improved morphologies. This has been demonstrated in conjugated polymer–fullerene bulk heterojunction solar cells in which changing the casting solvent for the active layer film can lead to a large increase in device photocurrent and efficiency.<sup>[36]</sup> Devices consisting of a blend of the polymer poly(2-methoxy-5-(3',7'-dimethyloctyloxy)-*p*-phenylene vinylene) (OC<sub>1</sub>C<sub>10</sub>-PPV) with the fullerene [6,6]-phenyl C<sub>61</sub>-butyric acid methyl ester (PCBM) (Fig. 3) showed nearly a factor of 3 enhancement in efficiency when cast from chlorobenzene as opposed to toluene. It was subsequently determined that the hole mobility in OC<sub>1</sub>C<sub>10</sub>-PPV is approximately 1 order of magnitude higher when cast from the chlorobenzene. From light-scattering measurements performed over a range of polymer concentrations, it was shown that the polymer does not truly dissolve in chlorobenzene, but instead forms a suspension.<sup>[37]</sup> A complete explanation for why this leads to higher carrier mobilities in the thin-film material has not been fully elucidated, but it has been postulated that the polymer chains collapse together into an aggregate that promotes  $\pi$ -electron sharing ( $\pi$ -stacking) between chains. Such solvent effects on carrier mobilities have also been demonstrated in the operation of OLEDs.<sup>[19]</sup> Electron mobilities in the bulk heterojunction OC<sub>1</sub>C<sub>10</sub>-PPV-PCBM blend have also been shown to be high ( $2 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ) when the film is cast from chlorobenzene, although, in this case, the explanation apparently is that chlorobenzene is a very good solvent for PCBM and reduces the amount of phase segregation that normally leads to large barriers to electron transport in the fullerene network.<sup>[38]</sup> Additional evidence for the effects of morphology on mobility and device performance has been reported in bulk heterojunction solar cells made from the conjugated polymer P3HT (Fig. 3). It was demonstrated that postproduction annealing of photovoltaic devices made from P3HT-PCBM blends results in a dramatic increase in device efficiency, from 0.4% to 3.5% as measured under white light illumination. This efficiency enhancement presumably arises from an increase in the ordering of the P3HT chains upon annealing.<sup>[39]</sup>

The general viability of the application of donor–acceptor systems as employed in bulk heterojunction organic solar cells has been demonstrated by a number of other recent results, including polymer–polymer<sup>[40]</sup> and polymer–quantum rod devices.<sup>[41]</sup> These all have the same criteria for high efficiency as the polymer–fullerene device, namely, small distances for exciton diffusion to an interface, exciton dissociation that is

fast, charge recombination that is slow, and large charge carrier mobilities. Reported efficiencies of organic solar cells to date have not exceeded 4% for several reasons. First, the amount of light that is absorbed by the devices is typically too small because 1) the optical band gap of the light-absorbing component is usually too large ( $>1.4 \text{ eV}$ ), resulting in poor overlap with the solar spectrum, and 2) the optical density is too small because the active layer of the device must be kept thin to limit charge carrier recombination. Second, the photovoltage that is generated is typically too low. This is limited, to first order, by the effective electronic band gap of the active layer, which is given by the difference between the HOMO level of the donor and the lowest unoccupied orbital (LUMO) level of the acceptor. Last, the fill factor, which is a measure of the quality of the diode, is too small. A necessary solution for many of these problems will be the development of new polymers and organic molecules. Concurrently, devising new ways to control the morphologies of the light-absorbing and -transporting materials to optimize the pathways for exciton/charge transport will be required. The organic–inorganic composite devices discussed in the next section provide a promising route to controlling morphologies on the nanoscale.

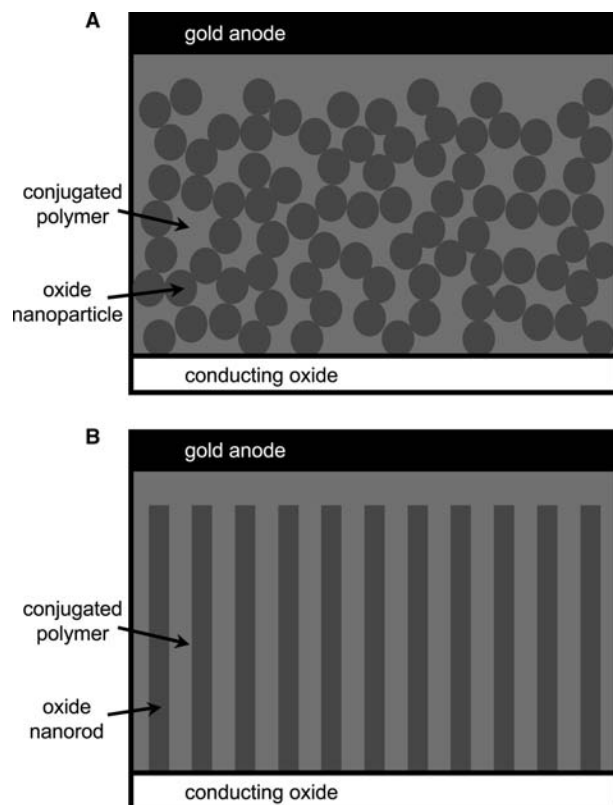

## ORGANIC–INORGANIC COMPOSITE PHOTOVOLTAIC DEVICE CONCEPTS

The bulk heterojunction solar cell is one approach to addressing the problem of short exciton diffusion lengths in organic semiconductors. However, the mixing of donor and acceptor species into an intimate blend introduces the problem of bulk recombination of carriers to the ground state, as previously discussed. Additionally, islands, defects, and cul-de-sacs in the transport networks that result in incomplete percolation paths may limit charge transport of one or both carriers in a bulk heterojunction cell. One promising route to high-efficiency solar cells that overcome these problems are devices that use a nanostructured, semiconducting metal oxide (such as TiO<sub>2</sub>, SnO<sub>2</sub>, or ZnO) as the electron-accepting and -transporting network. Such materials can be easily grown using low-temperature, solution-based routes to produce a variety of nanostructures, as is discussed in the next section. The topology of these nanostructures can be optimized to produce a continuous network that guarantees a percolation path for electrons to the electrode. This then opens up the possibility of organic–inorganic composite devices in which an organic semiconductor is deposited onto the surface of the oxide or used to fill the empty volume in a porous structure. In this way, the inorganic network can be used to induce a

specifically tailored morphological structure in the organic material and result in an overall device structure that has a large optical path length but short carrier-to-electrode path lengths.

The first example of a solar cell made using a porous oxide as an electron-transporting network was the solution-based, dye-sensitized solar cell.<sup>[42]</sup> In this device, a monomolecular layer of dye (typically a ruthenium complex) is chemisorbed through carboxylic acid binding groups onto the surface of a high surface area, mesoporous TiO<sub>2</sub> film. A liquid electrolyte (typically with an iodine/triiodide redox couple in an organic solvent) fills the pore spaces and makes contact to a platinum-coated counterelectrode. In the operation of the device, the dye molecules absorb light and inject electrons into the TiO<sub>2</sub>. The oxidized dye molecules are subsequently reduced by a reaction with the redox species. Transport of the charges out of the device occurs via diffusion of electrons through the TiO<sub>2</sub> and diffusion/ionic conduction of the redox species to the counterelectrode. Such devices have achieved 10% power conversion efficiency under solar illumination; however, the use of a liquid electrolyte makes them very difficult to implement for large-scale production. Recent progress has been made in replacing the liquid electrolyte with organic semiconductors, yielding devices with efficiencies reaching 3.2%.<sup>[43,44]</sup> Also, preliminary investigations into sensitizing a mesoporous oxide with quantum dots have been performed,<sup>[45]</sup> opening up the possibility of harnessing some of the “third-generation” photovoltaic mechanisms for achieving higher efficiencies such as hot carrier production or impact ionization.<sup>[46]</sup>

More recently, researchers have investigated solar cells based on conjugated polymer–semiconducting oxide composites. Such devices consist of a conjugated polymer embedded into a mesoporous metal oxide, which acts as an electron acceptor. Several studies have shown that metal oxide semiconductors can act as efficient electron acceptors for conjugated polymers.<sup>[47,48]</sup> The operation of these devices differs from that of the dye-sensitized cell in that light is absorbed in regions of the conjugated polymer potentially far from an oxide interface. Thus excitons must diffuse to an interface before electron transfer to the oxide can take place. Also, electric fields that contribute to the driving force for the current may be present in the device, which is not the case in the dye-sensitized cell because the ionic liquid shields all electric fields.<sup>[24]</sup> Several possible morphologies for such a composite device can be envisioned. As shown in Fig. 8, the polymer can be embedded in an isotropic, mesoporous oxide or in a “forest” of oxide nanorods that are vertically oriented to the substrate. To facilitate a direct path for charges to be transported to the electrode, the vertically oriented columns may be a better

**Fig. 8** Schematic diagram of conjugated polymer–semiconducting oxide composite photovoltaic devices with (A) an isotropic, mesoporous oxide and (B) a forest of oxide nanorods.

geometry. Aside from the goal of increased power conversion efficiency, these composite devices may result in increased morphological stability and robustness compared with pure polymer films, resulting in enhanced device lifetimes.

Fabrication of organic–inorganic composite devices has been performed via several techniques. Fig. 9A shows a mesoporous SnO<sub>2</sub> structure that was fabricated by spin-coating an aqueous solution of SnO<sub>2</sub> nanoparticles (diameter ~ 9 nm) mixed with polystyrene spheres (diameter ~ 100 nm). Upon heating the film to 450°C in an oxygenated atmosphere, the SnO<sub>2</sub> nanoparticles are sintered together to form a continuous oxide network. The polystyrene spheres are burned out of the film, leaving behind voids on the size scale of 100 nm. Fig. 9B shows a composite structure fabricated by soaking the above film in a solution of the conjugated polymer OC<sub>1</sub>C<sub>10</sub>-PPV for 8 hr. The SEM image shows efficient intercalation of the polymer into the porous SnO<sub>2</sub> structure. From optical measurements, the polymer was estimated to fill 75% of the free volume of the oxide. Several thermodynamic factors contribute to the degree of intercalation of a polymer into a porous medium.<sup>[49]</sup> Osmotic pressure drives the polymer chains into the pores. However,

**Fig. 9** Scanning electron microscopic images of the top surfaces of (A) a porous SnO<sub>2</sub> film with a thickness of 300 nm and (B) a SnO<sub>2</sub>/conjugated polymer (OC<sub>1</sub>C<sub>10</sub>-PPV) composite film. The porous SnO<sub>2</sub> film was fabricated by sintering a solution-deposited SnO<sub>2</sub> nanoparticle/polystyrene sphere mixture. The composite structure was fabricated by solution intercalation of the polymer into the porous SnO<sub>2</sub> structure.

the entropic force is in the other direction because of the reduced number of configurational states available to the confined polymer. The force that can tip the scales in either direction is the interaction energy between the polymer and oxide surface. A strong attractive force between the polymer and the oxide can overcome the entropic drive and result in efficient intercalation into the porous volume. Whether the oxide-polymer interaction is attractive or repulsive depends on a wide range of intermolecular forces, including the hydrophobic/hydrophilic and polar character of both materials, as well as the solvent in which the polymer is dissolved.<sup>[50]</sup> The hydrophobic/hydrophilic nature of the oxide surface can be substantially altered by cleaning processes or chemical derivatization to optimize the conditions for polymer intercalation. In a system in which there is a strong oxide-polymer attraction leading to efficient

**Fig. 10** Scanning electron microscopic image of an ordered, porous TiO<sub>2</sub> film fabricated using a self-organizing block copolymer as a templating agent. *Source:* From Prof. M.D. McGehee, Dept. of Materials Science and Engineering, Stanford University.

intercalation, the intercalated polymer can become essentially insoluble in solvents that would normally dissolve it, as is the case for the composite structure shown in Fig. 9B.

Other techniques that have been demonstrated include a self-assembly approach to fabrication of mesoporous TiO<sub>2</sub> using a block copolymer as a structure-directing agent.<sup>[51]</sup> Fig. 10 shows a highly ordered, mesoporous TiO<sub>2</sub> structure fabricated via this technique. Intercalation of this structure with the conjugated polymer P3HT resulted in a solar cell with approximately 0.5% power conversion efficiency under solar illumination. Also, a technique in which a Ti(OC<sub>3</sub>H<sub>7</sub>)<sub>4</sub> precursor was blended with a conjugated polymer and subsequently annealed to form a composite film with 100% filling has been demonstrated.<sup>[48]</sup> In the next section, we examine a variety of novel, low-cost techniques for fabricating metal oxide nanostructures that could potentially be used in an organic-inorganic composite solar cell.

## NOVEL FABRICATION TECHNIQUES FOR METAL OXIDE NANOSTRUCTURES

Over the past few years, the synthesis of semiconducting nanoparticles and nanorods has advanced substantially. There is considerable work demonstrating the synthesis of nearly monodisperse particles with sizes from a few nanometers to a few hundred nanometers. This allows tremendous flexibility in controlling the material band structure. There has been a remarkable

diversity of approaches to the synthesis of nanoparticles of various structures and of nanostructured surfaces. These include solution precipitation, sol-gel approaches, self-organization, and a range of physical vapor deposition (PVD)-based approaches including pulsed laser deposition, chemical vapor deposition, and sputtering.<sup>[52–61]</sup> One of the key emerging areas for controlling particle synthesis and incorporation into composite structures is the use of appropriate chelating ligands to promote self-organization.<sup>[53,62–70]</sup> There is quite a remarkable diversity of approaches being employed to both produce and tailor nanoparticulate materials. This provides an unprecedented degree of flexibility in the development of new materials. Interestingly, however, the vast majority of the work has been on a very few materials such as CdS, CdSe, silica, and ZnO.<sup>[62,71–80]</sup> This work served well

to develop the basic tools for the synthesis and capping of the nanoparticles for self-assembly or incorporation into composites. Recent work has also developed an array of tools for the synthesis of core/shell nanoparticles where the surface of the particle is a different material than the interior.<sup>[56,73,81]</sup> Overall, the development of these synthetic techniques provides the opportunity to pick a core material based on optical, electronic, and chemical properties and then cap it with another electronic material or to derivatize it with appropriate ligands to promote incorporation into a composite, or to lead self-assembly, or to control excitation or charge transfer properties. This presents an unprecedented ability to tailor the behavior of a composite material and has significant ramifications for a wide range of applications including solar cells, catalysis, and sensors.

**Table 2** Synthetic routes for the formation of nanofibers/nanotubes from a variety of inorganic semiconductors

Material	Synthetic method	Dimensions	Reference
H-TiO <sub>2</sub> nanotubes	Hydrothermal 10 M NaOH	5 nm radius, 150 nm length	[82,83]
TiO <sub>2</sub> nanofibers	Electrospinning of ethanol solution of poly(vinyl pyrrolidone)/titanium tetraisopropoxide	10–100 nm radius, up to several centimeters length	[84]
InAs nanofibers	2InCl <sub>3</sub> + 6KBH <sub>4</sub> + 2As → 2InAs + 6KCl + 6 BH <sub>3</sub> + 3H <sub>2</sub>	15–100 nm radius, 150–1000 nm length	[85]
GaP nanorods	Benzene reflux with GaCl <sub>3</sub> , Na, and P	20–50 nm radius, 200–500 nm length	[86]
CdE (E = S, Se, Te) nanorods	Direct reaction of the elements in organic solvents	10–40 nm radius, microns length	[87]
CuInE (E = S, Se) nanorods	Elements in organic solvents	10–40 nm radius, hundreds of nanometers length	[88]
ZnO, ZnS nanocables and nanotubes	Evaporation of the oxide followed by sulfiding	5–20 nm radius, hundreds of nanometers length	[89]
ZnO nanorods	Thermal decomposition of Zn <sup>II</sup> amino complex in aqueous solution	5–10 nm, 50–100 nm, and 0.5–1.0 μm radius, up to 10 μm length	[90,91]
ZnO nanobridges and nanonails	Thermal vapor transport and condensation method	25–100 nm radius, hundreds of nanometers to 2 μm length	[92]
GaP nanorods	Catalytic decomposition of Ga <sub>2</sub> O, P, and carbon nanotubes	50 nm radius, microns length	[93]
GaO nanoribbons	Direct reaction of GaN with oxygen	10–60 nm thick, hundreds of nanometers length	[94]
MnO <sub>2</sub> nanowires	Hydrothermal reaction of MnSO <sub>4</sub> –H <sub>2</sub> O with water in presence of ammonium persulfate	5–20 nm radius, microns length	[95]
CdWO <sub>4</sub> nanorods	Hydrothermal preparation	50 nm radius, 200 nm length	[96]
BaWO <sub>4</sub> nanorods	Reverse micelle synthesis	20–50 nm radius, hundreds of nanometers length	[97,98]
Vanadium oxide nanotubes	Hydrothermal synthesis with ammonium metavanadate and amines or quaternary ammonium salts	20–100 nm radius, 100–1000 nm length	[99]
MoS <sub>2</sub> , WS <sub>2</sub> , and NbS <sub>2</sub> nanotubes	High temperature synthesis of Mo with Se	100 nm radius, microns length	[100–103]

One of the newer developments in this area has been the development of synthetic approaches to nanorods or tubes with high aspect ratios. This leads to the possibility of anisotropic three-dimensional structures. The rods can be organized very differently than spherical particles and can be selectively attached or derivatized to control incorporation into a composite. As photoactive elements, nanomaterials with high aspect ratios can be used for transport of carriers and selective transport along the fiber or tube. For tubes, it may also be possible to delineate between the interior and exterior of the tube. The formation of nanorods and or tubes has been observed for a wide variety of systems, some of which are indicated in Table 2. While this list is not exhaustive by any means, it should serve to illustrate the extensive range of possible materials available with a wide variety of surface chemistries, optical, and electronic properties. Key is that simple hydrothermal or gas phase synthesis routes, which are very flexible allowing for derivatization of the materials and are very scalable, can make many of the materials. Figs. 11 and 12 show examples of TiO<sub>2</sub> nanofibers and ZnO microcrystallites grown in aqueous solutions.

There is also a very embryonic literature on the photochemistry of nanorods/tubes indicating that very facile charge transport can occur with appropriate surface derivatization (linkers) and produce useful chemistry such as polymerization, etc.<sup>[104–108]</sup> These results support the ability to apply the tunability of the semiconducting nanostructures through quantum confinement, coupled with rapid electron/exciton

**Fig. 11** Scanning electron microscopic image of TiO<sub>2</sub> nanofibers grown from an aqueous solution at 150°C.

**Fig. 12** Scanning electron microscopic image of ZnO microcrystallites grown from an aqueous solution at 95°C.

transfer with appropriate incorporation of the materials into the composite structure. These initial results point to the need for extensive work to understand the nature of excitonic and charge transfer in inorganic nanorods and nanotubes as well as the specifics of how to couple the nanomaterial to the outside environment such as a polymer or catalyst entity. However, there is every reason to believe at present that the diversity of materials and ligands will allow tailoring of the energetics and kinetics to produce specific redox behavior.

## CONCLUSION

Organic semiconductors are a promising class of materials for the fabrication of low-cost, large-scale production solar cells. Current state-of-the-art organic solar cells have achieved power conversion efficiencies exceeding 3%. This is an encouraging value, but a substantial increase in performance is required for these devices to be of practical use. To achieve higher efficiencies will require controlling the morphologies of the donor and acceptor materials to simultaneously optimize the exciton and charge transport pathways while allowing for an optically thick device. Recent advances in solution-based synthesis of metal oxide and other inorganic semiconductor nanostructures bring about the possibility of low-cost organic-inorganic composite devices with optimized morphologies. Many challenges exist in this area however. Further techniques for fabricating composite structures must be identified and refined, particularly with respect to efficiently intercalating polymers into nanostructured/porous media. Also, correct alignment of the charge transport pathways to the electrodes is necessary for efficient device operation, and thus the orientation of the nanostructures with respect to

the substrate must be precisely controlled. Perhaps the most vital, yet least understood, topic in this area is the organic–inorganic interface. Optimized device structures will require good mechanical contact and strong adhesion between the two components. Electronic properties of the interface are also crucial. Exciton quenching at the interface must be fast and efficient, and the relative electronic levels of the two materials must be optimized to yield the largest possible chemical potential difference across the interface for photogenerated charges. All these require a complete understanding of the chemistry and charge transfer reactions that occur at the interface. Meeting these challenges will be necessary to realize the full potential of organic semiconductor and organic–inorganic composite devices.

## ACKNOWLEDGMENTS

The authors thank Alex Miedaner for synthesis of TiO<sub>2</sub> and ZnO nanostructures and Bobby To for production of SEM images. The authors gratefully acknowledge funding from the U.S. Department of Energy, the National Center for Photovoltaics, and from an NREL Director's Discretionary Research and Development grant under the Department of Energy contract DE-AC36-19GO10337.

## INTRODUCTION

The synthesis of metal particles with well-controlled shapes and sizes is critical for catalytic applications in structure-sensitive reactions because the rates depend significantly on the metal crystallite size as well as on the orientation of the crystalline planes.<sup>[1]</sup> The morphology–catalytic reactivity relationship is generally unclear for the catalysts prepared by classical impregnation method because the resulting metal particles are non-uniform in size and shape, and are often too small to be precisely characterized. Additionally, there is a significant support effect on the catalytic reactivity of the small metal particles.<sup>[2–4]</sup> With other preparation methods such as vapor<sup>[5]</sup> and metal cluster deposition,<sup>[6]</sup> electron beam lithography,<sup>[7]</sup> etc., it is possible to control, to some extent, the size, but not the crystallographic orientation, of the metal particles.

The colloid method is one of the most promising ways to obtain relatively monodispersed metal particles with controlled shapes.<sup>[8]</sup> Among metals, platinum is a suitable precursor because different shapes of nanoparticles can be prepared by using suitable capping polymers.<sup>[9–11]</sup> The NO/CH<sub>4</sub> reaction was chosen to investigate the structure–catalytic reactivity relationship for the well-structured Pt nanoparticles. The conventionally prepared Pt/Al<sub>2</sub>O<sub>3</sub> catalysts give relatively high selectivity to NH<sub>3</sub> and CO. Because NO/CH<sub>4</sub> reaction is structure-sensitive, significant improvements in the catalytic behavior are expected through a fine control of the morphology of Pt particles.<sup>[12,13]</sup>

The general aim of our work is to bridge the gap existing between the science of clean single crystals surfaces and the world of real catalysis. Particularly, we intend to have a better understanding of the relationship existing between the structure of the supported Pt particles and the catalytic behavior for the NO/CH<sub>4</sub> reaction. From the practical point of view, our scope is to prevent or to considerably reduce the formation of undesired reaction products, such as NH<sub>3</sub>,

CO, and N<sub>2</sub>O. The approach to fulfill the abovementioned goals was to prepare well-defined Pt nanocrystals having mainly cubic structure, to support them on alumina, and to test their specific catalytic activity for the NO/CH<sub>4</sub> reaction.

## EXPERIMENTAL

The synthesis method for the controlled shape colloidal Pt nanoparticles was reported relatively recently.<sup>[10]</sup> In principle, the procedure consisted of the reduction of K<sub>2</sub>PtCl<sub>4</sub> precursor with H<sub>2</sub> in the presence of polyacrylate capping materials.<sup>[10,11]</sup> Morphological control in the synthesis of the well-defined Pt nanoparticles was further optimized by using NIPA (polymer of *N*-isopropylacrylamide) as a capping polymer and by changing the synthesis temperature.<sup>[9]</sup> The preparation method followed in the present study consisted of the reduction of K<sub>2</sub>PtCl<sub>4</sub> (10<sup>−4</sup> M) with H<sub>2</sub> in the presence of the NIPA polymer (10<sup>−3</sup> M) in the 10–40°C temperature range.<sup>[9]</sup>

The resulting Pt nanocrystals (with mainly cubic shape) were supported by adding, under stirring, 0.1 g of  $\gamma$ -alumina (Aerosil; 100 m<sup>2</sup> g<sup>−1</sup>) to 50 ml of colloidal Pt solution to get a final loading of Pt on 1 wt.% alumina. After water was removed from the suspension by freeze-drying, the remaining solid was calcined in air at 500°C for 8 hr to remove the NIPA polymer by decomposition. The calcined catalysts was pelletized, crushed, and sieved. The 335- to 1000- $\mu$ m fraction was used for catalytic tests. The Pt colloid as well as the calcined catalyst were characterized by transmission electron microscopy (TEM; Hitachi H-8100). Additionally, the catalysts were characterized by X-ray diffraction (XRD; Rigaku Multiflex diffractometer provided with peak assignment software), by N<sub>2</sub> adsorption for measurement of physical surface (Belsorb 28 SA), and by CO chemisorption for determination of metal surface (Yuasa ChemBET-3000).

**Table 1** The morphology of the Pt particles in different stages (Pt colloid, after deposition on alumina, and after high-temperature aging) as determined by TEM, XRD, and CO chemisorption measurements

Samples	Diameter (nm)								
	Colloidal stage			Active catalyst <sup>a</sup>			Aged catalyst <sup>b</sup>		
	$d_{\text{TEM}}^c$	$d_{\text{XRD}}^d$	$d_{\text{CO}}^e$	$d_{\text{TEM}}$	$d_{\text{XRD}}$	$d_{\text{CO}}$	$d_{\text{TEM}}$	$d_{\text{XRD}}$	$d_{\text{CO}}$
Pt{polycrystalline}/Al <sub>2</sub> O <sub>3</sub>	—	—	—	2.8	—	2.4	—	—	—
Pt{100}/Al <sub>2</sub> O <sub>3</sub>	13.6	—	—	13.4	11.7	23	15.1	10.6	21

<sup>a</sup>Catalyst working in the NO/CH<sub>4</sub> reaction mixture up to 600°C.

<sup>b</sup>Catalyst aged at 950°C for 4 hr in the NO/CH<sub>4</sub> reaction mixture.

<sup>c</sup>The average size was determined from TEM micrographs by counting more than 200 Pt nanoparticles.

<sup>d</sup>Size calculated from the broadening of the XRD peak of Pt(111) ( $2\theta \approx 40^\circ$ ).

<sup>e</sup>Average size determined from CO chemisorption data.

For convenience, the alumina-supported, well-structured Pt nanocrystals will be called, hereafter, Pt{100}/Al<sub>2</sub>O<sub>3</sub>. The activity of the Pt{100}/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalyst (0.05 g) for the NO/CH<sub>4</sub> reaction was tested in flow system by using a quartz microreactor (i.d. = 5 mm) operating at atmospheric pressure. The total flow rate of the reactant mixture (1% NO and 0.4% CH<sub>4</sub>, balance Ar) was 50 cm<sup>3</sup> min<sup>-1</sup> standard temperature and pressure (STP). The corresponding gas hour space velocity (GHSV) was 60,000 hr<sup>-1</sup>.

The analysis of gaseous mixtures was carried out with a gas chromatograph (GL Sciences-320) equipped with a thermal conductivity detector (TCD). N<sub>2</sub>, NO, and CH<sub>4</sub> were separated by a molecular sieve 13 $\times$  column and the CO<sub>2</sub> and N<sub>2</sub>O were separated by a Porapak-Q column.

The activity of well-structured platinum catalysts (Pt{100}/Al<sub>2</sub>O<sub>3</sub>) was compared with that of a standard catalyst supplied by Engelhard Corporation Japan (lot no. H-T1150-01). The Engelhard catalyst (metal loading, 1 wt.%), hereafter called Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub>, had metal and Brunauer–Emmet–Teller (BET) surface areas of 1.19 ( $\approx 44\%$  dispersion) and 114 m<sup>2</sup> g<sup>-1</sup>, respectively. The metal particle size, determined from chemisorption and TEM data, were 2.4 and 2.8 nm, respectively (Table 1).

The catalytic behavior in the NO/CH<sub>4</sub> reaction was expressed in terms of conversion, selectivity, and yield.<sup>[12]</sup>

## RESULTS

The configuration of NIPA thermosensitive polymer changes reversibly with temperature because a hydrophilic–hydrophobic transition takes place at  $\approx 36^\circ\text{C}$ . The influence of capping conditions on the morphology of Pt particles was investigated by carrying out the reduction of K<sub>2</sub>PtCl<sub>4</sub> both in hydrophobic and hydrophilic regions (10–40°C). The proportion of Pt cubic to other shapes passed through a maximum ( $\approx 70\%$ ) for a reduction temperature of 40°C (Fig. 1).

Fig. 2 presents the TEM images of the Pt nanoparticles in different stages. Fig. 2A shows the well-defined cubic Pt nanocrystals, of around 13 nm, in colloidal stage. Analysis by high-resolution transmission electron microscopy (HRTEM) revealed that the square particles were Pt single crystals with a surface relatively free of defects (smooth surface). The Pt nanoparticle shown in Fig. 2B is bounded by {100} facets because the distance between the adjacent lattice fringes of 0.196 nm corresponds to the interplanar distance of Pt{200}. Other crystallographic orientations (i.e., {111} and {110}) as well as steps and ledges are also possible<sup>[11]</sup> at the slightly rounded corners of the cubes. The cubic structure of the Pt nanoparticles was preserved after supporting them on alumina (Fig. 2C). The conversion of the square Pt nanoparticles to other shapes (i.e., irregular, round, and hexagonal) was observed after high-temperature aging (950°C for 4 hr) in the NO/CH<sub>4</sub> mixture (Fig. 2D). The impact of the morphological changes of the supported Pt nanoparticles on the catalytic activity and selectivity for the NO/CH<sub>4</sub> reaction will be analyzed hereafter.

Because the morphology of the Pt nanoparticles changes slightly from batch to batch and the NO/CH<sub>4</sub>

**Fig. 1** The relationship between the morphological distribution of the platinum nanoparticles in colloidal stage and the reduction temperature.

**Fig. 2** TEM images of (A) Pt colloid composed mainly of cubic nanoparticles ( $\approx 70\%$ ); (B) high magnification of an individual cubic Pt nanoparticle; (C) alumina-supported Pt nanoparticles; and (D) alumina-supported Pt nanoparticles aged at  $950^\circ\text{C}$  for 4 hr in the  $\text{NO}/\text{CH}_4$  mixture.

reaction is very sensitive to the metal structure, it is our standard procedure to characterize the Pt nanoparticles in colloidal stage as well as after deposition on alumina and catalytic tests by TEM, XRD, and CO chemisorption. Table 1 presents the average size of Pt particles in colloidal stage (TEM data), after deposition on alumina and catalytic tests up to  $600^\circ\text{C}$  (TEM, XRD, and CO chemisorption data), and after thermal aging ( $950^\circ\text{C}$ , 4 hr) in the  $\text{NO}/\text{CH}_4$  reaction mixture (TEM, XRD, and CO chemisorption data). The average size ( $d_{\text{TEM}}$ ) of the colloidal Pt nanoparticles ( $\approx 13.6\text{ nm}$ ) does not change after deposition on alumina or after catalytic reaction up to  $600^\circ\text{C}$  in the  $\text{NO}/\text{CH}_4$  reaction mixture ( $d_{\text{TEM}} \approx 13.4\text{ nm}$ ). Good thermal stability of the alumina-supported Pt nanoparticles is confirmed also by XRD data ( $d_{\text{XRD}} \approx 11.7\text{ nm}$ ).

Theoretical calculations, by considering the  $d_{\text{TEM}}$  average particle size of  $13.4\text{ nm}$ , predict a platinum dispersion of around 7%. Such a small dispersion is, in practice, difficult to measure by CO chemisorption. However, we attempted to measure it by using a sensitive chemisorption apparatus, which can generate and measure CO pulses on the order of microliters. The  $d_{\text{CO}}$  value of  $\approx 23\text{ nm}$ , determined for the catalysts working in reaction mixtures up to  $600^\circ\text{C}$ , is higher than those determined by TEM ( $d_{\text{TEM}} \approx 13.4\text{ nm}$ ) or by XRD ( $d_{\text{XRD}} \approx 11.7\text{ nm}$ ) (Table 1). Taking into account the extremely small dispersion, the low metal loading (1% Pt), and the small amount of catalyst (0.05 g) used for metal surface determination, the chemisorption data are quite satisfactory and may be

useful especially in revealing the evolution of metal surface area with temperature.

Morphological information regarding the thermally aged catalyst ( $950^\circ\text{C}$ , 4 hr in the  $\text{NO}/\text{CH}_4$  mixture) is given in Table 1 ( $d_{\text{TEM}}$ ,  $d_{\text{XRD}}$ , and  $d_{\text{CO}}$ ), Fig. 2D, as well as in Figs. 3 and 4 (morphological and size distributions, respectively). Apparently, the TEM data indicate a slight increase in particles size from  $13.4$  to  $15.1\text{ nm}$  for the thermally aged Pt nanoparticles (Table 1). In contrast, the XRD and chemisorption data ( $d_{\text{XRD}} \approx 10.6$  and  $d_{\text{CO}} \approx 21\text{ nm}$ ) suggest a slight decrease in particle size after thermal aging (Table 1). This apparent contradiction, between TEM data on one hand and chemisorption and XRD data on the other hand, will be analyzed later in the “Discussion” section.

The morphologies of the colloidal Pt nanoparticles synthesized at  $40^\circ\text{C}$  and of the thermally aged ( $950^\circ\text{C}$ , 4 hr in the  $\text{NO}/\text{CH}_4$  mixture) Pt nanoparticles supported on alumina are comparatively presented in Fig. 3. Around 53% and 17% of the colloidal Pt nanocrystals have been found to have “clear square” and “unclear square” shapes, respectively. The “clear square” particles were  $\text{Pt}\{100\}$  single crystals with surfaces relatively free of defects (Fig. 2B). The particles with “unclear square” shape were also cubic nanocrystals but with a rough surface (defected surface). Besides cubic, other shapes, such as hexagonal ( $\approx 9\%$ ), round ( $\approx 4\%$ ), small ( $\approx 5\%$ ), and irregular ( $\approx 12\%$ ), have been identified, too.

The initial morphological distribution was significantly altered after thermal aging at  $950^\circ\text{C}$  for 4 hr in

**Fig. 3** Morphological distribution of the (I) initial colloidal Pt nanocrystals deposited on  $\gamma$ - $\text{Al}_2\text{O}_3$  and (II) alumina-supported Pt nanoparticles subjected to thermal aging at  $950^\circ\text{C}$  for 4 hr in the  $\text{NO}/\text{CH}_4$  reaction mixture.

the  $\text{NO}/\text{CH}_4$  mixture. The “clear square” and the “unclear square” particles were practically completely converted to irregular ( $\approx 47\%$ ), round ( $\approx 25\%$ ), and hexagonal ( $\approx 17\%$ ).

From the Gaussian-type size distribution of the colloidal Pt nanoparticles, an average particle size of  $\approx 13.6$  nm was determined (Fig. 4, Table 1). The size distribution of the Pt nanoparticles became apparently broader after thermal aging at  $950^\circ\text{C}$  for 4 hr, but the average particle size increased only slightly, from 13.4 to 15.1 nm.

The catalytic activity of  $\text{Pt}\{100\}/\text{Al}_2\text{O}_3$  for the  $\text{NO}/\text{CH}_4$  reaction vs. temperature is presented in Fig. 5. The total conversion of NO was achieved for  $T \geq 350^\circ\text{C}$ . The concentration of  $\text{N}_2\text{O}$  goes through a maximum at  $400^\circ\text{C}$  and then decreases with increasing reaction temperature. In the lower-temperature domain ( $350$ – $500^\circ\text{C}$ ), the only product of methane oxidation was  $\text{CO}_2$ . The formation of CO was observed

for  $T \geq 500^\circ\text{C}$ . Small amounts of  $\text{NH}_3$  were detected only in the high-temperature region ( $T \geq 550^\circ\text{C}$ ). Experiments in which the catalyst was cycled up and down in the temperature range of  $300$ – $600^\circ\text{C}$  did not show any significant variations in catalytic activity.

The conversion of NO and  $\text{CH}_4$  as well as the reaction selectivity to various products are presented in Fig. 6. The reaction selectivity to  $\text{N}_2$  reaches a maximum at  $550^\circ\text{C}$  ( $\approx 99\%$ ). The selectivity to  $\text{N}_2\text{O}$  has a maximum at  $350^\circ\text{C}$  ( $\approx 40\%$ ) and then decreases with increasing reaction temperature. The selectivity to  $\text{NH}_3$  increased with increasing reaction temperature from  $\approx 1\%$  at  $550^\circ\text{C}$  to  $\approx 10\%$  at  $600^\circ\text{C}$ .

The catalytic behavior of  $\text{Pt}\{100\}/\text{Al}_2\text{O}_3$  for the  $\text{NO}/\text{CH}_4$  reaction was compared with that of a standard catalyst,  $\text{Pt}\{\text{polycrystalline}\}/\text{Al}_2\text{O}_3$ , at  $400^\circ\text{C}$  (Fig. 7) and  $500^\circ\text{C}$  (Fig. 8). In this manner, the observed differences would be ascribed to the morphological effects of the Pt particles on the  $\text{NO}/\text{CH}_4$  reaction.

**Fig. 4** The size distribution of the (I) colloidal Pt nanoparticles supported on alumina (initial) and (II) alumina-supported Pt nanoparticles subjected to thermal aging at  $950^\circ\text{C}$  for 4 hr in the  $\text{NO}/\text{CH}_4$  reaction mixture.

**Fig. 5** The conversion of NO to all products as a function of temperature for the  $\text{Pt}\{100\}/\text{Al}_2\text{O}_3$  catalyst. (x) NO; (●)  $\text{CH}_4$ ; (△)  $\text{N}_2$ ; (□)  $\text{N}_2\text{O}$ ; (■)  $\text{NH}_3$ ; (◇)  $\text{CO}_2$ ; (◆) CO; and (○)  $\text{H}_2$  (reactant mixture: 1% NO, 0.4%  $\text{CH}_4$ , and balance Ar).

**Fig. 6** The temperature dependence of the NO/CH<sub>4</sub> reaction conversion (X) and selectivity (S) for Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalysts. (×) X(NO); (●) X(CH<sub>4</sub>); (△) S(N<sub>2</sub>); (□) S(N<sub>2</sub>O); (■) S(NH<sub>3</sub>); (◇) S(CO<sub>2</sub>); (◆) S(CO); and (○) S(H<sub>2</sub>) (reactant mixture: 1% NO, 0.4% CH<sub>4</sub>, and balance Ar).

Both catalysts investigated exhibit comparable activity for NO conversion, increasing yield to N<sub>2</sub> (opposite trend for N<sub>2</sub>O) and increasing CH<sub>4</sub> conversion with temperature (Figs. 7 and 8).

Interestingly, significantly lower yields to CO and NH<sub>3</sub> were observed for the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst compared with the Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> catalyst (Figs. 7 and 8). On the other hand, the well-structured Pt nanoparticles showed higher yield to N<sub>2</sub>O.

The XRD pattern of the Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> presented in Fig. 9A indicates that Pt particles are too small ( $\approx 2.4$  nm) to give characteristic XRD peaks. The XRD patterns of the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalysts (Fig. 9B

and C) exhibit the characteristic XRD reflections of the large, well-crystallized Pt nanoparticles at  $2\theta \approx 40^\circ$  and  $2\theta \approx 81^\circ$ . The average sizes of Pt crystallites, calculated from the XRD peaks at  $2\theta \approx 40^\circ$  by using the Debye–Scherrer equation, were 11.7 nm for the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst working in the NO/CH<sub>4</sub> mixture at the 300–600°C temperature range and 10.7 nm for the same catalyst aged at 950°C for 4 hr in the reaction mixture. The XRD results suggest a remarkable size stability of the alumina-supported Pt nanocrystals.

## DISCUSSION

According to ultrahigh vacuum (UHV) investigations, the catalytic activities for numerous reactions vary from one metal crystal face to another.<sup>[14]</sup> For example, the NO/H<sub>2</sub> reaction proceeds with significantly different rates over Pt(100) and (110) monocrystals.<sup>[15]</sup> Therefore the rate of N<sub>2</sub> formation is at least five times higher on the surface of Pt(100) than on Pt(110). In fact, the studies performed on the clean surfaces predict that a strong structure–catalytic reactivity relationship should also exist in atmospheric pressure conditions.

The first step to better understand the structure–catalytic reactivity relationship is to have a good morphological control (shape and size) of the supported metal nanoparticles and to reduce or eliminate the support effect. In this way, the most important factors responsible for the significant differences observed between the catalytic behaviors of the large, well-defined Pt nanoparticles and the small, polycrystalline

**Fig. 7** Comparison between the NO/CH<sub>4</sub> reaction conversion (X) and yield (Y), and the products for Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> (Engelhard) and Pt{100}/Al<sub>2</sub>O<sub>3</sub> (well-defined Pt nanoparticles) catalysts at 400°C.

**Fig. 8** Comparison between the NO/CH<sub>4</sub> reaction conversion (X) and yield (Y), and the products for Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> (Engelhard) and Pt{100}/Al<sub>2</sub>O<sub>3</sub> (well-defined Pt nanoparticles) catalysts at 500°C.

Pt particles in the NO/CH<sub>4</sub> reaction can be identified and analyzed more easily. The catalytic tests show that, over the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst, the formation of CO and NH<sub>3</sub> is largely prevented, whereas the yield to N<sub>2</sub>O increases compared with the Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> catalyst.

It is clear that the interaction with the support is minimal in the case of the large (≈13 nm) Pt nanoparticles grafted after the formation on alumina. Boudart<sup>[16]</sup> observed that the catalytic behavior of particles larger than 5 nm mostly reflects the properties of bulk metals.

The main differences observed between the two catalysts compared are the dominant orientation of the crystallographic facets and the average size of Pt crystallites. The large Pt nanocrystals (≈13 nm) of the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst were, in majority (≈70%), cubic-shaped. In contrast, the conventional Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> catalyst had small, round-shaped Pt particles of ≈2.4 nm with random crystallographic orientations. The impact of the abovementioned factors, shape and size, on the catalytic behavior for the NO/CH<sub>4</sub> reaction will be discussed later in this work.

### Activation of NO

It is rational to consider that the first step of NO conversion is the dissociation from the metal surface:<sup>[17]</sup>

The absence of a reductant, which removes the strongly adsorbed O<sub>ads</sub>, prevents further NO decomposition.<sup>[18,19]</sup> We observed that in the absence of CH<sub>4</sub>, around 2–5% of NO decomposes for a short time (few minutes) over the reduced Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst. Burch and Ramli<sup>[20]</sup> suggested that the relative activities for various catalysts reflect the ease of catalyst reduction by a reducing agent (i.e., CH<sub>4</sub>).

The dissociation of NO over the clean surfaces of metal single crystals has been intensively investigated. The most important conclusions of these studies will be briefly reviewed to explain the catalytic behavior of Pt{100}/Al<sub>2</sub>O<sub>3</sub> in the NO/CH<sub>4</sub> reaction:

- I. The NO dissociation on clean metal surfaces is a coverage-dependent process.<sup>[21]</sup> Low NO

**Fig. 9** Comparative XRD patterns for polycrystalline and well-structured platinum particles supported on alumina. Spectrum (A): Pt{polycrystalline}/Al<sub>2</sub>O<sub>3</sub> (Engelhard) catalyst used in the NO/CH<sub>4</sub> reaction in the 300–600°C temperature range. Spectrum (B): Pt{100}/Al<sub>2</sub>O<sub>3</sub> (well-structured Pt nanoparticles) used in the NO/CH<sub>4</sub> reaction in the 300–600°C temperature range. Spectrum (C): Pt{100}/Al<sub>2</sub>O<sub>3</sub> after aging at 950°C for 4 hr in the NO/CH<sub>4</sub> reaction mixture.

coverage (typically  $\theta < 0.3$ ) favors the complete dissociation of NO.<sup>[22]</sup> It is likely that in real catalytic conditions, the adsorbed NO will be only partially dissociated because of the high surface coverage. Thus the molecular NO will coexist on the metal surface with  $N_{\text{ads}}$  and  $O_{\text{ads}}$  species.

- II. The dissociation of NO is very sensitive to crystallographic orientation. Desorption studies evidenced that only 5% of the adsorbed NO dissociates from Pt(111) and Pt(110), in contrast with Pt(100), which dissociates by around 50%.<sup>[22]</sup> Moreover, the Pt(111) facet is reported to be completely unreactive for NO decomposition at any coverage.<sup>[23]</sup> On the other hand, the high-index Pt planes are unusual active for NO decomposition. For example, more than 98% of the adsorbed NO is dissociated from the Pt(410) surface.<sup>[22]</sup>

Some studies pointed out that NO dissociates mainly at the steps.<sup>[17]</sup> The conventional catalyst, containing small Pt particles with random crystallographic orientation, is rich in high-index planes, edges, kinks, and steps. Therefore it is expected to show high activity for NO decomposition. In contrast, the large Pt nanocrystals have limited activity for NO decomposition because of the low concentration of high-index planes and surface defects. Our assumptions are confirmed by experimental facts. The Pt(100) single crystals are catalytically active but give a dissociation for NO  $\approx 50\%$  under conditions where the polycrystalline Pt samples give a dissociation of 75% for NO.<sup>[22]</sup> The activity for NO decomposition should have a great impact on the NO/CH<sub>4</sub> reaction selectivity to N<sub>2</sub>O and N<sub>2</sub>. We will discuss in detail these aspects in the next paragraph.

In fact, NO can be decomposed not only by metals but also by metal oxides. Winter<sup>[24]</sup> investigated the decomposition of NO to over 40 oxides (PtO<sub>x</sub> was not included in this screening) and found out that the most active oxides give a conversion of below 50% for NO. In our specific case, we could not provide evidence on the formation of PtO<sub>x</sub> species through any experimental method used [temperature-programmed reduction (TPR) and XRD]. Therefore it is safe to state that the bulk PtO<sub>x</sub> is not formed over the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst and, in consequence, is not involved in the decomposition of NO. On the other hand, we clearly observed that (in the absence of a reductant) the oxygen resulting from NO decomposition poisons the reaction because of the formation of a superficial layer of strongly adsorbed oxygen.<sup>[25]</sup>

In practice, NO decomposition can be even more complicated. From single crystal studies, two possible

structures have been found for the Pt(100) plane, indicated by (1 × 1) and (5 × 2).<sup>[26]</sup> The (1 × 1) surface has a square structure on a square substrate, whereas the (2 × 5) surface has a hexagonal structure on the square substrate. The (1 × 1) and (5 × 2) surfaces exhibit different adsorption and catalytic properties.<sup>[27]</sup> The dissociation of NO takes place only on the (1 × 1) phase, whereas the hexagonal one is inert.<sup>[18]</sup> However, at present, it is difficult to assess the impact of these structures, observed in UHV conditions, on catalytic behavior at atmospheric pressure.

It is likely that for a real catalyst under steady-state conditions, less active sites (e.g., terraces) will certainly come into play, so the overall reactivity will be the result of weighted contributions from various surface structure elements, dominated by active sites located at steps, edge, and kinks.<sup>[17]</sup>

### Formation of N<sub>2</sub> and N<sub>2</sub>O

There is almost a general agreement in the published literature, from catalytic investigations conducted under atmospheric pressure<sup>[2,28]</sup> and studies performed on clean metal surfaces,<sup>[22,23]</sup> that N<sub>2</sub> and N<sub>2</sub>O are formed via the following reactions:

There are also a few works assuming that N<sub>2</sub>O can be an intermediate during the reduction of NO by CH<sub>4</sub>.<sup>[29]</sup>

Our experimental results strongly support the mechanism for N<sub>2</sub>O formation described by Eq. (3). The generation of N<sub>2</sub>O is favored over the Pt{100}/Al<sub>2</sub>O<sub>3</sub> catalyst because the large, well-defined Pt nanocrystals exhibit low activity for NO decomposition. In contrast, high selectivity to N<sub>2</sub> was observed over the small ( $\approx 2.4$  nm) polycrystalline Pt particles because of the high efficiency shown for NO decomposition Eq. (2).

The dissociation equilibrium for NO is a temperature-dependent process. As the temperature increases, the reaction is shifted toward the dissociation of NO, thus the most favored reaction becomes the recombination of  $N_{\text{ads}}$  to give molecular N<sub>2</sub> Eq. (2) and Fig. (6).

### Conversion of CH<sub>4</sub>

Methane must overcome an activation energy barrier of around 7 kcal mol<sup>-1</sup> to chemisorb on metal surfaces, and the barrier height for breaking the C–H bond by kinetic energy is 29 kcal mol<sup>-1</sup>.<sup>[30]</sup> The dissociative adsorption of methane occurs either on the fully reduced Pt, or at mixed sites comprising Pt<sup>δ+</sup>O<sup>δ-</sup>,

but the fully oxidized Pt surface is less active than the reduced or partially oxidized surface.<sup>[31]</sup>

Then the  $\text{CH}_x$  and  $\text{H}_{\text{ads}}$  surface species are oxidized by the  $\text{O}_{\text{ads}}$  (resulting from NO decomposition) to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  over the Pt{100}/ $\text{Al}_2\text{O}_3$  catalyst. In other words, the high oxidizing activity of the adsorbed oxygen on the surface of large Pt particles explains the high selectivity to deep oxidation products despite methane excess used in our experiments.

The structure sensitivity of methane oxidation over platinum was explained by the different reactivities of the adsorbed oxygen.<sup>[32]</sup> The higher resistance of the large Pt particles against bulk oxidation<sup>[16]</sup> explains the enhanced catalytic activity for  $\text{CH}_4$  oxidation.<sup>[32]</sup> The catalytic activity of the large Pt particles for oxidation reactions was found to be at least one order of magnitude higher than the small, well-dispersed Pt particles.<sup>[33]</sup> The chemisorbed oxygen is bound more weakly to the metal surface and therefore is more ready to react with  $\text{CH}_x$  species.<sup>[34]</sup> The oxidation of  $\text{CH}_x$  on the large Pt nanocrystals ( $\approx 13$  nm) can be described by the following equation:

The subscript “L” indicates that the oxygen is adsorbed on large Pt particles. The hydrocarbon continuously removes the pool of  $\text{O}_{\text{ads}}$  then NO dissociation continues, mainly on high index planes and surface defects.

In contrast to the large Pt nanocrystals, the well-dispersed Pt particles, with an average size of 2.4 nm, give high selectivity to CO and  $\text{NH}_3$  (Figs. 7 and 8). These results can be explained as follows. The dispersed Pt particles can be successively converted, depending on the temperature, to PtO, PtO<sub>2</sub>, and, finally, PtAl<sub>2</sub>O<sub>4</sub>.<sup>[33,35]</sup> Because of the low oxidation activity of  $\text{O}^{\delta-}$  ( $\text{PtO}_x$ ) species, some of the surface  $\text{CH}_x$  species will undergo only partial oxidation:

The subscript “S” indicates that the  $\text{O}^{\delta-}$  is formed on small Pt particles.

In addition to CO, large amounts of  $\text{NH}_3$  are formed during the reduction of NO with  $\text{CH}_4$  over the conventional Pt/ $\text{Al}_2\text{O}_3$ <sup>[28]</sup> and Pt/ $\text{SiO}_2$ <sup>[36]</sup> catalysts. The selectivity to  $\text{NH}_3$  was observed to decrease with increasing oxygen concentration in reactant mixtures. It is likely that the lifetime of the  $\text{CH}_x$  and  $\text{H}_{\text{ads}}$  species on the small Pt particles is longer because of the low

oxidation ability of bulk  $\text{PtO}_x$ . Therefore the reactions responsible for ammonia formation are favored:

The formation of  $\text{NH}_3$  over Pt{100}/ $\text{Al}_2\text{O}_3$  was greatly reduced because the active oxygen chemisorbed on the large Pt particles rapidly removes, as do  $\text{CO}_2$  and  $\text{H}_2\text{O}$ , the carbonaceous and H species from the surface.

### Impact of Platinum Morphological Evolution on Catalytic Behavior

From the aforementioned results as well as from already published works,<sup>[12,13]</sup> it is clear that both the size and the facet have a determinant role in the catalytic activity of Pt particles for the NO/ $\text{CH}_4$  reaction. Morphological changes of the Pt nanoparticles are expected to take place in reaction conditions. Therefore a closer look was taken on the morphological evolution of the Pt nanoparticles with time in reaction conditions, as well as on the impact of this evolution on the catalytic behavior for the NO/ $\text{CH}_4$  reaction.

The catalyst was subjected to an accelerated thermal aging at 950°C for 4 hr in the NO/ $\text{CH}_4$  reaction mixture. Then, the catalytic behavior of the aged catalyst was checked again in the low-temperature region (300–600°C). Fig. 10 illustrates the aging effect on the catalytic behavior of alumina-supported Pt nanoparticles. For the sake of simplicity, only yields

**Fig. 10** Comparison between the NO/ $\text{CH}_4$  yield to  $\text{N}_2\text{O}$  ( $\Delta$ ,  $\blacktriangle$ ), CO ( $\circ$ ,  $\bullet$ ), and  $\text{NH}_3$  ( $\diamond$ ,  $\blacklozenge$ ) for the fresh (open symbols) and high-temperature (950°C, 4 hr) aged (closed symbols) alumina-supported Pt nanoparticles in the 350–600°C temperature range (reactant mixture: 1% NO, 0.4%  $\text{CH}_4$ , and balance Ar).

to the harmful products ( $\text{N}_2\text{O}$ ,  $\text{CO}$ , and  $\text{NH}_3$ ) were compared. The main changes observed after high-temperature aging can be summarized as follows: 1) the production of  $\text{N}_2\text{O}$  and  $\text{CO}$  decreased significantly (the formation of  $\text{CO}$  was prevented below  $550^\circ\text{C}$  and the yield to  $\text{N}_2\text{O}$  became negligible at  $T \geq 400^\circ\text{C}$ ); and 2) the formation of  $\text{NH}_3$  was completely suppressed (Fig. 10).

From the data presented in Table 1 and Fig. 3, it was found that aging had little effect on particle size, but a significant effect on the shape of Pt nanocrystals. The larger  $d_{\text{TEM}}$  value observed for the aged catalyst ( $\approx 15.1$  nm) compared with the fresh catalyst ( $\approx 13.4$  nm) can be explained by the flattening of the Pt particles on the support, rather than by sintering (no sign of particle agglomeration was observed). The flattening of Pt nanoparticles (or the decrease in thickness) is supported also by the decrease in  $d_{\text{XRD}}$  value from 11.7 to 10.6 nm after aging. As we already discussed, the initially square Pt nanoparticles (relatively free of defects) were converted during thermal aging to irregular-shaped, round-shaped, and hexagonal-shaped particles (Fig. 2D). In other words, the low index facets were gradually shifted at high temperature to higher index planes. It is well known that a rearrangement of the metal surface, called “surface roughening” or “surface melting,” can take place (below the melting temperature) if it is heated above some critical temperature. It is relatively common for a surface to show one equilibrium reconstruction at low temperature and to show another equilibrium surface structure upon heating.<sup>[37]</sup> In the case of alumina-supported Pt nanoparticles, the process of surface roughening was not a reversible one.

As it was already stressed, the low index Pt planes (i.e., Pt(100))<sup>[19]</sup> are less active for NO dissociation compared with higher index planes (i.e., Pt(410))<sup>[22]</sup> or surface defects.<sup>[17]</sup> The decrease in  $\text{N}_2\text{O}$  yield for thermally aged Pt nanoparticles, rich in surface defects, can be easily explained by taking into account their high activity for NO decomposition (Fig. 10).

The reasons for the significant decrease in  $\text{CO}$  and  $\text{NH}_3$  yields after thermal aging will be given hereafter. As it was already emphasized, the small Pt particles have lower catalytic activity for oxidation reaction because they easily form  $\text{PtO}_x$  species (bulk oxide).<sup>[33]</sup> The oxygen coverage as well as the desorption temperature are significantly higher on the small ( $\approx 2$  nm) Pt particles relative to the large ( $\approx 8.3$  nm) ones.<sup>[38]</sup> For our specific case, the  $\text{CH}_x$  species, formed by the dissociative adsorption of  $\text{CH}_4$ , will be further oxidized to  $\text{CO}_x$  by oxygen resulting from the dissociation of NO. The high activity of the restructured Pt nanoparticles (thermally aged) for NO decomposition increases the supply of active oxygen, which rapidly removes surface carbonaceous species such as  $\text{CO}_2$ . As a consequence, the reaction yield to  $\text{CO}$  decreases.

The same explanation is valid in the case of ammonia formation. It is accepted that  $\text{NH}_3$  is formed in the reactions between  $\text{N}_{\text{ads}}$  and a hydrogen source, either  $\text{CH}_x$  or  $\text{H}_{\text{ads}}$ .<sup>[28]</sup> In fact, a reduction in  $\text{NH}_3$  production can be reached if the active surface oxygen rapidly removes the hydrogen sources. The high activity of the restructured (rough) Pt nanoparticles to decompose NO increases the supply of surface oxygen, which can remove, as oxidation products ( $\text{CO}_2$  and  $\text{H}_2\text{O}$ ), the hydrogen sources ( $\text{CH}_x$  and  $\text{H}_{\text{ads}}$ ) responsible for ammonia formation. Thus the recombination  $\text{N}_{\text{ads}}$  Eq. (2) becomes favored and the reaction of ammonia formation Eqs. (7) and (8) can be prevented.

## CONCLUSION

The  $\text{NO}/\text{CH}_4$  reaction is structure-sensitive, depending both on the size and the shape (facet) of the Pt nanoparticles. The “facet effect” plays an essential role in NO dissociation, and thus is responsible for the reaction selectivity to  $\text{N}_2\text{O}$  and  $\text{N}_2$ . The “size effect” is responsible for the reaction selectivity to  $\text{CO}$  and  $\text{NH}_3$  by controlling the oxygen catalytic activity.

It is clear that accurate tuning of the supported metals' morphology (size and shape) can bring in future spectacular improvements in the catalytic activity and selectivity for structure-sensitive reactions.

# Polyelectrolyte Films with Incorporated Carbon Nanotubes

Jason H. Rouse

Peter T. Lillehei

Langley Research Center, National Aeronautics and Space Administration (NASA),  
Hampton, Virginia, U.S.A.

## INTRODUCTION

Since their discovery in 1993,<sup>[1,2]</sup> the synthesis, characterization, and manipulation of single-walled carbon nanotubes (SWNT) has received considerable attention. Single-walled carbon nanotubes are composed of a graphene sheet rolled into a seamless tube to produce a material with a diameter between 1 and 2 nm and lengths of up to tens of microns. As nanotubes are comprised of an extended  $\pi$ -system, they possess a unique combination of mechanical, electronic, and optical properties.<sup>[3]</sup> Researchers have envisioned that by incorporating nanotubes within a range of materials, there is potential to produce technologically important breakthroughs such as ultrastrong but light structural materials and molecular-scale electronic devices.

This entry reviews recent reports on the incorporation of SWNTs within thin polymer films using the sequential adsorption of polyionic species.<sup>[4,5]a</sup> Using the ability to introduce acid sites on SWNTs, researchers have shown that oxidized SWNT bundles can act as polyionic species, allowing the formation of polyelectrolyte/SWNT composite thin films.<sup>[4,5]</sup> In addition to minimizing a number of problems encountered with bulk processing techniques (vide infra), such as “bottom-up” approaches to the formation of polymer/SWNT composites may permit the formation of film structures not readily achievable using bulk techniques. The preparation of polymer/SWNT composite thin films via the Langmuir–Blodgett (LB) technique<sup>[8,9]</sup> will also be reviewed.

## RESULTS AND DISCUSSION

### Difficulties with Carbon Nanotube/Polymer Composite Processing

While carbon nanotubes possess remarkable properties, their incorporation within polymer composites has been hampered by their poor solubility and the tendency to aggregate into micron-size particles.<sup>[10,11]</sup> Efforts to overcome these difficulties have primarily focused on experimenting with various bulk processing techniques, such as sonication-assisted solution mixing,<sup>[12–15]</sup> melt mixing,<sup>[16]</sup> and in situ polymerization,<sup>[17–19]</sup> and more recently, the use of SWNTs modified with groups that improve their solubility and reduce aggregation.<sup>[20–22]</sup> While these methods have allowed the formation of polymer/SWNT composites showing some mechanical improvement, the reports generally lack (sufficient) microscopy evidence detailing the extent of nanotube dispersion within the composite. Because the presence of nanotube aggregates within a composite reduces the effective number of interactions between the nanotubes and the polymer, a lower than expected mechanical reinforcement of the polymer is achieved. Additionally, large aggregates may also lower the strength of the material by providing defect sites for mechanical failure. Therefore the development of techniques that would allow the formation of composites with high loadings of well-dispersed nanotubes is of great interest.

### Functionalization of Nanotubes

In recent years, researchers have demonstrated the ability to modify the carbon–carbon double bonds in the nanotubes and introduce functionalities that improve solubility and reduce aggregation.<sup>[23–41]</sup> A widely used modification strategy is the formation of carboxylic acids on the ends and/or sidewalls of the

<sup>a</sup>For reviews on the formation of thin films via the alternate adsorption of polyionic species, see Refs.<sup>[6,7]</sup>

nanotubes by chemical oxidation followed by further manipulation.<sup>[30–36]</sup> It has been shown that surfactant molecules and polymers can be attached to oxidized nanotubes either via zwitterionic complexation<sup>[31]</sup> or directly by converting the carboxylic acids to the corresponding esters or amides.<sup>[32–36]</sup> The presence of carboxylic acid sites on the nanotubes has also opened up the possibility of “assembling” nanotube structures.<sup>[37–41]</sup> By either attaching alkylthiol groups to the acid groups through an amide linkage<sup>[37]</sup> or by utilizing acid–metal chelation chemistry,<sup>[38–40]</sup> it has been possible to assemble shortened SWNTs vertically onto metal surfaces. The ability of these acid groups to allow oxidized SWNT bundles to act as polyanionic species and function as nanoscale building blocks within an electrostatic-based thin-film formation procedure will be discussed.<sup>[4,5]</sup>

### Electrostatic Film Formation

The formation of thin composite films via the sequential adsorption of oppositely charged species (polymeric or inorganic) has been shown to be a very versatile method of forming many types of technologically relevant structures (e.g., light-emitting diodes, humidity sensor, separation membranes, etc.)<sup>[42–50]</sup> (Scheme 1). This method of forming polymer/SWNT composites provides a number of important advantages over bulk processing techniques. First, it is possible to form films with high nanotube loading (vide infra), although the adsorption occurs from a dilute solution, helping to overcome the issue of nanotube solubility. Second, the adsorption of each component occurs from a separate solution, so the difficulty of finding a common solvent for both the nanotube and the polymer is removed. Finally, because the film is made in a stepwise manner, the morphology of the film at any point during its formation can be determined by techniques such as atomic force microscopy and

**Scheme 1** Schematic representation of the formation of a thin polymer film by the sequential adsorption of oppositely charged polyelectrolytes onto a substrate.

scanning electron microscopy (SEM), providing a clear indication of nanotube dimensions (bundle size and lengths), uniformity of surface coverage, and presence or absence of aggregates.

### Formation of Porous Polyelectrolyte/Single-Walled Carbon Nanotube Films

To assemble a polyelectrolyte/SWNT film, we first treated a silanol-bearing silicon wafer with the cationic polyelectrolyte poly(diallyldimethylammonium chloride) (PDDA).<sup>[4]</sup> The PDDA-treated wafer was then placed into a dilute *N,N*-dimethylformamide (DMF) suspension of purified HiPco nanotubes.<sup>[4]</sup> Atomic force microscopy (AFM, tapping-mode) images of the SWNTs-treated surface revealed the adsorption of a uniform and fairly dense layer of mostly SWNT bundles (5–10 nm diameter) 1–3  $\mu\text{m}$  in length (Fig. 1A). Spectroscopic characterization (X-ray photoelectron spectroscopy, Raman, UV–vis–NIR) of the nanotube bundles suggested a core–shell structure to the bundles—an inner core of pristine nanotubes surrounded by a layer of oxidized materials (nanotube or amorphous-like).<sup>[4]</sup> The reported procedure used to purify HiPco nanotubes<sup>[51]</sup> involves the oxidation of the amorphous carbon at elevated temperature, treatment with hydrochloric acid to remove the metal catalyst, and then a high-temperature annealing step

**Fig. 1** Tapping-mode AFM images of a PDDA/SWNT multilayer film prepared on a silicon wafer after various numbers of adsorption treatments: (A) PDDA/SWNT; (B) (PDDA/SWNT)<sub>3</sub>; (C) (PDDA/SWNT)<sub>6</sub>; (D) (PDDA/SWNT)<sub>9</sub>. Images are 5  $\mu\text{m}^2$  and the *z* scale in all images is 50 nm. *Source:* From Ref.<sup>[4]</sup>.

in argon to remove the oxidized groups and aromatize the nanotubes. We believe that in the case of our sample, the annealing step was insufficient to completely remove all oxidized defects present on the nanotubes. Therefore a fraction of nanotubes retained sufficient anionic character to adsorb onto a positively charged surface. While the data presented in this review concerning our research utilizes nanotubes adsorbed from this batch of purified HiPco nanotubes, for the ease of comparison, we have also been able to increase the concentration of oxidized bundles using a bulk-oxidation process. To minimize damage to the extended  $\pi$ -system, responsible for the remarkable properties of nanotubes, great care must be taken during the bulk-oxidation step to limit the number of acid sites to only that sufficient to allow for electrostatic adsorption.

Interestingly, repetitive treatment of a SWNT-terminated film with PDDA, followed again by SWNTs, produced negligible film growth. It is well known that the addition of a salt to a polyelectrolyte solution increases the amount of polyelectrolyte adsorbed per treatment by inducing the polyelectrolyte chains to adopt a globular morphology.<sup>[52–54]</sup> Hence the PDDA adsorption step was repeated with the addition of NaCl (1 M). Images of a PDDA/SWNT film after two additional PDDA–NaCl/SWNT treatments clearly indicated the buildup of a thicker layer of SWNTs on the substrate surface and that the film appeared to be porous (Fig. 1B). Compared to the sharp features of the initially adsorbed bundles (Fig. 1A), the bundles in Fig. 1B appeared to be covered with a layer of beads, indicating that PDDA was adsorbing in globular form to oxidized areas along the bundle length and not as a thin uniform layer. After six and nine adsorption cycles (Fig. 1C,D), AFM imaging revealed continued growth of a porous film. Additional confirmation of film uniformity and morphology was achieved from scanning electron microscopy performed on the nine-bilayer film. These images showed that a uniform film covered the entire silicon wafer (Fig. 2, top) and confirmed that the film was indeed porous (Fig. 2, bottom). The stepwise assembly of a 10-cycle film grown on a quartz slide was also monitored by UV–vis–NIR spectrophotometry. This experiment not only demonstrated that nanotube adsorption from cycle to cycle was reproducible but also that the adsorbed nanotube bundles had the same absorbance signature as that reported in the literature for purified HiPco nanotubes (Fig. 3).<sup>[51]</sup>

### Formation of Dense Polyelectrolyte/Single-Walled Carbon Nanotube Films

With porous films resulting from the sequential adsorption of PDDA followed by SWNTs onto a

**Fig. 2** Scanning electron micrographs of a (PDDA/SWNT)<sub>9</sub> film showing film uniformity (top) and porosity (bottom).

surface, we turned our attention to modifying our adsorption protocol to permit the formation of dense films. As the nanotube adsorption onto the initial PDDA-treated surface results in approximately 15% surface coverage (Fig. 1A), we envisioned that it should be possible to adsorb the negatively charged polyelectrolyte, poly(styrene sulfonate) (PSS), onto the non-SWNT covered areas. After the PSS adsorption step, the film could then be subjected to additional PDDA/PSS treatments until the areas between the nanotube bundles are filled in, resulting in a uniform dense film. A schematic representation of this method of forming dense polyelectrolyte/SWNT films by “filling in the gaps” between the adsorbed nanotubes is shown in Scheme 2. With nanotube adsorption occurring onto a “pristine” polyelectrolyte layer at each adsorption step, this method should allow: 1) the concentration of nanotubes within each layer to be controlled from ~1% to 15% by varying the adsorption time; and 2) the vertical placement of nanotubes within the film to be controlled by increasing the number of PSS/PDDA treatments used to fill in the film.

**Fig. 3** Measured UV-Vis-NIR absorbance after each PDDA/SWNT treatment for a 10-cycle film deposited on a quartz slide. The inset shows the measured absorbance at 1349 nm vs. the number of adsorption treatments; the line is a linear least-squares fit to the data. *Source:* From Ref.<sup>[4]</sup>.

**Scheme 2** Schematic representation of a method to form dense polyelectrolyte/SWNT multilayer films.

Atomic force microscopy images of a film prepared using this technique are shown in Fig. 4. A PDDA/SWNT-terminated film (Fig. 4A) was repeatedly treated with 1 wt.% aqueous solutions of PSS followed by PDDA (no NaCl was present in these solutions) until three PSS/PDDA bilayers were deposited. Images of the resultant film revealed a fairly uniform layer of polyelectrolyte with some areas indicating the presence of underlying SWNT bundles (Fig. 4B). Further treatment of the film with SWNTs, (PSS/PDDA)<sub>3</sub>, and then SWNTs demonstrated the reproducibility of both adsorbing SWNTs onto a dense film (Fig. 4C,E) and the ability to fill in the areas between the bundles with polyelectrolyte (Fig. 4D). Scanning electron microscopy imaging of the resultant PDDA/SWNT/[(PSS/PDDA)<sub>3</sub>/SWNT]<sub>2</sub> film indicated that the SWNT layer was uniformly deposited over the entire film surface (~1 × 3 cm).

In parallel to our work, Mamedov et al.<sup>[5]</sup> also reported a method of forming dense polymer/SWNT films using electrostatic interactions. In their study, SWNTs synthesized from the laser ablation of metal-doped carbon rods were refluxed in 65% HNO<sub>3</sub> under sonication to produce oxidized nanotubes that were stable in aqueous solution. Atomic force microscopy imaging revealed that the oxidized material was a mixture of individual nanotubes and 4–9 nm bundles with lengths of a few microns. As expected for water-soluble nanotubes, the UV-vis absorbance lacked the fine structure associated with pristine nanotubes. In contrast to our use of the fully quaternized PDDA, poly(ethyleneimine) (PEI), a polymer in which the degree of amine ionization can be controlled by pH, was utilized. Reminiscent of the difficulties that we incurred in

Polyelectrolyte - Polymer

**Fig. 4** Tapping-mode AFM images of a multilayer film prepared on a silicon wafer after various adsorption treatments: (A) PDDA/SWNT; (B) (PSS/PDDA)<sub>3</sub>; (C) SWNT; (D) (PSS/PDDA)<sub>3</sub>; and (E) SWNT. The final film structure is PDDA/SWNT/[(PSS/PDDA)<sub>3</sub>/SWNT]<sub>2</sub>. Images are 5 μm<sup>2</sup> and the *z* scale in all images is 50 nm.

assembling PDDA/SWNTs without NaCl, Mamedov et al. reported the need to apply a PEI/poly(acrylic acid) (PAA) layer after every five PEI/SWNT treatments to improve linear film growth. Although it was reported that the films prepared in the study contained ~50% SWNTs from the integration of carbon and nitrogen energy dispersive X-ray (EDS) peaks, the published microscopy images (AFM, SEM, TEM) do not support such a high SWNT loading. We believe that the AFM image of the (PEI/PAA)-(PEI/SWNT)<sub>5</sub> film suggests that the loading was more likely in the 10–15% range (Fig. 1C in Ref.<sup>[51]</sup>) and consistent with our results.<sup>b</sup>

<sup>b</sup>That apparent discrepancy between the SWNT loading estimated from EDS and our interpretation of the microscopy images may reflect the assumptions made in the EDS analysis regarding the amount of PEI, PAA, SWNT, and even glutaraldehyde present within the film.

A benefit of using PEI for film formation was the ability to cross-link the assembled film. First, the amine groups on the PEI and the acid groups in the SWNTs and the PAA were allowed to react at 120°C to form amide linkages, and then the remaining amine groups were cross-linked by treating with glutaraldehyde. After removal of the PEI-PAA-SWNT cross-linked film from the silicon wafer by treatment with hydrofluoric acid, SEM imaging revealed a uniform freestanding film with no evidence of nanotube aggregation. Mechanical analysis of the resultant freestanding film demonstrated a dramatic increase in tensile strength compared to a non-cross-linked polyelectrolyte film (PEI/PAA). Unfortunately, the lack of cross-linking in the PEI/PAA film does not allow the effect of only SWNT incorporation in the polymer matrix to be quantified.

### Langmuir-Blodgett Formation of Polymer/Single-Walled Carbon Nanotube Films

An alternative method recently reported to prepare thin polymer/SWNT films involves the use of multi-layer Langmuir-Blodgett (LB) technology.<sup>[7,8]</sup> Formation of films by the LB method involves forming a dense molecular film at the water/air interface by compression, followed by transfer of the film to a hydrophobic substrate.<sup>[55]</sup> Repetition of the procedure can result in the formation of a uniform film. In both studies reported, oxidatively shortened SWNTs were functionalized with octadecyl groups and dissolved in a chloroform solution of poly(*n*-dodecylacrylamide). The polymer/SWNT solution was then spread on top of a water layer and compressed to form a film. Although UV-vis-NIR data demonstrated the repeated incorporation of SWNTs within the deposited polymer film in both studies, the reports lacked microscopy illustrating the concentration and uniformity of the incorporated SWNTs. Because the LB method requires the use of a polymer/SWNT solution, it is hampered by the same difficulties faced by solution mixing and in situ polymerization techniques (i.e., formation of a stable solution containing a high nanotube to polymer ratio without aggregation).

### CONCLUSION

This entry has reviewed recent developments of incorporating single-walled carbon nanotubes within thin polymer films via the sequential adsorption of poly-ionic species by utilizing oxidized SWNT bundles as nanoscale polyanionic building blocks. The use of a sequential adsorption protocol solves a major difficulty in forming polymer/SWNT composites, the ability to

uniformly disperse the nanotubes within the polymer matrix. Depending on the adsorption regime chosen to form the polyelectrolyte/SWNT film, it is possible to assemble either porous or dense films containing a uniform distribution of SWNT bundles with loadings of up to ~15%. Using a protocol in which the assembled polymer/SWNT film could be cross-linked and then separated from its support, it has also been shown that the mechanical properties are increased compared to non-cross-linked polyelectrolyte films. Approaches for the assembly of polymer/SWNT films using the Langmuir–Blodgett method have also been reported. As the technique requires the use of a polymer/SWNT solution in film formation, this will probably make this technique less generally useful than the sequential adsorption protocol.

# Polyelectrolyte–Surfactant Complex Nanoparticles

Hans-Peter Hentze

Department of Chemical Engineering, University of Delaware,  
Newark, Delaware, U.S.A.

## INTRODUCTION

A variety of different colloidal systems can be produced by interaction between polyelectrolytes and oppositely charged surfactants. These complexes have attracted considerable interest because of their importance for both science and industrial applications.

By interaction of two oppositely charged polyelectrolytes, polyelectrolyte–polyelectrolyte complexes (PECs, or so-called symplexes) are formed. These PECs can be loose aggregates or well-defined nanoparticles.<sup>[1]</sup> In a similar way polyelectrolytes form complexes with oppositely charged surfactants and polyelectrolyte–surfactant complexes (PSCs) are obtained.<sup>[2,3]</sup> Here the mechanism of complex formation is not only based on electrostatic interactions and entropic factors, but also on the hydrophobic interaction between the surfactant tails. At surfactant concentrations below the critical micelle concentration (CMC), complex formation of polyelectrolytes with oppositely charged surfactants occurs. With increasing surfactant chain lengths, the formation of surfactant patches along the polyelectrolyte chain can be expected, because owing to hydrophobic interactions the preferred complexation binding site is the next closest position to an occupied site. This results in a zipperlike mechanism of polyelectrolyte–surfactant complex formation.<sup>[4]</sup> Typically three-dimensional networks form at concentrations above the CMC, where polyelectrolyte chains bridge discrete micelles without penetrating them.<sup>[5,6]</sup> At even higher surfactant concentrations, when all charges of the polyion are neutralized, polyelectrolyte–surfactant complexes usually precipitate from solution.<sup>[2,3,7]</sup> These bulk materials have a liquid crystalline-like mesostructure and display long-range order on the nanometer scale. The interaction between polyions and oppositely charged surfactants is a cooperative process in which the ionic head groups of the surfactant bind to the polyion, while the hydrophobic surfactant tails segregate into a hydrophobic microphase. Similar to amphiphilic block copolymers, this microphase separation occurs without macroscopic demixing.

One problem with most such polyelectrolyte–surfactant complexes is that they are usually

water-insoluble solids or semisolids and not suitable for particle applications. Within the last few years, different techniques of PSC nanoparticle synthesis have been developed to overcome this problem. These complexes are, unlike PSC bulk materials, redispersable in water or organic solvents as discrete nanoparticles without dissociation. For synthesis of PSC nanoparticles, polyelectrolytes that exhibit additional molecular entities have to be used, which provide solubility even after stoichiometric complexation and neutralization of all charges. In this way, particles are obtained that exhibit spherical core–shell structures, cylindrical or disk-shaped morphologies, or hollow spheres like vesicles. Whereas some of these morphologies appear to be equilibrium structures, others are non-equilibrium structures. The size, solubility, and morphology of PSC nanoparticles depend strongly on the molecular structure of the polyelectrolyte, the block ionomer lengths, the block length ratios, the structure and type of surfactant, and sometimes also on the way of preparation. Potential applications for this relatively new class of materials are drug and gene delivery, amphiphilic particles, and depot systems.<sup>[8,9]</sup>

## COMPLEXATION OF DOUBLE-HYDROPHILIC BLOCK COPOLYMERS—VARIOUS NANOPARTICLE MORPHOLOGIES

A very interesting family of polymers are double-hydrophilic block copolymers.<sup>[10]</sup> These consist of two covalently linked hydrophilic polymer block segments, which are chemically not equivalent, e.g., poly(ethylene oxide)-*b*-poly(sodium methacrylate). Double-hydrophilic block copolymers that contain a polymer block that is a polyelectrolyte are called block ionomers.

For the first time, redispersable nanoparticles of block ionomer–surfactant complexes have been obtained by complexation of poly(ethylene oxide)-*b*-poly(sodium methacrylate) (PEO-*b*-PMANa) with cetylpyridinium cations.<sup>[11]</sup> The segment lengths of the block ionomer were 176 and 186 repeating units for PEO and PMANa, respectively. Different aggregate morphologies could be distinguished within three

**Fig. 1** TEM micrograph of vesicles formed by the complex of PEO-*b*-PMANa with C<sub>16</sub>PyBr. *Source:* From Ref.<sup>[11]</sup>.

different surfactant concentration regions: At molar surfactant concentrations below the concentration of anionic polyion charges, the surfactant cetylpyridinium bromide (C<sub>16</sub>PyBr) binds electrostatically to the polyion and soluble complexes with negative  $\zeta$ -potentials were observed. Also, the stoichiometric and electrostatic neutral ( $\zeta = 0$ ) complexes were soluble and formed monodisperse nanoparticles with a diameter of 67 nm, as shown by dynamic light scattering (DLS) and transmission electron microscopy (TEM). A TEM micrograph is shown in Fig. 1. These discrete PSC complexes were first believed to exhibit a core-shell structure, where the core is formed by C<sub>16</sub>PyBr neutralized polyions, and the shell of PEO block segments. Later studies suggested a vesicular morphology.<sup>[12]</sup> At higher surfactant concentrations excess surfactant is incorporated into the particles, resulting in a positive  $\zeta$ -potential. The observed particles combine the properties of amphiphilic block copolymers and polyelectrolyte surfactant complexes, as they spontaneously form stable, water-soluble, and microphase separated aggregates.

Similar to mixtures of cationic and anionic single-tail surfactants,<sup>[13]</sup> spontaneous formation of vesicles is observed for the complexation of PEO-*b*-PMANa block ionomers with alkyltrimethylammonium surfactants [e.g., tetradecylammonium bromide (TTAB) or cetyltrimethylammonium bromide (CTAB)].<sup>[12]</sup> In contrast, complexation of the homopolymer PMANa with the same surfactants resulted in the formation of water-insoluble bulk materials. The wall of the PSC vesicles is composed of surfactant-neutralized polyion surrounded by the hydrophilic PEO shell, which sterically stabilizes the complexes in aqueous dispersions. The vesicular solutions are transparent or slightly opalescent. Vesicle diameters varied between 85 and

120 nm and increased with increasing chain length of the surfactant. The obtained dispersions are very stable and efficiently encapsulate and retain hydrophilic molecules in the internal aqueous volume.

The influence of the block ionomer block lengths and the surfactant structure on the solubility of PSC nanoparticles was also systematically investigated.<sup>[14]</sup> Therefore, complexation of a variety of PEO-*b*-PMANa block copolymers was performed with single-tail, double-tail, and triple-tail tetraalkylammonium surfactants. It was found that a minimum block length of PEO and a high enough block length ratio of PEO/PMANa are necessary to induce sufficient sterical stabilization in aqueous dispersions. Complex formation with stoichiometric amounts of the single-tail surfactants CTAB or C<sub>16</sub>PyBr resulted in rather small and monodisperse aggregates. These systems are believed to be in dynamic equilibrium with surfactant monomers in the dispersion. The critical aggregation concentration (CAC) was two to three orders of magnitude lower than the corresponding CMC. In contrast, the aggregate size of complexes formed with double-tailed surfactants [e.g., didodecyltrimethylammonium bromide (DDAB)] depended strongly on the way of preparation. This non-equilibrium behavior can be explained by the formation of preformed, membranelike surfactant aggregates, which is typical for double-tail surfactants. As is the case for single-tail surfactants, for triple-tail surfactants the formation of the aggregates is primarily controlled by the block ionomer structure and composition of the mixture. Different core morphologies can be expected for complexation with single- and triple-tail surfactants owing to the rather different packing parameters.

Not only linear block copolymers, but also grafted copolymers were used for PSC nanoparticle formation.<sup>[15]</sup> Unlike the vesicular morphologies formed by linear block copolymers, core-shell particles were obtained by complexation of poly(ethylene oxide)-*g*-poly(ethylene imine) (PEO-*g*-PEI) with anionic surfactants [e.g., sodium dodecyl sulfate (SDS) or sodium tetradecyl sulfate (TDS)]. In these micelle-like aggregates, apparently the hydrophobic core from the surfactant-neutralized PEI block is surrounded by the hydrophilic corona of PEO chains stabilizing the particles in aqueous media. The observed particle sizes, as determined by DLS and confirmed by TEM, are about 40–50 nm. Therefore, their size is comparable with micelle-like aggregates of amphiphilic block copolymers. The CAC was determined by fluorescence measurements using pyrene as a probe. CAC values were about two magnitudes lower than the corresponding CMC values of the pure surfactant. As the size of the obtained PSC particles is independent of the way of preparation, the complexes appear to be in equilibrium with unbound surfactants. With

increasing chain length of the anionic surfactants, excess surfactant was incorporated in the complexes, resulting in particles with negative  $\zeta$ -potentials.

Spherical core–shell morphologies can also be obtained by complexation of poly(ethylene oxide)-b-poly(ethylene imine) containing branched poly(ethylene imine) segments (PEO-b-PEI<sub>br</sub>) with the surfactant dodecanoic acid (C<sub>12</sub>).<sup>[16]</sup> In contrast, prolate particles can be obtained by complexation of the linear block copolymer PEO-b-PEI<sub>li</sub>. Even more elongated are the needlelike particles formed by C<sub>12</sub> and a PEO-b-PEI block copolymer with a cyclic architecture of the PEI segment (PEO-b-PEI<sub>cy</sub>). All these particles formed by C<sub>12</sub> and PEO-b-PEI block copolymers with a linear, branched, or cyclic PEI architecture exhibit a core–shell structure, as shown by atomic force microscopy (AFM). The core consists of poly(ethylene imine) dodecanoate surrounded by a corona of poly(ethylene oxide). All particles investigated in this study have an average size of about 200 nm (Fig. 2). Small-angle X-ray scattering (SAXS) of dried dispersions revealed that the complex formed with PEO-b-PEI<sub>cy</sub> has a lamellar morphology, while the ones of PEO-b-PEI<sub>li</sub> and PEO-b-PEI<sub>br</sub> show a lamellar-*within*-lamellar morphology.

pH-sensitive core–shell particles have been obtained in aqueous dispersions of poly(ethylene oxide)-b-poly(L-lysine) (PEO-b-PLL) complexes with retinoic acid.<sup>[17]</sup> Because of its amphiphilic properties, this vitamin A analogue can be considered as a surfactant. The complexes were characterized by SAXS as bulk material, as well as in aqueous dispersions. The diffractograms indicate that the cores of these complexes exhibit a smectic-A-like structure. By circular dichroism, an  $\alpha$ -helical conformation of L-lysine chains was found for pH values above 9. It was assumed that this conformation is stabilized by the PEO shell, as well as

**Fig. 2** Dried dispersions of the complex of PEO–PEI<sub>br</sub> with C12 form needlelike particles. *Source:* From Ref.<sup>[16]</sup>.

by protecting retinoate molecules. Below a pH of 3.7, a random coil structure is present, while mixtures of random coils and  $\alpha$ -helices form in the intermediate pH range. The complexes can be considered as a model for pH-sensitive drug-carrier systems.

Nanoparticle dispersions of polyelectrolyte–surfactant complexes have also been made from polyelectrolyte homopolymers.<sup>[18]</sup> Non-stoichiometric complexes containing excess polyelectrolyte or surfactant are generally soluble in water, and sometimes they form well-defined, discrete aggregates. Especially, PSCs of biopolymers, such as polysaccharides or polypeptides, have been investigated for drug and gene delivery purposes. As their stoichiometric, electro-neutral complexes are not redispersible and water insoluble they are not discussed in detail in this entry.

### “REVERSE” CORE–SHELL STRUCTURES BY COMPLEXATION OF HYDROPHILIC–HYDROPHOBIC BLOCK IONOMERS

In contrast to the core–shell structure of complexes from double-hydrophilic block ionomers, complexation of hydrophilic–hydrophobic block copolymers results in “reverse” morphologies—here the non-ionic, hydrophobic block segments form the core, which is surrounded by a surfactant neutralized polyion shell. For this reason the particles can be redispersed only in solvents that are also solvents of the polyelectrolyte homopolymer complex. A major difference compared to double-hydrophilic block copolymers is the aggregation of the polyion before addition of surfactant and complexation. Micelle-like aggregates are formed in aqueous solution owing to microphase separation of the hydrophobic polymer segments. This factor might limit the possibilities of this approach to form equilibrium structures.

One example is the synthesis of nanoparticles from polystyrene-b-poly(sodium acrylate) (PS-b-PAA<sup>−</sup>) and *N*-cetylpyridinium cations (C<sub>16</sub>Py<sup>+</sup>), which precipitate from aqueous solution at stoichiometric mixing ratios of surfactant and polyion units.<sup>[19]</sup> The formed precipitate is insoluble in tetrahydrofuran and toluene, which are good solvents for PS but non-solvents for PAA<sup>−</sup>/C<sub>16</sub>Py<sup>+</sup> complexes. Instead, chloroform, a good solvent for PAA<sup>−</sup>/C<sub>16</sub>Py<sup>+</sup>, could be used for redispersion. This clearly indicates a core–shell structure with a polystyrene core surrounded by surfactant neutralized polyion segments that stabilize the particles in solution.

Similar results were obtained for complexes from poly( $\alpha$ -methylstyrene)-b-poly(*N*-ethyl-4-vinylpyridinium bromide) (PMeS-b-PE4VP) and sodium bis(2-ethylhexyl)sulfosuccinate (AOT).<sup>[20]</sup> The precipitated complexes can incorporate small excess of surfactant.

Preliminary studies showed that PSC formed by the homopolymer PE4VP and AOT were soluble in various organic solvents without dissociation of the complex, e.g., cyclohexane, chloroform, and acetone. Neither of these solvents dissolves the block ionomer PMS-b-PE4VP, but all of them are good solvents for the complexes of the block ionomer with AOT. Again, this clearly hints on the described “reverse” core–shell morphology. The particle size of the redispersed PSCs in hexane/cosolvent mixtures is about 70 nm in diameter. The spherical morphology and the size of the particles were confirmed by TEM.

## COMPLEXATION OF POLYAMPHOLYTES

Polyampholytes are polyelectrolytes that contain both anionic and cationic repeating units. Complexes of ternary polyampholytes with cationic, anionic, and neutral repeating units with perfluorododecanoic acid (FC<sub>12</sub>) have been synthesized.<sup>[21]</sup> The obtained nanoparticles are highly fluorinated and stable in aqueous dispersions. By dynamic light scattering, it was shown that discrete particles with hydrodynamic diameters of 20–35 nm were formed. The diameter and the stability of the dispersions depend strongly on the composition

of the polyampholyte. More insight into the particles' morphology was gained by small-angle X-ray scattering. The geometry of the dispersed particles was characterized by indirect Fourier transform method.<sup>[22]</sup> Disk-shaped aggregates with a diameter of 30 nm were formed by complexes from the polyampholyte with the highest content of cationic repeating units. Complexes of polyampholytes with a lower content of cationic charges formed cylindrical aggregates with a length of about 25 nm. A partially interdigitated arrangement of the surfactant tails was assumed, owing to the small thickness of the disklike aggregates (2.2 nm) and the small diameter of the formed cylinders (3 nm). An overview of the different morphologies of PSC nanoparticles formed by the different polyion precursors is given in Table 1.

## HOLLOW SPHERES FROM POLYELECTROLYTE–SURFACTANT COMPLEX NANOPARTICLES

Besides vesicle formation, hollow spheres of PSCs can be also prepared by stepwise complexation and selective dissociation of poly(ethylene imine).<sup>[23]</sup> First, non-stoichiometric complexes of PEI homopolymer

**Table 1** Overview of the different types of polyion precursors used for complexation of oppositely charged surfactants, and the resulting nanoparticle morphologies

with dodecanoic acid were formed. The particles display a positively charged shell of free ethylene imine units and a PEI–dodecanoic acid core. Second, poly(ethylene oxide)-*b*-poly(methacrylic acid) block copolymer with a phosphonized carboxylic acid end group was added, resulting in particles with a core of PEI–dodecanoic acid and a shell of a phosphonized block ionomer/PEI complex. By decreasing the pH value below the  $pK_a$  value of dodecanoic acid, the PEI–dodecanoic acid core was selectively dissolved. The phosphonate–PEI shell was left unchanged, forming hollow spheres with a diameter of about 400 nm. TEM micrographs reveal a porous structure of the formed PSC shells, which might have formed owing to the high osmotic pressure inside the hollow spheres induced by dissociation of the core.

### COMPLEXATION OF PREFORMED CORE–SHELL LATEX PARTICLES

Core–shell particles of PSC complexes have also been made from preformed latex particles.<sup>[24]</sup> For this purpose core–shell latex particles with a polystyrene core and a poly(ethylene oxide) shell were synthesized by cross-linking emulsion polymerization of styrene, using a PEO macroinitiator system. Subsequent sulfonation of the PS core resulted in particles with a polyelectrolyte core of poly(styrene sulfonate) surrounded by a PEO corona (PEO-*b*-PSS). Complexation with tetraalkylammonium surfactants [e.g., dodecyltrimethylammonium bromide (DOTAB)] induced microphase separation within the core. Hereby polymer latex particles with a mesostructured core and a diameter of about 400 nm were obtained (Fig. 3). By small-angle

**Fig. 3** Micrograph of a microtomed sample of preformed latex particles with a PSS-TTAB core and a PEO shell. Source: Ref.<sup>[24]</sup>.

X-ray scattering, it was shown that the characteristic length of the formed core mesophase varied between 2 and 4 nm and increased with increasing chain length of the cationic surfactant.

### CONCLUSION

Complexation of block ionomers, polyampholytes, or preformed core–shell lattices enables the synthesis of well-defined, monodisperse PSC nanoparticles. Depending on the particular system, these nanoparticles form dispersions in water or organic solvents. In this way, particle applications of stoichiometric PSC have also been made possible.

Compared to bulk polyelectrolyte–surfactant complexes, the synthesis of PSC nanoparticles largely extends the opportunities of structuring nanoparticles. Morphological investigations indicate that self-assembly in these systems mainly depends on the block copolymer architecture. By using different types of polyion precursors, complexation with surfactants results in cylindrical, disk-shaped, prolate, spherical, and vesicular polymer structures. The obtained nanoparticles exhibit a long-range ordered inner mesostructure owing to microphase separation of the surfactant tails from the surfactant-neutralized polyion segments. Potential applications are especially drug and gene release systems.

## INTRODUCTION

The self-assembly of block copolymers has received considerable attention not only regarding its applications as functional materials, but also from a fundamental viewpoint. It is well known that the self-assemblies of block copolymers take various morphologies, including spherical particles, rod structures, and lamellar structures. Many studies on the block copolymer's self-assembly as spherical particles, i.e., polymeric micelles, which are characterized by a mesoscopic average diameter and a core–corona structure, have been reported. Recently, polyion complex (PIC) micelles were introduced as a new entity of polymeric micelles in aqueous medium. In this entry, we review the preparation and physicochemical properties of PIC micelles.

## PIC MICELLES

When water is used as the solvent, polymeric micelles are formed from hydrophilic–hydrophobic block copolymers driven by a hydrophobic interaction; in the formed micelles, a hydrophilic corona layer surrounds the core composed of hydrophobic segments. The formation of a corona of hydrophilic segments surrounding the core of the water-insoluble segments prevents progressive aggregation of the core and stabilizes the micelles of the block copolymers in the aqueous medium. The concept of polymeric micelle formation in an aqueous medium can be extended to include macromolecular association through a force other than hydrophobic interactions. We selected the electrostatic interaction in an aqueous medium and prepared a novel polymeric micelle system, the PIC micelle, from a pair of oppositely charged block copolymers (Fig. 1).

It is well known that an aqueous mixture of a pair of oppositely charged polyelectrolytes immediately forms visible aggregates, e.g., precipitates or coacervates, under an electrically neutral condition. In sharp contrast with this well-known phenomenon, a mixture of a pair of oppositely charged block copolymers with poly(ethylene glycol) (PEG) segments, i.e., PEG–poly( $\alpha,\beta$ -aspartic acid) block copolymer (PEG–PAA) with the PEG–poly(L-lysine) block copolymer (PEG–PLL) exhibits no precipitation even at a mixing ratio corresponding to electrical neutrality, and remains permanently transparent.<sup>[1]</sup> This is because of the formation of associates with a mesoscopic size range. The size of the formed associates is constant over a wide range of concentrations up to 1.0 wt%, and the associates also have a very small absolute zeta-potential value, suggesting that the PEG blocks effectively stabilizes the PIC core composed of PAA and PLL segments. In addition, the formed associates have an extremely narrow size distribution, which is comparable to that of natural viruses.<sup>[2]</sup> The associates have a core–corona architecture with a water-insoluble PIC formed from PAA and PLL segments, which are segregated as a core and separated from the aqueous medium by a corona composed of hydrophilic PEG segments. This type of associate was called a “polyion complex micelle” based on its structural similarity with a conventional block copolymer micelle.

The preparation procedure of PIC micelles by just mixing aqueous solutions containing oppositely charged components is simple and reproducible. It should be noted that in the case of polymeric micelles from block copolymers consisting of hydrophilic and hydrophobic segments, the exchange of solvent from the good solvent for both segments to water is usually needed to prepare the micelles with a well-defined core–corona structure; this can be done either by dialysis or by the drop-wise addition of water. The involvement

**Fig. 1** Concept of the formation of PIC micelles from a pair of oppositely charged block copolymers.

of the solvent exchange process, which is time dependent, often results in a broader distribution of the obtained micelles in terms of size and dispersion, especially for the kinetically frozen core segregation observed during the micellization of block copolymers with glassy segments. In contrast, the PIC micelle formation takes place in a buffered medium with a constant thermodynamic property. Consequently, the entire process of PIC micellization is thermodynamically regulated to give monodispersed micelles.

Polyion complex micelles were obtained from not only one pair of oppositely charged block copolymers, but also from a mixture of charged block copolymers with oppositely charged polyelectrolytes, including synthetic polymers, poly(amino acid)s, surfactants, enzymes, and DNA.<sup>[3–9]</sup> In this entry, we discuss the properties of the PIC micelles based mostly on our previous studies, in which PEG–PAA was used as an anionic block copolymer, and PEG–PLL and PLL were used as counter polymers. Because the complexation behavior and the properties of the polyion complexes generally depend on a specific combination in a pair of polyelectrolytes,<sup>[10]</sup> the properties of the PIC micelles might also depend on the combination selected for the pair of PIC core forming segments.

## PHYSICOCHEMICAL PROPERTIES OF PIC MICELLES<sup>[1,3,11]</sup>

### Hydrodynamic Radius of PIC Micelles Formed at Various Combinations

The PIC micelle solutions were prepared as follows: The PEG–PAA, PEG–PLL, and PLL block copolymers, in which the molecular weight of the PEG segment was fixed (5000 g/mol) and the polymerization degree (PD) of the charged segments was variable, were separately dissolved in sodium phosphate buffer (pH 7.4, 10 mM). The PEG–PAA solution was then added to the PEG–PLL or PLL solution to form

an electrically neutral mixture, corresponding to a (Asp):(Lys) = 1:1 ratio. The hydrodynamic radius of the PIC micelles prepared from various combinations of PEG–PAA and PEG–PLL or PLL was determined by dynamic light scattering (DLS) measurements. All combinations of PEG–PAA and PLL with varying lengths gave a sufficient scattering intensity to carry out the DLS measurements. However, for the PEG–PAA/PEG–PLL system, only a matched length pair gave an appreciable scattering intensity. It was significantly observed that there were lower scattering intensities for the combination of unmatched pairs compared with that for the matched combinations, indicating no formation of PIC micelles with a sufficiently large association number. As will be explained later, these length-unmatched pairs form associates with a minimal association number of PEG–PLL and PEG–PAA for charge compensation. All measurable combinations showed no angular dependence in the diffusion coefficient ( $D$ ), which is consistent with the assumed spherical shape. The formation of spherical micelles was also confirmed from the atomic force microscopy observations using mica as a support. Furthermore, the  $D$  values of the PIC micelles were independent of the concentration, suggesting the absence of secondary aggregates in the measured concentration region. Extrapolating the plots of the  $D$  values vs. concentration to zero concentration gave the  $D$  values at infinite dilution, from which the hydrodynamic radii ( $R_h$ ) were calculated using the Stokes–Einstein equation

$$R_h = k_b T / (6\pi\eta D)$$

where  $k_b$  is the Boltzmann constant,  $T$  is the absolute temperature, and  $\eta$  is the viscosity of the solvent. The  $R_h$  values are summarized in Table 1. The change in the  $R_h$  values with the length of the charged segments followed a different trend between PEG–PAA/PEG–PLL and PEG–PAA/PLL. In the case of PEG–PAA/PEG–PLL, the  $R_h$  values increased from 16 to 21 nm

**Table 1** Physicochemical properties of PIC micelles

PD of PAA	PD of PLL	$R_h$ (nm)	$R_g$ (m)	$R_g/R_h$	$M_{w,app}$ (g/mol)	Association number		
						PEG	PAA	PLL

37	45	24.7	18.7	0.757	4,490,000	253	253	208
37	82	24.5	18.6	0.759	4,510,000	255	255	117
78	20	24.2	18.0	0.744	7,470,000	307	307	1,197
78	45	24.5	18.6	0.759	7,540,000	303	303	525
78	82	24.3	18.2	0.749	7,510,000	304	304	289

with an increase in the length of the charged segments. On the other hand, the  $R_h$  values remained constant (24–25 nm) for the PEG-PAA/PLL regardless of the length of the charged segments.

### Critical Association Behavior

It is well known that polymeric micelles formed from block copolymers in selective solvents show a critical association behavior and have a characteristic critical micelle concentration. It was interesting to see whether the PIC micelles also show the critical association behavior. Also, the influence of the critical association concentration (CAC) should be taken into account for the detailed evaluation of the physicochemical properties of the PIC micelles based on static light scattering (SLS). The CAC was evaluated from the Debye plots of SLS expressed as the following equation, showing that the scattering intensity is a sensitive function of the weight-averaged molecular weight of the solute.<sup>[12]</sup>

$$KC/\Delta R(\theta) = 1/M_{w,app} + 2A_2C$$

where  $C$  is the concentration of the polymer,  $\Delta R(\theta)$  is the difference between the Rayleigh ratio of the

solution and that of the solvent,  $M_{w,app}$  is the apparent weight average molecular weight,  $A_2$  is the second virial coefficient, and  $K = [4\pi^2 n^2 (dn/dc)^2] / (N_A \lambda^4)$  ( $N_A$  is Avogadro's number). By monitoring the change in the  $KC/\Delta R(\theta)$  values with concentration, the weight-averaged molecular weight of the solute can be evaluated. In the case of the polymeric micelles having a critical association behavior, an increase in the  $KC/\Delta R(\theta)$  values with a decrease in the concentration, i.e., negative  $A_2$  values, should be observed in a concentration region below the CAC owing to a decrease in the averaged molecular weight.<sup>[12]</sup> All combinations of the PIC micelles followed a straight line with only a slight increase in the  $KC/\Delta R(\theta)$  values with an increase in the concentration, reflecting the  $A_2$  value of the PIC micelles, in the measured range from 0.01 to 4.0 mg/ml. There was no sign of a change in the  $KC/\Delta R(\theta)$  values even in the very diluted region, suggesting that the PIC micelles studied here are extremely stable upon dilution. This stability against the dilution might depend on the combination selected for the pair of core-forming polyelectrolyte segments. Indeed, a critical association behavior was observed for the micelle system prepared from PEG-PAA and the chicken egg white lysozyme.<sup>[7,13]</sup>

### Determination of $M_{w,app}$ and $R_g$

The  $M_{w,app}$  and  $R_g$  values were directly determined from the Zimm plots of SLS (Table 1). Notably, the  $M_{w,app}$  values of the PEG-PAA/PEG-PLL system were significantly different between the length-matched pairs and unmatched pairs of the charged segments. In the case of the matched pairs, the  $M_{w,app}$  values clearly depend on the length of the charged segments and increased with an increase in the length of the charged segment from 500,000 to 3,270,000 g/mol. This corresponds to association numbers for PEG-PAA and PEG-PLL from 31 to 87 as seen in Table 1. On the other hand, the length-unmatched pairs had extremely lower  $M_{w,app}$  values compared to the matched pairs. It is worthy to mention that in every unmatched combination of the block copolymers, a longer chain always had the association number of 1.0, indicating that the PEG-PAA/PEG-PLL system with an unmatched pair always forms a complex having a minimum association number to compensate their charges. These minimal charge-neutralized complexes are unable to grow further into the larger PIC micelles. The difference in the growth of the association induced an interesting feature of the PIC micelle formation, i.e., chain-length recognition, as will be introduced later.

As seen in Table 1, the  $M_{w,app}$  values of PEG-PAA/PLL were independent of the length of the PLL segment and dependent only on the length of the PAA segment in PEG-PAA. The trend of the change in the  $M_{w,app}$  values with the length of the charged segment of the block copolymer was similar between the PEG-PAA/PEG-PLL and PEG-PAA/PLL systems. The PEG-PAA/PLL system has a significantly higher  $M_{w,app}$  value than the PEG-PAA/PEG-PLL system. This significant difference in  $M_{w,app}$  reflects the difference in the association number, which is determined by the balance of several factors including the core radius, the PEG density at the core-corona interface, and the conformation of PEG in the corona.

The  $R_g$  values in Table 1 followed a similar trend in terms of the chain-length dependency on the  $R_h$  values. The  $R_g$  values increased with an increase in the length of the charged segment for the length-matched PEG-PAA/PEG-PLL system, whereas they remained at the constant value of 18.5 nm for the PEG-PAA/PLL system. The ratios of the  $R_g$  to  $R_h$  values ( $R_g/R_h$ ) are also summarized in Table 1. It is known that the  $R_g/R_h$  ratios for a hard sphere and a star molecule without a definite core are 0.775<sup>[14]</sup> and 0.707,<sup>[15]</sup> respectively. Assuming that the PIC micelles consist of a PIC core with a non-negligible size and a PEG corona layer with a density variation in the radial direction, it was reasonable to obtain  $R_g/R_h$  ratios of 0.739 to 0.762, which are between the values assumed for a star molecule and a hard sphere.

### Calculation of the Core Radius and the PEG Density at an Interface between the Core and Corona

The core radius was calculated from the density of charged segments (PAA and PLL) based on the assumption that the water volume in the PIC core may be negligible. In the former case, the core radius ( $R_{core}$ ) can be calculated from the densities of the charged segments by the following equation

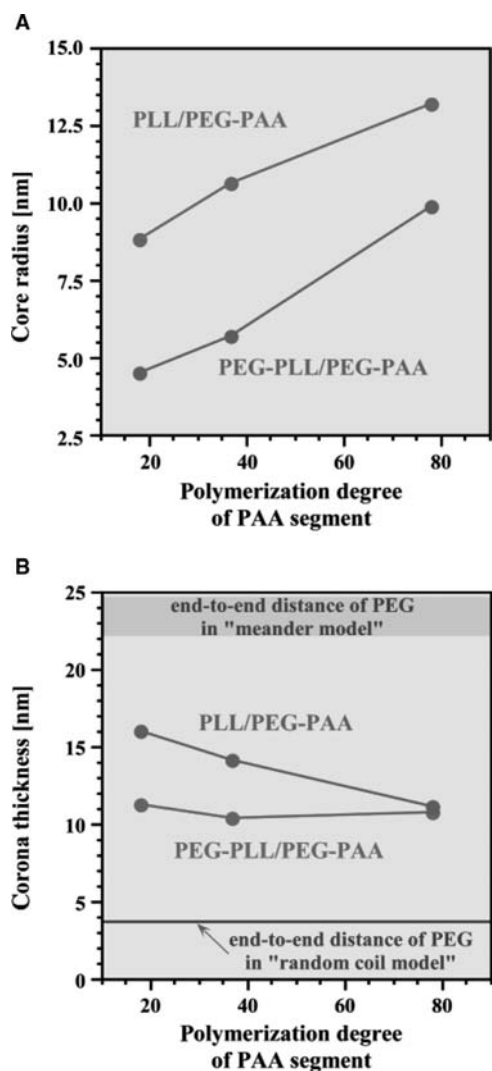

$$R_{core} = [(3/4\pi)V_{core}]^{1/3} = [(3/4\pi) \cdot (M_{w,PAA}/\rho_{PAA} + M_{w,PLL}/\rho_{PLL})/N_A]^{1/3}$$

where  $V_{core}$  is the core volume of a PIC micelle, and  $M_{w,i}$  are the weight-averaged molecular weights of the PAA and PLL segments, respectively, calculated from the  $M_{w,app}$  values and the weight fractions of each segment in the PIC micelles, and the  $\rho_i$  values are the densities of PAA and PLL, respectively. The density of PAA and PLL were determined from pycnometric measurements to be 1.084 and 1.093 g/ml, respectively. The calculated  $R_{core}$  values are shown in Fig. 2. The end-to-end distances of a fully expanded model of the poly( $\alpha$ -amino acid) segments with PDs of 18, 36, and 78 were calculated to be 9.9, 19.8, and 42.1 nm, respectively.<sup>[16]</sup> The obtained  $R_{core}$  values in Fig. 2 suggest that the charged segments in the core of the PIC micelle might not have a fully elongated conformation. For both the PEG-PAA/PEG-PLL and the PEG-PAA/PLL systems, the  $R_{core}$  values clearly increased as the PD of the PAA segment in PEG-PAA increased. The PEG-PAA/PLL system has a larger  $R_{core}$  value than the PEG-PAA/PEG-PLL system when the PAA length in PEG-PAA is identical. This might be attributable to the difference between the degree of freedom of PEG-PLL and PLL during the formation of the PIC micelle with a core-corona architecture.

Furthermore, the PEG density at a core-corona interface ( $\Phi_{PEG}$ ) was determined from the association number of the PEG segment ( $N_{PEG}$ ) and the  $R_{core}$  value using the following equation

$$\Phi_{PEG} = N_{PEG}/(4\pi R_{core}^2)$$

The calculated  $\Phi_{PEG}$  values for various combinations are shown in Fig. 3. Interestingly, the  $\Phi_{PEG}$  value decreased with an increase in the length of the PAA segment in PEG-PAA, although other factors such as the  $R_h$ ,  $R_g$ ,  $M_{w,app}$ , and  $R_{core}$  values were significantly different between the PEG-PAA/PEG-PLL and PEG-PAA/PLL systems. This strongly indicates that the  $\Phi_{PEG}$  value may be a crucial factor for determining the association process of the PIC micelles. The

**Fig. 2** Change in core radius and corona thickness with an increase in the PD of PAA segment in PEG-PAA.

$\Phi_{\text{PEG}}$  values decreased from 0.25 to 0.14 chain/nm<sup>2</sup> with an increase in the length of the PAA segments as shown in Fig. 3.

The conformation of the PEG segments in the corona layer might also influence the properties of the PIC micelles. To evaluate the change in the PEG conformation, the corona thickness ( $R_{\text{corona}}$ ) was calculated using the following equation

$$R_{\text{corona}} = R_{\text{h}} - R_{\text{core}}$$

The calculated  $R_{\text{corona}}$  values are also shown in Fig. 2. There were different trends for the change in the  $R_{\text{corona}}$  values between the PEG-PAA/PEG-PLL and PEG-PAA/PLL systems. The  $R_{\text{corona}}$  of PEG-PAA/PLL was dependent on the length of the PAA segments and decreased with an increase in the length

**Fig. 3** PEG density at core-corona interface.

of the PAA segments, although the  $R_{\text{corona}}$  of PEG-PAA/PEG-PLL remained constant in spite of any change in the  $\Phi_{\text{PEG}}$  values with the PD of the PAA segment. The corona thickness may be determined from the balance between the  $\Phi_{\text{PEG}}$  and the  $R_{\text{core}}$  values related to the curvature of the core. An increase in the  $\Phi_{\text{PEG}}$  and the  $R_{\text{core}}$  values oppositely influence the conformation of the PEG segments. Higher  $\Phi_{\text{PEG}}$  values induce a more elongated conformation to prevent the overlap of each PEG segment. On the other hand, a decrease in the  $R_{\text{core}}$  results in an increase in the curvature, allowing the PEG density in the corona layer to effectively decrease in the radial direction. For both the PEG-PAA/PEG-PLL and the PEG-PAA/PLL systems, a decrease in the length of the PAA segment in PEG-PAA results in the increased  $\Phi_{\text{PEG}}$  value and the decreased  $R_{\text{core}}$  value. Consequently, the opposite effects of the chain elongation and relaxation concomitantly work for the PEG segments. However, the change in the  $R_{\text{core}}$  values with the length of the charged segment of the block copolymer is more drastic for the PEG-PAA/PEG-PLL system than for the PEG-PAA/PLL system regardless of a similar trend in  $\Phi_{\text{PEG}}$  for both systems. For the PEG-PAA/PEG-PLL system, the effects of both an increased curvature because of the decreased  $R_{\text{core}}$  values and an increased  $\Phi_{\text{PEG}}$  value may compensate each other with a decrease in the length of the charged segment. On the other hand, in the case of the PEG-PAA/PLL system with a decreasing length of the PAA segment, the effect of an increased  $\Phi_{\text{PEG}}$  may be more significant than the effect of the increased curvature. Consequently, the  $R_{\text{corona}}$  value corresponding to the end-to-end distance of the PEG strands in the corona increased with a decrease in the length of the PAA segment in PEG-PAA.

## CHAIN-LENGTH RECOGNITION<sup>[17]</sup>

Molecular recognition and the resulting supramolecular assembly have received considerable attention in chemistry, biology, and applied fields. Carefully designed chemical architectures promote a precise molecular recognition, often leading to an assembly process. A common strategy to form supramolecular assemblies is the construction of spatially ordered networks of non-covalently bonded constituent molecules. Most of the studies in this area to date have focused on the design of spatially ordered structures where small differences in the steric factors of the constituent molecules significantly affect the thermodynamic stability and assembly of the system. Molecular recognition by length has been found to occur in the complexation process from the PEG-PAA and PEG-PLL systems.

The recognition of specific chain lengths upon the PIC micelle formation was directly confirmed by gel filtration chromatography (GFC) (Fig. 4). The gel filtration of the 1:1 mixture of PEG-PAA having different PAA lengths (the PDs of the PAA segments were 18 and 78, and code names were A-18 and A-78; based on content of Asp residue) provided a chromatogram with two clearly separated peaks corresponding to A-18 (elution volume: 17.4 ml) and A-78 (elution volume: 15.3 ml), respectively (Fig. 4A).

**Fig. 4** The GFC chromatograms for the mixture of PEG-PAA and PEG-PLL for varying combinations [(A) is the mixture of A-18 and A-78. (B) is PEG-PAA mixture (A) added C-18. (C) is PEG-PAA mixture (A) added C-78.] Source: From Ref.<sup>[17]</sup>.

A given amount of PEG-PLL having PLL with a PD of 18 (C-18) was then added to this mixture so as to neutralize 0.5 equivalents of Asp units in the solution. Complete disappearance of the A-18 peak from the chromatogram was observed, with the remaining A-78 peak totally intact without any change in the peak intensity (Fig. 4B). The peak corresponding to the PIC micelle was clearly observed in the exclusion volume of the chromatogram. Also, the chemical composition of the fractionated PIC micelle was determined by <sup>1</sup>H NMR in D<sub>2</sub>O containing 1.0 M NaCl, and the molar ratios for the Asp and Lys residues ([Asp]/[Lys]) in the PIC micelles were determined to be 1.0, and the observed ratio of PEG to the Asp and Lys residues was consistent with the calculated ratio assuming that the micelle exclusively includes the paired A-18 and C-18. Furthermore, the addition of PEG-PLL having PLL with a PD of 78 (C-78) to the mixture of A-18 and A-78 results in complete selection of A-78 as shown in Fig. 4C. The NMR analysis of the micelle fraction also revealed that the PIC micelle formation exclusively involves only A-78 and C-78. Thus, a pair of oppositely charged block

**Fig. 5** Schematic model for chain-length dependent recognition through the formation of PIC micelles. Source: From Ref.<sup>[17]</sup>.

copolymers exclusively selects matching partners with the same length of charged segments upon micellization.

As described above, the  $M_{w,app}$  values were quite different between the length-matched pairs and unmatched pairs of PEG–PAA/PEG–PLL. Although the matched pairs of PEG–PAA and PEG–PLL formed core–corona type multimolecular assemblies, i.e., PIC micelles, the unmatched pairs of PEG–PAA and PEG–PLL showed the formation of minimal charge-neutralized polyion complexes that were unable to grow further into larger PIC micelles (Fig. 5). Polymer complexes formed between unmatched pairs should be less stable than those formed with matched pairs, and consequently, in the competitive condition of coexisting matched and unmatched pairs, only the matched pairs form bimolecular complexes that grow into PIC micelles. The remaining block copolymers of unmatched length are left in the isolated form.

The key determinant in this recognition process is the strict phase separation between the PEG corona and PIC core domain, requiring regular alignment of the molecular junctions between PEG and charged segments at the interface of the two domains. Requirements for charge stoichiometry (neutralization) in the core is another essential factor in this recognition process. This eventually determines the number ratio of the participating polyanions and polycations in the core and restricts the spatial arrangement of segments in the core.

## CONCLUSIONS

We reviewed the preparation and physicochemical properties of PIC micelles in an aqueous medium. We first reported PIC micelles as a novel polymeric micelle system in 1995, using a pair of oppositely charged block copolymers. Since then, the research on the physicochemical characteristics of the PIC micelles continued in several research groups. An interesting feature of the PIC micelles, chain-length recognition, was found through fundamental studies. The length-selection property demonstrated with these flexible ionomer polymer strands provides a new approach for controlling the supramolecular assembly. Furthermore, PIC micelles have received considerable attention not only from fundamental viewpoints, but also in applied fields. In particular, the applications of PIC micelles in the biomedical field, including non-viral gene vectors have been previously reviewed.<sup>[12]</sup> Research continues on preparation and characterization of PIC micelles obtained from various combinations of polyelectrolytes.

## INTRODUCTION

This entry summarizes the recent advances in the synthesis of polymer–clay nanocomposite materials and polymer brushes on clay surfaces with the focus on the in situ polymerization method. This new type of composite materials is based on a wide range of polymers as the matrix and layered silicate clays as the reinforcing filler. Its advantages, structures, and synthesis routes as well as the special properties of layered silicate are briefly introduced. Among various synthesis methods including exfoliation–adsorption, melt intercalation, and in situ polymerization, detailed discussions are focused on the in situ polymerization approach, which is then categorized by the polymerization mechanism employed. A comprehensive coverage is given to the in situ free radical polymerization method, including free radical polymerization with original clay, organoclay modified with non-reactive ammonium cations or polymerizable surfactants, and clay intercalated with cationic initiator derivatives, i.e., the surface-initiated polymerization strategy. As different strategies applied by various studies are compared, the emphasis of the discussion is placed on the synthesis scheme and the resulting structure of the nanocomposites. Short discussions on polymer brushes and in situ living polymerization methods on clay particle surfaces are offered because of the limited number of related publications. From the standpoint of the category of polymeric materials, this review is primarily based on thermoplastic polymers that can be produced by polymerizing their vinyl monomers. Other materials from other in situ polymerization mechanisms, such as ring opening polymerization, are briefly introduced at the end of this entry.

## BACKGROUND

Polymer–clay nanocomposite (PCN) materials fall into the category of organic–inorganic hybrids consisting of organic polymers as the matrix and inorganic clay minerals as the reinforcing filler. The unique characteristics of PCN materials lie in the nanometer-scale mixing of the two components and the molecular-level interactions between them. They have a wide variety of highly improved mechanical, thermal, and barrier properties as compared with those of pure polymers and their macroscale counterparts, which was demonstrated in the seminal work on nylon 6-clay hybrids (NCHs) by Toyota researchers in the early 1990s (Table 1).<sup>[1–4]</sup>

### Properties of Layered Silicates

Polymer–clay nanocomposite materials are also usually referred to as polymer-layered silicate (PLS) nanocomposites because the inorganic fillers used are mostly natural or synthetic silicate materials such as montmorillonite, hectorite, laponite, fluorohectorite, etc. They possess a unique layered morphology of ordered stacks of quasi two-dimensional silicate sheets whose dimensions are about 1 nm in thickness and a few hundred nanometers in width and length. As illustrated in Fig. 1, the crystallographic structure in one single layer consists of an edge-shared octahedral sheet of alumina or magnesia sandwiched between two tetrahedral silica sheets. Metal ions such as Na<sup>+</sup>, Li<sup>+</sup>, and Ca<sup>2+</sup> usually occupy the interlayer spacings/galleries to counterbalance the negative charges in the anionic lattice, which are generated by the isomorphous cation substitution within the layers.<sup>[5]</sup> The metal ions inside

the silicate layers can be replaced by various organic cations such as alkylammonium by the cation exchange process, forming the “organically modified” layered silicate (OLS, also referred to as organoclay or organophilic clay). The exchangeable cations and layered morphology of these silicate clays lead to their two important physical properties: cation exchange capacity (CEC, often measured in the unit of meq/100 g, i.e., milliequivalents per 100 g) and specific surface area. For example, the specific area of montmorillonite clay has a range of 700–800 m<sup>2</sup>/g and its CEC varies from 80 to 150 meq/100 g.

### Structures of Polymer–Clay Nanocomposite Materials

Beyond traditional phase-separated macroscale composites, PCN materials can be structurally characterized into two categories in terms of their different

**Fig. 1.** Illustration of the structure of layered silicates. Source: From Ref.<sup>[5]</sup>. © 2003 Springer-Verlag GmbH & Co.KG.

microstructures resulting from different degrees of homogeneity between the organic and inorganic components:<sup>[6,7]</sup> 1) *Intercalated*, in which extended polymer chains are inserted between the clay layers, leading to an ordered multilayer morphology of alternating polymer/clay layers. As a result, the *d* spacing of the clay particle stacks is usually increased; 2) *exfoliated/delaminated*, in which the silicate layers are exfoliated into discrete sheets and uniformly dispersed in a continuous polymer matrix. This structure gives rise to a complete loss of the structural registry of the clay layers. Because of greater phase homogeneity with the latter, the exfoliated structure is more effective in improving the properties of the polymer, especially at very low clay loading. X-ray diffraction (XRD) *d*-spacing measurement and transmission electron microscopy (TEM) observation are two commonly used and complementary spectroscopic and microscopic tools to characterize and differentiate these microstructures. In addition to the two well-defined structures, intermediate structures comprising both intercalated and exfoliated domains are also observed. For the PCN samples of this mixed structure, the XRD peaks are often broadened and TEM analysis is imperative to characterize the overall structure.<sup>[8]</sup>

### Preparation Methods of Polymer–Clay Nanocomposite Materials

There are different numbers of synthetic routes toward PCN materials as classified by previous review articles.<sup>[9,10]</sup> The three primary methods are as follows:

- **Exfoliation–adsorption:** This generally involves the exfoliation of clay in a proper solvent and the adsorption of a soluble polymer to the clay surfaces. Polymer–clay nanocomposite materials, especially those based on polymers with high hydrophilicity, such as poly(vinyl alcohol), poly(ethylene oxide), and poly(acrylic acid), can be produced.<sup>[11,12]</sup> However, the main drawback is that a suitable solvent to promote compatibility of the inorganic clay and organic polymers is not always available.

- Melt intercalation: This is a simple mix-and-heat process, in which the layered silicate, usually organically modified, is mixed with the polymer matrix in the molten state. As compared with exfoliation–adsorption method, it is a versatile and green approach as a wide variety of polymers can be applied and no solvents are needed.<sup>[13–16]</sup> It also provides a model system in which the behavior of confined polymers can be studied.<sup>[17–22]</sup> Nonetheless, the ideal exfoliated structure is not always achieved.
- In situ polymerization: Monomers/comonomers are polymerized with the presence of original/modified clay via different polymerization mechanisms. This is also often referred to as intercalative or interlamellar polymerization, in which the chain growth is expected to be inside the galleries of the layered silicate. The advantage of this method is that as the polymerization inside the galleries progresses, the clay particles will be gradually swollen and ultimately exfoliated into discrete layers. As a result, this approach can more likely lead to PCN materials with a delaminated structure.

In this entry, we would like to focus on the strategy of in situ polymerization toward polymer brushes on clay particle surfaces and PCN materials. Details and characteristics of other methods such as template synthesis<sup>[23]</sup> and even a “general approach”<sup>[24]</sup> to PCN materials can be found in their respective reviews/reports and will not be discussed in this entry.

### Polymer Brushes on Clay Surfaces

Polymer brushes are defined as an assembly of polymer chains that are immobilized at one end to a surface by tethering, which is sufficiently dense so that the chains are forced to stretch away from the surface as a result of interchain repulsion.<sup>[25]</sup> Because of the layered morphology and negative surface charges, polymer chains that are ionically bound to clay surfaces can also be considered as polymer brushes if the surface charge density of the clay substrate is high enough so that the average distance between anionic sites is smaller than the radius of gyration of a polymer. They can exist in two different geometries. One is that the polymer brushes can be formed in bulk either by physisorption of one-end-charged polymers as described in the *exfoliation–adsorption* method (grafting-to) or by in situ polymerization using cationic monomer/initiator derivatives (grafting-from). Another is that the brushes can be grafted to/from a flat layer of clay particles on planar substrates prepared by the self-assembled monolayer (SAM) technique or the alternate polyelectrolyte deposition (APD) process.<sup>[26–28]</sup> The former

case has been extensively investigated in the form of PCN materials while there are few studies in the literature about the latter.

### METHODS OF IN SITU POLYMERIZATION

The history of in situ polymerizations with clay can be traced back to the 1960s. The type of clay involved was original clay or organoclay modified with organic cations with various functionalities. The form of polymerization ranged from bulk, solution, suspension, and emulsion. The PCN products could be thermoplastics or thermosets. Here we categorize the following in situ methods based on their individual polymerization mechanism. The emphasis of the discussion is focused on the synthetic routes and structures of the PCN materials rather than to their practical properties. It should also be noted that there is another case of in situ polymerization, in which clay minerals, especially when exchanged with transition metal cations, can also initiate/catalyze the polymerization of different monomers,<sup>[29,30]</sup> but this will not be discussed here.

#### In Situ Free Radical Polymerization

Many important thermoplastic polymers, such as polystyrene (PS) and poly(methyl methacrylate) (PMMA), can be produced by free radical polymerization mechanism using their vinyl monomers. The following discussion is focused on the PCN materials based on these two typical polymers, and in situ free radical methods are subcategorized by the initiators used.

##### Intercalative free radical polymerization using traditional initiators

Early studies on in situ free radical polymerization were focused on mixing vinyl monomers with unmodified/modified clay followed by polymerization with traditional azo, peroxide, or persulfate initiators. In the mid-1960s, in situ free radical polymerization with pristine clays was demonstrated by Blumstein<sup>[31]</sup> and Solomon and Rosser.<sup>[32]</sup> The effects of different types of clay on polymerization mechanisms and the interactions between different monomers and clay were studied. Lee and Jang<sup>[33]</sup> obtained PMMA–clay materials of intercalated structure through emulsion polymerization with original clay using potassium persulfate as the initiator. Later, they used the same method to prepare PS–clay nanocomposites. As compared with their earlier PMMA materials, the decreased *d* spacings of the intercalated PS composites were attributed to stronger hydrophobicity of the styrene monomer,

which had less compatibility to penetrate into the galleries of the hydrophilic clay.<sup>[34]</sup> Exfoliated PMMA nanocomposites was accomplished by Bandyopadhyay, Giannelis, and Hsieh<sup>[35]</sup> using different clays (montmorillonite and fluorohectorite) but similar initiator and emulsion methods. Using the same initiator, suspension polymerizations of MMA initiated with the presence of montmorillonite clay were investigated by Al-Esaimi,<sup>[36]</sup> but structural information of the composites was not reported. Structures from direct PMMA melt intercalation and in situ polymerization with alkylammonium-modified clay and 2,2'-azobisisobutyronitrile (AIBN) initiator were compared by Tabtiang, Lumlong, and Venables<sup>[37]</sup> and a finer degree of clay dispersion was observed for the latter. Exfoliated PS–clay nanocomposites were achieved by Chen, Ma, and Qi<sup>[38]</sup> using emulsion polymerization with ammonium persulfate as the initiator and cetyltrimethylammonium as the organic modifier of the clay. Similarly, Okamoto et al.<sup>[39]</sup> synthesized partially exfoliated PMMA–clay materials and intercalated PS–clay composites by bulk polymerization with lipophilized smectic clays. Later, they studied the effects of the addition of a small amount of different polar comonomers (acrylate and acrylamide derivatives) on the structure and properties of the PMMA–clay composites.<sup>[40]</sup> Likewise, Dietsche et al.<sup>[41]</sup> found that the addition of a small amount of dodecylmethacrylate (LMA) comonomer as a compatibilizer with organoclay [modified by dioctadecyldimethylammonium (DOD) cation] could promote clay exfoliation in the poly(MMA-co-LMA) matrix. By bulk polymerizations with AIBN as the initiator, Doh and Cho<sup>[42]</sup> systematically investigated the effect of different organic modifiers on the structure and properties of PS–clay nanocomposites. Although exfoliated structure was not observed, one of the three PS–clay products exhibited better clay dispersion and thermal property. The authors ascribed it to the structural affinity between the styrene monomer and the benzyl unit in one of the three alkylammonium cations employed. From the discussions above, it can be concluded that in the in situ intercalative polymerization, the compatibility between the monomer/comonomer

and organic groups in the organoclay plays an important role in the structure and properties of PCN materials. Fig. 2 illustrates the preparation method used by Chen, Ma, and Qi<sup>[38]</sup> which can also be used to schematically generalize the concept of in situ intercalative polymerization with organoclay modified by ammonium cations. Other than homopolymers, PCNs based on copolymers such as poly(styrene-co-acrylonitrile) (SAN) were also prepared by in situ polymerization with pristine or modified clay, indicating the versatility of this strategy.<sup>[43,44]</sup>

In the studies cited above, the polymer chains are freely formed and are not bound to the clay surfaces, as can be seen in Fig. 2. The following discussion will introduce recent studies on the in situ polymerization with clay modified by polymerizable cations by which a portion of the polymer chains is end-tethered to the clay surfaces. With two kinds of modified clays functionalized by charged acrylate derivatives, Biasci et al.<sup>[45]</sup> achieved intercalated PMMA–clay nanocomposites by solution polymerization initiated by AIBN. Similarly and using the same initiator, intercalated PS–clay materials were synthesized by Akelah and Moet<sup>[46,47]</sup> through ion exchanging with a vinylbenzylammonium cation and subsequent in situ free radical polymerization of styrene. As a continuation of the previous work, Dietsche et al.<sup>[41]</sup> synthesized the poly(MMA-co-LMA) materials from organoclay modified by a reactive cation containing two MMA end units [bis(2-methacryloyloxyethyl)-methyl-n-dodecyl-ammonium (DMMA)]. As compared with the old PCNs from non-reactive cation DOD, unusual combination of high stiffness and high toughness was observed in the new nanocomposites and attributed to the surface attachment of the polymers through covalent bonding with the polymerizable DMMA.<sup>[48]</sup> Exfoliated PS–clay nanocomposites were achieved from in situ bulk polymerization by Fu and Qutubuddin.<sup>[49]</sup> In their studies, organophilic clay was prepared by the insertion of a polymerizable cationic surfactant vinylbenzyltrimethylammonium chloride (VDAC), which was then directly dispersed in monomer solution followed by initiation by AIBN. They believed that exfoliation resulted from the special

**Fig. 2** Schematic illustration of the preparation of PS–montmorillonite nanocomposite via in situ intercalative polymerization. (A) Original sodium montmorillonite. properties of the VDAC modifier: the reactivity of the vinylbenzyl group, the solubility in styrene monomer, and the better swelling ability for clay.<sup>[50]</sup> Their results were confirmed by Zhu et al.,<sup>[51]</sup> as essentially the same reactive modifier also resulted in exfoliated PS–clay nanocomposites. In their comparative studies using bulk polymerization and AIBN initiator but different cationic surfactants, better thermal stability was found in the organoclay modified by a phosphonium salt than in the other two modified by ammonium salts, which might be useful if high processing temperatures were required for the PCN materials. Similar results were recently observed by Yeh et al.<sup>[52]</sup> as they found the PMMA–clay nanocomposite from alkylphosphonium as the intercalating agent displayed higher glass transition temperature ( $T_g$ ) than that from conventional alkylammonium salt. Depending on the clay content, exfoliated, intercalated, and mixed intercalated–exfoliated structures were found in their PMMA materials via in situ solution polymerization with benzoyl peroxide (BPO) as the initiator. However, it should be noted that neither of the “onium” molecules contained polymerizable groups. Clay exfoliation in both PS<sup>[53]</sup> and PMMA–clay<sup>[54]</sup> nanocomposites was accomplished by Choi, Kim, and their coworkers through emulsion polymerizations with 2-acrylamido-2-methyl-1-propane-sulfonic acid (AMPS) as the reactive surfactant. They were able to obtain the end-tethered polymers by a reverse ion-exchange process. The copolymerization between AMPS and styrene was confirmed by NMR measurements. Likewise, Zeng and Lee<sup>[55]</sup> prepared exfoliated PS– and PMMA–clay materials by bulk polymerization with clay modified by an ammonium salt containing an MMA end unit. Furthermore, by investigating the effects of different initiators including BPO and AIBN, they also stressed that compatibility of the monomer, initiator, and organoclay could strongly influence the clay dispersion in the polymer matrix. Based on PS and PMMA, Wang et al.<sup>[56]</sup> comprehensively studied the methods for PCN materials including in situ bulk, solution, suspension, and emulsion polymerization as well as melt intercalation. The effects of different initiators and ammonium ions on the in situ polymerizations were also compared. They also found that clay exfoliation were improved by the polymerizable group in the organic modifier that could participate in the polymerization. Fig. 3 shows the synthetic route utilized by Akelah and Moet,<sup>[46]</sup> representing the scheme of tethering polymer chain to clay surfaces with cationic comonomer derivatives. Here the end-tethered chains can also be considered as polymer brushes formed in-bulk by the grafting-from approach.

From the previous discussions, it is obvious that surface-attached polymer chains through polymerizable modifiers can indeed improve clay particle

**Fig. 3** In situ polymerization scheme as employed in Ref.<sup>[46]</sup>. The free radical polymerization of styrene with clay modified by a cationic comonomer resulted in surface-bound polymer chains.

exfoliation as compared with non-reactive alkylammoniums. Besides PS and PMMA, this concept has also been demonstrated by other PCNs such as poly(acrylamide)<sup>[57]</sup> and poly(acrylonitrile)<sup>[58]</sup> via in situ polymerization using traditional free radical initiators.

It is worth mentioning that the coworkers of Dietsche further continued their previous studies<sup>[41,48]</sup> by utilizing protonated amine-terminated oligostyrene<sup>[59]</sup> and cyclic amidinium cation-terminated oligoMMA and oligostyrene<sup>[60]</sup> as organic modifiers of the clay, which was applied in the subsequent melt compounding/extrusion processes with different polymers including polystyrene, PMMA, and styrene–acrylonitrile copolymer. The cationic oligomers (number average molecular weight 3000 g/mol for amidine-terminated species and 5800 g/mol for amine-terminated species) were first synthesized by controlled free radical and anionic polymerization methods and then attached to clay surfaces by ion exchange processes. Unlike clays intercalated with various alkylammonium cations, XRD measurements were even unable to detect the significantly increased  $d$  spacings of the well-swollen organoclays inserted with the oligomeric cations. It has to be pointed out that the OLSs here are analogs to the PCNs prepared by the exfoliation–adsorption method, except that the organic components are oligomeric cations rather than water-soluble polymers. Furthermore, these end-tethered oligomers are similar to the polymer brushes on clay surfaces by the grafting-to strategy described before, except for their low molecular weight nature. Effective exfoliation was observed by scanning electron microscopy (SEM) of the PCN materials after melt intercalation. Interesting rheological and thermal properties were found to be related with the interactions among polymer matrix, oligomer brushes tethered on clay surfaces, and the clay particles themselves.<sup>[61]</sup> Citing amine-terminated oligostyrene by anionic polymerization as an example, their synthetic scheme is illustrated in Fig. 4.

#### Surface-initiated free radical polymerization using cationic initiator derivatives

As for in situ free radical polymerization with clay, polymerization initiator derivatives can also be

**Fig. 4** Synthesis of the oligostyrene and preparation of the organoclay. Source: From Ref.<sup>[59]</sup>. © 2003 Wiley-VCH Verlag GmbH.

inserted into clay particles' galleries instead of reactive monomer cations or non-reactive surfactants. In this case, the surface-attached initiator not only renders the clay organophilic but also provides the initiation functionality for the subsequent in situ polymerization. Because it is the surface-attached initiator that activates the polymerization process and the polymer chain actually propagates from the surface, this type of in situ polymerization is also called the surface-initiated polymerization (SIP). The advantage of in situ polymerization with the initiator-intercalated clay lies in a sound assumption that, as the bound polymer chains propagate, the ordered silicate layers can be gradually pushed apart and finally exfoliated in the polymer matrix. Furthermore, as compared with the polymerizable surfactant route discussed above, the SIP strategy can presumably generate more end-tethered polymer chains with greater length, which provide more efficiency in exfoliation. Free radical SIPs using different AIBN initiator variants were demonstrated on various surfaces including spherical silica gel particles,<sup>[62,63]</sup> planar SiO<sub>x</sub><sup>[64]</sup> and gold substrates,<sup>[65,66]</sup> etc., on which the initiators were immobilized using the SAM method through covalent bonding. As for SIPs from clay surfaces, the initiator must be rendered cationic for ionic bonding with clay surfaces. The bound polymer chains after SIP can be cleaved for analysis by a counter-ion-exchange process using an excessive amount of alkali compound with greater cationic strength such as lithium bromide.

2,2'-Azobis(isobutyramidine hydrochloride) (AIBA) is a water-soluble, commercially available, and bicationic azo compound that can be used as a surface-attached azo free radical initiator. In the mid-1960s, its feasibility was demonstrated by Dekking<sup>[67,68]</sup> through the SIPs of several vinyl monomers. By bulk and emulsion polymerization, the effects of different clays (kaolin, bentonite, and hectorite) on the kinetics of the attached initiator decomposition and the subsequent chain propagation were studied. Similarly, Meier et al.<sup>[69]</sup> also employed AIBA to polymerize styrene from high-surface-area mica powder and the SIP mechanism was investigated. Although high molecular weight grafted polymer was obtained, they argued that the surface initiation and chain propagation played a minor role in the formation of surface-attached polymers. Instead, bound chains were created by the reaction between free polymers formed in solution and the surface-bound products of AIBA decomposition. However, no structural information of the composite products was reported. Huang and Brittain,<sup>[70]</sup> employing the same AIBA initiator and suspension SIP, achieved PMMA–clay nanocomposites with exfoliated structure. For comparison, they also prepared PMMA materials based on non-reactive and polymerizable methacrylammonium-modified clays via in situ polymerization using traditional AIBN initiator. It was observed that exfoliated structure was achieved and preserved after melt processing for the nanocomposites from AIBA and methacrylammonium-modified

**Fig. 5** Structures of the three cations used to modify layered silicates. 1) An alkyl ammonium chloride salt; 2) the AIBA initiator; 3) a reactive surfactant containing a polymerizable MMA unit. *Source:* From Ref.<sup>[70]</sup>. © 2003 American Chemical Society.

clays. In contrast, alkylammonium organoclay yielded only the intercalated structure both before and after melt processing and an even greater degree of order after melt processing. Thus, the authors believed that the end-tethered polymer chains not only promoted clay particle exfoliation but also helped preserve the exfoliated structure at elevated temperature by hindering the aggregation of the silicate layers. Between the nanocomposites from SIP with AIBA and polymerizable cation with AIBN, better thermal stability was observed in the former. Fig. 5 shows the structures of their three cationic modifiers, which also clearly present the three foregoing concepts in OLS modifications.

We synthesized another water-soluble monocationic azo compound.<sup>[71]</sup> The advantage of this AIBN derivative is that, unlike AIBA, the positive charge at one end is pH independent, which can tolerate different polymerization conditions. In addition, the other alkyl end of the molecule can greatly enhance the homogeneity of clay-monomer/solvent mixture of the SIP system. It should also be pointed out that, other than bound polymers, free ones also form in bulk/solution resulting from the other unbound free radical after the decomposition of the azo group. Through solution SIP, this initiator was first used to graft polystyrene brushes from clay surfaces adsorbed by the SAM technique on planar substrates. Fig. 6 shows the structure of the initiator as well as the synthesis scheme of the polymer brush and the free polymer formation. By surface-sensitive characterizations including ellipsometry and surface plasmon spectroscopy (SPS), it was found that the average initiator graft density (on the order of 0.1–1 molecules/nm<sup>2</sup>) and polymer layer thickness on flat clay surfaces were much lower than those on flat SiO<sub>x</sub> substrates from which the initiator/polymer were grafted by covalent bonding (on the order of 2–3 molecules/nm<sup>2</sup> based on silane surface coupling).<sup>[72]</sup> The reason was believed to be that the charge density of clay surfaces was much lower than the density of the reactive sites of the SiO<sub>x</sub> substrates. Therefore the bound polymers grafted from clay particles existed in the morphology of “mushrooms” rather than “brushes.” It should be noted that the results

**Fig. 6** Illustration of polymer brushes grafted from clay particles adsorbed on flat substrates and free polymer formation. *Source:* From Ref.<sup>[71]</sup>. © 2003 American Chemical Society.

depend on the physical properties of a specific type of clay, i.e., its CEC and specific surface area. The graft density can be varied if another type of clay is applied.

We further synthesized another similar but bicationic initiator, which was compared with the monocationic one in terms of the structures of their modified clays and the polystyrene–clay nanocomposites from solution SIPs.<sup>[73]</sup> The structure of intercalated clays after ion exchange was first studied by XRD measurements. Despite the similar structure and chain length of the two molecules, lower  $d$  spacing and less degree of order were observed in the organoclay modified by the bicationic initiator. This result was attributed to the combination of the two attachment possibilities of the bicationic initiator: 1) The two cationic ends were attached to the same side of one clay particle and; 2) they were bound to two sides of two adjacent particles. As for the SIP products, it was found that the monocationic initiator-modified clay was more likely to produce exfoliated structure. It was also found that the molecular weights of bound polymers were lower than that of the free ones. The differences caused by the two initiators, including organophilicity of the modified clays, clay particle dispersibility during SIP, diffusion and addition kinetics of monomer, and chain transfer and termination possibilities, were discussed and compared.

Using the monocationic initiator, we also prepared PMMA–clay nanocomposites via bulk, suspension, and solution SIPs.<sup>[74]</sup> Exfoliated structure was achieved by solution and bulk methods while suspension polymerization yielded a mixed exfoliation–intercalation morphology. It was ascribed to the amphiphilic characteristic of the initiator-modified clay, which probably formed aggregation at the monomer–water interface during suspension SIP. Intriguing results such as the effect of the affinity between immobilized initiator and monomer on the product structure, molecular weights, and molecular weight distributions of free and bound polymers as shown by gel permeation chromatography (GPC) analysis, were also observed and discussed.<sup>[75]</sup> It should be noted that although the molecular weight of the bound polymer was lower

than that of the free one, it was still much higher as compared with that of the bound chains from the reactive surfactant approach, where only oligomers were obtained.<sup>[54]</sup> This proves the higher efficiency of producing long end-tethered chains in SIP methods than in the polymerizable modifier strategy. Fig. 6 can also be used to represent the synthesis scheme used here except that the monomer is MMA and the clay particle is not ionically adsorbed to a planar substrate.

## In Situ Living Polymerization

It is well known that living polymerization methods are capable of synthesizing homopolymers with narrow polydispersity and controllable molecular weight and copolymers with desired architecture. On the other hand, they generally require more demanding polymerization conditions than the ordinary free radical approach. As compared with the intensive studies on living polymerization from other surfaces with various geometry (Ref.<sup>[76]</sup> and references therein), there were just a few attempts to prepare polystyrene–clay materials through in situ surface-initiated living polymerization from clay surfaces.

### Living anionic surface initiated polymerization

We synthesized a cationic derivative of 1,1-diphenylethylene (DPE) to anionically polymerize styrene from clay surfaces.<sup>[77,78]</sup> 1,1-Diphenylethylene was first modified to be a water-soluble ammonium bromide salt and then intercalated into montmorillonite clay by ion exchange. The subsequent living anionic surface-initiated polymerization (LASIP) successfully yielded free and bound polystyrene with controllable molecular weight and narrow molecular weight distribution. However, the bound polymers had lower molecular weight than the free ones and only intercalated structure was obtained in the composite products. The authors believed that the dispersibility of intercalated clay and monomer diffusion kinetics in this heterogeneous polymerization system were critical

**Fig. 7** Schematic illustration of living anionic surface-initiated polymerization (LASIP) from layered clay particles. Source: From Ref.<sup>[78]</sup>. © 2003 American Chemical Society.

factors of the LASIP process. Fig. 7 shows the synthetic route.

### Living free radical polymerization

Exfoliated polystyrene–clay nanocomposites with controllable molecular weight were prepared by Weimer et al.<sup>[79]</sup> by intercalating an ammonium cation initiator containing a nitroxide moiety into the montmorillonite clay. The following living free radical polymerization (LFRP) protected by the nitroxyl group effectively produced polystyrene materials with narrow polydispersity and exfoliated structure. Moreover, while keeping the clay loading constant, they

**Fig. 8** Exfoliated polystyrene–clay nanocomposites by living free radical polymerization. Source: From Ref.<sup>[79]</sup>. © 2003 American Chemical Society.

were able to control the molecular weight of the polymer matrix by varying the initiator concentration by cointercalating a non-initiating ammonium salt. The livingness of the reaction and block copolymerization viability was further confirmed by a successful effort of chain extension. It is worth mentioning that this is the first time that an exfoliated PCN material with controllable molecular weight has been achieved based on in situ polymerization with a vinyl monomer. Fig. 8 illustrates the synthesis scheme.

### Other In Situ Polymerization Methods

Other than thermoplastic polymers prepared by in situ addition polymerization of their vinyl monomers, there has been tremendous work on other polymeric materials by other polymerization mechanisms. In fact, early studies by Toyota scientists on nylon-based PCN materials demonstrated in situ ring opening polymerization of  $\epsilon$ -caprolactam with organoclays modified by protonated amino acids.<sup>[80–82]</sup> By using the similar strategy, Messersmith and Giannelis<sup>[83,84]</sup> synthesized poly( $\epsilon$ -caprolactone)–clay nanocomposites. Aside from their highly improved mechanical, thermal, and barrier properties, unique viscoelastic behaviors of those end-tethered polymers were also discovered.<sup>[85,86]</sup> The latest progress on in situ ring opening polymerization can be found in the recent reports and related reviews by Dubois et al.<sup>[87–89]</sup> Indeed, the versatility of the in situ polymerization strategy has been demonstrated by a broad spectrum of other polymers via their individual polymerization mechanism including thermosets,<sup>[90–93]</sup> elastomers,<sup>[94,95]</sup> polyolefins,<sup>[96,97]</sup> and even conducting polymers.<sup>[98–100]</sup>

### CONCLUSION

In situ polymerization synthesis methods for PCN materials and polymer brushes on clay nanoparticles are summarized and categorized. The emphasis is placed on free radical and living polymerization approaches. Earlier investigations have shown that in situ polymerization with organoclays modified by reactive modifiers, in which a portion of the polymers is attached to clay surfaces by polymerizable cations, is more likely to give exfoliated PCNs than with organoclays modified by non-reactive alkylammoniums or pristine clay. Previous studies have also demonstrated that in situ polymerization by SIP method, in which more and longer polymer chains can be end-tethered to clay surfaces by cationic initiators than by polymerizable modifiers, can also achieve effective exfoliation. The viability of achieving molecular weight-controllable PCNs has been demonstrated

as well by several attempts on in situ living polymerization approaches from clay surfaces. Although the discussions in this entry are primarily based on thermoplastic polymers from addition polymerization of their vinyl monomers, the versatility and efficiency of in situ polymerization strategy have been verified by PCNs via other in situ polymerization mechanisms, which are briefly introduced. The related report and review references are also given.

## ACKNOWLEDGMENT

The authors would like to thank the U.S. Army Research Office, Alabama Tri-Campus Materials Science Program, and the Chemistry Department of the University of Alabama at Birmingham for financial support.

# Polymer Colloids and Their Metallation

Lyudmila M. Bronstein

Department of Chemistry, Indiana University, Bloomington, Indiana, U.S.A.

## INTRODUCTION

Polymer colloids with metal nanoparticles is a fast-developing field of nanoscience and nanotechnology as encapsulation of metal inside the polymer—or, vice versa, formation of polymer inside the nanocomposite colloids—show a promise for exciting applications: catalytic, optical, magnetic. Metal or semiconductor nanoparticles can be 1) formed inside the polymer colloids (block copolymer micelles, dendrimers, or other functionalized polymer colloids); 2) positioned on the outer surface of the polymer colloids; or 3) polymer layer can be formed or adsorbed on the preformed nanoparticle surface. This entry discusses the above routes to prepare polymer nanocomposite colloids considering possible advantages and disadvantages of different methods. The major methods to characterize composition and structure of these nanomaterials include those used for polymer colloid characterization and metal nanoparticle assessment. Some methods allow gathering information on both polymer and nanoparticle structure; some methods are very specific for nanoparticle characterization. Transmission electron microscopy (TEM) is widely used to characterize both polymer colloids and metal (semiconductor) nanoparticles; the latter especially provide high electron contrast. High-resolution TEM (HRTEM) is used to determine the sizes of small particles and to characterize their inner structure. X-ray diffraction (XRD) is used for crystalline nanoparticles to determine their structure and mean particle size. Scattering techniques, small angle X-ray scattering (SAXS) and small angle neutron scattering (SANS), can be used both for polymer colloid and nanoparticle assessment. The latter is possible if polymer structure does not change after particle formation so scattering from polymer particles can be subtracted. If this is not the case, anomalous SAXS is employed because it allows one to establish nanoparticle size and particle size distribution independently of changes in the nanostructured polymer. Spectroscopic techniques are often used to characterize nanoparticles because properties are dependent on nanoparticle size (Au, Ag, semiconductor nanoparticles). In the sections below, examples of polymer colloid and nanoparticle characterization are presented.

## NANOPARTICLE FORMATION INSIDE POLYMER COLLOIDS

### Nanoparticle Formation in Block Copolymer Micelles

Amphiphilic block copolymers form micelles in selective solvents (a good solvent only for one block), yet the size and shape of micelles depend on the block chemical structure, molecular weight of each block, and solvent type.<sup>[1,2]</sup> Block copolymer micelles can be treated as polymer colloids being in dynamic equilibrium with unimers (individual macromolecules in solution) and with each other, which results in exchange between micelles. Although this exchange is a slow process for block copolymer systems compared to surfactant micelles, this can ensure very useful properties (ability to assemble and disassemble in certain conditions can play very important role for some “delivery” applications) or demonstrate a disadvantage, as it can facilitate metal-species exchange between polymer colloids.

Depending on the structure of the block copolymer, nanoparticles can be formed both in the micelle core (when the core is functionalized, while corona is not) or in the corona, when the core is not functionalized.

### Nanoparticle formation in the micelle core

If the block containing the functional groups (able to react with metal compounds, giving complexes or salts) forms the micelle core, it can be loaded with a corresponding metal compound (by incorporating the metal compound in the block copolymer solution) and can further serve as a nanoreactor for nanoparticle formation. In so doing, because the core-forming block is not soluble in a selective solvent, the micelle core can be treated like a quasi solid, thus additionally stabilizing the nanoparticles. Examples of “functional” blocks are polyvinylpyridines [P2(4)VP], polymethacrylic and polyacrylic acids (PMAA and PAA), polybutadiene (PB), polyisoprene (PI), and others. A block containing no functional groups but providing solubility and micelle stability in the solution should form the micelle corona. These can be polystyrene (PS), poly(ethylene oxide) (PEO), polyisobutylene (PIB), etc.

**Fig. 1** Electron micrographs of Pd colloids synthesized in PS-*b*-P4VP block copolymer micelles via reduction with hydrazine (top) and NaBH<sub>4</sub> (bottom). Source: From Ref.<sup>[9]</sup>. © 1997 by the American Chemical Society.

The synthesis of metal or semiconductor nanoparticles in the cores of amphiphilic block copolymer micelles was almost simultaneously reported by several research groups.<sup>[3–7]</sup> The metal nanoparticle formation in PS-*b*-P4VP block copolymer micelles demonstrated the strong dependence of nanoparticle morphology on the type of reducing agent. When a sluggish reducing agent is used, one nanoparticle per micelle (“cherry-like” morphology) can be formed if there is no exchange between micelles (e.g., the micelle is cross-linked).<sup>[8]</sup> Fast reduction leads to the formation of many small particles per micelle (“raspberry-like” morphology), which is considered to be preferable for catalytic applications (Fig. 1).<sup>[9]</sup> Using block copolymer micelle cores as nanoreactors allows synthesis of monometallic and bimetallic nanoparticles, yet bimetallic particle morphology depends on a metal pair,<sup>[10]</sup> i.e., on the ability of metal species to be reduced in particular conditions. For the Pd–Au pair, core–shell particles are formed with a gold core and a palladium shell. For Pd–Pt pair, cluster-in-cluster particles are obtained. These different morphologies significantly change the catalytic properties of such systems although the nanoparticle sizes are similar.<sup>[10]</sup>

Co nanoparticles of different sizes and shapes can be prepared either by incorporation of CoCl<sub>2</sub> in the PS-*b*-P2VP micelles followed by reduction or by thermal decomposition of Co<sub>2</sub>(CO)<sub>8</sub> species embedded in

the micelle cores.<sup>[11]</sup> Stable suspensions of superparamagnetic cobalt nanoparticles were also prepared in poly(dimethylsiloxane) (PDMS) carrier fluids in the presence of poly[*dimethylsiloxane-block*-(3-cyanopropyl)methylsiloxane-*block*-dimethylsiloxane] (PDMS-*b*-PCPMS-*b*-PDMS) triblock copolymers as steric stabilizers.<sup>[12]</sup> Similar to PS-*b*-P2VP, these copolymers formed micelles in toluene and served as nanoreactors for thermal decomposition of the Co<sub>2</sub>(CO)<sub>8</sub> precursor. The nitrile groups on the PCPMS central blocks are thought to adsorb onto the particle surface, while the PDMS end blocks protrude into the reaction medium to provide steric stability. Adjusting the cobalt-to-copolymer ratio can control the particle size. Transmission electron microscopy shows non-aggregated cobalt nanoparticles with a narrow size distribution and the particles are evenly surrounded with copolymer covering.

The formation of iron oxide particles in cross-linked block copolymer micelles is described in Ref.<sup>[13]</sup> A polyisoprene-*block*-poly(2-cinnamoyl ethyl methacrylate)-*block*-poly(*tert*-butyl acrylate), PI-*b*-PCEMA-*b*-PtBA, forms spherical micelles in THF/hexane mixture with 65% volume fraction of the latter. The micelles consist of a PI corona, a solvent-insoluble PCEMA shell, and a PtBA core. Their structure is locked in by photo-cross-linking the PCEMA shell to yield nanospheres (Fig. 2). Similar to core cross-linking, this approach prevents exchange between micelles. The nanospheres were made water-dispersible by hydroxylating the PI double bonds. The core was made compatible with inorganic species by removing the *tert*-butyl groups of PtBA. The possibility of using such nanospheres as nanoreactors for inorganic nanoparticle preparation was demonstrated by incorporating iron

**Fig. 2** Preparation of water-dispersible magnetic nanoparticles. Photolysis cross-links the PCEMA shell (gray to dark). The PI corona chains are made water-soluble by hydroxylating the double bonds (wavy lines to free-hand lines). The core is made inorganic compatible by removing the *tert*-butyl groups (light gray to gridded pattern). Soaking the nanospheres in aqueous FeCl<sub>2</sub> enables proton exchange by Fe<sup>2+</sup> (slant to vertical grids) and the Fe<sup>2+</sup> ions are precipitated and oxidized to yield cubic  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> magnetic particles using NaOH and H<sub>2</sub>O<sub>2</sub> (last step). **Fig. 3** Transmission electron microscopic images of PI-*b*-PCEMA-*b*-PtBA nanospheres at each stage in the synthesis: (A) after PCEMA cross-linking and PI hydroxylation (stained with OsO<sub>4</sub> overnight); (B) after removal of *tert*-butyl groups (stained with OsO<sub>4</sub> over a weekend); and (C) after Fe<sub>2</sub>O<sub>3</sub> loading (no staining). *Source:* From Ref.<sup>[13]</sup>. © 2000 by the American Chemical Society.

salt and formation of iron oxide magnetic particles in the cores (Fig. 3).

As seen from the above examples, many amphiphilic block copolymers form micelles with a functionalized core in the organic medium. When aqueous solutions are preferred, the choice of block copolymers is very limited and metal particle formation is normally more complicated as the pH of the medium should be taken

**Fig. 4** Transmission electron microscopic image of Pt nanoparticles prepared in PB-*b*-PEO micelles by NaBH<sub>4</sub> reduction. *Source:* From Ref.<sup>[15]</sup>. © 1999 by the American Chemical Society.

into consideration. A few examples of such block copolymers include P2VP-*b*-PEO and PB-*b*-PEO,<sup>[14,15]</sup> yet the former block copolymer micellization depends on the pH value:<sup>[16]</sup> At pH below 5, P2VP-*b*-PEO becomes molecularly soluble in water. At the same time, decrease of pH of the P2VP-*b*-PEO micellar solution after incorporation of metal compounds or metal nanoparticle formation results in no micelle decomposition although the micelle density decreases. In the case of PB-*b*-PEO, micelles formed in water are very dense, so they successfully fulfill two roles: They serve as nanoreactors for Pd, Pt, and Rh nanoparticle formation (Fig. 4) and as metal-particle-containing templates for mesoporous silica casting.<sup>[15]</sup>

If the P2VP block is a middle block in PS-*b*-P2VP-*b*-PEO triblock copolymer, the “layered,” well-defined micelles are formed in water with the PS core, P2VP shell, and PEO corona.<sup>[17]</sup> Here the P2VP shell serves as a nanoreactor for gold nanoparticle formation. As the shell is formed by the pH-sensitive P2VP block, the authors believe that this system can be useful for encapsulation and/or release of active species. However, one should remember that after metal particle formation, this block loses its ability to dissolve at low pH.<sup>[14]</sup> So this property can be hardly realized in this system if nanoparticles or metal complexes are formed in the P2VP shell.

The formation of spherical assemblies of CdS-containing block copolymer reverse micelles in aqueous solution was reported in Ref.<sup>[18]</sup>. These stable assemblies were formed by slow addition of water to mixtures of the reverse micelles formed by PS-*b*-PAA and single PS-*b*-PAA chains. Large compound micelles (LCMs) with quantum-confined CdS nanoparticles dispersed throughout a spherical PS stabilized in water by a layer of solubilized hydrophilic chain matrix were obtained. The size of the CdS particles (approximately 3 nm) is determined by the ionic block length of the

**Fig. 5** Transmission electron microscopic images of spherical aggregates in LCM, with Pd/Pt shadowing (A) and without shadowing (B). The dark particles inside the spheres are CdS nanoparticles. *Source:* From Ref.<sup>[22]</sup>. © 1998 by the American Chemical Society.

block copolymer forming the reverse micelle (Fig. 5). The formation of LCMs was found to depend on the amount of the added stabilizing copolymer. This method allows transferring the CdS nanoparticles formed in the micelle cores in organic medium to aqueous medium without loss of stability and nanoparticle aggregation.

#### Block copolymer micelle coronas

Nanoparticles can be synthesized in the corona of amphiphilic block copolymer micelles. However, if the corona is functionalized, addition of a metal salt can result in immediate formation of large aggregates because of the interaction between micelles and their precipitation; thus this method can be used only in very dilute solutions. If the corona does not contain groups able to coordinate with metal compounds, particle stabilization can be ensured because of the hydrophobic interactions with the hydrophobic core. This feature was used when synthesis of Pd, Pt, Ag, and Au nanoparticles was performed in aqueous solutions of PS-*b*-PEO and PS-*b*-PMAA by reduction of the corresponding salts in block copolymer solutions.<sup>[19,20]</sup> However, the stability of such systems, solely provided by the hydrophobic interactions with the PS core, is not satisfactory. On the other hand, accessibility of particles in the micelle coronas can be favorable from the viewpoint of catalytic applications.

Enhanced stabilization in the micelle coronas was achieved when hybrid micelles consisting of PS-*b*-PEO and surfactants were formed.<sup>[21–23]</sup> Surfactant hydrophobic tails were expected to penetrate the PS

**Fig. 6** Schematic image of the PS-*b*-PEO/SDS micelle. *Source:* From Ref.<sup>[22]</sup>. © 2000 by Academic Press.

core while surfactant head groups are located on the micelle core surface or in its vicinity. As shown in Fig. 6, exchange of surfactant counterions for ions of interest would lead to saturation of the core with the given ions. Dynamic light scattering (DLS) and sedimentation in an ultracentrifuge showed that incorporation of positively or negatively charged surfactants results in increase of size and weight of micelles and micellar clusters up to a certain surfactant concentration (which is different for different surfactants). Further increase of surfactant loading (as a rule, above critical micelle concentration for surfactants) results in a moderate decrease of micelle size and weight. Incorporation of surfactant was found to increase the mobility of the PS core and to decrease the mobility of surfactant tails. Both these facts proved comicellization of block copolymer molecules and cationic or anionic surfactants. Ion exchange of surfactant counterions in the PS-*b*-PEO/CPC (cetyl pyridinium chloride) system for  $\text{PtCl}_6^{2-}$  or  $\text{PdCl}_4^{2-}$  ions results in saturation of micellar structures with Pt or Pd ions. Subsequent reduction of metal-containing hybrid micellar systems PS-*b*-PEO/CPC/ $\text{MX}_n$  with  $\text{NaBH}_4$  or  $\text{H}_2$  leads to the formation of metal nanoparticles mainly located within the micelles. The morphology and stability of Pd and Pt nanoparticles synthesized in these systems depends on the metal compound loading and the type of a reducing agent.  $\text{NaBH}_4$  reduction leads to decomposition of micellar clusters and formation of micelles with embedded nanoparticles. These systems display exceptional stability (for years) if metal salt loading does not exceed  $1.24 \times 10^{-2}$  M. Hydrogen reduction results in metal nanoparticle formation both in micelles and micellar clusters (micelle aggregates), so stability of colloidal solutions is ensured at metal salt concentration of less than  $3.36 \times 10^{-3}$  M. Rh nanoparticles with diameters of 2–3 nm have been obtained in the hybrid micelles formed by PS-*b*-PEO anionic surfactants: sodium dodecylsulfate (SDS) or sodium dodecylbenzenesulfonate (SDBS) using Rh cations  $[\text{Rh}(\text{Py})_4\text{Cl}_2]^+$  (Fig. 7). As found, nanoparticle size does not depend on the type of reducing agent

**Fig. 7** Transmission electron micrographs of Rh nanoparticles formed in the PS-*b*-PEO/SDS system. *Source:* From Ref.<sup>[22]</sup>. © 2000 by Academic Press.

(contrary to the nanoparticles formed in other block copolymer solutions),<sup>[4,14]</sup> but depends on the type of metal.<sup>[21–23]</sup> This could be governed by the strong interaction of surfactant head groups with growing nanoparticles.

Thus incorporation of surfactants in the block copolymer micelles containing no functional groups allows reliable stabilization of metal nanoparticles of 2–6 nm in size. Using both cationic and anionic surfactants allows one to explore an infinite variety of metal ions and to prepare different kinds of nanoparticles. The disadvantage of these systems is a lack of the direct methods to tune the particle size.

### Nanoparticle Formation in Dendrimers

The most commonly used and studied dendrimers (commercially available) are poly(amidoamines) (PAMAM), whose structure is presented in Ref.<sup>[24]</sup>. By varying the dendrimer size (dendrimer generation) and metal compound loading, one can vary the size of nanoparticles. Dendrimers were used for stabilization of gold and silver nanoparticles with subsequent self-assembling of metal-containing dendrimers on the surface with monolayer formation.<sup>[25]</sup> Poly(amidoamine) dendrimers with terminal hydroxyl groups were used as templates and stabilizers for controlled synthesis of monodisperse, catalytically active nanoparticles.<sup>[26]</sup> In the first step, metal ions were absorbed by the dendrimer as a result of the formation of metal complexes with amino groups. Subsequent reduction results in the formation of metal nanoparticles encapsulated in the dendrimers. For hydroxyl-terminated dendrimers, a deficiency of metal exchange between dendrimer molecules provides very narrow particle size distribution and subtle control over nanoparticle

growth: The nanoparticle size is exactly determined by the amount of metal atoms loaded in the dendrimer. These metal-containing dendrimers are water-soluble and very stable (no precipitation is observed for months). It is considered that a metal particle is formed in the cavity of the dendrimer. This location provides a certain stabilization of the particles. At the same time, the presence of functional (amino) groups allows additional stabilization of nanoparticles. Metal particle formation resembles the growth of nanoparticles in the cross-linked cores of block copolymer micelles when exchange between micelles does not occur. If PAMAM contains surface (terminal) amino groups, exchange between dendrimer molecules results in a broader particle size distribution than for PAMAM with terminal hydroxyl groups (Fig. 8).<sup>[27]</sup>

Dendrimer generation is an important factor to influence the particle characteristics.<sup>[28]</sup> Gold colloid formation upon reduction of a gold salt precursor in protonated PAMAM was studied to follow the influence of reaction conditions and dendrimer generation on the resulting polymer nanocomposite colloids.<sup>[29]</sup> Methods such as TEM, SANS, and SAXS show that the gold particles are formed inside the dendrimer and located offset from the center (probably in a dendrimer cavity). Lower generation dendrimers aggregate when nanoparticles are formed. Dendrimers of generation 6–9 can template one gold nanoparticle per dendrimer molecule; the number of gold atoms added per dendrimer determines the particle size. These data well agree with those described in Ref.<sup>[26]</sup>. For generation 10, multiple smaller gold particles per dendrimer

**Fig. 8** Electron micrographs of gold colloids and histograms of particle size distribution at molar ratio of surface amino group of G5 and HAuCl<sub>4</sub>: 1:1 (top) and 4:1 (bottom). *Source:* From Ref.<sup>[27]</sup>. © 1998 by the American Chemical Society.

**Fig. 9** Transmission electron micrograph of gold containing G8 PAMAM (A) and G10 PAMAM (B) dendrimers obtained for 1:1 loading and slow reduction. were observed and dendrimers aggregated (Fig. 9). Poly(propyleneimine) dendrimers with stearyl end groups, combining both hydrophilic and hydrophobic moieties, were also used for metal particle formation.<sup>[30]</sup> These dendrimers form inverse micelles in toluene. While the initial dendrimers have a spherical structure with a collapsed core, solubilization of metal salt hydrate leads to the formation of cylindrical multidendrimer structures with swollen, metal-salt-filled dendrimer cores. When the gold salt inside the dendrimers is reduced to form colloidal particles, the cylindrical structure breaks up and spherical nanoparticles are formed. In so doing, the particle sizes are larger than would be expected if the gold-salt loading of one dendrimer formed one particle, indicating that the ions from several dendrimers are combined. Apparently, dendrimers of this kind provide no control over nanoparticle growth. In addition, these dendrimer aggregates, although resembling block copolymer micelles, are less defined and more complex. So advantages of such amphiphilic dendrimers are not evident.

Along with metal particles, a number of semiconductor particles, CdS,<sup>[31–33]</sup> CdSe,<sup>[34]</sup> and complex core-shell CdSe/ZnS,<sup>[32]</sup> were successfully prepared in dendrimers. The absorption and emission of the

CdS/PAMAM (hydroxylated) systems are a function of the generation of the dendrimer that is related to the dependence of nanoparticle size on dendrimer generation and the dependence of optical properties on a semiconductor nanoparticle size.<sup>[32]</sup>

Aqueous assemblies of adamantyl-derivatized poly(propylene imine) (PPI) dendrimers and  $\beta$ -cyclodextrin ( $\beta$ -CD) (Fig. 10) have been used as nanoreactors in the preparation of gold and platinum nanoparticles in water.<sup>[35]</sup> These particles have been formed by the reduction of aurate or platinate anions in the presence of the generation 4 ( $4_{\beta}$ -CD)<sup>32</sup> and 5 ( $5_{\beta}$ -CD)<sup>40</sup> assemblies (Fig. 11). Lower generation assemblies did not provide stable nanoparticles. The authors believe that the persistent shape of the adamantyl-derivatized dendrimers and the dense shell of adamantyl- $\beta$ -CD complexes provide a kinetic barrier for nanoparticle escape, thus prolonging their lifetime. However, particle size distribution inside  $\beta$ -CD-modified dendrimers is not particularly narrow,<sup>[35]</sup> thus demonstrating poorer control over particle size than in hydroxy-terminated PAMAM.

### Nanoparticles in Polyelectrolyte Microgels

Microgels are gel spherical particles having diameters in a nanometer range.<sup>[36,37]</sup> Internal cross-linking leads to stability of their sizes and properties, while their size (in nanometer range) ensures formation of colloidal solutions. When these microgels are formed by polyelectrolytes, they contain charged groups allowing ion exchange and solubilization in water. This allows considering microgels as nanoreactors for controlling nanoparticle growth. Gold nanoparticle formation was studied in microgels based on sulfonated PS.<sup>[38]</sup> Morphologies of nanoparticles formed are strongly determined by the degree of microgel cross-linking. The higher the cross-linking density, the higher the probability of the formation of spherical particles embedded in the microgels. The other key factor is the type of reducing agent. Fast reduction ( $\text{NaBH}_4$ ) in water leads to gold nanoparticles of 4.5 nm in diameter located in microgels. If  $\text{NaBH}_4$  is added in alkaline solution (0.1 N NaOH), it slows the reduction and results in 7-nm nanoparticles forming long “threads.” Yet only 20% of microgels contain nanoparticles. Thus slow nucleation allows Au clusters and ions to migrate out of microgel areas where aggregation easily occurs. High-resolution TEM allows determining that particles grow from one nucleus and the microgel environment governs the particle shape. In a similar fashion, Pd and Pt nanoparticles have been grown in microgels. These metal-particle-containing microgels were also used as cotemplates (along with amphiphilic PS-*b*-PEO block copolymers) for mesoporous silica

Fig. 10 Poly(propylene imine) dendrimer generations 1–5, solubilized by  $\beta$ -cyclodextrin. Source: From Ref.<sup>[35]</sup>.

Fig. 11 Transmission electron microscopic images of gold (top) and platinum (bottom) nanoparticles stabilized by the 5 · ( $\beta$ -CD)<sub>40</sub> assembly and size distributions of colloids stabilized by 4 · ( $\beta$ -CD)<sub>32</sub> and 5 · ( $\beta$ -CD)<sub>40</sub> (amine/metal=2:1, H<sub>2</sub>O, T=25°C). Source: From Ref.<sup>[35]</sup>.

formation.<sup>[39]</sup> Here microgels play a dual role: They are nanoreactors for metal particle formation and pore-forming templates when mesoporous materials are formed.

### Nanoparticle Formation in Functionalized Polysilsesquioxane Colloids

Synthesis of functionalized polysilsesquioxane based on hydrolytic condensation of functionalized silanes was recently described in Ref.<sup>[40]</sup>. Using *N*-(6-amino-hexyl)aminopropyltrimethoxysilane (AHAPS) as a precursor, well-defined colloidal particles composed of a nearly fully condensed poly(amino-hexyl)(amino-propyl)silsesquioxane (PAHAPS) were synthesized. According to solid state <sup>29</sup>Si CP-MAS (cross-polarization magic angle spinning) nuclear magnetic resonance (NMR), PAHAPS structure contains mainly C-SiO<sub>3/2</sub> species. The sizes of PAHAPS colloids vary in the range 10–200 nm and depend on the reaction conditions: pH, solvent, and AHAPS concentration (Fig. 12). When hydrolytic condensation is carried out in water with no HCl added, self-assembling of AHAPS tails results in the formation of lamellar ordering with Bragg spacing of about 3.0 nm, which matches to two layers of fully extended AHAPS tails. When PAHAPS is fully or partially protonated (HCl is added to water), no ordering occurs. Similarly disordered structures are formed in THF, which is a good solvent for AHAPS tails. Unlike water, THF also facilitates cross-linking between colloids, so the colloids are attached to each other. Interaction of PAHAPS colloids with Pt and Pd salts followed by chemical reduction results in the formation of discrete metal nanoparticles stabilized within the colloids even at metal content of 30–45 wt.% (Fig. 13). The particle size depends on the

**Fig. 12** Transmission electron microscopic image of PAHAPS colloids obtained in water at a precursor concentration of 17 wt.%.

**Fig. 13** Transmission electron microscopic image of Pt nanoparticles formed in protonated PAHAPS prepared in water at a concentration of 1.5 wt.%.

type of metal compound and, in some cases, on type of the reducing agent. Particles formed after reduction of K<sub>2</sub>PtCl<sub>4</sub> within PAHAPS measure ca. 1–2 nm in diameter when the fast reducing agent (NaBH<sub>4</sub>) is reduced. With the sluggish reducing agent (hydrazine-hydrate), both small particles of 1.5 nm and larger particles with diameters of 2.5–4.0 nm are formed. When metal precursor is K<sub>2</sub>PtCl<sub>6</sub>, very narrowly distributed particles measuring about 1.5 nm are formed for both types of reducing agents. Apparently, particle nucleation does not influence the particle size when mass transfer of the PtCl<sub>6</sub><sup>2-</sup> ions is restricted. Poly(amino-hexyl)(amino-propyl)silsesquioxane colloids form very strong elastic films because of the intercolloid interactions that makes possible the formation of freestanding films and coatings of different thicknesses on various supports.

Another interesting feature of these particles is that dendrites differing in size and shape are observed to form from aqueous solutions containing PAHAPS colloids loaded with metal salts or metal nanoparticles (Fig. 14).<sup>[40]</sup> While formation of dendrites is common for a number of salts or metals,<sup>[41,42]</sup> it has not been reported so far for colloidal particles or nanoparticle-loaded colloidal systems. Because the size and shape of the dendrites produced here can be easily controlled, metal-loaded PAHAPS may be suggested as catalytically active membranes in which select surface coverage is important. Another possible application for PAHAPS loaded with metal nanoparticles is as a conductive layer between two surfaces, as described elsewhere<sup>[43]</sup> for pure Pd dendrite crystals. At the same time, unlike pure metals, metal-loaded PAHAPS possesses a number of practical advantages, including lower cost and greater structural stability.

Another precursor of interest for synthesis of polymer colloids using sol-gel reaction is octadecyldimethyl

**Fig. 14** Transmission electron microscopic image of dendrites formed by PAHAPS colloids filled with Pd nanoparticles.

(3-trimethoxysilylpropyl)ammonium chloride (ODMACl). The hydrolytic condensation of this precursor both in acidic and basic solutions results in the formation of colloidal particles showing lamellar ordering with Bragg spacing  $d$  of about 3.6 nm. This Bragg spacing is significantly smaller than two layers of extended ODMACl tails, so one can assume either tilting of ODMACl chains (they are not perpendicular to the lamellar surface) or interpenetration of the tails of the two layers (or both). As the PODMACl colloids are much larger than twice the  $d$  spacing, they should have a multilamellar structure. Because PODMACl colloids contain ionic groups in their tails, they can be subjected to ion exchange that results in replacement of  $\text{Cl}^-$  ions for ions of interest:  $\text{PdCl}_4^{2-}$ ,  $\text{PtCl}_6^{2-}$ ,  $\text{AuCl}_4^-$ . The subsequent reduction leads to metal nanoparticle formation within PODMACl colloids. Moreover, independently of reducing agent type, lamellar ordering is preserved, while particle size and shape strongly depend on the nucleation rate. With  $\text{NaBH}_4$ , narrowly distributed spherical particles with a mean diameter of  $\sim 2$  nm are obtained. When nucleation is slow, particle growth is directed by the lamellar ordering, so rod-like particles of  $2 \times 13$  nm are formed and their positioning is well regulated by the ordered structure. This suggests new opportunities for growing rod-like particles derived from different metal or semiconductors within ordered polymeric colloids. Such materials can be promising for tailoring optical, magnetic, and electrical properties of nanocomposites by tuning the particle shape.

### NANOPARTICLES FORMED ON THE POLYMER COLLOID SURFACE

Micrometer and submicrometer Au-shell PS latex beads have been prepared by combining the self-assembly

and seeding methods.<sup>[44]</sup> The PS beads are first covered with positively charged poly(ethyleneimine) (PEI) via electrostatic interaction and hydrogen bonding; then, the Au shell is formed via the reaction of PEI-PS with  $\text{NH}_2\text{OH}$  and  $\text{HAuCl}_4$ . This method allows efficient control of the gold coverage and leads to relatively stable products. Using TEM, formation of Au clusters and gold nanoparticles on the surface of the PS beads was confirmed. The results suggest that the PEI polymer chains are probably stretched out on the surface of the PS beads. The UV-visible extinction spectrum for gold-covered particles is significantly affected by the plasmon resonance absorption.

For preparation of Au-shell magnetic particles, sulfonated polystyrene beads were first exchanged with  $\text{Fe}^{2+}$  ions under  $\text{N}_2$  gas flow and then treated with NaOH solution. The last stage involves heating the beads at  $100^\circ\text{C}$  for 1 h. Iron oxide layer was later covered with a gold shell as described for Au shell/PS colloids. Self-assembled structures of Au-covered particles were induced by an external magnetic field.<sup>[44]</sup> This conductive grid was suggested for use as a tunable polarizer for microwaves and milliwaves, as the conducting lines that can be switched into a non-conductive state by an external field. Waveguides for plasmon, i.e., excitation of the plasmon resonance at one end of the lines and detection at the other end, is another interesting application.

Well-dispersed Ag nanoparticles were formed in situ on the surface of poly(*N*-isopropylacrylamide, PNIPAAm)-coated polystyrene microspheres.<sup>[45]</sup> The surface-grafted PNIPAAm chains serve both as steric stabilizers to prevent the flocculation of the polystyrene particles and interact with silver salts with subsequent adsorption of the forming Ag nanoparticles onto the surfaces of the microspheres. By varying the concentrations of initiator and silver nitrate, the particle sizes and distributions for both Ag nanoparticles and polystyrene microspheres can be altered. As PNIPAAm is a well-known, temperature-sensitive polymer, the PNIPAAm-protected Pt colloids show unusual temperature dependence of activity in the aqueous hydrogenation of allyl alcohol, which can be explained by different density of PNIPAAm layer at different temperatures. In addition, Pt colloids on the microspheres show higher activity than the commercial Pt/C catalyst and retain high activity on recycling in the same reaction. Polystyrene microspheres with silver nanoparticles can be used as the active substrates for surface-enhanced Raman scattering, chemical, electronic, and optical sensors, and photocatalysts for solar energy conversion.

Another example of PS beads covered with nanoparticles is described in Ref.<sup>[46]</sup>. Surface-functionalized PS microbeads and nanobeads were prepared by grafting the *p*-acetoxystyrene monomer during the last

30 min of the fabrication of polystyrene bead core by emulsifier-free emulsion polymerization followed by hydrolysis of the acetoxy group by a base. The size of the resulting beads is mostly dictated by the size of the core. Hydroxyl-derivatized polystyrene microspheres have been used for anchoring catalytically active silver and ruthenium nanoparticles. This was performed by adsorption of preformed nanoparticles on the functionalized bead surface. The bead formation, surface functionalization, and coating with metal nanoparticles were studied using scanning electron microscopy (SEM), TEM, energy dispersive X-ray spectrometry (EDS), Fourier-transform IR spectrometry, and Auger analysis.

### NANOPARTICLES WITH ADSORBED POLYMER LAYER

Any nanoparticle synthesis in polymer solution normally results in the adsorption of polymer molecules on the nanoparticle surface. Usually, these materials are not considered as metallated polymer colloids. Nevertheless, in some cases including ones cited below, adsorption or chemical interaction of polymers with nanoparticles is accompanied with formation of a polymer layer of different nature than that used for nanoparticle synthesis.

Reduction of Pd, Pt, or Au ions in dimethyl sulfoxide (DMSO) solution by a  $\pi$ -conjugated poly(dithiafulvene) (PDF) having strong electron-donating properties resulted in the adsorption of oxidized polymer on the forming nanoparticle surface, which protected the metal nanoparticles (Fig. 15).<sup>[47]</sup> As found, all the DF units of PDF were uniformly oxidized by electron transfer, which means that they participated in the reduction, and resided on the particle surface.

**Fig. 15** Schematic illustration of the formation of the PDF-protected metal nanoparticles via reduction of metal ions by the  $\pi$ -conjugated, electron-donating PDF. *Source:* From Ref.<sup>[47]</sup>. © 2002 by the American Chemical Society.

**Fig. 16** Transmission electron microscopic image of PIB-coated nanoparticles made with 80 g of  $Fe(CO)_5$  and 11 g of PIB-TEPA (tetraethylenepentamine). *Source:* From Ref.<sup>[48]</sup>. © 2002 by the American Chemical Society.

The average size of the formed Pt nanoparticles increased with the increases of the PDF concentration and reaction temperature. All of the Pt nanoparticles formed at different temperatures showed narrow size distribution, high dispersibility, and great thermal stability.

Magnetic materials comprised of polymer-iron nanoparticle composites have been prepared by thermal decomposition of iron pentacarbonyl in the presence of ammonia and several types of polymeric dispersants.<sup>[48]</sup> The nanoparticles consist of metallic cores, each of which is coated with a strongly bound polymer layer (Fig. 16). The polyisobutylene- and polyethylene-based dispersants lead to more uniform particle sizes and the materials are composed principally of individual core-shell particles. Large, complex particles, formed by the aggregation of smaller particles, as well as simple core-shell particles, were obtained with polystyrene-based dispersants in 1-methylnaphthalene. Aggregation leading to complex particles was found to be a result of a mismatch between the solubility parameters of the dispersant and the reaction solvent. When the solvent was better matched with the solubility parameter of polystyrene, simple core-shell nanoparticles of fairly uniform size were obtained. Electron diffraction revealed that the core material is iron. High-resolution TEM showed highly ordered or crystalline regions within the polymer shell, possibly because of the dense packing of the strongly bound dispersant chains (Fig. 17). Magnetic interactions between particles cause formation of secondary structures such as clusters, coils, loops, and strings of particles. The nanocomposites can be dispersed in organic solvents or cast as films. The

**Fig. 17** High-resolution TEM image of PIB-coated nanoparticles made with 60 g of  $\text{Fe}(\text{CO})_5$  and 11 g of PIB-TEPA. Lattice planes are visible in the shell region of the particles. Source: From Ref.<sup>[48]</sup>. © 2002 by the American Chemical Society.

polystyrene-iron composites are rigid solids at room temperature but can be melted at temperatures of 65–100°C. The nanoparticle composites showed different magnetic behavior depending on the particle size. Samples with the smallest particles proved to be superparamagnetic but their saturation magnetizations were low. Hysteresis was observed for materials with larger particles, and the materials possessed larger magnetizations. The magnetization was correlated with the particle size where samples with larger particles showed higher magnetizations. The samples with higher iron contents, achieved using higher iron pentacarbonyl loadings or by removing unbound polymer dispersant, showed the highest magnetization.

## CONCLUSION

This entry clearly shows several approaches to constructing nanocomposite polymer colloids containing nanoparticles. In all cases, polymer colloids are soluble in organic or aqueous media (depending on the exterior of the colloids) and retain solubility after nanoparticle formation. This key feature allows the formation of thin deposited or freestanding films (the latter were obtained with block copolymer micelles and functionalized polysilsesquioxane colloids) that makes possible a number of important applications for nanolithography in optical and magnetic materials. For catalytic applications, both homogeneous (solutions) and heterogeneous systems (after deposition on the support) proved to be promising with the polymer colloids filled with nanoparticles. It is worth mentioning that the polymer nanoenvironment significantly changes the nanoparticle properties via modification

of the nanoparticle surface with polymer groups; therefore the choice of polymer type and structural organization of polymer colloids play a crucial role in material properties and should be taken into consideration for specific material application.

## INTRODUCTION

Polymer self-assembly of nanoparticles yields stabilized metal and semiconductor nanocomposites as well as provides access to structured nanoscale materials. The properties of these materials can be tuned by varying the size and shape of the metal cluster as well as by altering the composition of the monolayer that covers the particles. Furthermore, the functionality and structure of the polymer can be modified, which lends an additional element of control to the entire assembly process. This “bottom-up” approach provides a methodology that is complementary to “top-down” lithographic methods, providing access to structures smaller and with greater 3-dimensional (3-D) control than is possible through sophisticated lithographic techniques such as electron-beam lithography.<sup>[1–4]</sup> Presently, one of the major obstacles facing nanotechnology is the successful integration of these two general approaches. Multiscale engineering of this sort would allow for the fabrication of intricate functional devices with atomic level structural control that manifests and spans itself into the macroscopic world.

One of the key initial goals in polymer-mediated nanoparticle assembly is the design of catalytic nanocomposites. We have therefore designated a section within this entry solely to polymer–nanoparticle assemblies as applied to catalytic systems. The remaining sections describe the use of polymers to assemble nanoparticles into interesting and potentially useful architectures. Because of lack of space, this entry is not an exhaustive review of the literature but instead contains selected examples, which we feel highlight many of the different methodologies that have been employed for the assembly of polymer-based nanoparticle composites. When necessary the reader will be directed to more in-depth articles and reviews that contain information pertinent to the area.

## GENERAL APPROACHES TO POLYMER-MEDIATED ASSEMBLY OF NANOPARTICLES

Metal and semiconductor nanoparticles embedded within polymer matrices are attractive materials as

they share the processing and handling advantages of bulk materials as well as unique possessing properties arising from the nanoscopic size of the components. Traditional preparation of polymer–nanoparticle composites has been accomplished by in situ generation of metal nanoclusters, typically by chemical reduction of a metal salt contained within a polymer matrix (Fig. 1, route A). The primary function of the polymer matrix is to provide a protective barrier against aggregation of the metal particles during this reduction process. As shown in Fig. 1, a variety of different polymers (homopolymers, block copolymers, and dendrimers) have been employed in this regard in an effort to create well-ordered nanocomposite materials for various applications.

A similar but separate approach involves the assembly of polymer scaffolds with preformed monolayer-protected clusters (MPCs). Monolayer-protected clusters already contain a surface monolayer that prevents the metal from agglomerating and allows for ease of handling and processing (Fig. 1, route B). As such, MPCs can be readily dispersed into polymer matrices taking advantage of designed interfacial interactions between the monolayer functional groups and the polymer backbone. Multiple groups have demonstrated over the past several years that the latter approach provides a versatile alternative method for the fabrication of novel nanoparticle-polymeric materials.

## POLYMER SCAFFOLDS AND NANOPARTICLE BUILDING BLOCKS

### Polymer Scaffolds

Polymers are large molecular structures in which many small repeat units are linked together. These repeat units can be linked together in a linear array, as is the case with the homopolymers and block copolymers described in Fig. 1, or in branched fashion as is the case with dendrimers. Many different routes were followed to synthetically prepare the various types of polymers described in this entry; however, because of space limitations this is beyond the scope of the present chapter.

**Fig. 1** Polymer-mediated approaches to fabrication of ordered nanocomposites. Route A: In situ formation of particles within polymer matrices. Route B: Polymer-mediated assembly of preformed monolayer protected clusters (MPCs).

Suffice it to say there has been significant recent progress in the area of polymer synthesis specifically with respect to the formation of block copolymers via living polymerization techniques.<sup>[5-7]</sup>

Block copolymers represent a new and significant class of materials because of their remarkable ability to form unique micro- and nanophase morphologies. These properties are unattainable with homopolymers or their corresponding polymer blends. Diblock copolymers differ from traditional homopolymers in that two chemically distinct polymer chains are covalently connected end-to-end. The immiscibility of the different blocks with each other or with a solvent causes these polymers to phase separate, as such diblock copolymers are able to self-assemble into solvent-stabilized micelles, vesicles, and regular surface stabilized lamellar, cylindrical, or spherical arrays. Several examples will illustrate how appropriately functionalized diblock copolymers are able to incorporate nanoparticles or their precursor metal salts into specific polymer blocks.

Dendrimers are hyperbranched polymers that differ from their traditional linear counterparts in that the repeating units cascade outwardly from a central core rather than elongating in a linear fashion.<sup>[8]</sup> Dendrimers with sufficient layers (generations) take on 3-D/globular morphologies containing interior voids and cavities capable of accommodating guest species. Functionality can be accurately placed throughout the core and at the periphery of dendrimers providing control over such features as site-specific molecular recognition events, interior cavity

size, and overall polymer solubility. The internal attributes described above have been used to incorporate nanoparticles inside of dendrimers, while their distinct generational size-dependent morphologies have been used to define interparticle spacing between metal nanoparticles.

The use of biological polymers such as DNA to assemble and organize nanoparticles is an attractive strategy as the degree of non-covalent complementarity between these polymers can be effectively tuned. As the scope of nanoparticle-biopolymer interactions is exceedingly large in essence commanding its own chapter, we will not cover the topic here, there are, however, several recent examples worth noting that exemplify this type of assembly strategy.<sup>[9-11]</sup>

## Nanoparticle Building Blocks

Fig. 1 describes two of the most typically followed routes to the formation of polymer-nanoparticle composites. Route A generally involves using the polymer as both a template for the formation of nanoparticles into nano- or microdomains defined by the polymer as well as an organic stabilizer to prevent agglomeration after nanoparticle formation. Fairly monodisperse nanoparticles can be assembled using this methodology; however, in many instances the supporting polymer matrix does not offer long-term stability against agglomeration of the metal cores.

Route B typically involves the assembly of polymers with preformed nanoparticles already possessing a

stabilizing monolayer. One of the most frequently encountered MPCs is that of the alkanethiolate-stabilized gold cluster synthesized by the solution-phase method developed by Brust et al.<sup>[12]</sup> (Fig. 2). In this procedure chemical reduction of a gold salt by a hydride-reducing agent in the presence of thiol capping ligands furnishes the desired monolayer-protected nanoparticles. By carefully controlling the reaction conditions and by varying the stoichiometry of the metal salt to capping ligand a variety of different core sizes (1.5–8 nm) can be obtained.

Surface modifications of these nanoparticles can be achieved through a place exchange reaction, where new incoming thiol ligands displace monolayer thiols on the parent MPC to afford mixed monolayer-protected clusters (MMPCs).<sup>[13]</sup> This monolayer modification technique is extremely versatile as it allows for the incorporation of virtually any functionalized thiol into the preexisting monolayer. This permits the interfacial interactions on the surface of the nanoparticle to be precisely tuned to that of the assembling polymer strands.

Gold MPCs are attractive building blocks for the fabrication of nanoscale architectures as their synthesis permits good control over their size and polydispersity. Furthermore, the alkanethiolate monolayer provides excellent stability to intercore agglomeration both in air and in solution. This permits the particles to be handled (i.e., dissolved in solvents, isolated, dispersed in matrices) multiple times without significant degradation occurring and allows for easy characterization using standard solution-phase techniques such as nuclear magnetic resonance (NMR), infrared (IR), and UV–VIS spectroscopy.<sup>[14]</sup>

There are many other types of metallic, bimetallic, and semiconductor nanoparticles available;<sup>[15,16]</sup> however, in most instances, the chemistries of their formation are quite harsh, which substantially reduces the variety of functionalities that can be placed in their protecting monolayers. This makes assembling these types of nanoparticles into extended ordered structures substantially more difficult. Nanoparticle chemistry is still very much in its infancy and it is only a matter

of time before new procedures are created or existing procedures are modified to permit a wider variety of functionalities onto these other types of nanoparticles.

Monolayer-protected clusters clearly provide excellent “building blocks” of regular shape and size for the fabrication of larger ordered structures. These attributes provide part of the solution to the problem of multiscale fabrication as discussed earlier. What remains is their successful incorporation into desired functional ensembles.

## ASSEMBLIES OF NANOPARTICLES FOR CATALYTIC APPLICATIONS

Creation of nanoparticle assemblies possessing an open, porous framework is an attractive strategy for catalyst design. Various noble metals such as palladium, platinum, etc., are used for catalysis in numerous important chemical transformations, including hydrogenation, oxidation, and Heck coupling.<sup>[17–19]</sup> A high surface area-to-volume ratio is desirable for the creation of efficient heterogeneous catalysts as the cost of these precious metals is significant. Small nanoparticles (1–4 nm) are excellent candidates for catalysts in this respect as they exhibit extremely high surface area-to-volume ratios by virtue. Catalytically active materials obtained by metal nanoparticles dispersed in polymeric matrices display increased stability, improved processability, recyclability, and solubility in a variety of organic solvents.

A major thrust in the area of nanoparticle-based catalysts has been the preparation of palladium colloids within the micelles of amphiphilic block copolymers.<sup>[20]</sup> Forster and Antonietti have utilized poly-4-vinylpyridine-*b*-polystyrene (P4VP-*b*-PS) as the block copolymer and Pd(OAc)<sub>2</sub> as the palladium source in the preparation of metal colloids (Fig. 3). Distinct colloidal morphologies can be obtained by carefully controlling the method of reduction: A “raspberry morphology” is created with rapid reduction vs. a “cherry morphology” with a slower reduction rate.<sup>[21]</sup> Colloidal aggregates with the “raspberry morphology,” where

**Fig. 2** Brust et al.’s solution phase MPC synthesis,<sup>[12]</sup> followed by MMPC synthesis using the place exchange process developed by Murray.<sup>[13]</sup>

**Fig. 3** Preparation of palladium colloids in P4VP-*b*-PS block copolymer micelles.

the particle size is smaller, demonstrated excellent catalytic activity in the carbon-carbon bond forming Heck reaction. Although the catalyst reactivities were similar to other widely used phosphine ligand/Pd complexes, the polymer-bound Pd nanoparticle catalyst showed much higher stability.

Li and coworkers have shown that palladium nanoparticles stabilized by poly(*N*-vinyl-2-pyrrolidone) (PVP) can be used as efficient catalysts for Suzuki coupling reactions in 40% ethanolic aqueous media.<sup>[22]</sup> Good conversions were obtained upon refluxing for 12–48 hr; however, the PVP homopolymer does not provide adequate stability under such harsh reaction conditions as precipitation of the palladium metal occurs at the end of the reaction.

Underhill and Liu have employed triblock copolymer cross-linked nanospheres as templates for Pd nanoparticles.<sup>[23]</sup> Micelles of a polyisoprene-*b*-poly(2-cinnamoyloxyethyl methacrylate)-*b*-poly(*tert*-butyl acrylate) (PI-*b*-PCEMA-*b*-PtBA) were formed in 65% hexane/THF mixture. The micelles consisted of PI coronas, PCEMA shells, and PtBA cores. Photocross-linking the PCEMA shell produced stable nanospheres, hydroxylation of the terminal isoprene units provided water-dispersibility, and subsequent

hydrolysis of the PtBA groups provided poly(acrylic acid) (PAA) cores capable of complexing PdCl<sub>2</sub>. Loading of PdCl<sub>2</sub> into the acrylic acid core followed by reduction using hydrazine yielded polymer-stabilized palladium nanoparticles (Fig. 4). These palladium-loaded nanospheres were used to study hydrogenation reactions of tetraethylammonium bromide, vinylacetic acid, methylmethacrylate, and ethylene glycol dimethylacrylate. Although the diffusion barriers created by the encapsulating nanospheres led to slightly lower reaction rates compared to palladium black, the hydrogenation kinetics can be controlled by changing the pH as the core structure of the nanospheres is pH sensitive, which ultimately affects the transport of charged substrates into the nanospheres.

Dendrimers have also been used to sequester nanoparticles within their hyperbranched polymer architectures. Crooks et al. have employed poly(amidoamine) (PAMAM) and poly(propylene imine) (PPI) dendrimers as templates for the in situ generation of nanoparticles within the polymer shell of the dendrimer in an effort to create catalytically active nanocomposites.<sup>[24]</sup> Monodisperse nanoparticles can be created inside the dendrimer shell by first introducing a metal salt that strongly complexes to the interior tertiary

**Fig. 4** Cross-linked triblock copolymer nanospheres encapsulating Pd nanoparticles.

amine groups followed by subsequent reduction of the metal ions producing a trapped-stabilized zero-valent metal nanoparticle. They were able to demonstrate size selective hydrogenation catalysis of  $\alpha$ -substituted allyl alcohols by employing Pd stabilized by hydroxy-terminated PAMAM dendrimers (Fig. 5).<sup>[25]</sup> As generations were added to the dendrimers (G4OH  $\rightarrow$  G6OH  $\rightarrow$  G8OH) turnover frequencies of all the substrates decreased. Furthermore, within a given generation of dendrimer the turnover frequencies were always smaller for the larger substrates. The observed selectivity is a result of the steric crowding at the periphery of the dendrimer, which increases with the dendrimers generation. In essence, the periphery of the dendrimer behaves like a molecular filter which can be tuned in a generational fashion, ultimately hampering access of larger substrates to the catalytically active site.

Recently, Mecking et al. have utilized amphiphilic hyperbranched poly(glycerols) to prepare catalytically active and stable palladium colloids.<sup>[26]</sup> This amphiphilic *dendrimer-like* molecule is capable of solubilizing precursor palladium salts (e.g., PdCl<sub>2</sub>, Pd(OAc)<sub>2</sub>) in non-polar solvents such as toluene and chloroform. Slow reduction using hydrogen results in stable colloidal palladium. The authors suggest that the *soft* binding polyglycerols tend to avoid any ligand poisoning that may result in the amine-functionalized systems because of stronger coordination between the metal and the polymer–ligand. Subsequent catalytic hydrogenation reactions on cyclohexene using this amphiphile-stabilized palladium colloid proceeded at an impressive rate of 700 turnovers hr<sup>-1</sup>, with no significant decrease in rate during recyclable use.

In the example shown above, Crooks et al. employed the hindering effect of a dendrimer sheath in an advantageous way to obtain size selective catalytic discrimination. The polymer casing effectively controls substrate access to the catalytically active site. In general, however, this tends to be a drawback of polymer-supported catalysts as the substrates must find their way through the stabilizing polymer shell in order to reach the buried metal catalyst. This

ultimately results in inefficient mass transport mechanisms for these types of catalysts.

In an alternative approach to the polymer-stabilized nanoparticle catalysts described above, we employ directed self-assembly strategies to develop porous catalyst systems. Mixed monolayer-protected clusters of catalytically active metals can be utilized as building blocks in the presence of a suitable polymeric mediator to obtain macromolecular assemblies. Subsequent removal of the stabilizing polymers and ligands through calcination provides materials with tailored catalytic properties and with improved access to the catalytically active sites.

Preliminary studies to investigate this strategy involved a polymer-mediated three-component system employing both carboxylic acid-terminated gold and SiO<sub>2</sub> nanoparticles, and an amine-functionalized polystyrene random copolymer.<sup>[27]</sup> This type of assembly strategy is based on acid–base chemistry resulting in the electrostatic attraction between the basic polymer and the acidic nanoparticles when combined. Well-integrated nanocomposites were obtained upon the addition of the polymer to a mixture of the two nanoparticles, whereas segregated clusters were formed upon premixing of one of the MPCs with the polymer followed by the addition of the other nanoparticle.

This strategy was then applied to fabricate high-efficiency palladium catalysts.<sup>[28]</sup> Preformed SiO<sub>2</sub>–COOH/poly-NH<sub>2</sub> was used as a scaffold to assemble catalytically active Pd–COOH nanoparticles. The two-phase assembly strategy was necessary to obtain a high exposure of the catalytic metal on the surface of the final aggregate. Calcination removed all of the organic matter creating a highly porous Pd–SiO<sub>2</sub> composite material free of any polymer and monolayer stabilizers (Fig. 6).

The catalytic activity of the calcinated aggregates was investigated for the hydrogenation of 9-decen-1-ol. High turnover frequencies (TOF) (10,100 hr<sup>-1</sup> for the 1:1:1 w/w/w composition of Pd/Si/polymer, respectively) were observed, compared to the 7200 hr<sup>-1</sup> found under the same conditions for the commercial 1% Pd/C catalyst (Fig. 7). In addition, these systems

**Fig. 5** (A) Representation of a PAMAM-stabilized Pd nanoparticle catalyzing the hydrogenation of  $\alpha$ -substituted allyl alcohols. (B) Turn-over frequencies of the hydrogenation reactions of various allyl alcohols with generation 4-, 6-, and 8-hydroxy-terminated dendrimers.

proved to be excellent catalysts for Heck coupling reactions between electronically activated bromoarenes and styrene or methyl acrylate at very low catalyst loadings (0.045 mol% of Pd).

Unlike commonly used homogeneous Pd-catalysts, all of the nanoparticle-based catalysts described above required no activation by additional ligands such as phosphines and most could be recycled with only small decreases in their activity. Furthermore, nanoparticle catalysts are much simpler both to separate from their reaction mixtures and to recycle than typical homogeneous catalysts. The combination of these attributes makes them particularly attractive and useful catalysts for a variety of chemical transformations.

## ORGANIZED NANOPARTICLE ASSEMBLIES

The creation of discrete organized nanoparticle assemblies provides a structural motif for nanotechnology.<sup>[29–31]</sup> Highly structured, 3-D nanocomposites display unique magnetic, electronic, and optical behaviors that are both size and distance dependent. An effective way to control both the size and assembly of metallic nanoparticles is through the use of diblock

copolymers. As discussed earlier, diblock copolymers consist of two chemically distinct segments capable of organizing into various structural morphologies because of microphase separation. The size and morphology of the domains are easily controlled by varying the lengths of the individual blocks.<sup>[32]</sup> These self-assembled structures can act as scaffolds for patterning with metallic nanoparticles, employing selective wetting or complexation of the polymeric domains with metal clusters.

Rutnakornpituk and coworkers were able to prepare superparamagnetic cobalt nanoparticles within poly[di-methylsiloxane]-*b*-poly[(3-cyanopropyl)methylsiloxane]-*b*-poly[di-methylsiloxane] (PDMS-PCPMS-PDMS) triblock copolymer templates.<sup>[33]</sup> The copolymer forms micelles in toluene with the PCPMS block being oriented toward the interior of the micelle. Introduction of the cobalt precursor (Co<sub>2</sub>(CO)<sub>8</sub>) into the PCPMS block followed by subsequent thermal decomposition of the metal carbonyl complex yields stable nanoparticles. It is thought that the nitrile groups adhere to the particle surface while the bulky PDMS endblocks provide the steric stability against the core-to-core agglomeration.

Moore and coworkers synthesized several metal nanoparticle clusters using ionomers as templates.<sup>[34]</sup> The size of such ionic microdomains in these

Fig. 7 Rates of product formation in hydrogenation reactions of 9-decen-1-ol with different polymer ratios.

ion-containing copolymers can be controlled by choice of structure of the ionic monomer, whereas in diblock ionomers with spherical microdomains, the radii of the ionic core can be varied between 15 and 100 nm by varying the ionic block length. Utilizing these as microcompartments for nanocluster synthesis allows control over their size. In this approach the control of aggregate size is achieved primarily through ionomer aggregate size and not through varying ion concentration and subsequent annealing conditions.

Ng Cheong Chan et al. have demonstrated that block copolymers created from living ring opening metathesis polymerization reactions of methyltricyclododecene (MTD) and metal-functionalized norbornene monomers can yield stable nanoparticles. They have shown that both a precursor metal complex ( $\text{Ag}(\text{Hfacac})(\text{COD})$ )<sup>[35]</sup> as well as preformed monolayer-stabilized  $\text{CdSe}$ <sup>[36]</sup> nanoparticles can be incorporated into MTD and phosphine-functionalized norbornene block copolymers. In the case of the silver nanoparticles, the silver salts coordinate to the phosphine ligands within the core of solvent-stabilized micelles. Heating the silver-loaded micelles in water produces single nanoclusters (Fig. 8). Both fabrication methods yield stable spherical nanocomposites, but the latter method (akin to route B in Fig. 1) allows for the introduction of preformed nanoparticles that display a much narrower particle size distribution.

We have developed a different approach for using polymer scaffolds to direct the assembly of preformed nanoparticles. Our approach, which we have coined “bricks-and-mortar” self-assembly, involves functionalized nanoparticles as the building blocks or “bricks,” and polymer scaffolds bearing complementary recognition units that serve as the “mortar.” The complementary recognition motif is based on the three-point hydrogen bond between thymine-functionalized gold

**Fig. 8** Phosphine-containing diblock copolymer (bottom left) forming silver-loaded micelles (bottom right). Subsequent thermal treatment leads to stabilized individual silver nanoclusters (top right).

nanoparticles (Au-thy) and diaminotriazine-functionalized polystyrene (poly-triaz) (Fig. 9).

Addition of a triazine-substituted random copolymer (poly-triaz) to concentrated solutions of thymine-functionalized gold nanoparticles (Au-thy) in non-polar solvents results in the formation of insoluble aggregates.<sup>[37]</sup> The TEM images of the THF-soluble fraction of the poly-triaz/Au-thy precipitate revealed the formation of large spherical clusters approximately 100 nm in diameter composed of 3000–7000 individual gold particles (Fig. 10). Small-angle X-ray scattering (SAXS) analysis of the aggregates suggests that the nanoparticles are regularly dispersed within the polymer matrix providing evidence that individual polymer strands weave the nanoparticles together. When hydrogen bonding is disrupted, as is the case with the methylated Au-thy nanoparticles, no such aggregates are formed. This provides direct evidence that the specific hydrogen bonding interactions between the polymer and the nanoparticle drive the assembly process.

Thermal control of the assembly process leads to aggregates of well-defined size and morphology. For instance, highly size-dispersed networks of spherical aggregates were obtained by performing the assembly at 10°C, while performing the aggregation at –20°C yields even larger, individual aggregates. These aggregates are 5–10 times larger than the aggregates formed at 23°C, ranging from 0.5 to 1 μm in diameter and composed of 0.6–5.0 million (!) individual Au-thy nanoparticles, and are among the most complex synthetic self-assembled structures ever constructed.

A follow-up study was undertaken aimed at understanding how secondary molecular interactions such  $\pi$ - $\pi$  stacking in combination with the primary three-point hydrogen bonding interaction would influence the overall aggregation process.<sup>[38]</sup> Here various combinations of nanoparticle and polymer were synthesized containing different recognition elements consisting of either an electron-rich anthracene moiety or an electron-poor naphthalimide moiety in conjunction with a primary hydrogen bonding element. This study showed that weaker secondary interactions are indeed important to aggregate formation and that overall aggregate morphology is directly related to supramolecular events that occur at the colloid-polymer interface.

While we were able to demonstrate a limited level of control over the size and the morphology using monoblock copolymers by carrying out the assembly at different temperatures, we were never able to fully rationalize the observed trends. A solution to this problem is to employ a diblock copolymer where one of the blocks is functionalized as before and the second block remains unfunctionalized.<sup>[39]</sup> In this approach the functionalized block will provide the required hydrogen bonding interactions for the assembly, while

**Fig. 9** Three-point hydrogen bonding recognition between thymine-capped gold nanoparticles and diaminotriazine-functionalized polymers leads to extended network formation.

the inert second block will prevent extensive network formation. As only the functionalized block is capable of incorporating nanoparticle, the overall core size should depend primarily on the length of the functionalized block (Fig. 11A).

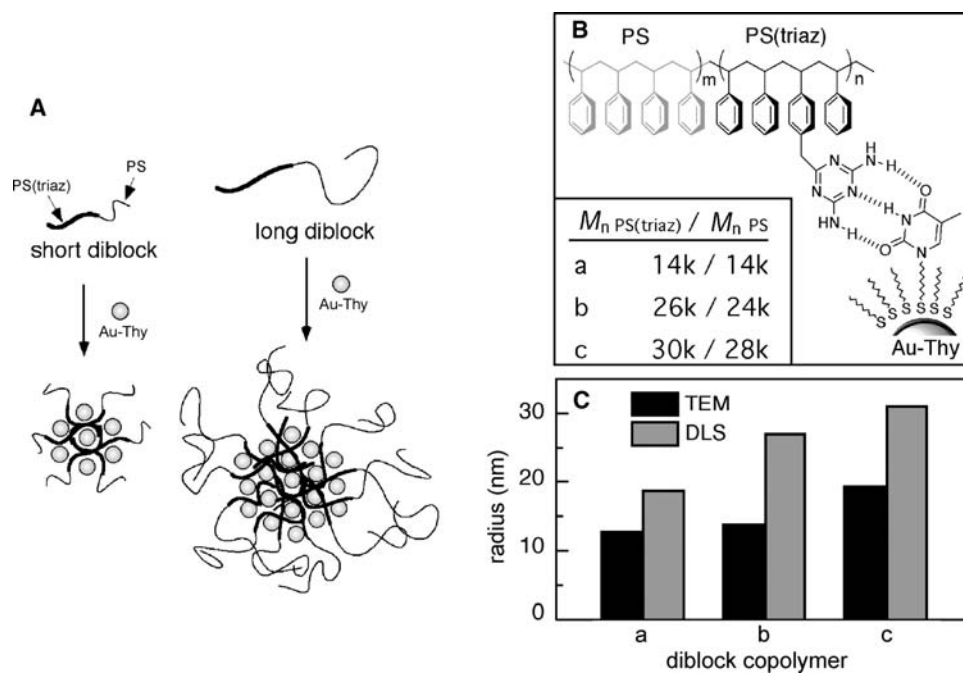

The feasibility of diblock-based control of aggregate size was demonstrated by employing three symmetric diblock copolymers (Fig. 11B) with varying total lengths. Combining Au-thy with the various polymers (A–C) results in aggregates with core sizes of  $13.2 \pm 1.3$ ,  $13.9 \pm 1.2$ , and  $19.4 \pm 1.8$  nm, respectively, as revealed by TEM analysis. Dynamic light scattering (DLS) experiments of the polymer micelles reveal the effective hydrodynamic radii  $R_h$  (core and polystyrene corona) to be 18.7, 27.1, and 31.1 nm for

the polymers (A–C), respectively. Comparison of core size by TEM to the overall aggregate size observed by DLS suggests that the polymer segments within the core are extended as compared to the polystyrene segments lying in the exterior, as the corona contributes less than half of the overall radius (Fig. 11C).

The ability to control the spacing between nanoparticles is an important issue as the electronic, and in certain cases the magnetic, properties of the nanoclusters are affected by neighboring particles. We were able to employ the size-dependent properties displayed by different generations of PAMAM dendrimers to both assemble and control the distance between gold nanoparticles.<sup>[40]</sup> Electrostatic self-assembly between the dendrimer and nanoparticle components was provided

**Fig. 10** (A) TEM of Au-thy/poly-triaz aggregates formed at 23°C. Inset: Representative self-assembled nanoparticle-polymer microspheres. (B) TEM of Au-thy/poly-triaz aggregate network formed at 10°C. (C) TEM of Au-thy/poly-triaz spherical aggregate formed at -20°C.

**Fig. 11** (A) Schematic representation of diblock length controlling nanoparticle core and corona size. (B) Different length PS(triaz)-*b*-PS polymers assembled with Au-Thy. (C) Observed nanoparticle core size by TEM compared to hydrodynamic radii of the micelles determined by DLS.

by salt-bridge formation between a carboxylic acid-functionalized nanoparticle and the terminal amine groups on PAMAM dendrimers (Fig. 12).

Examination of the resulting assemblies by TEM revealed that varying the ratios of MMPC to dendrimer resulted in two distinct morphologies. Low dendrimer to MMPC ratios led to network-like structures, which showed little evidence of spatial control. In contrast, high ratios of dendrimer to MMPC (10:1 based

**Fig. 12** Schematic representation of electrostatic self-assembly of carboxylic acid gold nanoparticles and PAMAM dendrimers.

on functional group equivalence) resulted in spherical aggregates ranging from 0.5 to 1.5  $\mu\text{m}$  in diameter (Fig. 13A). In these assemblies, qualitative differences in inter-MMPC spacing could be readily discerned.

Quantification of interparticle distance in the dendrimer MMPC nanocomposites was obtained using SAXS. When the carboxylic acid-functionalized nanoparticle was assembled with PAMAM dendrimers, the primary peak shifted to lower  $q$  values (translating into greater interparticle distances) as the particle is assembled with larger dendrimers ( $G_0 \rightarrow G_1 \rightarrow G_2 \rightarrow G_4 \rightarrow G_6$ ), (Fig. 13). This example clearly demonstrates how different generations of dendrimers can be effectively used to control the spacing between nanoparticles.

Dendrimer-nanoparticle composites have also been used to form functional sensors.<sup>[41]</sup> Vossmeier et al.

**Fig. 13** (A) Self-assembled nanoparticle-dendrimer microspheres. (B) Graph of correlation between PAMAM generation and interparticle spacing derived from SAXS data.

Polyelectrolyte - Polymer

created thin films of chemically cross-linked gold nanoparticles and polyphenylene dendrimers and deposited them onto glass substrates containing interdigitated gold electrodes. The rigid polyphenylene dendrimer provides a highly porous film for the incorporation of analyte while the nanoparticles provide a high surface-to-volume ratio leading to excellent signal transduction through the film. They were able to show ppm sensitivity to various volatile organic compounds (VOCs) such as toluene and tetrachloroethylene by measuring the change in electrical resistance through the films after exposure to the VOCs. This example demonstrates how the directed assembly of polymers and nanoparticles can lead to working composite devices.

### HIGHLY ORGANIZED POLYMER-NANOPARTICLE ASSEMBLIES ON SURFACES

The previous examples show how polymers have been used to both create finite ordered nanoparticle arrays and assemble nanoparticles into discrete ordered entities extending into the microscale realm. The formation of these large complex structures from small polymeric building blocks is a testament to the power of self-assembly. For many purposes, the controlled ordering at this level may be adequate; nevertheless, functional device applications such as nanoelectronics or memory media (optical or magnetic) require higher degrees of ordering. To create such sophisticated devices it is essential to fabricate not only highly *ordered* arrays but also arrays that are highly *extended* over vast distances (nm→cm).

To this end, Spatz and coworkers have used micelles obtained from diblock copolymers of polystyrene-polyvinylpyridine (PS-*b*-PVP)<sup>[42,43]</sup> and polystyrene-polyethylene oxide (PS-*b*-PEO)<sup>[44]</sup> for synthesis of

metallic and semiconductor nanoparticles. In the case of the PS-*b*-PVP, the pyridine units within the micellar cores can uptake transition metal salts because of hard acid/soft base interactions (Fig. 14). This strategy allows one to obtain size-controlled synthesis of gold nanoparticles by controlling the amount of the precursor salt. Micelles containing the gold salt arranged into quasi-hexagonal packing when transferred onto a flat surface. Subsequent treatment with oxygen plasma completely removed all of the polymeric material yielding highly ordered bare gold nanoclusters.<sup>[45]</sup> Reducing the gold salts in the micellar core before plasma treatment gave clusters of similar size. Varying the concentration of metal salt allows one to obtain cluster sizes from 1 to 15 nm, whereas changing the length of the blocks allows one to get interparticle distances from 30 to 140 nm.

Using a different approach, similar to that of the layer-by-layer (LBL) assembly of oppositely charged polyanions developed by Decher,<sup>[46]</sup> Schmid, Bäuml, and Beyer were able to assemble [Au<sub>55</sub>(Ph<sub>2</sub>PC<sub>6</sub>H<sub>4</sub>SO<sub>3</sub>H)<sub>12</sub>Cl<sub>6</sub>] clusters onto poly(ethyleneimine) (PEI)-covered surfaces (Fig. 15).<sup>[47]</sup> They found that the clusters ordered on the surface into the typical hexagonally close-packed arrangement, but they also found large domains of nanoparticles with an unusual cubic lattice structure. They attribute this high level of surface ordering to the use of PEI with a moderate molecular weight (60,000), which they believe allows the polymer to uncoil on the surface creating a more ordered polymer template. In this case the nanoparticles are packed immediately next to one another as there is no thick polymer sheath surrounding the nanoparticle. There are several examples of LBL assemblies containing multiple layers of polymers with gold,<sup>[48-51]</sup> semiconductor,<sup>[52]</sup> or magnetic nanoparticles,<sup>[53]</sup> and the interested reader is directed to those references.

Using the MTD and phosphine-functionalized norbornene block copolymers as described earlier (Fig. 8),

**Fig. 14** Deposition of nanoparticles in a block copolymer micelle onto a surface. (A) Subsequent removal with oxygen plasma yields bare nanoparticles. (B) Schematic representation showing hexagonal packing arrangement of nanoparticles.

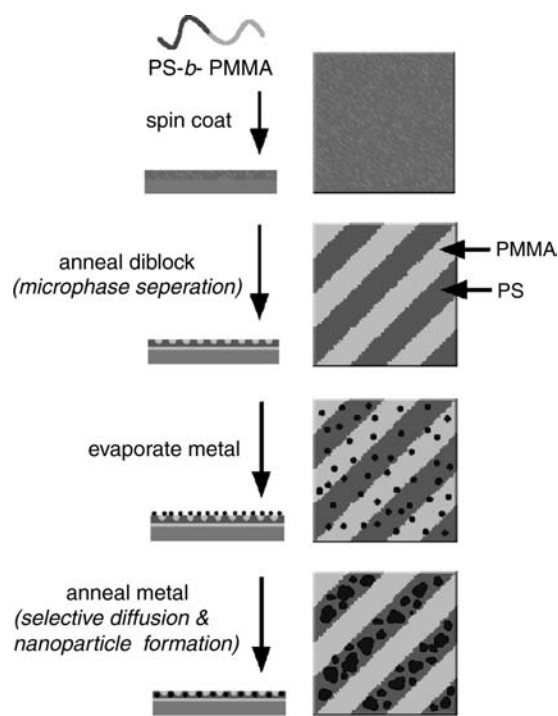

**Fig. 15** Poly(ethyleneimine)-mediated assembly of sulfonated gold nanoparticles arranging into (A) hexagonal and (B) cubic-packed formations.

Ng Cheong Chan et al. were able to form ordered surface assemblies of silver and gold nanoparticles.<sup>[54]</sup> In these studies the phosphine-containing block of the copolymer can selectively coordinate, in a “dative” fashion, to gold and silver, forming coordination complexes in benzene solutions. Films cast from the block copolymer silver solutions yielded lamellar structures while those cast from the gold solutions gave cylinders. Thermally annealing the films yielded striped domains of silver nanoparticles (2–10 nm in diameter) and spherical domains of gold nanoparticles (1.5–4 nm). In both cases long-range ordering occurred and the interdomain spacing was consistent with the length of the unfunctionalized block. This type of methodology

was extended to the incorporation of zinc and cadmium into similar norbornene block copolymers to form the sulfides of these metals within specific lamellar block copolymer microdomains.<sup>[55]</sup>

More recently, Lopes and Jaeger have demonstrated that ultrathin films of phase-separated diblock copolymers can be utilized as templates allowing for the incorporation of metal nanoclusters with selectivity approaching 100% into the desired domain.<sup>[56,57]</sup> In these studies metal vapors were allowed to permeate an ultrathin film consisting of laterally alternating domains of PS and PMMA, obtained using a PS-*b*-PMMA diblock copolymer (Fig. 16). The PS domains preferentially absorb Au and Ag, while the PMMA domains show preference for In, Pb, Sn, and Bi. Near-perfect selective absorption is observed for the deposition of Ag. In the cases where the deposition is only partially selective to one block, selectivity is obtained by annealing the system above the glass transition temperature of the diblock copolymer. Depending on the annealing protocol, distinct separate nanoparticles could be formed within the decorated polymer block. Alternatively, metal nanowires can be obtained by a repeated deposition and annealing sequence. It was shown that the *nanowire* diblock templates display linear current–voltage (*I*-*V*) characteristics over a wide range of conditions, while the *nanoparticle* diblocks exhibit highly nonlinear *I*-*V* curves.

**Fig. 16** Steps for creating ordered arrays of nanoclusters and nanowires in phase-separated PMMA-*b*-PS diblock copolymer films.

## CONCLUSION

Polymer-mediated assembly of nanoparticles is a versatile and effective method for the creation of nanocomposite materials. The ability to chemically control both the polymer structure and the nanoparticle core and shell at the molecular level provides access to a wide variety of resulting materials with tunable properties. This combinatorial approach, coupled with the wealth of structures that can be obtained through self-assembly, makes polymer–nanoparticle composites

potentially useful for a variety of applications. Nanoparticle chemistry and polymer self-assembly are still emerging disciplines and as such we are just beginning to learn the rules that govern their assembly. As we learn these rules and begin to put them to the test, both the complexity and the resulting utility of nanoparticle-polymer composites will increase dramatically.

## INTRODUCTION

This entry discusses materials and techniques used to generate polymer replicas of nanostructures by molding, embossing, and printing. Nanostructures are defined as those that have lateral dimensions of less than 100 nm. The effect of spatially confining materials to these dimensions gives rise to physical, electronic, mechanical, magnetic, and optical properties, e.g., quantum behavior,<sup>[1,2]</sup> superparamagnetism,<sup>[3]</sup> depressed melting point,<sup>[4,5]</sup> and increased hardness,<sup>[6,7]</sup> that differ, at times significantly, from those of microstructures and macrostructures.

The fabrication and characterization of nanostructures are important for applications in optics,<sup>[8]</sup> computation,<sup>[9]</sup> data storage,<sup>[10,11]</sup> specialty materials,<sup>[7]</sup> and biology.<sup>[12]</sup> Most processes for producing electrically, magnetically, and optically functional devices containing nanostructures include four basic steps: 1) fabrication of a “master” (i.e., a substrate from which replicas are formed); 2) replication of the master; 3) transfer of the replica into a functional material (e.g., semiconductor or metal); and 4) registration of the pattern of a master (the same as or different than the one used originally) with that of the replica for multilayer structures. This article focuses on the polymers and the molding techniques useful for the second step of this process.

## OVERVIEW

### Why Replication of Nanostructures into Polymers?

Replication of nanostructures into photosensitive polymers by photolithography is routine in fundamental and applied research and in commercial manufacturing.<sup>[13]</sup> The process replicates features from a photomask that is prepared by a serial lithographic technique such as electron-beam lithography,<sup>[14,15]</sup> focused-ion milling,<sup>[16–18]</sup> or scanning probe lithography.<sup>[19–21]</sup> The fabrication of masters by these

techniques is slow ( $\sim 10 \text{ hr/cm}^2$ ) because each feature in the mask is drawn individually. The lateral dimensions of the structures that can be patterned by photolithography are limited by the wavelength of the illumination source; state-of-the-art, 157-nm sources can fabricate features as small as 50 nm.<sup>[22]</sup> The techniques for making masters and for sub-100-nm photolithography require specialized, expensive equipment; such equipment is readily accessible in industry, but is not commonly available in academic research laboratories.

### Advantages and Disadvantages of Replication of Nanostructures into Polymers

Replication of nanostructures by the molding of polymers shares the attractive feature of photolithography (that is, it can replicate all the features on a master in one step), but with a much lower limit, in principle, for the lateral dimensions of features ( $\sim 1 \text{ nm}$ ) than that for photolithography. This limit is set by the size of the molecules in the replica. The molding of polymers has four advantages over photolithography: 1) the techniques can replicate nanostructures over large areas ( $> 1 \text{ m}^2$ ); 2) the dimensions of the features replicated into polymers are not distorted by problems common to photolithographic techniques (e.g., variations in focus, intensity, and exposure dose); 3) the materials and the facilities necessary are inexpensive and readily accessible; and 4) the process may be compatible with low-cost manufacturing processes (e.g., roll-to-roll processing).

The replication of nanostructures by molding in polymers has seen only limited commercial applications to date. Replication of sub-10-nm features is still difficult to obtain reproducibly over large areas because of lateral collapse of the features in the polymeric replica. Defect densities are currently too high for use in most high-performance electronic devices; no defects must be observed over an area of several square centimeters for commercial applications. The process of replication does not reduce the dimensions of features; that is, the dimensions of the features

defined in the master must be the same as those desired in the replica. This characteristic differs from photolithography where dimensions in a mask can be reduced optically.

## POLYMER MATERIALS AND PROPERTIES FOR USE IN REPLICAS

Table 1 summarizes some of the types of polymers used to replicate masters by molding and the properties relevant to molding. Two properties that influence the quality of a polymer replica are the coefficient of thermal expansion of the master and the polymer and the dimensional change in the polymer during curing. The dimensions of features defined in masters or replicas made of polymers with large coefficients of thermal expansion can be distorted by changes in the temperature. The polymer replica also can shrink during curing because of evaporation of solvents, cross-linking of the polymer, and/or thermal expansion of the polymer (for heat-based curing)<sup>[23]</sup> These processes can also yield replicas with distorted features.

Some processes of replication reshape thin films of polymers by softening them at elevated temperatures; the temperature at which the polymer softens is the glass transition temperature ( $T_g$ ). Low glass transition temperatures (i.e.,  $45^\circ\text{C} < T_g < 150^\circ\text{C}$ ) can minimize distortions of the critical dimensions of the features because of thermal expansion of the master during

heating and thermal contraction of the replica during cooling. Temperatures within this range also make the process compatible with a wide range of substrate materials (e.g., polymers and low-melt glasses).

Mechanical instabilities in the polymers can lead to vertical and lateral collapse of the features in the replica. The elasticity or the tensile modulus of the material used to make the replica determines the importance of these distortions. They are significant for nanostructures defined in polymers that have a low tensile modulus ( $< 2\text{ MPa}$ ), and they limit the minimum dimension ( $> 300\text{ nm}$ ) and the minimum aspect ratio (0.4; height/width) of the features these polymers (e.g., derivatives of polydimethylsiloxane (PDMS) such as 184-PDMS and s-PDMS) can replicate.<sup>[24–26]</sup> A number of groups have developed formulations of PDMS (e.g., *h*-PDMS and *hν*-PDMS) that have a medium to high elastic modulus (4–10 MPa).<sup>[23,27,28]</sup> These formulations of PDMS are particularly useful for the replication of nanostructures, as they can replicate features with lateral dimensions as small as 30 nm and with vertical dimensions as small as 2 nm.<sup>[27,29]</sup>

The process removing a rigid replica from a rigid master can damage the fragile nanostructures defined on each surface. The physical toughness of the polymer is an indication of how much stress it can tolerate before cracking. The potential for damage to the features in the master and in the replica decreases when using a polymer with a tensile strength of  $> 0.1\text{ MPa}$

**Table 1** Properties of polymers used commonly in replication

	Tensile modulus (MPa)	Toughness (MPa)	Surface free energy (dyn/cm <sup>2</sup> )	Coefficient of linear thermal expansion (ppm/°C)	Glass transition temperature (°C)	Method of curing	Commercially available

(e.g., PDMS) as the material for the replica. Polymers with a high toughness tend to have a low tensile modulus.

The surface free energy of the polymer is a parameter that determines the ease of release of the polymer replica from the master and thus the damage to the replicated nanostructures during this process. PDMS is a useful material for use in replicas because it has a low surface free energy ( $\sim 21.6$  dyn/cm).<sup>[30]</sup> After molding, the surface energy of PDMS replica can be lowered further to  $\sim 12$  dyn/cm by coating the surface with a fluorosilane;<sup>[31,32]</sup> this process makes the surface properties of the stamp similar to poly(tetrafluoroethylene) (Teflon<sup>®</sup>).

## TECHNIQUES FOR THE REPLICATION OF NANOSTRUCTURES BY THE MOLDING OF POLYMERS

### Replica Molding

Replica molding is a technique used routinely to fabricate macroscale and microscale objects, e.g., compact disks, digital versatile disks (DVD), holograms, and plastic parts, by molding a polymer against ceramic, metallic, or rigid plastic masters (Fig. 1). Typically, the surface of the master is modified chemically to lower its surface free energy by coating it with a fluorinated molecule or polymer; this layer facilitates the separation of the master from the replica after molding. Damage to the nanostructures defined in the master and/or the replica occurs most commonly during this separation. The use of elastomeric polymers in replica molding helps to minimize damage to the nanostructures, especially in the replica, during separation because of the toughness and elasticity of the polymers. An example of replica molding into PDMS is the replication of rings of photoresist into a composite polymer made of a thin layer ( $40\ \mu\text{m}$ ) of *h*-PDMS and a thick layer ( $>1$  mm) of 184 PDMS (Fig. 2). The composite PDMS structure can replicate

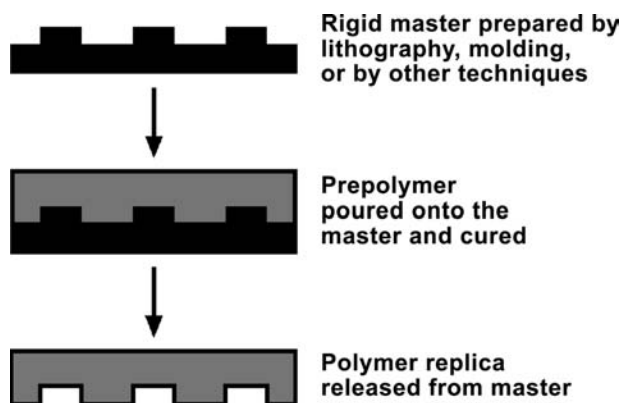

Fig. 1 Scheme for replica molding.

From Ref.<sup>[28]</sup>.

sub-100-nm features by molding and can be removed easily from a master without damaging the nanostructures on either surface.<sup>[27,28]</sup>

### Soft Lithography

Soft lithography is a suite of techniques that use a PDMS-based stamp—prepared by replica molding—as the master (Fig. 3).<sup>[13,31,32]</sup> Replica molding (RM),<sup>[33]</sup> microtransfer molding ( $\mu\text{TM}$ ),<sup>[34]</sup> micromolding in capillaries (MIMIC),<sup>[35]</sup> and solvent-assisted micromolding (SAMIM)<sup>[36]</sup> are four soft-lithographic techniques that replicate features by the molding of polymers. For many of these techniques, the inherent low surface free energy of PDMS is enough to permit the stamp to be separated from the replica without the need of a release layer.

**Fig. 3** Schematic illustrations of the procedures used in the corresponding soft lithographic techniques. (A) Replica molding (RM); (B) microtransfer molding ( $\mu$ TM); (C) micromolding in capillaries (MIMIC); (D) solvent-assisted micromolding (SAMIM).

### Replica molding

The soft lithographic version of replica molding uses a PDMS stamp as the master instead of a rigid material (Fig. 3A). Fig. 4 shows the replica molding of nanostructures into an UV-curable polyurethane. The PDMS stamp can be used repeatedly; no measurable

**Fig. 4** Atomic force micrographs of (A) a chrome master; (B) a polyurethane replica of the master produced by replica molding; (C) atomic force micrographs of chrome master; (D) atomic force micrographs of polyurethane replica. *Source:* The images in this figure are reproduced with permission from *Advanced Materials*. From Ref.<sup>[33]</sup>.

difference in feature quality is observed after successive replication into polyurethane more than 20 times from the same stamp.

### Microtransfer molding

Microtransfer molding prepares a replica by first filling the recessed regions of the stamp with a curable prepolymer (Fig. 3B). The excess prepolymer is scraped from the surface of the stamp using a thin slab of PDMS; this scraping process does not remove the excess polymer completely, and, often, a thin film of excess polymer remains on the replica. The filled stamp is placed onto a rigid substrate under slight pressure. The prepolymer is cured by the appropriate technique, and the mold is removed manually. This technique is well suited for UV-curable materials because the PDMS stamp is optically transparent above  $\sim 290$  nm.

### Micromolding in capillaries

Micromolding in capillaries uses capillarity to fill channels in a PDMS stamp with a photocurable or thermally curable polymer (Fig. 3C). A PDMS-based stamp is placed in conformal contact with a surface. The stamp is topographically patterned with a series of channels that extend from one end of the stamp to the other. A drop of liquid prepolymer placed at one

Polyelectrolyte - Polymer

**Fig. 5** (A) Atomic force micrograph of lines of photoresist patterned by MIMIC. (B) Scanning electron micrograph of Novalac photoresist patterned by SAMIM. *Source:* The images are reproduced with permission from *The American Chemical Society*. From Ref.<sup>[28]</sup>.

end of the stamp fills the channels by capillarity. The polymer is cured once the entire channel network is filled. The replication of nanochannels in a 184-PDMS stamp is difficult because the channels tend to collapse when the stamp is placed in contact with a surface.<sup>[28]</sup> Composite stamps of *h*-PDMS and 184-PDMS overcome this limitation and can be used to replicate features with critical dimensions below 300 nm (Fig. 5A). Unlike  $\mu$ TM, this technique does not produce an excess polymer film on the replica.

#### Solvent-assisted micromolding

Solvent-assisted micromolding is similar operationally to traditional embossing techniques, but it uses solvent to reshape a polymer rather than elevated temperatures, and it uses an elastomeric stamp instead of a rigid master (Fig. 3D). Elastomeric stamps are especially useful in embossing because the stamp conforms to the surface of the polymer and contacts uniformly over large areas. The stamp is wet with a solvent for the polymer that is to be molded and placed in contact with a thin film of this polymer. The solvent is

allowed to evaporate, and the stamp is removed to reveal the replica in the polymer. Air bubbles and voids in the replica as a result of poor evaporation of the solvent before removal of the stamp are not observed because the stamp is gas-permeable. This process has been demonstrated for a number of polymers including: Novalac photoresists, poly(styrene), poly(methylmethacrylate), cellulose acetate, poly(vinyl chloride), and precursors to conjugated organic polymers.<sup>[36]</sup> An example of nanostructures prepared by this technique is in Fig. 5B. The molded structure can also act as its own optical element for further size reduction of the features.<sup>[37]</sup>

#### Advantages and disadvantages of soft lithography

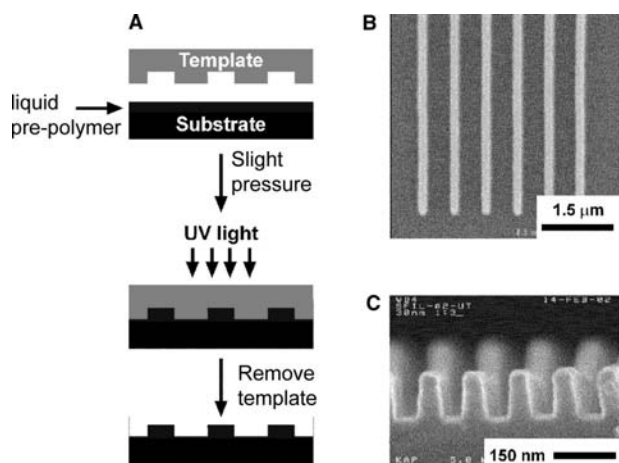

The advantages of soft lithography are that: 1) it uses inexpensive materials and equipment; 2) it can replicate over large areas and on nonplanar surfaces; 3) it uses stamps that are compatible with a large number of polymers; and 4) it uses stamps that are gas-permeable. The disadvantages are that: 1) the PDMS molds are not compatible with many organic solvents or high temperatures; 2) the softness of PDMS can cause distortions in molded structures; 3) the use of PDMS-based stamps requires careful temperature control because of the high coefficient of thermal expansion; that is, small changes in temperature can change the dimensions of the nanostructures; and 4) the registration of multilayer patterns is difficult.

#### Imprint Lithographies

Step-and-flash imprint lithography (developed by Willson et al.<sup>[38–41]</sup>) and nanoimprint lithography (developed by Chou et al.<sup>[42–44]</sup>) are two forms of imprint lithography that are used for the replication of nanostructures into polymers. Both techniques work by placing a topographically patterned, rigid master in contact with a formable material coated on a rigid surface. The rigid master is prepared by photolithographic replication of the features into a polymer that is coated on a rigid substrate (e.g., quartz and silicon). The structures are transferred into the substrate by etching.

#### Step-and-flash imprint lithography

Step-and-flash imprint lithography uses a low-viscosity, photocurable polymer as the material for the replica (Fig. 6)<sup>[41]</sup> The low viscosity of the polymer eliminates the need for high temperatures and pressures. A quartz master is placed in contact with the photocurable polymer under slight pressure. Flood illumination through the backside of the master cures the polymer replica. The master is transparent to the

**Fig. 6** (A) Schematic illustration of step-and-flash imprint lithography. (B) Scanning electron micrograph of lines of polymer on a silicon substrate patterned by the technique. (C) Scanning electron micrograph of the cross-section of the lines in (B). *Source:* The images in (B) and (C) are reproduced with permission from *Proceedings of the SPIE*. From Ref.<sup>[45]</sup>.

wavelengths necessary to cure the polymer. Treatment of the surface of the master with a fluorosilane lowers its surface free energy and facilitates the removal of the master from the replica. The technique can replicate features with lateral dimensions greater than 30 nm and with aspect ratios as high as 8:1 (for 50-nm lines).<sup>[41,45]</sup> Step-and-flash lithography is “self-cleaning” because particulates on the surface of the master are trapped in the replica during the curing process. Repeated use of a master actually lowers the density of defects in the replica.<sup>[46]</sup>

The advantages of step-and-flash imprint lithography are that: 1) it is a room-temperature technique and is therefore not subject to thermal- or pressure-induced deformations of the nanostructures; 2) it is a rapid process (< 5 min/cycle);<sup>[40,47]</sup> and 3) it uses optically transparent masters that permit alignment of the replica with underlying features. The disadvantages are that: 1) the masters are more difficult to prepare than those used in soft lithography; 2) the replication of non-planar masters is difficult;<sup>[48]</sup> and 3) the technique is not good for the replication of isolated, recessed features in the master.<sup>[41]</sup>

### Nanoimprint lithography

Nanoimprint lithography differs from step-and-flash imprint lithography in that it reshapes a polymer at temperatures above its glass transition point, e.g., 90–100°C, and requires high pressures, e.g., 50–100 bar (Fig. 7).<sup>[43,44]</sup> The high temperatures lower the viscosity of the polymer enough to fill the master uniformly. The replica and mold are allowed to cool before separation.

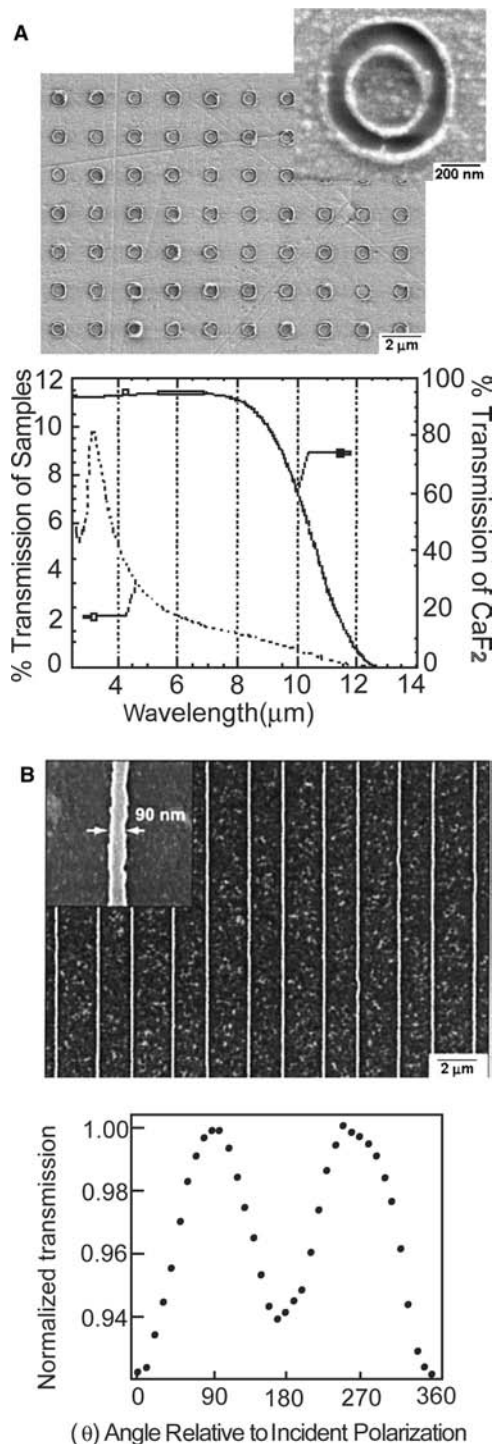

**Fig. 7** (A) Schematic illustration of the process used in nanoimprint lithography. (B) Scanning electron micrograph of the SiO<sub>2</sub> master. (C) Scanning electron micrograph of the polymer replica of the master in (B) made by nanoimprinting. *Source:* The images in (B) and (C) are reproduced by permission of *MRS Bulletin*. From Ref.<sup>[43]</sup>.

The technique can replicate nanostructures as small as 10 nm and aspect ratios as large as 10:1.<sup>[43]</sup> Transparent masters can be used to permit multilevel registration of replicas. Nanoimprint lithography can be carried out in a sequential, step-by-step process similar to that of step-and-flash. The fidelity of replication of nanostructures with critical dimensions of less than 50 nm is poor over large areas because the polymer chains in the materials used in the replicas tend to relax and spread over distances of tens of nanometers.<sup>[47]</sup> These factors can only be corrected by designing the original master to account for polymer shrinkage in the processing steps. Another disadvantage of nanoimprinting is that it requires 10–15 min per replication for the heating and cooling cycles; this interval is 3–5 times longer than that necessary for the entire replication process for step-and-flash imprint lithography and some soft lithographic techniques.<sup>[47]</sup>

### Uses for Polymeric Replicas with Nanostructures

Replication of nanostructures into polymers is used to make electronic,<sup>[49–59]</sup> optical,<sup>[60–64]</sup> and mechanical<sup>[65–69]</sup> devices. Single-layer, subwavelength, optical elements, e.g., frequency-selective surfaces (Fig. 8A), are one example of such a device fabricated by soft lithography.<sup>[57,62,70,71]</sup> A master was replicated into Novalac photoresist by solvent-assisted micromolding. The replica acted as a photomask, and the edges of the raised features

From Ref.<sup>[77]</sup>.

were transferred into the underlying photoresist upon exposure to UV-light. The PDMS replica prepared by standard replica molding was used to fabricate polarizers by a similar, phase-shifting lithography technique (Fig. 8B).<sup>[70]</sup> The PDMS replicas can also be used to replicate nanostructures into metals by microcontact printing. This process uses the PDMS replica as a stamp to print an organic molecule selectively onto a metal surface. This molecule acts as an etch resist and permits the selective etching of unprotected regions. This technique was used to fabricate polarizers,<sup>[28]</sup> hydrogen-gas sensors,<sup>[72]</sup> transistors,<sup>[50,52]</sup> and microelectromechanical systems (MEMS) devices.<sup>[69,73]</sup> The imprint lithographies use the polymer replica as an etch resist to transfer the pattern of the replica into a functional material. These techniques have been used to make photonic crystals,<sup>[74]</sup> polarizers,<sup>[75,76]</sup> photodetectors,<sup>[56]</sup> and transistors (Fig. 9).<sup>[58,59,77]</sup>

## CONCLUSION

Although replication will not replace the techniques used currently for the preparation of masters, it is extremely useful as a research tool for the rapid prototyping of devices using nanostructures. The combination of the two techniques could enable the fabrication of nanostructures to become routine and cost-effective. Polymeric replicas containing nanostructures may be most useful in the process of fabricating low-cost, low-to-medium performance optical and electronic devices (e.g., RF-ID tags, large area displays, optical filters, and polarizers). Efforts to improve the capabilities of replication will lead to the fabrication of new devices based on the unique properties of nanostructures.

## INTRODUCTION

Polymer nanocomposites are composites with a polymer matrix and a filler with at least one dimension less than 100 nm. The fillers can be plate-like (clays), high aspect ratio nanotubes, and lower aspect ratio or equiaxed nanoparticles. While some nanofilled composites (carbon black<sup>[1]</sup> and fumed silica<sup>[2,3]</sup>-filled polymers) have been used for over a century, in recent years the dedicated research and development of nanofilled polymers has greatly increased. This is due to our increased ability to synthesize and manipulate a broad range of nanofillers and significant investment by government and industry in this field.

Current interest in nanocomposites has been generated and maintained because nanoparticle and carbon nanotube-filled polymers exhibit unique combinations of properties not achievable with traditional composites. For example, the inclusion of equiaxed nanoparticles in thermoplastics, and particularly semicrystalline thermoplastics, increases the yield stress, the tensile strength, and Young's modulus<sup>[4]</sup> compared to pure polymer. Other examples include scratch-resistant transparent amorphous thermoplastic coatings.<sup>[5]</sup> These combinations of properties can be achieved because of the small size of the fillers, the large surface area the fillers provide, and in many cases the unique properties of the fillers themselves. As will be shown, in many cases these large changes in the material properties require small to modest nanofiller loadings. Unlike traditional micron-filled composites, these novel fillers often alter the properties of the entire polymer matrix while, at the same time, imparting new functionality because of their chemical composition and nanoscale size.

This entry will give a general introduction to polymer nanocomposites and address what is unique to nanofillers compared to traditional micron-scale fillers. The second section will briefly address nanofiller surface modification and the third will provide specific

examples of mechanical, electrical, and optical properties in nanoparticle-filled polymers. The last section provides a detailed description of the mechanical properties of nanotube-filled polymers and a brief description of some electrical and optical properties that have been reported.

## WHAT MAKES NANOCOMPOSITES UNIQUE

The small size of nanofillers leads to several factors that distinguish nanocomposites from traditional composites. First of all, nanofillers are small mechanical, optical, and electrical defects compared to micron-scale fillers. This means that the addition of nanofillers to a polymer does not necessarily lead to a decrease in the ductility of the polymer and in some cases can increase it.<sup>[6,7]</sup> It also means that below about 50 nm,<sup>[8]</sup> many fillers do not scatter light significantly. Thus it is possible to make composites with altered electrical or mechanical properties that maintain their optical clarity. Finally, as small electrical defects, nanofillers do not concentrate electromagnetic fields as sharply as micron-scale fillers and indeed may act to trap charge and increase the electrical breakdown strength of polymers.

Secondly, although many properties of a material are said to be intrinsic, they often depend upon matter being assembled above a critical length scale. When the nanoparticles decrease below this size, the properties of the particles can differ significantly from the bulk material; thus variations in melting temperature, color, magnetization, and charge capacity are often observed.<sup>[9]</sup>

Third, the small size of the fillers leads to an exceptionally large interfacial area in the composites. Fig. 1A shows the surface area per unit volume as a function of particle size for spherical particles that are ideally dispersed. If one compares the surface area of a 10- $\mu\text{m}$  carbon fiber to that of a 1-nm single-walled nanotube

**Fig. 1** (A) The surface area per unit volume as a function of particle size for spherical particles showing the large surface area in nanoparticles. (B) The interparticle spacing of nanoparticles arranged on a simple cubic lattice showing the variation with particle size (15, 50, and 100 nm diameter) and volume fraction.

(SWNT) for the same total volume of the two, the surface area increases by a factor of 10,000. In addition (Fig. 1B), the interparticle spacing decreases such that at small volume fractions of filler, the interparticle spacing is similar to the radius of gyration of the polymer ( $\sim 100$  Å). The high surface area becomes even more significant when one considers that there is an interaction zone (IZ) surrounding the filler. This is a region in which the structure and properties have been altered because of the presence of the filler. It could be a region of altered chemistry, polymer conformation, chain mobility, degree of cure, or crystallinity. This zone of affected polymer has been approximated to be between 2 and 9 nm thick,<sup>[10]</sup> but may be much larger. If we assume that this IZ is about 10 nm in thickness, then at 2.5 vol.% of a 20-nm equiaxed nanoparticle well dispersed, 37% of the polymer has different properties from the bulk polymer. Therefore the IZ can be a significant portion, if not the entire bulk, of the matrix.

Thus the nanofillers can alter the expected properties of the composite considerably.

An example of the influence of the IZ on behavior can be seen by monitoring the glass transition temperature,  $T_g$ . The  $T_g$  of a bulk part can be raised and lowered with the addition of nanoparticles due to the immobilization of polymer chains by the particles or, conversely, an increase in polymer mobility due to non-interacting particles. Both increasing<sup>[11–13]</sup> and decreasing<sup>[14,15]</sup>  $T_g$  cases have been shown. The physical nature and extent of this IZ has recently been probed through some recent work on multiwalled carbon nanotubes (MWNTs).<sup>[16]</sup> In this study, a solvent processing method was used to make MWNT polymer nanocomposites. Upon observation of the composite fracture surface, a polymer layer was observed on the nanotubes (Fig. 2) that had pulled out of the opposing side of the fracture. This “sheath” was confirmed to be polymer from the matrix, but with obviously altered thermal and mechanical properties from the bulk. The thickness of this interfacial layer increased with chemical modification of the nanotubes.

Nanoparticles can also influence the polymerization, curing, or crystallization aspects of polymer synthesis. For example, nanoparticles can serve as nucleation sites in semicrystalline polymers and result in changes in crystalline content and spherulite structure.<sup>[17]</sup> Fig. 3 shows an AFM micrograph of unfilled polyethylene and nanoparticle-filled polyethylene. Note that in the case of the nanofilled polyethylene, the crystalline structure is much less organized.<sup>[18]</sup> Similar results have been seen in polyethylene terephthalate (PET).<sup>[19]</sup>

## SURFACE MODIFICATION OF NANOFILLERS

The nanoscale sizes and subsequently higher surface energies of nanofillers lead to some unique challenges in the processing of these materials. The most critical of these challenges is dispersion of the nanofiller. Any agglomeration of the filler reduces the interfacial area in the composites and thus reduces the opportunity to take advantage of the unique nanofiller properties mentioned in the previous section. Thus aggregated nanoparticles are simply micron fillers.

Controlling the size and degree of agglomeration of nanoparticles is difficult due to their large radius of curvature and subsequent increase in surface energy. As these high surface area fillers tend to aggregate, silanes and organotitanates are used extensively both to tailor the particle surface properties to mimic the surrounding matrix and to lower their surface energy and reduce their tendency to agglomerate.<sup>[20–22]</sup> Other methods to alter the surface properties of the nanoparticles include radiation grafting,<sup>[23]</sup> chemical vapor

**Fig. 2** Polymer-coated nanotubes observed in the fracture surface of MWNT reinforced polycarbonate composite. *Source:* From Ref.<sup>[16]</sup>.

deposition, and a host of complicated synthesis procedures that attempt to polymerize polymer chains off of initiating agents coupled to the surface.<sup>[24–26]</sup> An excellent review by Caruso<sup>[27]</sup> provides an extensive background on the modification of nanoparticle surfaces. In addition to achieving better dispersion, these techniques control the nature of the interaction between the nanofillers and the polymer and thus the properties and size of the IZ.

Carbon nanotubes not only tend to agglomerate but are often prepared in a bundle-like structure, as illustrated in Fig. 4. In order to take advantage of their high surface area for interacting with the polymer, the bundles have to be separated into individual nanotubes. For MWNT this can usually be accomplished with sonication.<sup>[28,29]</sup> For SWNT, exfoliation is a more difficult process but progress is being made.<sup>[30–34]</sup> The challenge is in exfoliating the bundles without shortening the SWNT and introducing significant numbers of defects. Once the nanotubes have been separated, it is important to disperse them uniformly in the polymer matrix, preventing agglomeration of nanotubes. This

is accomplished with functional groups which also mediates the interaction of the nanotubes with the polymer.

Non-covalent surface modification of carbon nanotubes includes all treatments that cause a change in the functional groups that face the solvent (or the polymer), without modifying the chemical nature of the nanotube. The advantage of the non-covalent surface modification is that the basic structure and hence the mechanical and electrical properties of the tubes are not affected due to the modification.<sup>[35]</sup> Non-covalent attachment is possible if there is a secondary bonding between these groups and the surface of the nanotube.<sup>[36,37]</sup> For example, wrapping of the nanotubes by polymer chains, in particular conjugated polymers, has been observed.<sup>[36,38–40]</sup>

Covalent attachment of chemical groups to the outer wall of the nanotubes can occur particularly at defect sites. One example is the attack of the defect sites by concentrated nitric acid, in order to form carboxylic acid groups.<sup>[41]</sup> The reaction with nitric acid also eliminates the catalysts that are left from the

**Fig. 3** Atomic force micrographs showing the change in crystalline morphology for unfilled and nanofilled low-density polyethylene, (A) neat low density polyethylene, (B) low-density polyethylene with 5 wt.% titania nanoparticles. *Source:* From Ref.<sup>[18]</sup>.

**Fig. 4** An SEM micrograph showing the bundled nature of multiwalled carbon nanotubes grown using a chemical vapor deposition process.

nanotubes preparation process. This reaction has been applied on SWNT and MWNT. The resultant carboxylated nanotubes can then be further covalently modified by means of reactions based on the carboxylic acid groups.<sup>[42,43]</sup> There are also other variations of the chemical oxidation of carbon nanotubes (for example, applying a mixture of sulfuric acid and  $H_2O_2$ <sup>[44]</sup>). The presence of carboxylic acid groups on the nanotube walls enables various reactions for the further attachment of functional groups.<sup>[43,45–50]</sup>

Other types of covalent surface modification of carbon nanotubes are based on chemical reactions between the carbon–carbon bond structures and specific reagents such as fluorination<sup>[51]</sup> or on radical attachments.<sup>[52,53]</sup> These reactions and many others<sup>[54–58]</sup> enable tailoring of the nanofillers to the specific application and environment. The potential for using surface modification to improve the properties of nanotube-reinforced polymer composites has just begun to be explored.

## NANOPARTICLE-FILLED POLYMER PROPERTIES

Nanoparticle fillers are relatively equiaxed with diameters less than 100 nm (Fig. 5). Nanoparticles (carbon black) have been used as fillers in polymers for the past century, but the advent of new particle synthesis techniques has made available industrial quantities of ceramic, piezoelectric, metal, and even polymer nanoparticles for use in polymer nanocomposite research. Synthesis of these nanoparticles is accomplished using a variety of methods, each with its own advantages and disadvantages.<sup>[59]</sup> This section focuses mainly on the

**Fig. 5** Typical poly-disperse oxide nanoparticles synthesized in a forced gas condensation process.

unique mechanical, thermal, optical, and electrical properties obtained when nanoparticles are used as fillers in polymer systems.

## Mechanical Properties

One of the primary reasons for adding fillers to polymers is to improve mechanical performance. Traditional polymer composites filled with micron-size fillers often show improvements in stiffness and heat resistance in the form of increases in modulus, yield strength, and glass transition temperature.<sup>[4,60]</sup> In micron-filled composites, unfortunately, this often comes at the cost of a substantial reduction in ductility, and sometimes in impact strength, because of stress concentrations caused by the fillers. Well-dispersed nanofillers, on the other hand, are able to improve modulus and strength, and to maintain or even improve ductility because they are much smaller than the critical crack size for polymers and need not initiate failure. In addition, large amounts of traditional fillers are often required to achieve the desired properties, often diminishing the weight-savings gained in using low-density polymers.

Polymer nanocomposites have been shown to provide unique combinations of mechanical and thermal properties often at very low filler weight fractions. For example, dramatic improvements in the yield stress (30%) and Young's modulus (170%) have been shown in nanofilled polypropylene compared to micron-filled polypropylene.<sup>[61]</sup> These composites also showed no decrease in the strain-to-failure when filled with silica ranging from 7 to 40 nm in diameter (Fig. 6).

**Fig. 6** Stress–strain curves of a silica/polypropylene (PP) nanocomposite with fillers of four different diameters (A300 and A130 = nanosilica-filled PP, PP100% = neat polymer, and G735 = micron-filled PP). *Source:* From Ref.<sup>[4]</sup>.

In addition, nylon 6 filled with 50-nm silica particles displayed increases in tensile strength (15%), strain-to-failure (150%), Young's modulus (23%), and impact strength (78%) with only 5 wt.% nanoparticles.<sup>[62]</sup> In a rubbery polyurethane elastomer, Petrovic and Zhang<sup>[63,64]</sup> found that a sixfold increase in the elongation-at-break and a threefold increase in the modulus were achievable with 40 wt.% 12-nm silica compared to micron-size filler that embrittled the polymer. Furthermore, the nanocomposites showed no reduction in transparency even at these relatively high loadings unlike the micron-size filled systems. In attempting to modify an already two-phase system, Zhang et al.<sup>[65]</sup> filled high impact polystyrene (HIPS) with nanoparticles and showed increases in notched impact, tensile strength, and elastic modulus of the blend. In a study by Ash et al., the mode of yielding in polymethylmethacrylate, a brittle thermoplastic polymer, was changed from dilatational (craze) to shear

by the incorporation of nanoparticles that showed no affinity for the matrix polymer.<sup>[66]</sup> Extensions as high as 80% but averaging 30% were routinely seen and were accompanied by a necking phenomenon (Fig. 7). The transition from crazing to shear yielding was hypothesized to be due to poorly bonded nanoparticles that are well dispersed in the polymer matrix. In this way, the polymer was hypothesized to detach from the nanoparticles and deform in response to the tensile stress, thus delocalizing the yield damage and preventing the typical craze-to-fracture brittle failure.

The most dramatic increases in the modulus of nanocomposites occur in the region above the  $T_g$ . Often, these increases are much greater (4000%) than those that occur below  $T_g$ .<sup>[14,67]</sup> This is hypothesized to be due to the creation of crosslinks, either temporary or permanent, between nanoparticles and polymer which serve to increase the plateau modulus. Indeed, the ability to strictly control the size and surface activity of nanoparticles in recent dynamic mechanical studies on silica/polyvinylacetate nanocomposites above the  $T_g$  has shed new light on the non-linear reinforcement behavior of rubbery melts.<sup>[68]</sup> In this study, the modulus of the polymer nanocomposite melt is shown to vary depending on the imposition of a large or small amplitude strain. The corresponding hypothesis concludes that the nanoparticles act as centers for trapped, non-labile polymer chains that serve as temporary entanglements. In this work, the destruction and eventual recovery of the network offer an alternative to the particle filler networks widely believed to be responsible for the behavior known as the Payne effect.<sup>[69]</sup>

Studies of the wear behavior of nanofilled polymer composites have also demonstrated encouraging results. In composites using micron-size fillers, the wear resistance increases, but often the coefficient of friction does as well. In silica/epoxy nanocomposites at low volume fractions ( $\sim 2$  vol.%), however, sliding wear tests showed that both the frictional coefficient

**Fig. 7** Stress–strain curves for alumina/polymethyl methacrylate (PMMA) nanocomposites showing transformation from brittle to ductile behavior at 5 wt.% 39-nm-diameter alumina nanoparticles. *Source:* From Ref.<sup>[66]</sup>.

and the specific wear rate were lower than either the unfilled epoxy or epoxy filled with micron-size fillers.<sup>[70]</sup> This is significant because most filled systems display the decreased wear rate, but also show an increase in the friction coefficient. Nanoparticles are theorized to be able to significantly reduce wear rates because the wear mechanism changes from severe abrasion wear to mild sliding wear. This is due to the reduction in the angularity of the filler particles and the fact that the transfer film, where abrasion is taking place, can be strengthened because the nanoparticles would have the capability of blending well with wear particles. In addition, the material removal of nanoparticulate composites is thought to be much milder than that of conventional composites because the fillers have the same size as the segments of the surrounding polymer chains.<sup>[70]</sup>

The scratch resistance of nanocomposites is also improved over their micron counterparts.<sup>[71]</sup> Ng et al. reported that nano-TiO<sub>2</sub>-filled epoxy showed greater scratch resistance with the scratch track being much smoother than either the neat polymer or a micron-filled system.<sup>[72]</sup> In addition, the depth and width of the scratch track decreased in the nanofilled system. This behavior has also been seen in alumina/gelatin nanocomposites.<sup>[73]</sup>

Nanoparticles have also been recently used to reinforce shape memory polymers for microelectromechanical systems (MEMS) applications. Gall et al.<sup>[74]</sup> demonstrated that the microhardness and elastic modulus could be increased through the use of SiC nanoparticles. In this case, the small size of the MEMS devices necessitates the use of nanoparticles for incorporation into the device, but the nanoparticles actually increased the force of recovery from 300 mN for the unfilled resin to 450 mN for a 20 wt.% nano-filled composite.

As with most mechanical systems, the property enhancements shown above experience an initial increase followed by a decrease usually in the 2–5 vol.% range. The observation of a particular weight fraction at which mechanical behavior is optimized has been observed in other nanocomposite studies.<sup>[14,62,65]</sup> It is obvious that at lower particle loadings, there is generally not enough material altered by the presence of the particles to permit large-scale changes in material properties. Higher loadings induce agglomeration, which degrades the polymer performance through, for example, inclusion of voids that can act as preferential sites for crack initiation and failure.

## Thermal Properties

The thermal properties of polymers and their composites are important from a mechanical stability

perspective as well as a processing perspective. Thus the ability to alter this behavior, either by increasing or decreasing the processing or service temperature, is highly important in finding new markets for polymer products.

One of the most widely measured values to quantify thermal properties in polymers is the glass transition temperature. Changes in the glass transition temperature,  $T_g$ , as a function of the filler content have been reported for a variety of polymer composites containing a wide variety of nanoscale fillers. Most researchers report an increase in the  $T_g$  as a function of filler content;<sup>[10,14,75]</sup> in fact, Avella and coworkers have shown a 35°C increase in the  $T_g$  of PMMA filled with just 6 wt.% CaCO<sub>3</sub> nanoparticles.<sup>[76]</sup> On the other hand, decreases in the nanocomposite  $T_g$  have also been reported.<sup>[11,15]</sup>

The increases in  $T_g$  have been linked to the immobilization of the matrix within an IZ which hinders cooperative motion by raising the energy barrier for intermolecular chain movement.<sup>[11,75]</sup> However, attempts to relate the  $T_g$  reductions to existing theories of the glass transition have been limited. Becker, Mueller, and Schmidt<sup>[11]</sup> reported that, over the range of filler volume fractions considered (0–10 vol.%), the  $T_g$  of their acetoxypolypropyltrimethoxysilane (APTS)-treated silica-filled PMMA–HEMA copolymer system decreased by 16°C, while the  $T_g$  of their composites prepared with as-received filler decreased by 9°C. This was contrasted with the increases in  $T_g$  observed for 10-nm silica coated with methacryloxypropyltrimethoxysilane (MPTS). In these latter specimens, the  $T_g$  increased by 10°C at 10 vol.% filler. However, the 100-nm silica used in the study produced no changes in the  $T_g$  with either coating at any filler concentration. Thus the increased surface area of the 10-nm silica and the interface between the APTS- and MPTS-coated particles and the polymer dramatically changed the polymer mobility in the bulk at fairly low volume fractions resulting in both increasing and decreasing  $T_g$  values.

In some instances, the particle, IZ, and matrix have been modeled as a core-shell scheme to incorporate the interaction zone/low mobility region. If the volume fraction of the interaction zone is high enough, this model shows two  $T_g$ s, while most researchers do not see this, there have been reports that show the additional relaxation mode corresponding to the restricted polymer network in contact with the nanofiller.<sup>[77,78]</sup>

Recent work by Sternstein and Zhu<sup>[68]</sup> on silica/polyvinylacetate nanocomposites indicates that a greater far-field effect is at work in altering chain dynamics than simply a local immobilization of the polymer chain as has been previously suggested.<sup>[78]</sup> This far-field effect may have a very large effect on

the glass transition as shown recently by Ash, Schadler, and Siegel<sup>[15]</sup> In this work, the  $T_g$  of alumina/PMMA nanocomposites at 1.0 wt.% filler drops by 25°C when compared to the neat polymer (Fig. 8). Further additions of filler do not lead to additional  $T_g$  reductions. This novel thermal behavior is shown to vary with particle size, but this dependence can be normalized with respect to specific surface area. The nanocomposite  $T_g$  phenomenon is hypothesized to be due to non-adhering nanoparticles that act as well-dispersed internal void/polymer interfaces that break up the percolating structure of dynamically heterogeneous domains recently suggested by Long and Lequeux<sup>[79]</sup> to be responsible for the  $T_g$  reductions in polymer ultrathin films.<sup>[80]</sup> The results also point to a dramatically increased scope of the so-called IZ and its “far-field” effect on the entire matrix.

A closely related topic in polymers and nanocomposites is the diffusivity of these materials. Studying gas transport of nanosilica-filled polymer by <sup>129</sup>Xe NMR permeativity increased with increasing filler content while retaining gas molecule size selectivity.<sup>[81]</sup> Similar results were shown using pulsed field gradient (PFG) NMR techniques with an order of magnitude increase in translational diffusion seen at 30 wt.% silica in a random copolymer.<sup>[82]</sup>

## Optical Properties

As stated in the Introduction, the scattering of light by nanoscale particles is markedly reduced when the particle size is decreased less than 50 nm.<sup>[8]</sup> Thus nanoparticles may be added to polymers to increase wear, toughness, etc., while maintaining the optical transparency that many organic materials possess. An excellent review, both historical and current, of

the phenomena of light absorption and scattering by nanoparticles in solution and in nanocomposites was recently given by Caseri.<sup>[8]</sup> Apart from maintaining clarity in the visible wavelengths, adding nanoparticles can add interesting functionality in the form of UV absorption<sup>[83]</sup> and the alteration of the refractive index of the matrix polymer. The addition of TiO<sub>2</sub> nanoparticles to many polymers results in such a material where the particles act to absorb the UV radiation and increase the refractive index.<sup>[71,84]</sup> Indeed, nanocomposites of lead sulfide and polyethylene oxide now boast a refractive index of 3.9,<sup>[3,85]</sup> while gold nanoparticles contained in gelatin have reduced the refractive index to about 1.<sup>[86]</sup> Dichoric behavior has also been observed in nanoparticle-filled polymers that have been highly stretched, resulting in “string of pearls”-type structures of fillers with very high aspect ratios. In these composites, the interaction with polarized light varies with the direction of both the incoming radiation and the orientation of the filler strands and results in both color<sup>[87]</sup> and intensity changes.<sup>[88]</sup> This type of composite response can be used in the liquid crystal displays<sup>[8]</sup> or in strain-based schemes for light-filtering devices.

## Electrical Properties

The opportunities to tune the electrical properties of polymers with nanocomposites extend beyond enhancing conductive polymers; superparamagnetism in magnetic materials<sup>[89,90]</sup> or tunable band gaps in quantum dot semiconductor arrays show promise when incorporated into polymers for additional functionality. In addition, the percolation threshold has been shown to be lower in nanocomposites than in traditional filled composites with values as low as

**Fig. 8** Glass transition behavior of alumina/PMMA nanocomposites (■—38/39-nm alumina, ●—17-nm alumina). Note that the filler weight fraction is plotted on a log scale to show the behavior of the lower values more clearly. The neat PMMA is plotted as 0.01 wt.% on the above graph. Following coating with GPS, the  $T_g$  returns to the neat value (▲—GPS-coated). *Source:* From Ref.<sup>[15]</sup>.

0.03 vol.% reported.<sup>[91]</sup> Hong et al. using a ZnO/LDPE nanocomposite showed a lower percolation limit and a slower decrease in the resistivity with nanofiller concentration compared to conventional composite.<sup>[92]</sup> The dielectric breakdown strength of nanocomposites can also be enhanced over compositions with micron-scale fillers.<sup>[18]</sup>

In addition to traditional filler roles, organic-inorganic nanocomposites have found their way into etch resists used in semiconductor nanolithography. With line sizes in CMOS technology approaching 100 nm, adding silica nanoparticles to traditional organic resists, such as PMMA, have been shown to increase rigidity and display a higher glass transition temperature which enhances resist performance for nanometer pattern fabrication.<sup>[93]</sup>

### CARBON NANOTUBE/POLYMER NANOCOMPOSITES

Carbon nanotubes are in some ways the ideal fiber. The almost defect-free structure of the nanotubes results in mechanical properties that are comparable to those of a graphene sheet. Recent studies have focused on the assessment of the mechanical properties of carbon nanotubes through both experiment and modeling. The Young's modulus of these almost-perfect fibers has been predicted to be between 0.64 and 5.0 TPa for a SWNT.<sup>[94–100]</sup> The tensile strength of SWNTs was calculated to range from 50 to 100 GPa depending on the type and number of defects present.<sup>[101]</sup> The nanometer-scale size of the nanotubes introduces technical difficulties in the experimental measurement of their mechanical properties. However, Yu and coworkers conducted tensile testing experiments on individual MWNTs that were attached to opposing AFM tips on both ends.<sup>[102]</sup> They obtained values of 11–63 GPa for the tensile strength and 270–950 GPa for the elastic modulus of the MWNT. Yu and coworkers also conducted tensile tests on SWNT bundles and obtained 320–1470 GPa for the elastic modulus.<sup>[103]</sup> Thus the strengths obtained by experimental measurements are lower than the calculated values, possibly due to intrinsic nanotube defects that cause premature mechanical failure or to other errors in the experimental methodology. Indirect measurements have yielded similar values for modulus and strength.<sup>[104,105]</sup>

In addition to their unique mechanical properties, carbon nanotubes have a high aspect ratio, high thermal conductivity, high electrical conductivity, and low coefficient of thermal expansion.<sup>[106]</sup> In short, carbon nanotubes theoretically have the properties of an ideal graphite fiber. This alone makes them attractive for incorporation into polymers. In addition,

their small size introduces the possibility of synthesizing transparent materials with low volume fractions of filler.

### Mechanical Properties

Studies have been conducted in order to explore the mechanical properties of nanotube-reinforced polymer composites, keeping in mind the challenges to be addressed. MWNT-polystyrene films were prepared from solution in toluene and tested in tension.<sup>[28]</sup> 1 wt.% of MWNT caused an increase of 36% in the elastic modulus, and 25% increase in strength. In another study, 5 wt.% MWNT-epoxy samples were prepared and tested under tension and compression.<sup>[107]</sup> An increase of 20% in the tensile elastic modulus and the compression elastic modulus was observed. Insights into the mechanisms of load transfer were discussed for this system, because of the interesting behavior of the composites under tension and compression, as measured by Raman spectroscopy (see next section for details). In another study, carbon nanofiber reinforced poly(etherether)ketone (PEEK) nanocomposites were prepared by twin-screw extrusion and tested by dynamic mechanical analysis and tensile tests.<sup>[108]</sup> A gradual increase in the elastic modulus as a function of nanofiber concentration was observed such that a loading of 15 wt.% nanofibers resulted in a 40% increase in the modulus. The effect of non-covalent modification of carbon nanotubes on the mechanical and thermal properties of nanotube-epoxy composite was investigated<sup>[37]</sup> using polyoxyethylene 8 lauryl as a surfactant. In this work by Gong et al. an increase of 25°C in the glass transition temperature and a 30% increase in the elastic modulus, as measured by dynamic mechanical analysis, were observed with the incorporation of only 1 wt.% nanotubes. Using polyvinylidene fluoride, again as a non-covalent modifier, in MWNT-polymethyl methacrylate (PMMA) nanocomposites<sup>[109]</sup> the dispersion of the nanotubes in the polymer was better, and the storage modulus, as measured by dynamic mechanical analysis, increased. In situ polymerization has been attempted also in the presence of carbon nanotubes, in order to achieve the participation of the nanotubes in the polymerization process and hence get a covalent attachment of the growing polymer chains to the nanotube surface. Such a study was conducted with methyl methacrylate polymerization and MWNT.<sup>[110]</sup> Evidence for nanotube-polymer interactions was observed from the examination of the fracture surface of the composites. An increase in the heat deflection temperature was also observed with the incorporation of nanotubes. This in situ polymerization procedure was also used in a SWNT-polyimide system.<sup>[111]</sup> In this

research the electrical conductivity of the nanocomposite increased by 10 orders of magnitude at 0.2 wt.% SWNT loading while the mechanical properties also improved. Fluorinated MWNT-reinforced polyvinyl alcohol composites were prepared and mechanically tested.<sup>[112]</sup> A 400% increase in the storage modulus (as measured by dynamic mechanical analysis) was obtained for 4 wt.% functionalized MWNT composite as compared to pure polyvinyl alcohol.

From a mechanical properties viewpoint, the characteristic bending and looping of SWNTs is problematic if the maximum reinforcement is to be obtained. Therefore research has been conducted to align the nanotubes by magnetic fields<sup>[113]</sup> and by melt spinning.<sup>[114]</sup> In both cases nanocomposites with anisotropic properties were obtained with increases in the elastic modulus realized in the alignment orientation.

Few if any of the nanotube-filled polymer composites reported in the literature have achieved the properties expected by their high modulus and strength. This is because of three closely related factors: dispersion, load transfer, and volume fraction. For example, SWNTs are synthesized in bundles. In the bundle form, the load-bearing portion of the bundle is only the outermost tubes. The tubes inside the bundle slide are relative to the others and do not carry significant load. To solve this problem, the SWNT must be separated from the bundles and as mentioned earlier progress is being made in this area. MWNTs on the other hand, can be separated from their bundles. MWNTs however, are concentric tubes with poor bonding between the carbon layers. Therefore even if the outermost tube of a MWNT is carrying load, the inner layers may not be. This also reduces their efficiency. Finally, the high surface area of the nanotubes makes it difficult to process composites with high volume fractions of fillers because the viscosity of the nanotube/matrix mixture is prohibitively high.

### Electrical and Optical Properties

One likely application of nanotube-filled polymers is for applications requiring high electrical conductivity. Their high aspect ratio leads to percolation at extremely low loadings. A recent paper claimed percolation at 0.0025 wt.%<sup>[115]</sup> and several others report levels near 0.3 wt.%.<sup>[116]</sup> This low percolation loading and relatively high conductivity leads to the promise of transparent conducting coatings or other multifunctional applications where the conductivity is improved, but other properties are not compromised. Changes in conductivity as high as 8 orders of magnitude have been observed in nanotube/PPV composites with little loss in photoluminescence/electroluminescence yield. In addition, the mechanical strength simultaneously

improved.<sup>[117]</sup> In situ polymerization under sonication has also been used to assist the dispersion of SWNT in a polyimide matrix. Enhancement of the conductivity by 10 orders of magnitude was measured in this system for 0.2 wt.% of SWNT, while maintaining transparency of the nanocomposite.<sup>[111]</sup> Alignment has also been found to improve conductivity.<sup>[114]</sup> The conductivity that can be achieved is somewhat limited by the mixture of semiconducting and metallic nanotubes produced. Improvements in the ability to separate metallic from semiconducting nanotubes will likely lead to further improvements in conductivity. Other electrical properties such as permittivity have also been investigated.<sup>[118]</sup>

The conduction properties of nanotubes can also be used to alter the optical response of polymers. For example, functionalization of nanotubes and doping of chemically modified nanotubes in low concentration to photoactive polymers such as PPV have been shown as a means to alter the hole transport mechanism and hence the optical emission of the polymer.<sup>[119]</sup> Such hole-collecting properties seem to be a quite general property of some conjugated polymers. Specifically, SWNTs in a polymer matrix trap holes injected from the anode in organic light emitting diodes (OLEDs).<sup>[120]</sup>

The optical limiting behavior of polymer nanotube-filled composites has been investigated with success. It has been reported that polymerization of phenylacetylene in the presence of short nanotubes results in a solvated product of tubules wrapped with poly(phenylacetylene). The optical limiting properties of this composite are excellent and far better than the pristine polymer and polymer filled with other carbon structures. They also fare well in photovoltaic applications suggesting that such nanocomposites could find an array of potential applications in optics-related and laser-based technologies.<sup>[121]</sup>

### NANOTUBE AND NANOPARTICLE COMPOSITE MODELS

The dramatic changes in mechanical properties observed in nanofillers challenge existing theories of mechanical reinforcement. In traditional composites, the modulus can be predicted, usually between upper and lower bounds,<sup>[122]</sup> by modeling the effectiveness of load transfer from the matrix to the polymer. As the particles are, in large part, stiffer than the surrounding matrix, this load transfer results in a stiffer composite than the neat polymer. With the nanoparticles, however, the “span” required for effective load transfer is extremely small and thus can contribute only a small portion of the dramatic gains in modulus seen in nanocomposites. In addition, because of their

unique geometry, the theoretical modeling of the mechanical behavior of nanotube polymer composites is even more complex. The hollow shape of the nanotubes, the wall-wall interactions in MWNT, and the molecular level interactions between the nanotubes and the polymer matrix have to be considered in these models. Odegard and coworkers<sup>[123]</sup> transformed the SWNT and the neighboring polymer chains into an effective fiber. By using molecular dynamic considerations, the effects of nanotube alignment and length on the elastic modulus were calculated. These theoretical calculations were compared to the experimental results of SWNT-polyimide composite mechanical properties.

Addressing the presence of a large volume fraction of the IZ that has properties different from the bulk polymer is also paramount to successful modeling. The alteration of the matrix that takes place at the IZ, as previously mentioned, is a likely candidate for property enhancement. Modeling the IZ is difficult; however, as imperfect bonding, mechanical stresses, and chemical interactions can all play a decisive role in determining its behavior. Ji et al.<sup>[124]</sup> recently modified a composite model to incorporate the interphase zone and were able to successfully model the increases in the modulus of a clay/nylon-6 nanocomposite system. Their treatment modeled the interphase zone as a linear gradient change in the modulus between the surface of the filler and the matrix and introduced the critical effect of particle size (through the increase in volume fraction of the interphase) into the theory. The curves predicted by the model were shown to be in good agreement with the experimental nanocomposite mechanical behavior.

## CONCLUSION

Polymer nanocomposites incorporating carbon nanotubes or nanoparticles are a novel class of composite materials that are often multifunctional, adding the unique optical, electrical, or mechanical properties of the nanofillers while maintaining, if not enhancing, the neat polymer properties. These composites are often characterized by low volume fractions of filler, which may then affect the entire matrix, due to their large surface-area-to-volume ratio, through an interaction zone. The unique nature of these particles presents both challenges and unique opportunities to create a wide range of multifunctional polymer composites.

# Polymer Nanofibers Prepared by Electrospinning

Roland Dersch

Andreas Greiner

Joachim H. Wendorff

*Philipps-Universität Marburg, Marburg, Germany*

## INTRODUCTION

The use of fibers has a long history, the traditional application being in clothing. Natural fibers such as silk, wool, or cotton provide attractive properties for such applications. Fiber diameters characteristic of such natural fibers are 15–40  $\mu\text{m}$  for sheep wool, approximately 20  $\mu\text{m}$  for cotton, and approximately 20  $\mu\text{m}$  for cultivated silk. Natural fibers compete in this area of applications with synthetic fibers. Man-made fibers are predominantly produced by melt spinning, which leads to fiber diameters typically in the range from about 5 to more than 70  $\mu\text{m}$ , thus covering the diameter range characteristic of natural fibers. To produce such fibers, the polymer melt is pumped through a spinneret. Fiber stretching is applied not only to obtain a certain reduction of the diameter but also to simultaneously enhance the chain orientation and mechanical properties.

## OVERVIEW

The range of fiber end-uses is obviously not restricted to clothing. Among others, fibers are used as sorbants, for thermal insulation, filtration, protective clothing, in composites to reinforce a polymer matrices, etc. Such applications frequently require the reduction of the fiber diameter to obtain microfibers, ultramicrofibers down to nanofibers, for example for increase of efficiency by increase of the specific surface area. Polymer fibers with diameters down to 10 nm and below are in demand for a broad range of applications to be discussed below in more detail. These include nanoscaled reinforcement, tissue engineering, specialty fibers, and templates for the formation of hollow fibers with inner diameters in the nanometer range.<sup>[1–9]</sup>

Melt blowing invented close to 50 years ago has become a process of choice for the production of microfibers. It is basically a process in which a high-velocity stream of gases or fluids—steam, air, or other fluids—blows molten thermoplastic resins from an extruder die tip onto a substrate, a conveyor, or a

take-up screen. The characteristic feature is that this process provides a fine fiber web; that is, non-wovens rather than textile fibers.

Another approach toward microfibers involves the spinning of two polymers together to form fine-diameter fibers within the matrix of the second polymer. The matrix is dissolved to yield the microfiber. A related approach consists in splitting the composite fiber by mechanical forces, a high-velocity stream of water. None of these techniques is able to produce polymer fibers down to the nanometer range. The only technique currently available to yield such extremely thin fibers is electrospinning, which is also called electrostatic spinning.

The intention of this review on electrospinning of polymers is not to be comprehensive nor to demonstrate the historical evolution but rather to show concepts and disclose further challenges in electrospinning.

## ELECTROSPINNING PROCESS: THEORETICAL BACKGROUND

The experimental observation is that electrospinning is able to yield well-defined nanofibers with diameters down to a few nanometers for many polymers. Yet a broad range of parameters seems to influence fiber formation and it is a frequent observation that electrospinning does not give rise to homogeneous fibers but rather to beaded fibers; that is, fibers in combination with droplets (Fig. 1). Theory is helpful for understanding the main mechanism causing fiber formation and how particular parameters affect fiber formation.

In electrospinning, a strong electrical field is applied to a droplet formed by a polymer solution or polymer melt at the tip of a die acting as one of the electrodes (Fig. 2). The charging of the fluid leads, as shown by Taylor<sup>[10]</sup> in a set of papers, to a conical deformation of the droplet—the well-known Taylor cone and eventually to the ejection of a jet from the tip of the cone. Taylor found that the critical field required for such deformation is strongly controlled by the surface tension. The electric dispersion of liquids based on this

**Fig. 1** Beaded poly(vinylalcohol) fibers by electrospinning from aqueous solution.

phenomenon is widely used today, for instance in ink jet printing, for crop spraying, to prepare aerosols from liquids, and to produce propellants for rockets.

In electrospinning of fibers, the conventional view is that the charged viscoelastic jet is accelerated toward the counter electrodes, and rapidly thins during this period because of elongation and evaporation of the solvent. In some cases, splitting of the jet into multiple jets has been observed leading to a further thinning.<sup>[11]</sup> Solidification takes place and solid fibers are randomly deposited onto the substrate with a deposition rate in the order of several meters per second.<sup>[12]</sup>

However, a more detailed experimental and theoretical analysis has shown that the electrospinning process is much more complex.<sup>[13–19]</sup> It is controlled by various types of instabilities such as the Rayleigh instability, an axisymmetric instability, and finally by a so-called whipping or bending instability. In particular, the whipping instability has been identified as the one controlling elongation and thinning of the electrospun fibers. The other

**Fig. 2** Schematical graph of the electrospinning setup.

types of instability causes fluctuations of the radius of the jet and may eventually result in droplet formation.

The Rayleigh instability in the presence of electrical fields is the electrical counterpart of the well-known surface energy driven Rayleigh instability observed for liquid threads in the absence of external forces. This type of instability is characterized by statistical fluctuation of the radius of the jet and the growth of such fluctuations with specific wavelength. The effect of an applied field is that the wavelength for fluctuations with positive growth rate is shifted to larger and larger wavelength with increasing field strength until these fluctuations are finally suppressed at a still larger field strength.

However, the jet is still unstable because a new type of instability—the so-called axisymmetric mode. A statistical modulation of the radius of the jet induces a modulation of the density of the surface charges. These modulations result in tangential stresses, which in turn accelerate the liquid and thus enhance the modulation of the radius. Again, the formation of droplets can be the final state. It is the absolute value of the charge density at the surface, which controls other factors when this instability becomes dominant.

Finally, the whipping or bending type of instability occurs at higher field strengths and this is apparently the most important type for electrospinning of fibers. The strong thinning of the jet as well as the strong elongational deformation, which takes place during electrospinning, has been attributed to this mode of instability. For large static charge densities, the whipping mode tends to dominate because high-charge densities at the surface simultaneously tend to suppress both the Rayleigh and the axisymmetric mode of instability. It has even been claimed that the onset threshold for electrospinning corresponds to the excitation of the whipping mode.

The whipping mode corresponds to long-wavelength oscillations of the centerline of the jet; that is, the jet is subjected to bending modes. Dipolar components arise if a charged jet is subjected to bending because the charge density is no longer uniform across the cross section of the jet. An elastic force resulting from the viscous flow of the liquid counteracts the bending mode. This force is related to the rate of strain and thus to the time derivative of the curvature of the jet. For larger static charge densities, the whipping mode tends to dominate because high surface charges simultaneously suppress the axisymmetric mode.

These theoretical considerations point out the important role of surface charge and thus of the conductivity of the material used for spinning as well as of the surface energy. The role of viscoelastic properties of solutions or melts are less well known and require further experimental investigations. Furthermore, the expectations are that structure formation processes have to rapidly occur during electrospinning because of the large

deposition rates, which in turn should lead to non-equilibrium structures within the nanofibers. A second feature should be high orientations as a result of the strong deformation, which occur in the whipping mode.

## PARAMETERS AFFECTING FIBER FORMATION

Fiber diameters and the absence or presence of beads are features that have to be reproducibly controlled. A set of parameters including surface free energy, viscosity, electrical conductivity, molecular weight, and its distribution control fiber formation can have an effect on the formation of beaded fibers. In the following, experimental results will be discussed exploring the importance of these parameters.

### Surface Free Energy

The critical field for the onset of fiber formation is predicted to be proportional to the square root of the surface tension. This finding is roughly in agreement with experimental findings. The more important question is whether this parameter affects fiber diameters. The observation is that a variation of surface free energy keeping the other controlling parameters constant did not significantly modify the fiber diameter.

### Electrical Conductivity

A second key parameter is the conductivity of the melt or solution.<sup>[20,21]</sup> An increase of the conductivity is expected to increase the surface charge density, which in turn should lead to a stabilization of the whipping modes giving rise to fiber extension. Furthermore, bead formation arising from other modes of instability should be suppressed. Experiments performed on solutions of polylactide (PLA) in dichloromethane doped with various amount of pyridinium formate showed that in fact an increasing concentration of the dopant lead to a reduction of bead formation and to smaller diameters of the fibers (Fig. 3).

These results agree in principle with those from Baumgarten.<sup>[22]</sup> The prediction was that the final fiber diameter depends on the conductivity and that it varies as the cube root of the resistivity. Baumgartner also stated that only droplets are generated if the conductivity is too high and he also reported that no continuous spinning could be achieved if the conductivity is too low. The reason is that the flow rate is too small in this case.

### Concentration of the Polymer in Solution

There is a direct correlation between concentration and fiber diameter. For instance, a decrease of the PLA

**Fig. 3** Scanning electron microscopy images of electrospun PLA fibers from 2% PLA solution in dichloromethane with different concentrations (w/w in solution) of pyridinium formate: (A) 0%; (B) 0.2%; (C) 0.3%; (D) 0.4%; (E) 0.6%; (F) 0.8%.

concentration in dichloromethane from 5 to 0.8 wt.% causes a reduction of the fibers from approximately 500–1000 to approximately 10–70 nm.<sup>[20]</sup> Provisions have to be made to reduce bead formation. Electrospinning from more diluted solutions requires a certain degree of electrical conductivity.

Subsequent investigations revealed that the control of the fiber diameter, the presence or absence of drop formation, the control of the surface morphology, and also the control of the texture of the web that is produced by electrospinning depend on a much broader range of parameters. These are among other thermodynamic properties of the solvent and the polymer—vapor pressure, crystallization and glass transition temperature, solubility of the polymer in the solvent or mixture of solvent. A reduction in molecular weight or an increase of the concentration of the lower molecular weight component in blends have been found to cause a reduction of the fiber diameter.

The concept of electrospinning is simple; yet, it is a demanding task to adjust the electrospinning parameters for a given system to be able to spin nanofibers in a controlled manner.

## A BRIEF SURVEY ON ELECTROSPUN POLYMER SYSTEMS

A broad range of polymer systems has been subjected to electrospinning. Most of the papers published on electrospinning of polymer fibers consider spinning from solution. One advantage of electrospinning is that water can be used as a solvent. Water-soluble polymers such as poly(ethylenoxide) (PEO) or poly(vinylalcohol) (PVA) can thus be electrospun.<sup>[21,23,24]</sup> Electrospinning without any solvent from the melt was reported by Larrando and Manley<sup>[25–27]</sup> for poly(propylene) and poly(ethylene terephthalate), although true nanofibers as major products have not been obtained so far by melt electrospinning. Besides PEO and PVA, electrospinning of numerous polymers to nanofibers has been reported including poly(acrylonitrile),<sup>[28]</sup> PLA,<sup>[9,20,29]</sup> poly(styrene),<sup>[11]</sup> poly(methylmethacrylate),<sup>[30]</sup> poly(amides),<sup>[12]</sup> poly(imides),<sup>[31]</sup> poly(caprolactone),<sup>[32,33]</sup> and poly(vinylidene fluoride),<sup>[11]</sup> just to name a few.

Electrospinning of blends<sup>[34–37]</sup> or composites<sup>[9,37–41]</sup> considerably broadens the range of fiber properties and applications and might lead to novel functionalities. Polymer nanofibers can be loaded with drugs or other biologically active molecules by spinning of polymers from ternary solutions containing the reagent. For example, Kenawy et al.<sup>[42]</sup> studied the release of tetracycline hydrochloride from poly(ethylene-co-vinylacetate), PLA, and a blend thereof. Similarly, but with a different purpose, He<sup>[43]</sup> investigated electrospinning of PVA–Pt/TiO<sub>2</sub> and subsequent photocatalytic

degradation of the PVA nanofibers. Core–shell fibers with concentric variation of concentrations were obtained by concentric coelectrospinning of a solution of palladium(II)acetate (core) and PEO (shell),<sup>[44]</sup> which can be extended to other systems as well.

## STRUCTURE FORMATION DURING ELECTROSPINNING

A characteristic feature of the electrospinning process is the rapid evaporation of the solvent in the case of solution spinning and the rapid temperature decrease in the case of electrospinning from the melt. Thus structure formation has to happen on a millisecond scale. The nucleation of crystals should therefore be strongly quenched. A second feature is the strong deformation taking place during the whipping mode, which should give rise to orientational process within the fibers.

Experiments performed on nanofibers made from polymers able to crystallize such as polyamides, polyethylene oxide, or PLA have revealed that crystals are able to grow. In fact, the degree of crystallinity and the perfection of the crystal are not much different from those observed for thicker fibers obtained from melt extrusion or for thicker films.<sup>[45]</sup>

High degrees of crystal orientation have been found for various electrospun polymers including polyethylene oxide and polyamides (Fig. 4). Performing selected area electron diffraction studies, it was shown for polyamide fibers that the degree of orientation directly obtained by electrospinning corresponds to the one obtained for melt-extruded fibers only after considerable stretching. On the other hand, no crystal orientation has been reported for electrospun fibers made from PLAs.<sup>[46]</sup> It is currently not obvious why crystal orientation is absent in this case. Crystal formation, degree of crystallinity, and the crystal orientation are parameters that considerably affect properties and functions of the fibers.

**Fig. 4** Crystal orientation in PA6 fibers as obtained from selective area electron diffraction on an individual fiber with a diameter of 50 nm.

**Fig. 5** Nanoporous electrospun PLA nanofibers from a dichloromethane solution.

The properties and functionality of electrospun nanofibers can be also modified by their surface morphology. The concept is to use phase-separation processes during electrospinning. One approach considers electrospinning of ternary systems composed of two incompatible polymers and a solvent.<sup>[34]</sup> The resulting nanofibers are characterized in this case by phase morphologies corresponding either to cocontinuous spinodal type morphologies or dispersed binodal-like morphologies. Such internally structured fibers are of interest for many applications. Yet one might also selectively remove one of the components to generate fibers characterized by porous structures or other types of topologies. Such surface topologies are known to affect surface free energy, wetting, as well as adhesion. The experimental finding is that such types of phase separation processes may also occur during electrospinning in binary systems composed of one polymer and a solvent.<sup>[29,30]</sup> PLA nanofibers electrospun from dichloromethane solution typically show a nanoporous surface (Fig. 5).

Nanoporous electrospun fibers were also obtained for a variety of other polymer systems such as polycarbonates or polystyrene.<sup>[30]</sup> Interestingly, electrospinning at different humidities had a significant effect on the porosity of the electrospun fibers. It has been concluded that pore formation arising from rapid solvent evaporation most likely occurred because of the formation of water droplets from atmospheric water as a result of the evaporative cooling of the polymer solution on its way to the counter electrode in the electrospinning process.

## APPLICATIONS OF ELECTROSPUN NANOFIBERS

Electrospun nanofibers offer wide applications such as in the fields of specialty filters,<sup>[47]</sup> tissue engineering,<sup>[4]</sup> wound healing,<sup>[48]</sup> reinforcement,<sup>[1,49]</sup> protective

**Fig. 6** Transmission electron micrograph of poly(*p*-xylylene) (PPX) nanotubes (A) and of PPX nanotubes loaded by copper nanoparticles.

clothing,<sup>[2,50]</sup> drug release,<sup>[42]</sup> sensors,<sup>[51]</sup> catalysis,<sup>[52,53]</sup> and templating,<sup>[8,9,54,55]</sup> to name a few. Presently, most patents on electrospinning are focused on applications rather than on new materials or on new processes. Commercialized applications were accomplished by several companies worldwide in specialty filters (air filtration, coalescence filters) with an increasing market in the coming years. Tissue engineering is going to be another successful field of applications for electrospun biodegradable nanofibers (e.g., PLA) because cells including stem cells grow well on these nanofibers. An additional plus is the large potential for loading of electrospun nanofibers by biologically active agents ranging from salts to drugs and proteins.<sup>[42,56]</sup> Protective clothing, in particular in combination with special reagents, is expected to enhance the performance of military protective clothing.<sup>[6]</sup> The main focus here is on trapping of aerosols of chemical and biological warfare agents.

A unique application of electrospun nanofibers is their use as templates for the preparation of other nano-objects such as nanotubes.<sup>[8,9,55,56]</sup> Coating of electrospun nanofibers by different materials and coating techniques and subsequent removal of the core template fibers generates a whole set of nanotubes of different sizes and materials combinations, which has by far not been exploited (Fig. 6). The versatility of this approach is enhanced again by the option of loading of electrospun nanofibers directly during electrospinning or coelectrospinning.<sup>[44]</sup>

## CONCLUSION

As electrospinning of polymers is a rather old technique that has just recently been rediscovered, a new community has been established dealing with electrospinning. The number of papers is exponentially increasing as obvious from the papers published per year. The technique will be certainly optimized within the next few years but a precise understanding of the impact of different processing parameters based on

empirical observations together with theoretical considerations will be a key issue for optimum results. Many new open questions remain concerning materials choice but major new developments are expected in the area of structuring of electrospun nanofibers, loading of nanofibers by new additives for special applications, and the development of smart nanofibers. Clearly, a major driving force of new developments in the field of electrospun nanofibers will be new applications, which nicely unites researchers from different areas such as polymers, physics, engineering, inorganic and organic chemistry, medicine, pharmacy, or rheology, to name a few.

## INTRODUCTION

The rapid development in the chemistry of nanoparticles over the past 20 years has driven tremendous advances in the field. While there remains significant interest in the use of nanoparticles as fillers in polymer materials to enhance physical and mechanical properties, many are now engaging in research efforts that focus on precise structures of nanoparticles in polymers, including their assembly in arrays and along interfacial boundaries. The combination of precise organic chemistry on nanoparticle materials has led to developments in the growth of polymers from nanoparticle surfaces, allowing one to tailor the properties of the particles by the choice of polymer and its inherent functionality. Such nanoparticle–polymer composite materials are generating interest in several applications, including electronic and optical materials, based on the properties of metallic and semiconductor particles used. In addition, efforts in catalysis are under way using nanoparticles in polymer scaffolds. These and other topics form the basis of this review article, which will start in the next section with a brief account of early studies in the field, and progress from clay-based composites to metallic- and semiconductor-based nanoparticle–polymer composites.

## NANOPARTICLES IN POLYMERS: FROM CLAY TO SEMICONDUCTORS

The integration of nanoparticles into polymers is of significant theoretical and experimental interest, with a rich history in the polymer and engineering communities. Inorganic fillers have been used for some time in conjunction with organic polymer materials, largely in an effort to enhance the physical and mechanical properties over those of the polymers alone. In the mid-19th century, research efforts by Charles and Nelson Goodyear, pioneers in the chemistry of rubber, showed that vulcanized rubber can be toughened significantly by the addition of zinc oxide and magnesium sulfate.<sup>[1–3]</sup> In the early 1900s, Leo Baekeland

investigated the use of silicate clay in phenolic resins that helped Bakelite®, the first mass-produced synthetic polymer composite, become a commercial success.<sup>[1–4]</sup> Many additional commodity materials have been developed based on the enhanced properties that result from filling rubber with clay.<sup>[5]</sup> More recently, it was found that rubber particles embedded in nylon and other polymer matrices afford composites with outstanding impact resistance.<sup>[6]</sup> These are among the many examples of composite materials on which new research efforts have been constructed. These efforts have focused on the integration of a variety of nanoscopic materials into polymers and the impact of these composites over a broad spectrum of applications, from engineering plastics to electronic materials to biotechnology.

There is no question that nanotechnology is revolutionizing the scientific approach across many disciplines, including chemistry, biology, materials science, engineering, and theory.<sup>[7–10]</sup> For example, research centered on nanoscopic materials extends from the semiconductor industry, where the ability to produce nanometer-scale features leads to faster and less expensive transistors,<sup>[11–13]</sup> to biotechnology, where, e.g., luminescent nanoparticles are extremely interesting as bioprobes.<sup>[14–16]</sup> Tremendous advances in characterization technology is a common thread through all disciplines in nanotechnology, where nanoscopic objects and materials can be visualized with greatly improved resolution relative to only 10–15 years ago. Fig. 1 illustrates a few examples of “nanomaterials” with dimensions of 1 micron and less. In the nanoparticle–polymer area, current efforts now reach far beyond (or below) the use of micron-sized particle fillers (e.g., layered silicates) and into very small metallic and semiconductor nanoparticles as small as 1–2 nm in diameter.

This entry will highlight recent research in the area of polymer–nanoparticle composites, focusing especially on preparative techniques that afford well-dispersed nanocomposites, because such dispersion is a major target in the field. A leading discussion of clay-based nanocomposites will be followed by a focus

Fig. 1 Building blocks for nanotechnology.

on metallic and semiconductor-based hybrid materials. The use of polymers as a means to provide exquisite order to nanoparticles will be described, based on the ability of polymer materials to assemble into nanostructures. Finally, potential applications of polymer–nanoparticle composites will be discussed, with a special focus on the use of dendritic polymers and nanoparticles for catalysis.

### Clay–Nanoparticle Polymer Composites

The use of clay (i.e., hydrated silicates of aluminum) in combination with polymer materials can provide significant advantages in physical properties relative to the polymers alone.<sup>[17]</sup> Early discoveries in this area described blends of layered silicate nanoparticles with nylon-6 to afford composites with greatly enhanced thermal and mechanical properties.<sup>[18–20]</sup> Further advances in such composites in terms of melt processing allow these materials to be prepared in the absence of organic solvents.<sup>[21]</sup> Manias and coworkers have developed polypropylene–montmorillonite composites by varying the volume fraction of montmorillonite nanoparticles and varying block lengths of polypropylene–styrene or polypropylene–poly(methyl-methacrylate) copolymers to probe mechanical and thermal properties.<sup>[22]</sup> For example, a 3% inorganic loading into polypropylene gave a 30% increase in Young's modulus and a 30°C increase in heat deflection temperature when compared to native

polypropylene. In addition, there is significant interest in the fire-retardant properties of polymer–clay nanocomposites, as integration of clay into the structure inhibits the inherent flammability of most organic-based polymers.<sup>[23]</sup>

Significant challenges are associated with blending polymers and nanoparticles to afford homogeneous, well-dispersed inorganic material within the polymer. In order for dispersion to be achieved, the entropic penalty associated with addition of the nanoparticles must be balanced by favorable enthalpic interactions. Typical polymer–clay hybrids composed of layered nanoparticles (silicates, talc, and mica) are aggregated to some degree, as the immiscibility of clay in the polymer leads to a very close proximity of sheets to one another.<sup>[24]</sup> The degrees of dispersion in these composites are generally referred to as unmixed (highly aggregated), intercalated (minimally aggregated), and exfoliated (well dispersed). In the intercalated case, polymer chains interpenetrate stacked silicate layers with small separation distances (few nanometers) between the layers. In the exfoliated or delaminated morphology, the silicate layers are well dispersed within the polymer matrix (Fig. 2). When polar polymers are used, exfoliation can be achieved by the addition of a surfactant to the material, typically a long-chain alkylammonium salt. However, for non-polar polymers such as poly(ethylene) and poly(propylene), the addition of a surfactant is not sufficient to overcome the entropic penalty; thus a functional comonomer such as methyl methacrylate

Fig. 2 Depiction of three types of clay–polymer hybrid materials showing different levels of particle dispersion.

must be incorporated into the nonpolar polymer to allow nanoparticle dispersion within the matrix.<sup>[22]</sup> Advances in processing have also led to decreased aggregation in clay–polyethylene materials, such as the use of supercritical CO<sub>2</sub> during polyethylene extrusion.<sup>[25,26]</sup> Because the physical properties of these composites depend on the ability to produce controlled intercalation or exfoliation, the interest in small molecule and polymeric additives tuned to this target is growing significantly.

Recent studies by Balazs and coworkers describe models based on self-consistent field theory to determine the interactions needed to allow polymer chains to penetrate nanoparticle layers or sheets, leading to a further increase in the composite's physical properties.<sup>[27]</sup> Their findings indicate that the introduction of small amounts of functionalized polymers to the homopolymer system will greatly increase the thermodynamic stability of the clay–polymer composite and increase the degree of intercalation or exfoliation in the system. Based on these and other findings, a much research has been dedicated to optimizing the properties of these clay–polymer systems based on blend ratio, degree of cross-linking, curing behavior, and size and dispersity of the nanoparticles.<sup>[28]</sup>

### Composites of Polymers with Metallic and Semiconductor Nanoparticles

Related to research efforts in clay–nanoparticle composite materials are efforts to integrate metallic and semiconductor nanoparticles into polymer materials. While targets such as controlled dispersion and self-assembly parallel those of the clay-based materials, the metal and semiconductor-based composites offer clearly distinct materials in that electronic, magnetic, and optical properties offered by the particles are now present. For example, nanoparticles composed of gold, cobalt, palladium, copper, and cadmium selenide are of great interest for their potential role in nanotechnology applications.<sup>[29–34]</sup> Nanoparticles such as these are generally synthesized by “bottom-up” chemistry that affords nanoparticles with narrow size distributions. Very small nanoparticles (i.e., <10 nm) are especially interesting for the quantum confinement effects inherent in particles of that size.<sup>[29,30,35]</sup> Semiconductor nanoparticles such as cadmium selenide and cadmium telluride are of special interest because of their narrow (ca. 20–25 nm FWHM) and tunable (based on size) fluorescence emission wavelengths.<sup>[30,36]</sup> Key to the behavior of these nanoparticles is their organic ligand shell that provides a protective encapsulating layer to prevent aggregation and oxidative or chemical degradation, all of which serve to diminish or destroy the nanoscopic integrity and properties of the nanoparticles (Fig. 3).

**Fig. 3** Representation of nanoparticles passivated by organic ligands.

To provide dispersion of these organic-capped nanoparticles in a polymer matrix, there must be favorable interactions between the nanoparticle ligands and the polymer environment. Several approaches have been investigated, such as 1) mimicking the nanoparticle ligand coverage with side chains on the polymer structure; 2) preparing polymers that contain ligands to bind to the nanoparticles; 3) the attachment of polymers to the nanoparticles by functionalized chain-ends, also known as “grafting-to”; and 4) the attachment of polymerization initiators to nanoparticle surfaces, followed by polymer growth from outward from the surface, also known as “grafting-from.” Method 4 is proving to be an excellent approach whereby a high density of initiators can be attached to nanoparticles, and a diverse range of monomers can then be grown off the particles; this will serve as the focus of the next section.

### POLYMER GROWTH FROM NANOPARTICLE SURFACES

Functionalization of nanoparticles with polymer chains opens new avenues in nanostructured materials and composites by tailoring the interactions of the nanoparticle with its environment based on the properties of the polymer encapsulant. This concept may be used to introduce an enormous diversity of chemical functionality into composite systems that can be used directly, or modified further. This chemical functionality can be tailored to provide specific solubility or miscibility, or used for further coupling chemistry, e.g., to reactive surfaces.

There are two general methods used for attachment of polymers to nanoparticle surfaces. The first is coupling of end-functionalized polymers onto the surface of nanoparticles in a “grafting-to” approach. Although this procedure is commonly used because of the simplicity of the approach, less than optimum grafting density may result, because of the steric shielding that arises on placement of each successive polymer chain onto the nanoparticle. Some recent examples using this

“grafting-to” method include thiol-functionalized polystyrene (PS) grafted to gold nanoparticles,<sup>[37]</sup> pyridine-functionalized poly(ethylene glycol) grafted to CdSe nanoparticles,<sup>[38]</sup> thiol-functionalized poly-(caprolactone) grafted to CdS nanoparticles,<sup>[39]</sup> and a variety of copolymers with end-thiol functionality, including water-soluble particles, for stabilization of gold nanoparticles.<sup>[40]</sup>

The second method used to connect polymers and nanoparticles involves polymerization from the nanoparticle surface, using nanoparticles functionalized appropriately with polymerization-active ligands. The appeal of this “grafting-from” method is derived from the facile attachment of small molecules to the nanoparticle surface relative to chain-end functionalized polymers, and the ability to subsequently grow a compact shell of polymers outward from the surface. Critical to this “grafting-from” process is the compatibility of the nanoparticle with the polymerization conditions chosen, such that neither the attachment of functional ligands nor the polymerization process appreciably alters the fundamental features of the nanoparticles. Although these requirements pose a considerable challenge, much progress has been made in recent years. It should be noted that nanoparticle surfaces differ from flat surfaces as substrates in the “grafting-from” process, as higher surface curvature of the spherical nanoparticle can reduce steric crowding during chain growth, which may lead to more effective polymerization from the nanoparticles.

Polymerization techniques utilized in the “grafting-from” method include controlled radical polymerization, “living” anionic polymerization, and ring-opening metathesis polymerization (ROMP).<sup>[41]</sup> Optimum control over the properties of these composites can be achieved by varying the type of nanoparticle and by adjusting the composition, molecular weight, and functionality of the attached polymer shell. ROMP is proving to be especially useful in grafting from nanoparticles, due in part to the excellent chemical tolerance of the ruthenium-based catalysts used in ROMP, and the mild conditions under which they perform. Watson and coworkers recently reported the surface functionalization of gold nanoparticles with polymerizable moieties that were used to prepare nanocomposites by ROMP.<sup>[41]</sup> This was accomplished by functionalization of gold nanoparticles with 1-mercapto-10-(*exo*-5-norbornen-2-oxy)decane, where the thiol group binds to the gold surface, and a ROMP-active functionality is left available for polymerization. *bis*(Tricyclohexylphosphine)benzylidene ruthenium dichloride (i.e., first-generation Grubbs catalyst) was used as a surface-immobilized ROMP catalyst, and a ferrocene-substituted norbornene was then polymerized from the nanoparticle surface (Fig. 4). The “living” nature of this ROMP method was demonstrated by the preparation of block copolymers from the gold surface, using two different ferrocene esters. Cyclic voltammetry of the composite exhibited two distinguishable waves characteristic of oxidation/reduction of the different ferrocenyl moieties. From the integrated current

**Fig. 4** Schematic representation of the preparation of polyolefin-functionalized gold (left) and CdSe (right) nanoparticles by ring-opening metathesis techniques.

**Fig. 5** Reaction scheme of gold-nanoparticle-initiated cationic polymerization of 2-substituted oxazolines.

associated with these waves, a copolymer composition of 1.4:1 [poly(*exo*-5-norbornen-2-yl-ferrocenecarboxylate):poly(*exo*-5-norbornen-2-yl-ferroceneacetate)] was calculated.

Recently, Skaff and coworkers applied the “grafting-from” concept to semiconductor nanoparticles, using ca. 3-nm CdSe nanoparticles and cyclooctene-based monomers.<sup>[42]</sup> This involved the synthesis and use of a new ligand for CdSe, *p*-vinylbenzyl-di-*n*-octylphosphine oxide, prepared from di-*n*-octylphosphine oxide and 4-vinylbenzyl chloride. This ligand is first used to functionalize the nanoparticles, followed by metathesis chemistry of the vinyl moiety with Grubbs’ catalyst (generation 1) to afford a macroinitiator that is suitable for polymerization of cyclic olefins (Fig. 4). For example, cyclooctene was polymerized outward from the surface of the macroinitiator nanoparticle, and excellent particle dispersion was observed in the resulting poly(cyclooctene)–CdSe hybrid material. In addition, other cyclic olefins such as *exo*-7-oxanorbornene-2,3-dicarboxylic anhydride and *exo*-*N*-ethyl-7-oxanorbornene-2,3-dicarboxylimide proved applicable to this approach, and it is expected that many other cyclic olefins could be polymerized from this versatile nanoparticle-based macroinitiator.

Jordan and coworkers used  $\omega$ -functionalized self-assembled monolayers of thiolates on gold nanoparticles to initiate living cationic ring-opening polymerizations of 2-oxazoline monomers.<sup>[43]</sup> *N,N*-di-*n*-Octadecylamine was introduced as a terminating agent to provide a hydrophobic region and thus afford an amphiphilic polymer shell around the gold core. A schematic illustration of the preparation of such nanoparticles is given in Fig. 5. Tethered polymers were liberated from the nanoparticles by using NaCN solution and analyzed by matrix-assisted laser desorption ionization time-of-flight (MALDI TOF) mass spectrometry. These polymerizations were observed to proceed in a living fashion, as judged from the linear

relationship between molecular weight of the grafted polymer after cleavage from the nanoparticle surface and reaction time.

Surface-initiated anionic polymerization from nanoparticle surfaces has also been reported, e.g., using 1,1-diphenylethylene with a chlorosilane end group to functionalize silica nanoparticles, followed by anionic polymerization of styrene (Fig. 6).<sup>[44]</sup> Although the molecular weight distributions ( $M_w/M_n = 1.2$ – $1.8$ ) of the surface-bound polymers were broader than typical solution anionic polymerization, this is a rare example where living anionic polymerization is performed on nanoparticle surfaces; it will be interesting to see the progress in this area in terms of which nanoparticle compositions can be used in conjunction with the living anionic chemistry.

Atom transfer radical polymerization (ATRP) is among the most extensively exploited methods for polymer growth from nanoparticle surfaces. Recent studies on ATRP from silica<sup>[45–47]</sup> and core-shell CdS/SiO<sub>2</sub> nanoparticles<sup>[48]</sup> have demonstrated the ability to grow well-defined PS or poly(methylmethacrylate) (PMMA) layers from these modified inorganic surfaces. In these studies, some interesting effects of nanoparticle size were reported. In the case of 75-nm-diameter silica nanoparticles, good molecular weight control of PS was observed. However, the growth-from method on larger silica nanoparticles (300-nm diameter) did not show characteristics of a living polymerization. This was attributed to the high ratio of monomer to initiator per unit mass of silica used in the latter case. However, in each case the CdS/SiO<sub>2</sub> nanoparticles were dispersed throughout the polymer, with no signs of aggregation.

Other examples of the preparation of polymer-attached particles by “grafting-from” ATRP methods were reported by Hallensleben and coworkers.<sup>[49,50]</sup> In this case, *tris*(2-dimethylaminoethyl)amine was used as the ATRP ligand, which enabled the polymerization to

**Fig. 6** Schematic representation of polymer growth from nanoparticle surfaces by anionic polymerization (left) and atom transfer radical polymerization (right).

proceed at room temperature (Fig. 6). This low reaction temperature has the advantage of suppressing side reactions, such as desorption of thiol-functionalized ATRP initiators from the gold surface, and thermal initiation of *n*-butylacrylate monomer.<sup>[50]</sup> Gold nanoparticles had varying numbers of the polymer chains, which resulted in a relatively broad molecular weight distribution, as judged by the gel permeation chromatography (GPC) trace of poly(*n*-butylacrylate)-grafted gold nanoparticles.

An interesting approach to prepare silica nanoparticle–polymer hybrid materials has been demonstrated by Mori et al., where a hyperbranched polymer (HBP) was grown from the particle surface.<sup>[51]</sup> Typical hyperbranched polymerizations that proceed by polycondensation chemistry would result in cross-linked networks when performed in the presence of functionalized nanoparticles that participate in the chemistry. However, in this case self-condensing vinyl polymerization<sup>[52]</sup> of an acrylic “inimer” was used, where the inimer functions as both a monomer and an initiator. This inimer is designated as “AB\*,” where A is a vinyl

group and B\* is a functional group that can be transformed to an active center capable of initiating polymerization. Bulk polymerization of the inimer, 2-(2-bromopropionyloxy)ethyl acrylate, with the silica nanoparticles functionalized with 2-bromoisobutyryl fragment (B\*) was performed via ATRP, resulting in the formation of HBP shell on the silica surface (Fig. 7). These efforts are promising for providing diverse polymer architecture to nanoparticle-based composites, because HBPs have distinctive chemical and physical properties due to their globular shape and many end groups. This may also provide a rapid alternative to the synthesis of dendrimer–nanoparticle hybrid materials, which require the tedious dendritic synthesis.<sup>[53,54]</sup>

## ORDERED ASSEMBLIES OF NANOPARTICLE–POLYMER COMPOSITES

Well-ordered nanoparticles within polymers are expected to provide access to new materials that

Fig. 7 Schematic representation of self-condensing vinyl polymerization of  $AB^*$  inimer from functionalized silica nanoparticles.

combine the unique physical properties of the particles with the superior processibility of the polymers. The ability to control the assembly of nanoparticles in materials promises advances in information storage, nanoelectronics, and quantum computing. A variety of nanoparticle assembly methods are under investigation, e.g., into superlattice structures reported by Murray and Bawendi for CdSe nanoparticles with aliphatic ligands of various size.<sup>[33,55]</sup> These highly ordered structures are prepared by slow crystallization to give ordered nanoparticle assemblies with remarkably few defects.

Theoretical models of Balasz and coworkers are addressing the impact of nanoparticles on phase separation in A–B diblock copolymers.<sup>[32,56–58]</sup> These calculations are driven by a combination of self-consistent field theory, which is preferred for diblock copolymers, and density functional theory, which is optimal for studying ordered colloidal particles. The theory accounts for key parameters such as nanoparticle size, chain length of the polymer blocks, and the relevant interaction parameters, including those between nanoparticles and polymer A, nanoparticles and polymer B, and polymer A with polymer B. These models show that nanoparticles can be directed to the center or the edges of phase-separated lamella or spherical domains by choosing systems with the appropriate parameters. The increased complexity of the system that results from placing ligands on the nanoparticles

would certainly have an impact on the outcome of these calculations.

A report by Fogg et al. in 1997 on nanoparticle–polymer assemblies was one of the early papers to address specific polymer–nanoparticle interactions to promote assembly in phase-separated systems.<sup>[59]</sup> In this study, a diblock copolymer was prepared by ROMP, where one of the blocks contained phosphine or phosphine oxide moieties as nanoparticle ligands. This diblock copolymer was annealed in the presence of CdSe nanoparticles, resulting in polymeric phase separation and the nearly exclusive presence of the nanoparticles within the functionalized block, as shown by transmission electron microscopy (TEM) analysis, and illustrated schematically in Fig. 8.

Several research groups have recently been active in the field of polymer–nanoparticle composites and assemblies. Rotello and coworkers have been active in self-assembly of gold nanoparticles that are functionalized with ligands that contain recognition sites.<sup>[60,61]</sup> Specifically, gold nanoparticles were synthesized with aliphatic thiols containing a specific hydrogen bonding sequence, specifically triazine and diaminopyridine derivatives. When these nanoparticles are blended with a polymer or block copolymer containing the complementary hydrogen bond sequence recognition of the two components drives the self-assembly process. Several other methods have been reported for producing ordered assemblies of polymers and nanoparticles.

**Fig. 8** Schematic representation of nanoparticle segregation to the ligand-rich phase of an AB diblock copolymer.

For example, Kotov and coworkers have prepared “nanorainbows” using a multilayer approach,<sup>[60–62]</sup> where a thin polymer film of poly(diallyldimethylammonium chloride) containing cadmium telluride nanoparticles is deposited onto a quartz slide. Subsequent deposition of larger cadmium telluride nanoparticles with progressively longer wavelengths (e.g., yellow, orange, and red) were then deposited in layer-by-layer fashion. This resulted in a multilayer film that has a color gradient oriented normal to the surface, a material of interest in photonic and electronic devices.

Recent work by Lopes showed self-assembly of various nanoparticles (e.g., gold, silver, indium, and lead) within a PS–PMMA diblock copolymer matrix under nonequilibrium conditions.<sup>[63]</sup> Under appropriate annealing conditions, the polymer matrix will phase separate into an ordered lamella structure with the nanoparticles residing exclusively in the polystyrene phase because of the more favorable gold–polystyrene interactions. At loadings of 30% gold particles, the polystyrene blocks are capable of conducting an electric charge, essentially converting the polystyrene segments into nanowires. Yuan and coworkers have studied amphiphilic triblock copolymers, such as poly(ethylene oxide-*b*-propylene oxide-*b*-ethylene oxide) as scaffolds for nanostructured silica.<sup>[64]</sup> When cast from an acidic ethanol solution containing tetraethoxysilane (TEOS), a silica precursor, the copolymer undergoes phase separation to afford an assembly of polymer cylinders. The hydrophilic poly(ethylene oxide) and TEOS form the periphery, and the hydrophobic poly(propylene oxide) is found at the center of the cylinders. The nanostructured silica

is formed by calcination of the TEOS, yielding a hollow silica cylinder with a wall thickness of ca. 4 nm.

A different approach to nanoparticle assemblies was reported by Misner and coworkers using templates prepared from diblock copolymers.<sup>[65]</sup> These templates consist of a cylindrical PMMA phase within a PS matrix, where the cylinder diameter is of the order of 15–20 nm.<sup>[66,67]</sup> CdSe nanoparticles were driven into these cylinders by capillary forces present on withdrawal of the templates from dilute solutions of CdSe nanocrystals (Fig. 9). This method is quite promising in that nanoparticle coverage in the template was shown to be approximately 70% by TEM (i.e., 70% of the cylinders are filled with nanoparticles), and conditions were developed to the point where >95% of the nanoparticles reside in the cylinders rather than on the PS matrix. Solid-state fluorescence measurements of these templates showed that the nanoparticles retained their fluorescence throughout the assembly and substrate removal (acid etching) process, and that fluorescence intensity could be controlled by changing the concentration of solution into which the templates were dipped. New deposition methods currently under investigation are expected to produce templates with complete coverage.<sup>[68]</sup>

A novel technique for controlling the location of nanoparticles has been demonstrated by Firestone and coworkers.<sup>[69]</sup> This report shows that by controlling the surface characteristics of silver nanoparticles, one can control their location within a multitier phospholipid bilayer system. Particles that are passivated by lithium dodecyl sulfate reside entirely in the aqueous layer, while alkyl derivatized particles are in the hydrocarbon portion of a lipid bilayer. The use of

**Fig. 9** Nanoparticle-filled templates prepared from self-assembled diblock copolymers are used to direct the assembly of nanoparticles.

**Fig. 10** Schematic representation of a lipid-based gel with selective nanoparticle placement that depends on the nanoparticle ligand environment.

underivatized silver particles results in assembly at the lipid–water interface (Fig. 10). The authors suggest that the particle interacts with the poly(ethylene oxide) (PEO) chains that have been grafted to some of the surfactant molecules. These hydrophilic polymer chains extend from the bilayer into the aqueous phase, and passivate the bare silver particles. Interestingly, it has been shown by small-angle X-ray scattering that these particles do not aggregate within the fluid, leaving their unique optical and electronic properties intact.

## NANOPARTICLE–POLYMER COMPOSITES FOR CATALYSIS

Catalytic methods are of vital importance in the chemical and petroleum industries. Catalysts represent the oldest commercial application of nanoparticles, typically consisting of small metal particles, often in the nanometer size regime, that are dispersed on a microporous oxide. Many studies on the catalytic properties of metal surfaces, such as platinum,<sup>[70,71]</sup> nickel,<sup>[72]</sup> iron,<sup>[73,74]</sup> and molybdenum<sup>[75,76]</sup> have been explored since the 1920s.<sup>[77]</sup>

Catalytic processes are greatly affected by the complexity of catalyst surface composition and structure. The catalytic efficiencies of metals increase dramatically with increasing surface-to-volume ratio; thus nanoparticles have inherent advantages. As the high surface energy associated with nanoparticles leads to aggregation, the use of surface-confined stabilizers has been induced. Ideally, these stabilizers should

possess rather weak surface activity, as strong adsorption would diminish significantly the catalytic activity. Protective stabilizers can influence not only the stability of the catalyst but also the catalytic properties by creating specific environments around the active sites.

Aside from the conventional commercialized catalytic processes, there have been some very interesting recent studies on nanoparticles in catalysis of organic reactions. For example, El-Sayed reported that Pd nanoparticles stabilized by poly(*N*-vinyl-2-pyrrolidone) (PVP) efficiently catalyze Suzuki cross-coupling reactions in aqueous medium.<sup>[78]</sup> Successful coupling of arylboronic acids to aryl iodides gave reasonably high yields even though the Pd particles precipitated during the reaction. The reaction rate was observed to depend on the Pd concentration in a linear fashion, indicating that catalysis occurs on the Pd surface. Hydroxyl-terminated poly(amido amine) (PAMAM) dendrimers and polystyrene-*b*-poly(sodium acrylate) were also reported to be efficient stabilizers for the Pd nanoparticles in the Suzuki reactions between phenylboronic acid and iodobenzene.<sup>[79]</sup> Overall, the careful choice of the type of stabilizer, metal precursors, as well as reaction conditions can lead to the preparation of the desired catalyst system.

Dendrimers have been recognized as suitable hosts for metal nanoparticles for a variety of reasons. Their uniform composition and three-dimensional structure provides a homogeneous environment for the particles, whereas their periphery of terminal end groups can be controlled in terms of functionality to control solubility and allow for catalyst recovery. Substrate

**Fig. 11** Schematic illustration of the synthesis of metal nanoparticles within a dendrimer template.

selectivity can be affected by the size and polarity of the terminal groups, and the size of the host dendrimer can be varied systematically through well-defined growth chemistry that affords dendritic macromolecules with precise structures and molecular weights.

Dendrimers have been used as both templates and stabilizers for nanoparticles, and have been found to effectively impede their aggregation. In some cases, nanoparticles are confined within the host dendrimer by steric effects, without significant surface passivation. Metal nanoparticles can be sequestered within dendrimers by adsorbing suitable precursor metal ions into the template dendrimer and subsequently reducing the composite (Fig. 11). Several systems have been explored with dendrimers, e.g., in the group of Crooks dendrimer-encapsulated metal nanoparticles were prepared in fluorosol media, leading to easy separation and recycling of the catalyst. Chechik and Crooks describe a case where Pd nanoparticles in PAMAM dendrimers were complexed with carboxylic end groups of perfluoropolyethers in fluorosolvents.<sup>[80]</sup> Hydrogenation of various alkenes, including 1-hexene and methylacrylate, was performed to assess the catalytic activity of the system. Pd–dendrimer nanocomposites were observed to be catalytically active without appreciable loss of activity after 12 cycles. The wide range of turnover frequency numbers was observed exhibiting the possibility of selective hydrogenation; more polar substrates were hydrogenated faster because of the hydrophilic interior of the dendrimer that promotes contact between the metal nanoparticles and the polar substrates.

Yeung and Crooks also presented examples of carbon–carbon bond formation in biphasic fluorosol/

organic solvent systems catalyzed by dendrimer-encapsulated nanoparticles.<sup>[81]</sup> The perfluorinated polyether-derivatized poly(propylene imine) (PPI) dendrimers containing Pd(0) nanoparticles effectively catalyzed Heck couplings of aryl halides with *n*-butylacrylate. Because PPI dendrimers are more stable at elevated temperatures than PAMAM dendrimers, they are better suited for the Heck reaction, which requires high temperatures and long reaction times. Whereas the selectivity for the production of *n*-butyl-*trans*-formylcinamate was previously reported to be in the 74–98% range in the absence of the dendritic stabilizer,<sup>[82]</sup> the PPI–Pd(0) catalyst provides 100% selectivity for the *trans* isomer. This result suggested that the sterically confined environment of the dendritic interior may impart regioselectivity.<sup>[83,84]</sup> It should be noted that the activity of catalysts can also be influenced by the dendrimer size. Equal amounts of metal nanoparticles of nearly the same particle size could be prepared within dendrimers of varying generations. A fifth-generation dendrimer/Pd(0) catalyst gave substantially greater product yield than the fourth-generation catalyst, which Crooks attributes to the larger dendrimer host that provides a less confining space for the Pd nanoparticles, resulting in easier access of substrate to the particle.<sup>[81]</sup>

Dendrimer–nanoparticle composites have been used in conjunction with supercritical CO<sub>2</sub>, an alternative to hydrocarbon solvents, and a “greener” approach to catalysis with nanoparticles. Crooks has previously shown that Pd nanoparticles, encapsulated by PPI dendrimers having covalently grafted perfluorinated-polyether chains, were easily solubilized in this supercritical medium without requiring perfluorinated ligands or

**Fig. 12** Formation of palladium and silica nanoparticle catalysts directed by the interactions of functionalized polymers and nanoparticles.

toxic solvents.<sup>[84]</sup> Whereas the standard Pd-catalyzed Heck coupling between iodobenzene and methylacrylate resulted in the *cis*- and/or *trans*-cinnamate product, the CO<sub>2</sub>-soluble Pd-based nanocomposite exclusively produced methyl 2-phenylacrylate. The high selectivity is presumably related to both the steric environment of the dendrimer template and the properties of supercritical CO<sub>2</sub> because the same dendrimer-encapsulated Pd(0) yielded only the *trans*-cinnamate product using organic/fluorocarbon solvent system instead of supercritical CO<sub>2</sub>.<sup>[81]</sup>

Amphiphilic block copolymers have been used for the stabilization of metal nanoparticles.<sup>[85–88]</sup> They are versatile components for polymer–metal systems because they can offer several options for tuning the system in catalytic applications. PS-*b*-PMMA and PS-*b*-PEO block copolymers were observed to be suitable for controlling both metal size and size distribution. The catalytic activities of the palladium and platinum nanoparticles stabilized by block copolymers were tested by hydrogenation of cyclohexene, which provided 100% conversion. The nanoparticle morphologies and catalytic activities were strongly dependent on many factors, including the type and ratio of polymer blocks, choice of metal precursor type, and the reduction method and conditions. These findings suggested that amphiphilic block copolymers could offer a tremendous versatility to the design of tailored catalysts.

Galow and coworkers have reported electrostatic-mediated assembly of highly reactive heterogeneous

catalysts in which mixed monolayer protected clusters (MMPCs) were used as both building blocks and active catalysts.<sup>[89]</sup> Catalysts were formed through calcinations of the mixture of palladium colloid and silica–polymer aggregates (Fig. 12). A series of hydrogenation reactions and Heck reaction were performed and substantially high catalytic ability was observed. In the case of the Heck reaction between nitroarene and styrene, only 0.045 mol% of Pd was required to show a dramatic improvement over commercial counterparts.

The fabrication of nanoparticle-based templates that exhibit site-isolated nanoparticles in long-range ordered arrays may be ideal for some catalytic applications; thus future efforts in catalysis will be directed toward constructs as described in Fig. 9 above. Such studies, performed previously with CdSe nanoparticles, should translate well to other nanoparticle systems studied in catalysis. Because selectivity is not understood as well as activity, future research should focus on achieving exceedingly high selectivity for the desired product. Through systematic variation of particle size and interparticle distance by using block copolymer templates with different molecular weight, structural ingredients responsible for selectivity of catalyst may be investigated in the near future.

## CONCLUSION

In summary, it is clear that nanoparticle–polymer composite materials are playing an increasingly important

role in nanotechnology. This article has summarized only a few of the many outstanding achievements in the field. As our ability to prepare and assemble these composites continues to improve, the specificity of the applications that can be addressed will increase accordingly. Nevertheless, progress to date has been most impressive, and all indications point toward further growth in the future.

## ACKNOWLEDGMENTS

T.E. gratefully acknowledges the contributions of his group in nanoparticle-polymer composite materials, including Kevin Sill, Dr. Seunghoo Yoo, Habib Skaff, Rui Hong, Qingling Zhang, and Korisha Ramdhanie. Financial support for T.E.'s research group in nanoparticle-polymer composites was provided by the National Science Foundation (CAREER grant #0239486), the Eastman Kodak Company, and the U.S. Army Center of Excellence at U.Mass. Amherst.

# Polymer Nanowires Conjugated by Controlled Chain Polymerization

Yuji Okawa

Masakazu Aono

Nanomaterials Laboratory, National Institute for Materials Science,  
Ibaraki, Japan

## INTRODUCTION

The present-day silicon-based electronic devices have grown more powerful as their basic subunit, the transistor, has shrunk in size. However, the laws of quantum mechanics and the limitations of fabrication techniques may soon prevent further reduction. Thus we must develop a novel device concept, which can be applied at the nanometer scale. This exploration of a novel device concept beyond silicon-based transistors is analogous to the search for a replacement for the vacuum tube half a century ago, and its discovery will make a profound impact on society in this century. Many ideas have been proposed for the novel device concept, and one promising possibility is the construction of novel electronic devices using organic molecules.<sup>[1–14]</sup> However, even if we could make individual molecules that function as single-molecule transistors or diodes, the next problem would be the absence of good methods by which to arrange them in the desired pattern and to interconnect them with one another. Regarding this problem, it is necessary to develop a method of fabricating conductive wires of nanometer width (nanowires) at designated positions.

We usually use metals for wires whose width is larger than the order of micrometers. However, in the case of nanowires, the use of metals becomes much more difficult because of their poor stability and difficulties in their fabrication. If we want to use metals for nanowires, we must devise some method of stabilizing them.<sup>[15]</sup> Hence many materials other than metals have been considered as candidates for nanowires, including inorganic compounds,<sup>[16]</sup> carbon nanotubes,<sup>[4,8,9,12,14,17–19]</sup> DNA,<sup>[20–24]</sup> and other conductive organic molecules or polymers,<sup>[25–30]</sup> although we must conduct further basic studies before we can put them to practical use.

In this entry, we will present a method of fabricating a conjugated polymer nanowire at designated positions by controlling linear chain polymerization using the probe tip of a scanning tunneling microscope (STM).<sup>[29,30]</sup> A demonstration is presented for a self-ordered monomolecular layer of 10,12-pentacosadiynoic acid and 10,12-nonacosadiynoic acid, which are

amphiphilic diacetylene compounds, adsorbed on a graphite substrate. We have succeeded in controlling the initiation and termination of chain polymerization with a spatial precision on the order of 1 nm. The obtained polydiacetylene is a conjugated polymer, so that we can expect that it will become conductive when excess electrons or holes are supplied to it from the surroundings.

## SELF-ORDERED MOLECULAR LAYER

The monomer molecules we use are diacetylene compounds with the general formula  $R-C\equiv C-C\equiv C-R'$ , where  $C\equiv C-C\equiv C$  is the diacetylene moiety, and R and R' are substituent groups. It is well known that this molecular species in the form of solid crystals<sup>[31]</sup> or Langmuir–Brodgett films<sup>[32]</sup> polymerizes into polydiacetylene compounds on appropriate stimulation such as heating or ultraviolet irradiation (Fig. 1). Several studies have dealt with STM observations of physisorbed layers of various diacetylene compounds on graphite surfaces.<sup>[33–35]</sup> According to those studies, a variety of molecular arrangements are formed depending on the species of substituent groups, the method of film preparation, and the incorporation of foreign molecules.

In our work, we chose 10,12-pentacosadiynoic acid [ $CH_3(CH_2)_{11}-C\equiv C-C\equiv C-(CH_2)_8COOH$ ] and 10,12-nonacosadiynoic acid [ $CH_3(CH_2)_{15}-C\equiv C-C\equiv C-(CH_2)_8COOH$ ] as monomer molecules. These two species gave essentially the same results. To prepare their thin films, the monomer molecules were dissolved in chloroform and the solution was applied onto the surface of purified water. After the evaporation of chloroform, the thin films of monomer molecules on the water surface were transferred to a freshly cleaved surface of highly oriented pyrolytic graphite (HOPG) by nearly horizontal dipping.

The STM images were recorded using the Digital Instruments NanoScope STM system under ambient conditions in the constant current mode. A typical STM image of the 10,12-pentacosadiynoic acid layer is shown in Fig. 2A. The image consists of parallel bright lines separated by two different alternating

**Fig. 1** Polymerization of diacetylene compounds into polydiacetylene compounds.

spacings of about 3.0 and 3.8 nm, indicating that the 10,12-pentacosadiynoic acid molecules on the graphite surface are self-ordered after the transfer from the water surface. A magnified STM image of the layer is shown in Fig. 2B, in which individual molecules are

**Fig. 2** (A) Typical STM image of 10,12-pentacosadiynoic acid layer on a graphite surface (sample bias voltage  $V_S = -1.0$  V; tunneling current  $I_t = 0.07$  nA). (B) Magnified STM image of the layer ( $V_S = +0.5$  V;  $I_t = 1.0$  nA). The arrows in the image indicate the main crystal axes of graphite. (C) Top and side views of the proposed model for molecular arrangement. *Source:* From Ref.<sup>[30]</sup>; © American Institute of Physics, 2001.

resolved. Based on such STM images, we proposed the molecular arrangement shown in Fig. 2C. The molecules are aligned in phase to form straight chains and the chains are arranged such that the COOH end groups of a chain are opposite to those of a neighboring chain. Each bright line in Fig. 2A corresponds to the linear array of diacetylene moieties in Fig. 2C because the multiple bonds are, in general, observed to be higher than single bonds in STM images.<sup>[36]</sup>

At appropriately small sample biases and high tunneling currents, the STM image of the graphite substrate can be observed. On comparing such an image with the images of the molecular layer taken previously, it was found that the alkyl side chains of each molecule are oriented parallel to the main crystal axis of graphite. For many other molecules on graphite surfaces, it has been reported that their alkyl chains are also oriented parallel to the main crystal axis of graphite.<sup>[34,36–40]</sup> In Fig. 2B, a modulation of the image contrast is observed as a moiré pattern because of the lattice mismatch between the molecular layer and the graphite substrate. The periodicity of the moiré modulation indicates that the spacing between neighboring molecules in the molecular layer is 0.47 nm.

## PHOTOPOLYMERIZATION

First, we examined whether such chain polymerization could be induced by ultraviolet irradiation in the monomer film described above, and how the created polymers are observed in STM images. For this purpose, the molecular layer was irradiated with ultraviolet light from a low-pressure mercury lamp (254 nm wavelength and 1.3 mW/cm<sup>2</sup> power density at the sample position) for a period of 20 min.

Fig. 3A shows a typical STM image of the 10,12-pentacosadiynoic acid layer after ultraviolet irradiation. As we can see, very bright lines appeared. One of these very bright lines is imaged on a magnified scale at various sample biases, as shown in Fig. 3B–E. The number density of the very bright lines increased almost linearly with increasing duration of ultraviolet irradiation, as shown in Fig. 3F. Hence these very bright lines are considered to be polydiacetylenes, created by the photopolymerization of the linear array of diacetylene moieties.

The moiré modulation described above was also observed for the polymer, as seen in Fig. 3C. An important point is that the moiré pattern in the created polymer is the same as that in the monomer array. This means that the spacing between the alkyl side chains in the polymer is the same as that in the monomer—0.47 nm. This also indicates that the orientation of the alkyl chains is maintained parallel to the main crystal axis of graphite even after polymerization.

**Fig. 3** (A) An STM image obtained after ultraviolet irradiation ( $V_S = -1.0$  V;  $I_t = 0.07$  nA). (B–E) Magnified STM images of a polymer obtained at the same tunneling current ( $I_t = 0.1$  nA) and various sample biases  $V_S$ . (F) Plots of the number density of the polymer  $D$  against the duration of ultraviolet irradiation. (G) The proposed structural model of a polymer. The arrows indicate the backbone of polydiacetylene. Source: From Ref.<sup>[30]</sup>; © American Institute of Physics, 2001.

Based on these results, we proposed the structural model for the polymer, as shown in Fig. 3G. In this model, the polydiacetylene backbone is raised so that the alkyl side chains are parallel to the main crystal axis of the graphite substrate.

The most plausible mechanism of photopolymerization is illustrated in Fig. 4, by analogy with the case of bulk crystals of diacetylene compounds.<sup>[41]</sup> In the array of monomer molecules (Fig. 4A), the diacetylene moiety of one of the molecules is excited by photoabsorption into an excited state. As shown in Fig. 4B, a diradical state in the *trans* form with an unpaired electron at either end is a reasonable representation of the lowest excited  $\pi\pi^*$  singlet or triplet state located at 3.7 and 3.1 eV above the  $\pi\pi$  ground state,-

**Fig. 4** Illustration of the mechanism of photopolymerization. (A) Array of the monomer molecules. (B) Diradical formation by photoabsorption. (C) Approach of a neighboring diacetylene moiety by vibrational excitation. (D) Dimer formation by an addition reaction. (E) Extended chain propagation. respectively.<sup>[42,43]</sup> Within the lifetime of the diradical state, if a neighboring diacetylene moiety on either side approaches the diradical because of thermal vibration (Fig. 4C), an addition reaction occurs, forming a dimer of diacetylene (Fig. 4D). Because the created dimer of diacetylene still has radicals at both ends, a similar addition reaction occurs on both ends. Hence the repetition of such addition reaction occurs and results in extended chain polymerization, as shown in Fig. 4E. Therefore we can expect that if the excited diradical state in the first step (Fig. 4B) can be created by stimulation with the STM tip instead of photoabsorption, the extended chain polymerization will follow.

#### CHAIN POLYMERIZATION INITIATED BY A SCANNING TUNNELING MICROSCOPE TIP

Fig. 5A shows an STM image of the 10,12-pentacosadiynoic acid layer. The same area was imaged again in Fig. 5B, in which the STM tip is scanned rapidly in the

**Fig. 5** (A) An STM image of the original monomolecular layer of 10,12-pentacosadiynoic acid ( $V_S = -1.0$  V;  $I_t = 0.07$  nA). (B) Image of the same area observed from the bottom to the top, but with pulsed sample bias voltage applied at the point indicated by the arrow. (C) The same area imaged once again. (D, E) Diagrams illustrating the initiation of chain polymerization using an STM tip. Source: From Ref.<sup>[30]</sup>; © American Institute of Physics, 2001.

horizontal direction and slowly from the bottom to the top at a sample bias of  $-1$  V. When the tip passed the point indicated by an arrow, a pulsed sample bias ( $-4$  V in height and  $5 \mu\text{s}$  in width) was applied, as shown on the left-hand side of the figure. As can be seen, a very bright line appeared starting from the point where the pulsed sample bias was applied. This very bright line is identical in structure to those observed in Fig. 3. Namely, stimulation with the STM tip induced chain polymerization and created a polymer. The same area was imaged once again and the result is shown in Fig. 5C. We can see that chain polymerization occurred on both sides of the point of stimulation.

In the case of Fig. 5B, a negative pulsed sample bias ( $-4.0$  V) was applied, and we found that chain polymerization occurred at both polarities of the pulsed sample bias. This is seen in Fig. 6, where the frequency of the occurrence of chain polymerization  $P_{\text{STM}}$  is

**Fig. 6** Plots of the frequency of occurrence of chain polymerization  $P_{\text{STM}}$  in units of reactions per electron against the height of the pulsed sample bias voltage  $V_S$ . Source: From Ref.<sup>[30]</sup>; © American Institute of Physics, 2001.

plotted against the height of the pulsed bias voltage  $V_S$  at both polarities; these measurements were carried out using a 10,12-pentacosadiynoic acid layer at a fixed pulse width of  $10 \mu\text{s}$  while monitoring the tunneling current. As we can see, the reaction probability was symmetric with respect to the polarity of the pulsed sample bias, and the threshold voltage for polymerization was  $2.9 \pm 0.2$  V. This value is close to the energy separation between the  $\pi\pi$  ground state and the lowest excited  $\pi\pi^*$  triplet state of the diacetylene moiety— $3.1$  eV.<sup>[43]</sup> This suggests that the diacetylene moiety was excited by electrons tunneling between the tip and the substrate, which passed inelastically through the intermediate molecular layer.

As seen in Fig. 5C, the polymers created were usually terminated at domain boundaries. In other words, the chain polymerization initiated by the STM tip propagated in the domain without any additional energy other than thermal energy, and terminated when it encountered the domain boundary that acted as a kind of structural defect. Exploiting the fact that the chain reaction is terminated by a structural defect, we can also control the termination of chain polymerization by forming an artificial structural defect in advance. An example of a 10,12-nonacosadiynoic acid layer is presented in Fig. 7. First, the original monomolecular layer was imaged (Fig. 7A). Then we created an artificial defect at the center of the image, as shown in Fig. 7B, using a previously reported method.<sup>[44]</sup> Namely, an STM tip was placed at that position and a high pulsed sample bias ( $+5$  V in height and  $10 \mu\text{s}$  in width) was applied (Fig. 7F and G). The created defect was a hole with a diameter of  $6$  nm in the graphite substrate. The same area was imaged again from the top to the bottom, as shown in Fig. 7C, but a pulsed sample bias ( $-4$  V in height and  $5 \mu\text{s}$  in width) was

**Fig. 7** (A) An STM image of the original monomolecular layer of 10,12-nonacosadiynoic acid ( $V_s = -1.0$  V;  $I_t = 0.07$  nA). (B) Creation of an artificial defect in advance with an STM tip. (C) First chain polymerization, initiated at the point indicated by arrow 1 and terminated at the artificial defect. (D, E) Second and third chain polymerizations initiated at the points indicated by arrows 2 and 3, respectively. (F, G) Diagrams illustrating the creation of an artificial defect in advance. (H, I) Diagrams illustrating the initiation and termination of chain polymerization. *Source:* From Ref.<sup>[29]</sup>; © Macmillan Magazines Ltd., 2001.

applied when the scanning tip passed the point marked by arrow 1. A very bright line appeared between the point of stimulation and the artificial defect, indicating that chain polymerization was initiated at the stimulation point and terminated at the artificial defect (Fig. 7H and I). We imaged the same area once more from the top to the bottom, as shown in Fig. 7D, applying another pulsed sample bias when the tip passed the point marked by arrow 2. In this case as well, chain polymerization was initiated at the indicated point and terminated at the artificial defect. Note the chain polymerization initiated at the point marked by arrow 1 propagated on both sides of the point, as described above. In a similar manner, we created a third polymer nanowire by initiating chain polymerization at the point marked by arrow 3 in Fig. 7E.

This result shows that we can control the initiation and termination of chain polymerization with spatial precision on the order of 1 nm. Furthermore, this result also indicates that at least three polymer nanowires can be connected to an object as small as 6 nm. This means that the source, drain, and gate electrode of a nano-scale single-molecule transistor, for instance, will be connectable.

### ADVANTAGES OF THE METHOD

It is well known that we can manipulate individual atoms or molecules with an STM tip,<sup>[45–48]</sup> so we

should be able to create nanowires using such atom-by-atom crafting. It is also known that if a thin molecular film is stimulated by a biased STM tip, a local chemical reaction or reorientation is sometimes induced,<sup>[49–53]</sup> so that continuous modification will be possible by scanning of a biased STM tip. Although such work is essential to fundamental advances, the chain polymerization technique used in our work has several advantages.

First, the nanowires obtained are guaranteed to have perfect structures without any defects. If defects exist, the chain reaction itself will be terminated, as has been discussed above. Hence if the chain reaction proceeds, the nanowire reaction product is guaranteed to have perfect structures. For a chain reaction proceeding in a large domain without any defects, polymers longer than 500 nm have been observed. Furthermore, a single conducting polymer chain in a free state, such as a solution, generally has a coiled conformation, which prevents the occurrence of  $\pi$ -electron conjugation along the whole chain. In contrast, the polydiacetylene nanowires on a graphite surface obtained in our method are straight, so they can be considered ideal  $\pi$ -conjugated systems. Second, the nanowires are stable at room temperature. Third, we can create a long nanowire by applying only one pulsed bias voltage at one point; the propagation speed of the chain reaction is high (we roughly estimated the propagation speed of the chain polymerization to be

0.1–1 m/sec), so that the entire process is accomplished in a short time. Fourth, the process required no additional energy for the chain propagation reaction, other than the first stimulation.

The controlled chain reaction methods have many advantages for the fabrication of nanosized structures. However, despite these advantages, reports on controlled chain reaction are few (Lopinski et al.<sup>[54]</sup> have reported another type of chain reaction—a spontaneous growth of a molecular styrene line from a silicon dangling bond).

Finally, we would like to discuss whether or not the nanowires are conductive. According to electronic energy band calculations for various polydiacetylene compounds,<sup>[55–57]</sup> their polydiacetylene backbones have almost the same band structure and are nearly independent of substituent groups. Namely, the conjugated  $\pi$ -electrons of the polydiacetylene backbone form valence and conduction bands, which are separated by an energy gap of about 1.6 eV.<sup>[57]</sup> Because of the existence of this band gap, the polydiacetylene backbone is expected to be a nonconductor. However, because the highest valence band and the lowest conduction band have fairly strong dispersions,<sup>[57]</sup> the polydiacetylene backbone should act as an electronically conductive nanowire on the transfer of charge from the surroundings. For example, excess electrons, created by light illumination on a polydiacetylene chain, move in response to an electronic field with an ultrahigh drift mobility,<sup>[58]</sup> and the conductivity of polydiacetylene films increases on doping with iodine.<sup>[59]</sup> The polymer nanowire on the graphite surface created by our method is also expected to be conductive if a charge transfer between the polymer and the graphite surface exists. We are now planning to measure the conductivity of the polymer nanowire.

## CONCLUSION

We have demonstrated that we can initiate the linear propagation of the chain polymerization of unsaturated organic molecules at any predetermined point and terminate it at another predetermined point with a spatial precision on the order of 1 nm, using the probe tip of an STM. In our demonstration, we used a self-ordered monomolecular layer of the amphiphilic diacetylene compounds, 10,12-pentacosadiynoic acid and 10,12-nonacosadiynoic acid. Because the polydiacetylene backbone has a conjugated  $\pi$ -electron system, we can expect that it will function as an electrically conductive nanowire when charge is transferred from the surroundings.

In the future, this method will be useful for fabricating novel molecular devices comprising conjugated polymer nanowires, and for interconnecting novel

nanoelectronic devices. Furthermore, because the obtained polymer is considered to be a long, linear, conductive nanowire with high structural perfection, it will be an ideal system for the basic study of the physics of one-dimensional conductors. We also hope that this work will provide a new experimental method for chemists investigating the kinetics and mechanisms of chain reactions.

# Polypropylene and Thermoplastic Olefins Nanocomposites

Francis M. Mirabella, Jr.

Analytical Department, Equistar Chemicals, LP, Cincinnati, Ohio, U.S.A.

## INTRODUCTION

The purpose of this chapter is to review the progress toward the preparation of polypropylene/clay and thermoplastic olefin/clay nanocomposites. Further, the structure and properties of these type of nanocomposites are discussed and, where possible, structure/property relationships are described. Lastly, the progress toward the achievement of commercially viable nanocomposites of this type is assessed.

Polyolefins account for about 185 billion pounds per year or about 50% of the total worldwide plastic's industry production. Polypropylene (PP) accounts for about 20% of this total or 74 billion pounds per year production. Therefore polypropylene is one of the most widely used thermoplastics not only because of its balance of physical and mechanical properties, but also because of its environmental friendliness (e.g., recyclability) and low cost. The most common type is isotactic PP, while syndiotactic PP is a minor contributor to the PP market. Polypropylene has an attractive combination of low density, high stiffness and toughness, and heat distortion temperature above 100°C, which endows it with extraordinary versatility of properties and applications ranging from molded parts to films and fibers. Innovative catalyst and process technologies have significantly simplified its production, resulting in the minimization of catalyst residues, waxy byproducts, and low stereoregularity components, by the use of high activity and highly stereoselective catalysts, such as Ziegler–Natta and metallocene catalysts. Highly energy-efficient processes, such as gas phase and liquid-pool processes, have minimized the need for solvents. Polypropylene offers ready means for recycling by remolding or feedstock recovery or by recovery of its energy content in power plants and steel mills. It has also continued to make inroads into the engineering plastics markets by replacing more expensive and less environmentally friendly resins. The addition of mineral fillers to polypropylenes has widened its sphere of applications by enhancing its stiffness properties. However, the concomitant effect is typically a decrease in toughness properties because the inorganic filler particles act as stress concentrators.

Montmorillonite (mmt) is the most common clay mineral used in polymer/clay hybrids and is composed

of an octahedral alumina sheet sandwiched between two tetrahedral silica sheets. The anionically charged sheets, or clay platelets, are strongly held together by cations, such as  $\text{Na}^+$ ,  $\text{Li}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Fe}^{2+}$ , and  $\text{Mg}^{2+}$ . The tightly bound stacks of clay platelets may be readily separated by simple dissolution in a polar solvent, such as water. In addition, the natural clay is miscible with polar polymers in which the platelets readily disperse. However, separation of the clay platelets in a nonpolar polymer is difficult. The thickness of the individual clay platelets is about 1 nm and the gallery spacing (spacing is defined in terms of d-spacing from X-ray diffraction and small-angle X-ray scattering, which is the distance from one clay platelet center to the next) of the platelets in natural clay is about 1 nm. Organic modification of the clay with alkyl ammonium chlorides, in which the alkyl chain is typically composed of 6 to 15 carbons, expands the gallery spacing to about 2.2 to 2.4 nm in typical commercial organoclays. Addition of maleic anhydride-modified PP often results in intercalated clay with gallery spacing of greater than 3 nm. The typically desired state is, upon addition of PP, the complete dispersion, i.e., exfoliation and dispersal, of the clay platelets so that there is no correlation between platelets and therefore no maxima in the X-ray scattering pattern. Considering that clay is composed of platelets that are about 1 nm in thickness and around 1000 nm in lateral dimensions and assuming a density of 2.65 g/cm<sup>3</sup> yields an upper limit of about 750 m<sup>2</sup>/g surface area per gram for fully exfoliated clay. This is 5 to 10 times the surface area per gram achievable with ordinary fillers. Exfoliated clay in polymers was shown to endow unique properties to the system, such as increased T<sub>g</sub>, increased stiffness, maintenance of impact strength, increased barrier to gases and liquids, increased flame retardancy, etc.

## POLYPROPYLENE

### Structure

The extraordinary property enhancements accessible through the formation of polymer/clay mineral hybrid systems were pioneered by Toyota workers about a decade ago. In a series of papers, the synthesis of

nylon-6/clay hybrids was described by the swelling of natural montmorillonite (fractionated from bentonite) with  $\epsilon$ -caprolactam to form an intercalated compound, followed by the thermolytic polymerization of the  $\epsilon$ -caprolactam to nylon-6.<sup>[1,2]</sup> The remarkable enhancements of the thermal and mechanical properties of the nylon-6 were further reported by the Toyota workers.<sup>[3]</sup> The dispersion of the silicate layers in such nylon-6/montmorillonite hybrids is generally excellent. The clay platelets are essentially completely exfoliated, resulting in a morphology as shown in the transmission electron microscopy (TEM) photomicrograph in Fig. 1. The clay platelets are seen to be completely dispersed and uncorrelated with each other. Therefore no X-ray signal from a periodic stacking of clay platelets would be expected from x-ray diffraction (XRD) or small angle x-ray scattering (SAXS) measurements.

In a technological advancement of this development, Vaia, Ishii, and Giannelis<sup>[4]</sup> reported the formation of polymer/clay hybrids by the direct intercalation of polystyrene in organically modified montmorillonite. The montmorillonite was modified with alkyl ammonium cations to maximize the enthalpic interactions of the

modified clay with the polystyrene and thus overcome the unfavorable loss of conformational entropy associated with the confinement of the polymer inside the clay galleries. The intercalated polymer was claimed to exist in a collapsed, two-dimensional conformation, and, as evidence of this, it was demonstrated that the normal glass transition temperature of the polystyrene was essentially absent for the intercalated polymer.<sup>[4]</sup> In further work, this group studied the chain dynamics of polystyrene in organically modified clay hybrids. They defined an effective diffusion coefficient and found that it increased with increasing alkyl chain length of the alkyl ammonium cation functional groups on the clay.<sup>[5]</sup>

The organic modification of natural clay minerals typically involves exchange of cations on the natural clay with alkyl ammonium cations. Commercial mmt typically is modified with hydrogenated tallow, which is ~65% C<sub>18</sub>, 30% C<sub>16</sub>, and 5% C<sub>14</sub> alkyl chain lengths. The typical commercial organoclay is modified with an alkyl ammonium compound as shown in Fig. 2.

Two alternative synthetic routes were proposed by Manias et al.<sup>[6]</sup> to prepare organically modified mmt that would be readily dispersed in polypropylene. These small-scale studies were intended to explore the thermodynamics required to intercalate and exfoliate mmt with polypropylene. The first route relied on improving the favorability of the polypropylene–mmt enthalpic interactions to disperse the mmt. This was performed by functionalizing the polypropylene with 0.5–1.0 mol% of methyl styrene monomer. This random copolymer was then further functionalized with maleic anhydride and ethanol resulting in three random copolymers of polypropylene. The functionalized PP/dimethyl dioctadecylammonium–mmt hybrid systems were formed by static melt intercalation in a vacuum oven at 180°C. The organo-mmt was observed by XRD to be intercalated with the functionalized PP and by TEM measurements to be dispersed in these random polypropylene copolymers to the extent of about 25–40% exfoliated clay platelets. The second route relied on decreasing the enthalpic interactions between the surfactant and the mmt. This is expected to effectively render the polymer–mmt interactions more favorable. This was performed by the partial fluorination of the alkyl chains in an mmt. The mmt was organically modified with dimethyldioctadecyl ammonium and with partially fluorinated alkyltrichlorosilane. The

**Fig. 2.** Structure of typical organic modifier for clay.

organically modified mmt was statically melt intercalated with neat polypropylene. Measurements by XRD showed that the mmt was intercalated by the PP, indicating that the thermodynamics were favorable for nanocomposite formation. Further shear mixing of these two types of systems was expected to lead to further dispersion of the mmt in the polymer.

The promise of extraordinary improvement in end-use properties of polyolefin/clay hybrid systems has spurred great interest and intensive activity on the part of the players in the polyolefin and allied industries. Academic participation in these developments has also been vigorous. Optimistic predictions were made early in the drive to apply nanotechnology to the polyolefins industry. Probably, partly because of the promise of the technological benefits of nanotechnology and to the large size of the polyolefins industry, it was predicted that the largest impact of nanocomposites on the plastics industry would be in polyolefins. Wilson<sup>[7]</sup> of Inspired Innovations, LLC, predicted that nanocomposite versions of polyolefins will displace engineering thermoplastics and thermosets in many traditional applications and will open new opportunities to displace metal and glass in many traditional applications. Well over one-half of all the current applications for polymers could be improved by this new technology, according to Wilson. This author predicted millions of tons of nanocomposite polyolefin production and replacement of an equal amount of annual glass and metal production for the foreseeable future. Sinclair,<sup>[8]</sup> STA Research, predicted that polypropylene would be the largest growth polymer in nanocomposites and that PP nanocomposites would reach a volume of millions of tons per year by 2010. Both of these prognosticators emphasized that complete exfoliation of the clay was required to imbue the polyolefins with the improved end-use properties that could drive such massive commercial volumes of polyolefin nanocomposites. However, these goals could only be achieved by overcoming the very problematic dispersion of naturally polar clay in nonpolar polymers.

The attraction of clay mineral additives is their low cost to recover from the earth in their natural state. The incorporation of the clay in polypropylene, on the other hand, requires much more than natural clay. The technological challenges to formulating stable polypropylene/clay nanocomposites have proven to be formidable. Furthermore, the achievement of enhanced end-use properties has barely been explored because of this inability to form the systems with suitable clay dispersions.

Although studies continue aiming at novel modification of clay and functionalized polymer for improving the intercalation and exfoliation of the clay in polypropylene, the vast majority of experimental

studies and commercial developments employ polypropylene with maleated polypropylene (PP-MA), or more rarely another functionalized PP, as a compatibilizer to form PP/clay nanocomposite hybrid systems. The approximate individual costs of organically modified mmt and PP-MA are about five times that of the polymer on a per pound basis. This means that the production of polypropylene nanocomposites with properties sufficiently enhanced to justify the additional costs is a doubly formidable problem.

In the earliest studies, the morphology of several systems was determined to compare various strategies to form intercalated and exfoliated polypropylene/clay hybrids systems. Low molecular weight polypropylene (12,000–30,000) functionalized with maleic anhydride or hydroxyl groups was found to intercalate into C<sub>18</sub>-mmt.<sup>[9]</sup> Higher concentrations of functionalization were correlated with successful intercalation of the PP into the clay, while lower concentrations failed to exhibit intercalation of the PP. The same group then showed that PP homopolymer was not intercalated into Na-mmt, but a polyolefin diol was used to intercalate diasteryldimethylammonium-mmt followed by exfoliation of the clay by PP homopolymer.<sup>[10]</sup> In a further study, these workers employed PP-MA with two concentrations of maleic anhydride functionalization to intercalate C<sub>18</sub>-mmt, followed by exfoliation of the clay with PP homopolymer.<sup>[11]</sup> It was found that too high a concentration of maleic anhydride functionalization resulted in immiscibility of the PP-MA compatibilizer with the PP homopolymer. The reinforcement of the system was judged best for the lower concentration of maleic anhydride in the PP-MA, which had a higher storage modulus and good miscibility with the PP homopolymer.

Many groups, to investigate strategies for improved clay dispersion in polypropylene and to probe the resulting morphologies, extended the foregoing early work by Okada et al. It was confirmed in some of these studies that PP homopolymer could not intercalate into organoclays.<sup>[12,13]</sup> The use of considerable amounts of PP-MA compatibilizer was necessary to intercalate the clay and to facilitate subsequent exfoliation of the clay platelets by PP homopolymer.<sup>[12,13]</sup> Xu et al.<sup>[12]</sup> found that C<sub>16</sub>-mmt was intercalated in composites containing 2 wt.% clay only when the concentration of PP-MA (containing 0.9 wt.% maleic anhydride) exceeded 10 wt.% in the composite. Similarly, Walter et al.<sup>[13]</sup> found that C<sub>18</sub>-synthetic clay was intercalated in polypropylene composites containing 7 wt.% clay and 20 wt.% PP-MA (containing 4.2 wt.% maleic anhydride), but that no intercalation of the PP occurred in the absence of the PP-MA. Fig. 3 shows TEM photomicrographs of a 7 wt.% clay composite with no PP-MA exhibiting no intercalation of the clay (Fig. 3A) and a 7 wt.% clay composite with

**Fig. 3.** Transmission electron microscopic image of polypropylene compound containing 10 vol.% organophilic fluoromica (M100/ODA) without addition of PP-g-MA compatibilizer (A, left) and the corresponding ME100/DA nanocomposite obtained in the presence of 20 wt.% PP-g-MA compatibilizer. *Source:* From Ref.<sup>[13]</sup> with permission from Marcel Dekker, Inc.

20 wt.% PP-MA exhibiting intercalation of the clay and some evidence of exfoliation of the clay “tactoids” by the PP homopolymer (Fig. 3B). Tactoids are defined as stacks of clay platelets that are intercalated with polymer chains, thereby expanding the galleries between succeeding clay platelets, as in Fig. 3B. Tactoids are distinguished from clay particles, which are composed of closely spaced clay platelets, which do not exhibit expanded galleries, as in Fig. 3A.

Reichert et al.<sup>[14]</sup> showed that the alkyl chain in clays organically modified with alkylammonium cations must exceed 8 carbon atoms in length to promote intercalation and that increasing the concentration of the maleic anhydride functionality in the PP-MA promoted exfoliated nanocomposite systems with PP homopolymer matrices. Alkyl chain lengths of C<sub>4</sub> to C<sub>8</sub> gave a similar clay interlayer distance of 1.3 nm, while C<sub>16</sub> and C<sub>18</sub> chain lengths afforded spacing of 1.7 and 2 nm, respectively (the nonmodified synthetic clay spacing was 0.95 nm). This indicated that sufficient molar mass of the alkyl chain in the organically modified clay was necessary to promote favorable interactions of the silicate organic modifier with the polymer chains intercalating the clay platelets. This type of observation was made in original work on organic modification of clay to promote intercalation of clay by nonpolar species.<sup>[15,16]</sup> Reichert et al.<sup>[17]</sup> further investigated the stability of polypropylene composites prepared with PP with Mw = 350,000, 20 wt.% of PP-MA with Mw = 32,000, and 4.2 wt.% MA and 5 wt.% of C<sub>18</sub>-synthetic clay melt blended in a twin screw at 200°C. The as-prepared system exhibited typical nanocomposite morphology with well-intercalated tactoids and partial exfoliation of clay platelets in TEM photomicrographs, as well as a broad “hump” in the wide angle x-ray scattering (WAXS) pattern

**Fig. 4.** Thermogravimetric analysis curve of Cloisite 20 A™ (Southern Clay Products) organo-mmt. The onset of thermal decomposition is at 190°C.

indicative of a broad distribution of interlayer distances. Upon annealing of the material at 220°C for 200 min, the morphology observed in the TEM appeared to show a collapse of the structure to much more tightly spaced stacks and no evidence of partial exfoliation of clay platelets. However, it was argued on the basis of WAXS data on this system that because no peak was observed and the broad “hump” observed for the as-prepared and the broad “hump” observed for the annealed system, the clay exfoliation was further improved by the annealing process. The upper temperature limit of stability of the organic functionality, i.e., alkylammonium cations (C<sub>18</sub>-ammonium cation in this case), on typical clays is about 190°C, as shown in Fig. 4.<sup>[18]</sup> Above this temperature, the organic functionality degrades and the intercalated clay tactoids characteristically collapse to a stacked platelet structure. This appears to be the case in this study and the TEM photomicrograph showing clay platelet stacks was strong evidence for collapse of the intercalated clay tactoids at the annealing temperature of 220°C.<sup>[17]</sup>

Many other studies of clay dispersion in polypropylene are available. Analytical methods to probe the morphology in such systems were discussed by Morgan and Gilman.<sup>[19]</sup> They recommended TEM as the best means to qualitatively assess the degree of dispersion of clay in polymer matrices. Their TEM photomicrographs demonstrated that unintercalated clay platelet stacks, intercalated tactoids, and exfoliated platelets could be recognized. They recommended XRD to measure d-spacing in ordered, unintercalated stacks and ordered, intercalated tactoids, but cautioned that XRD is insufficient for determining disordered and exfoliated clay because these exhibit no reflection peak. These analytical methods were used to probe the morphology in studies of melt intercalated

PP/clay hybrid systems.<sup>[20–27]</sup> These studies all relied on significant concentrations of a functionalized polypropylene (predominantly PP-MA) to intercalate organically modified clay (predominantly alkylammonium-mmt) in a PP homopolymer matrix, followed by shearing of the melt to exfoliate the clay to the extent possible. In all cases, the best dispersion of the clay observed was partially as ordered, intercalated tactoids and partially as disordered, exfoliated clay platelets; however, nonuniform dispersion of the clay was commonly observed in all of these studies. The factors investigated were the MA concentration of the functionalized PP-MA and the concentration of PP-MA in the blend,<sup>[12,20,24,26,27]</sup> various melt compounding techniques,<sup>[12,20–22,25]</sup> and organic modification of clay.<sup>[23,24]</sup>

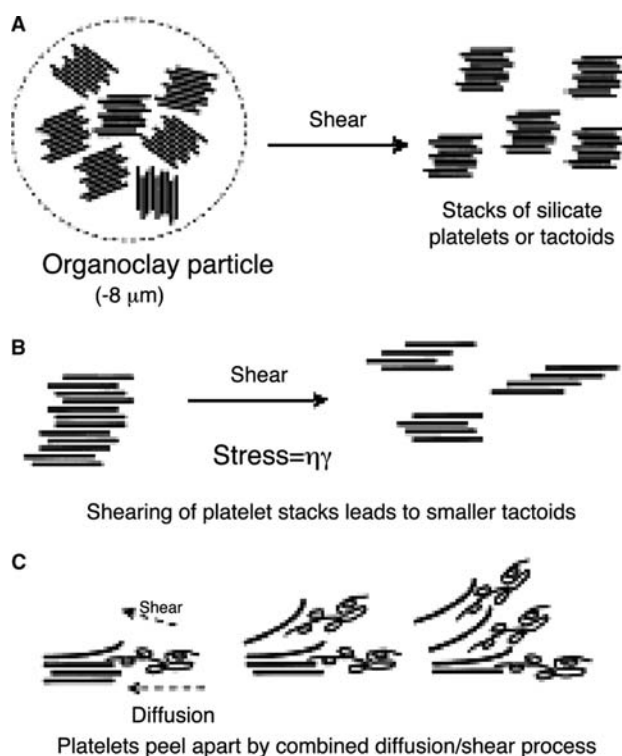

More uniform dispersion of alkylammonium-mmt in polypropylene was achieved by the intercalative polymerization of propylene in the galleries of the clay.<sup>[28]</sup> The TEM photomicrographs showed that the clay platelets were uniformly dispersed in the polypropylene. This strategy is attractive because no functionalized polypropylene compatibilizer is required; however, in situ polymerization of monomers in the clay galleries has not been demonstrated for commercial practice. Therefore melt intercalation remains the desired strategy for commercial production of polypropylene/clay hybrid nanocomposites. This goal has not been achieved for widespread commercial practice.

### Mechanism of exfoliation

A mean-field, lattice-based model of polymer intercalation in organically modified silicates was presented by Vaia and Giannelis.<sup>[29,30]</sup> The thermodynamic factors which control polymer intercalation into the clay galleries were outlined in terms of an interplay between entropic and energetic factors. The entropic penalty for confining the polymer inside the clay gallery may be partially compensated for by an increase in entropy of the surfactant chains (alkyl chains on organic modifier) as the clay layers separate. Although the tethered alkyl chains cannot increase their entropy by an increase in translational freedom, the expanded gallery spacing permits increased conformational entropy. Intercalation will be thermodynamically possible when favorable polymer–organically modified silicate energetic interactions overcome any unfavorable entropic factors. Further separation, i.e., driving exfoliation, depends on maximization of favorable polymer–surface interactions with the organically modified silicate, as well as minimization of unfavorable interactions with the tethered alkyl chains of the organic modifier. This explains the use of polymer functionalization with polar moieties. The polar functionalities on polypropylene participate in polar–polar interactions with the silicate surface, decreasing the free energy of

the system. If the total free energy of the system is decreased by the combined entropic and energetic factors, then intercalation and exfoliation may occur.

The further effects of shear forces on intercalated clay stacks (tactoids) have been elucidated by subsequent studies.<sup>[31,32]</sup> Fornes et al.<sup>[31]</sup> proposed a model explaining exfoliation of intercalated silicate stacks by the stepwise skewing of the silicate sheets in the tactoids, followed by peeling, one-by-one, of the silicate layers off the silicate stacks by combined diffusion/shearing, as shown in Fig. 5. The tactoids were shown to first skew apart forming shorter stacks of fewer and fewer numbers of silicate layers, followed by peeling of the individual layers off the tactoids forming exfoliated and dispersed layers, without short-range order with other silicate layers. The matrix polymer needs to have sufficient affinity for the silicate surface to cause spontaneous wetting of the surface to drive exfoliation. This is the required thermodynamic driving force. However, shear forces play a kinetic role by driving the peeling of silicate layers off the tactoids during the residence time of the system in the shear process. It was found that the higher the melt viscosity of the matrix polymer, the greater the stress exerted on the tactoids, driving this skewing and peeling process. Therefore higher

**Fig. 5.** Stepwise mechanism of clay platelet exfoliation in the melt compounding of nanocomposites: (A) organoclay particle breakup, (B) clay tactoid breakup, and (C) platelet exfoliation. *Source:* From Ref.<sup>[31]</sup> with permission from Elsevier Science Ltd.

**Fig. 6.** Transmission electron micrograph of silicate layers peeling apart via a fan-shaped intermediate. Source: From Ref.<sup>[32]</sup> with permission from John Wiley and Sons, Inc.

molecular weight matrix polymer was associated with higher stresses and a higher degree of exfoliation. This model was supported by a further experimental study in which the clay tactoid was observed to be in the process of peeling apart in TEM images, as shown in Fig. 6.<sup>[32]</sup> The silicate layers in the tactoid can be seen to be sliding and peeling apart from one another, like a deck of cards, in Fig. 6.

## CRYSTALLIZATION

The effects of crystallization on polypropylene/clay hybrids have been investigated from two vantage points. The effects of the clay on the crystallization of the polypropylene matrix and the effects of the crystallization of the polypropylene on the clay morphology have been reported. The rate of crystallization was found to be increased for polypropylene-mmt nanocomposites as compared with neat polypropylene, as measured by crystallization half-times determined from differential scanning calorimetric data.<sup>[33,34]</sup> The nucleating effect of mmt has also been discussed in detail.<sup>[35,36]</sup> The nucleating effect was found to strongly depend on the origin and treatment of the mmt.<sup>[35]</sup> The spherulite diameter was decreased in PP-MA/mmt nanocomposites, as compared with neat polypropylene, in quiescent isothermal crystallization.<sup>[36]</sup>

The quiescent, isothermal crystallization kinetics of PP/PP-MA/mmt nanocomposites were found to be slightly retarded in comparison to the neat polypropylene, but were not significantly different from the PP/PP-MA blend.<sup>[26]</sup> However, marked

flow-induced acceleration of crystallization for PP/PP-MA/mmt nanocomposites was observed at strain rates for which flow had only a modest effect on the neat PP.<sup>[26]</sup> This behavior of the PP/PP-MA/mmt nanocomposites was further inferred to be largely due to the PP-MA compatibilizer, by comparing a blend of the PP/PP-MA, under these conditions.

The detailed crystalline morphology of the polypropylene matrix in PP/PP-MA/mmt nanocomposites has been reported.<sup>[36–38]</sup> Modifications observed were a fibrous crystalline morphology, instead of the usual spherulitic morphology after quiescent, isothermal crystallization.<sup>[38]</sup> Okamoto et al.<sup>[36,37]</sup> reported an interfibrillar structure composed of a disordered arrangement of crosshatched lamellae among the dispersed clay platelets, which arose after quiescent, isothermal crystallization of a PP-MA/mmt nanocomposite because of crystallization occurring between clay particles, thereby disordering the usual spherulitic structure. Polarized optical microscopy, XRD, SAXS, and TEM measurements were correlated to propose a morphology in which fibrils of about 3–5 polypropylene lamellae reside between dispersed clay platelets, forming a disordered spherulitic superstructure.

Okamoto et al.<sup>[36,39]</sup> proposed an intercalation mechanism of PP-MA into mmt in PP-MA/mmt nanocomposites involving the interplay of crystallization and residence time in the melt state. Their results indicated that slower rate of crystallization permits more time for the polymer to intercalate the mmt by diffusing into the clay galleries, while faster crystallization rate inhibits this diffusion. They found that clay gallery spacing, measured by XRD, became larger as crystallization temperature was increased near the melting temperature. Interestingly, because crystallization is also slow just above glass transition temperature ( $T_g$ ), it was similarly claimed, based on XRD measurements, that clay gallery spacing became larger for crystallization just above the glass transition temperature. In addition, gallery spacing was increased as clay concentration in the nanocomposite was decreased.

## MECHANICAL PROPERTIES

A primary goal for nanocomposites is to achieve enhanced mechanical properties. The addition of inorganic fillers to polymers is widely practiced in the plastics industry. The common enhancement to polymer mechanical properties, by the addition of talc, calcium carbonate, glass fibers, wollastonite, glass beads, mica, wood flour, etc., is the increase in stiffness (Young's modulus, tensile modulus, and flexural modulus), while strength properties (tensile strength, elongation at break, and flexural strength) and toughness (Izod and

**Fig. 7.** Composite Charpy notch toughness vs. talc mean particle size of ternary composite (26 wt.% talc). *Source:* From Ref.<sup>[40]</sup> with permission from John Wiley and Sons, Inc.

Charpy impact strength) may decrease or be maintained.<sup>[40,41]</sup> The degradation in strength and toughness properties is a result of the concentration, degree of dispersion, and particle size of the inorganic filler.<sup>[40,41]</sup> Typically, the degradation in properties is correlated with the size of the particulate because the particle acts as a stress concentrator, thereby initiating cracks and degrading strength and toughness properties.<sup>[40,41]</sup> For example, the decrease in notched Charpy impact strength vs. talc particle diameter is shown in Fig. 7.

The early promise of nanocomposites was to provide a type of inorganic filler that would enhance stiffness and strength properties, while simultaneously maintaining or even improving toughness properties.<sup>[1]</sup> This development was expected to be related to three unique structural characteristics of nanofiller particles: 1) their approximately 1-nm size in one dimension; 2) their large aspect ratio; and 3) their ability to be preferentially oriented because of the large aspect ratio.

Another advantage, demonstrated by Walter et al.,<sup>[13]</sup> was the increase in matrix reinforcement achievable with nanocomposites with much lower inorganic filler concentration. The effectiveness of nanodispersed silicate relative to microdispersed talcs is shown in Fig. 8.

In the case of polypropylene, the further significant challenge is to achieve property enhancements that

**Fig. 8.** Young's modulus of polypropylene compounds, prepared by melt compounding, as a function of filler content using organophilic fluoromica and talc with 3 and 10  $\mu\text{m}$  average particle diameter. *Source:* From Ref.<sup>[13]</sup> with permission from Marcel Dekker, Inc.

justify the incremental cost increase associated with the production of nanocomposites. This challenge is formidable because of the very low cost of polypropylene resins.

There have been relatively few studies on polypropylene nanocomposite properties and structure/property relationships in nanocomposites. This is partly because of the fact that the formation of anything approaching ideal PP nanocomposites has been unsuccessful. Therefore, as stated previously, most work has focused on the preparation and characterization of PP nanocomposites.

Early studies by Toyota workers, led by Hasegawa et al.,<sup>[42]</sup> focused on the increase of the dynamic storage modulus. PP/PP-MA/C18-mmt nanocomposites were formed, e.g., by blending 5 wt.% mmt and 22 wt.% PP-MA (MA acid number 52 mg KOH/g) with isotactic PP. It was found that only large concentrations of PP-MA afforded reasonable clay dispersion; however, even in these type blends partial exfoliation and partial intercalation (as intercalated tactoids of mmt) were observed in TEM measurements. In the nanocomposite blend cited above, the storage modulus was 1.8 times higher than that of the corresponding PP at 80°C. Hasegawa et al.<sup>[43]</sup> prepared PP-MA (0.2 wt.% MA)/C18-mmt (5.3 wt.% mmt) nanocomposites, which exhibited apparently complete exfoliation of the mmt, and had 1.9 times higher tensile modulus than the PP-MA matrix polymer. However, a simple PP/C<sub>18</sub>-mmt composite had a slightly higher tensile modulus than this PP-MA/C18-mmt nanocomposite.

Reichert et al.<sup>[14]</sup> made an extensive study of PP/PP-MA/synthetic clay compounds prepared with fluoromica-modified synthetic clays, organically modified with alkyl chains ranging in length from C<sub>4</sub> to C<sub>18</sub>.

These workers found that 10 wt.% synthetic clay modified with C<sub>16</sub> organic modifier in conjunction with 20 wt.% PP-MA with 4.2 wt.% MA was sufficient to achieve effective PP matrix reinforcement. This nanocomposite exhibited exfoliated and well-dispersed silicate layers in the TEM and an increase in Young's modulus from 1490 to 3460 MPa and yield stress from 33 to 44 MPa with respect to bulk PP. However, notched Izod impact strength decreased from 1.7 to 1.4 kJ/m<sup>2</sup> with respect to bulk PP.

In other studies, polypropylene/clay nanocomposites exhibited enhancements in tensile strength and modulus<sup>[44]</sup> and also flexural strength and modulus.<sup>[45]</sup> Improvements in tensile properties were shown to be accompanied by maintenance or modest increases in fracture toughness.<sup>[46,47]</sup>

Monotonic increase in tensile modulus and decrease in elongation at break were observed for PP-MA/tallow-mmt nanocomposites up to 20 wt.% clay.<sup>[48]</sup> Tensile modulus increased rapidly up to about 5 wt.% clay, but then remained constant up to about 15 wt.% clay and then decreased at up to 20 wt.% clay. Notched impact strength remained approximately constant up to 20 wt.% clay, exhibiting modest increases between about 3 and 10 wt.% clay. The best mechanical properties were observed for the highest molecular weight PP-MA.

In a study of PP/PP-MA/C<sub>16</sub>-mmt nanocomposites, it was found that the best intercalation efficiency was achieved by the highest concentration of PP-MA (20–30 wt.%) and by a higher concentration of MA (0.9 wt.% better than 0.6 wt.%) in the PP-MA.<sup>[12]</sup> Tensile strength and notched Izod impact strength were found to increase and then decrease according to similar patterns, as shown in Figs. 9 and 10, as

**Fig. 9.** Plot of tensile strength vs. concentration of PP-g-MAH. The mass percent of Org-MMT was 2 wt.%. *Source:* From Ref.<sup>[12]</sup> with permission from John Wiley and Sons, Inc.

**Fig. 10.** Plot of impact strength vs. concentration of PP-g-MAH. The mass percent of Org-MMT was 2 wt.%. *Source:* From Ref.<sup>[12]</sup> with permission from John Wiley and Sons, Inc.

PP-MA concentration in the nanocomposite increased at 2 wt.% mmt concentration. Attempts to intercalate the same clay with the bulk polypropylene indicated little or no entry of the PP into the clay galleries.

The incorporation of radiation-grafted SiO<sub>2</sub> nanoparticles into polypropylene was shown to lead to well-dispersed SiO<sub>2</sub> nanoparticles grafted to the PP homopolymer matrix.<sup>[49]</sup> Reinforcement and toughening of the PP matrix were observed at concentrations between 0.5 and 5 wt.% SiO<sub>2</sub>.

The micromechanics of nanocomposites reinforced with platelet-shaped fillers was addressed by the development of a theoretical model.<sup>[50]</sup> The model was aimed at predicting the buckling of platelets in reinforced materials under compressive loading. The model predicted a critical strain above which platelet buckling would lead to reduction in the compressive modulus relative to the tensile modulus. The model predicted a significant reduction in reinforcement efficiency as a result of incomplete exfoliation of platelets into “pseudoparticle” stacks containing polymer layers sandwiched between successive clay platelets (tactoids), rather than into individual perfectly exfoliated and well-dispersed platelets. The model also predicted the reduction of reinforcement efficiency as a result of the deviation of the platelet from perfect biaxial in-plane orientation.

The common finding in these studies of the mechanical properties of polypropylene nanocomposites is that a large concentration of PP-MA is necessary to produce intercalated and exfoliated compounds with polypropylene. The nanocomposites exhibit imperfect dispersion of the clay with morphologies containing partial intercalated tactoids and partial exfoliated clay platelets. The improvements of polypropylene properties (tensile and toughness) are

typically not sufficient to justify the additional costs to modify the polypropylene.

## RHEOLOGY

The effects of clay and the orientation of the clay platelets on the rheology of polypropylene nanocomposites have been an area of particular interest, secondary to mechanical properties.<sup>[25,51–59]</sup> The rheological response of PP/PP-MA/mmt nanocomposites was studied.<sup>[58,59]</sup>

Lele et al. found that the zero-shear viscosity of the compatibilized nanocomposites (PP/PP-MA/tallow-mmt) was at least 3 orders of magnitude higher than that of the matrix PP and the uncompatibilized hybrids, as shown in Fig. 11. The strong dependence of melt viscosity on clay concentration was claimed to arise from frictional interactions between the silicate layers and not because of immobilization of confined chains between silicate layers. At low shear rates, a 3-D percolated structure of dispersed clay tactoids

having a high zero-shear viscosity was postulated. At higher shear rates, this network was speculated to break, imparting a solid-like behavior to the melt, which exhibited yielding and decreasing viscosity as shear rate increased. Rheo-XRD experiments gave direct evidence of flow-induced orientation of the clay tactoids. Yielding was linked to the cooperative orientation of the clay. The rheological data for the uncompatibilized hybrid exhibited a much lower zero-shear viscosity and much less pronounced yield behavior, and the corresponding rheo-XRD data showed a smaller orientation of the clay tactoids.

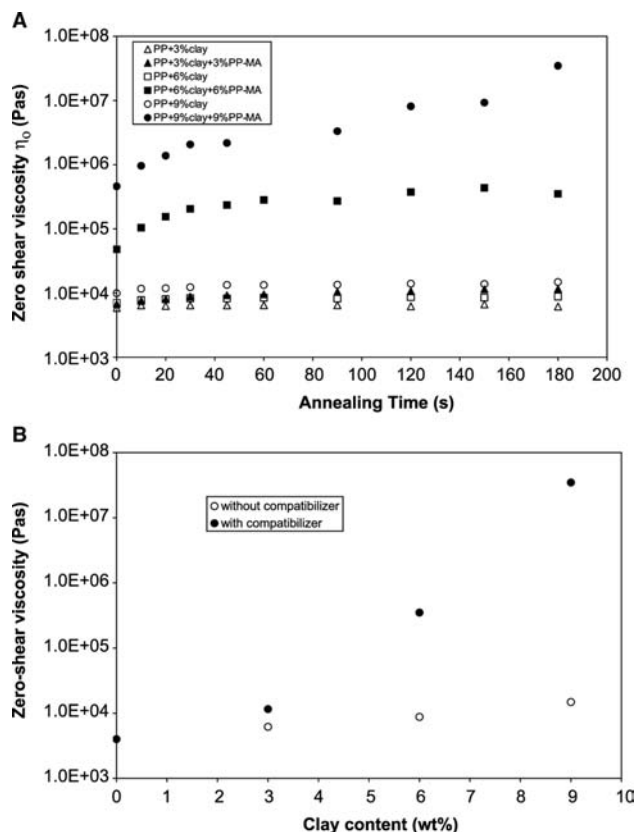

This dramatic increase in low shear rate viscosity has been utilized to prepare polypropylene homopolymers and copolymers/clay compounds with improved melt strength in extrusion for the production of films, fibers, and a variety of molded articles.<sup>[60]</sup> The rheology of such clay compounds was shown to be controllable by the variation of the ratio of PP-MA compatibilizer/clay.

## BARRIER

The enhancement of barrier properties of polypropylene is obviously an important application for nanocomposites. The platelet morphology of dispersed clay would be expected to impart enhanced barrier properties to fabricated articles, and extraordinary barrier properties might be imparted by the preferential orientation of the platelets in such fabricated articles. Blow-molded containers, based on high-density polyethylene (HDPE)/mmt nanocomposites, were shown to have a much higher barrier to organic liquids compared with the neat HDPE.<sup>[61]</sup> The HDPE was melt-compounded with mmt, and the blow-molding process was optimized to obtain a high degree of orientation of the exfoliated clay platelets to maximize barrier performance. However, there have been only a few reports concerning the enhancement of barrier properties in polypropylene.<sup>[6,62]</sup> These workers reported that the permeability of PP/PP-MA/mmt or PP-MA/mmt nanocomposites, containing 4 wt.% mmt, was one-half of that of the matrix material, while solvent uptake was also decreased accordingly.

## FLAMMABILITY AND THERMAL STABILITY

Montmorillonite-based fillers have been shown to promote flame retardancy in polypropylene composites. The mechanism of this flame-retardant behavior has been shown to be based on the formation of a carbonaceous-char layer on the outer surface of the composite article by Gilman et al.<sup>[63]</sup> The surface char layer was found to have a high concentration of mmt

**Fig. 11.** (A) Zero shear viscosity as a function of annealing time for several PPCH samples in the presence (denoted by filled symbols) and absence (denoted by open symbols) of PP-MA. (B) Zero-shear viscosity as a function of clay content for samples with and without compatibilizer. *Source:* From Ref.<sup>[58]</sup> with permission from the American Chemical Society.

**Fig. 12.** Comparison of the heat release rate (HRR) for pure PPgMA and two PPgMA-layered silicate nanocomposites, at  $35 \text{ kW/m}^2$  heat flux, showing a 70–80% reduction in peak HRR for the nanocomposites with a mass fraction of only 2 or 4 wt.% layered silicate, respectively. *Source:* From Ref.<sup>[63]</sup> with permission from the American Chemical Society.

layers and was claimed to become an excellent insulator and mass transport barrier, slowing oxygen diffusion into the surface and the escape of combustion products out of the surface. These workers showed that the heat release rate (HRR) was 75% lower for PP-MA/mmt (4 wt.%) nanocomposite compared with the neat PP-MA matrix (Fig. 12). In addition, the mass loss rate (MLR) of the same PP-MA/mmt (4 wt.%) nanocomposite was about one-quarter of that of the PP-MA matrix polymer (Fig. 13). These workers further found that the type of layered silicate, degree of dispersion, and the processing conditions affected the magnitude of the flammability reduction in the nanocomposites.

**Fig. 13.** Mass loss rate plots for PPgMA and two PPgMA-layered silicate nanocomposites. *Source:* From Ref.<sup>[63]</sup> with permission from the American Chemical Society.

**Fig. 14.** Limiting oxygen index of composites with different inert fillers. *Source:* From Ref.<sup>[64]</sup> with permission from John Wiley and Sons, Inc.

In another study, similar results were obtained and explained by a similar mechanism, based on the formation of a char layer.<sup>[64]</sup> A comparison was made between nanocomposites, based on a PP-MA matrix, containing 2.5 to 10 wt.% clay, with talc composites having the same PP-MA matrix. It was found that the limiting oxygen index (LOI, ASTM 2863-87) was increased for the PP-MA/clay nanocomposites over the talc composites (Fig. 14). Furthermore, the time from ignition to the first occurrence of dripping was shown to increase with clay loading (Fig. 15). Burning was reported to be much less intensive in the nanocomposites in comparison to the neat matrix polymer. In addition, ash layers of about 1 mm in thickness were formed on the nanocomposites, which were correlated with the minimization of burning intensity and

**Fig. 15.** Time from taking off the gas flame from the sample to the dripping of first burning parts. *Source:* From Ref.<sup>[64]</sup> with permission from John Wiley and Sons, Inc.

dripping. In other studies, it was similarly reported that HRR and time-to-ignition were reduced in PP/clay nanocomposites.<sup>[6,65,66]</sup>

The detailed thermal behavior and the formation of char layers on PP/PP-MA/clay nanocomposites were reported.<sup>[67]</sup> The thermal oxidation process of the polymer was significantly slowed in the nanocomposites exhibiting high char yield. The inhibition of oxidation was explained on the basis of a physical barrier effect of the surface char layer, by ablative reassembling of the silicate and by a chemical catalytic action, because of the silicate and of the amine modifier on the silicate.

## HEAT DEFLECTION TEMPERATURE

The heat deflection temperature (HDT) of a PP/fluoro-organo-mmt nanocomposite was found to increase from 109°C to 152°C compared to the neat PP.<sup>[6]</sup> The increase in HDT was attributed to better mechanical stability of the nanocomposite and not to an increase in melting temperature, which remained invariant in the nanocomposite relative to the neat PP.

## ELECTRICAL PROPERTIES

A process to prepare electrically conducting PP-MA/graphite nanocomposites was reported.<sup>[68]</sup> It was found that the percolation threshold for conductivity was much lower than that of conventional conducting composites.

## THERMOPLASTIC OLEFINS

Although the vast majority of work that has been published, relative to propylene-based polymers, concerns the development of polypropylene nanocomposites, there has been little incentive to commercially produce these compositions. Polypropylene is a very low cost commodity thermoplastic and the improvements in the properties so far demonstrated for polypropylene nanocomposites have not justified the increased cost to produce nanocomposites commercially.

On the other hand, far more interest has been generated in developing thermoplastic olefin (TPO) nanocomposites. The applications of TPOs, especially targeted for nanocomposite development, are those in the automotive sector. Thermoplastic olefins are usually reinforced with large quantities (up to 50 vol.%) of mineral fillers, such as talc and calcium carbonate. The outlook of replacing these conventional composites with lighter weight and better-performing nanocomposites has driven intensive efforts to achieve this objective. Because of the much

higher cost basis of TPOs, relative to polypropylene homopolymer, this objective appears to be much easier to achieve.

Some relative disadvantages of PP are that it is brittle and has poor low-temperature properties. However, the addition of a rubber, such as ethylene-propylene rubber (EPR), or ethylene-propylene-diene-monomer (EPDM) results in dramatic improvements in the impact strength and low-temperature properties. These rubber-modified PPs have a greatly expanded sphere of applications, relative to PP, and are often called impact copolymer-polypropylene (ICP) and thermoplastic olefins (TPOs). Rubber toughening of polypropylene continues to be an active area of investigation.<sup>[69]</sup> It is well known from previous studies that, among other factors, the rubber particle diameter is of critical importance.<sup>[69–71]</sup> These studies indicate that the modification in the rubber domain size to an optimum diameter improves the impact strength of PP. It is also well known that the addition of the rubber to polypropylene results in a decrease in stiffness.<sup>[72]</sup> Thus although successes in improving the impact properties of PP have been attained by rubber toughening, its application, e.g., in the automotive industry, is still limited because of the opposing trends of stiffness and toughness.

An attractive strategy to improve the stiffness, while maintaining the impact strength of PP and rubber-modified PP, is the formation of nanocomposites. Addition of mineral fillers, such as talc, CaCO<sub>3</sub>, and glass to PP, provides an increase in stiffness, but these particulates are stress concentrators and result in concomitant decrease in impact strength.<sup>[73,74]</sup> The fact that the filler is at the nanometer-size scale in these systems gives promise of achieving improved stiffness without significant loss of impact strength.<sup>[75]</sup> This is under the assumption that the clay platelets do not act as stress concentrators because of their nanometer size scale. Thus this desirable combination of improved stiffness and maintenance of impact strength by the addition of clay in TPOs, if attained, could boost the application of TPOs in the automotive and other industries.

For example, Oldenbo<sup>[76]</sup> from Volvo Car Corp., Sweden, recently presented data regarding the effect of addition of clay on the impact and flexural properties of TPO/clay nanocomposites. The desirable combination of improvement in stiffness and maintenance of impact strength was not observed in that study. Monotonic increase in stiffness was observed, but a precipitous decrease in impact was observed, as clay loading increased. The decrease in impact strength was ascribed to the lack of good dispersion of the clay. The existence of clay tactoids and “chunks” was supposed to be the cause of poor impact strength because these acted as stress concentrators.

Very little work has been published on the development of TPO nanocomposites. Much of what has been published resulted from the joint development of TPO nanocomposites for injection-molded automotive components by General Motors Research and Basell Polyolefins. This joint development was described in a publication, which highlighted the process ability advantages of a TPO/clay nanocomposite over a conventional TPO/talc composite.<sup>[77]</sup> This TPO nanocomposite is covered in patents assigned to Basell Poliolefine Italia S.p.A.<sup>[78]</sup> and Basell Technology Company BV.<sup>[79]</sup> No reports on the morphology and the specific degree of intercalation and exfoliation of the clay in the material developed by General Motors Research and Basell Polyolefins have been published.

This development and other similar developments of TPO/clay nanocomposites for automotive and other applications were heavily reported in the trade literature.<sup>[80–87]</sup> In one of these trade journal articles, it was claimed that, “much of the development work done before 1998 with natural montmorillonites having amorphous silica impurities is of little practical value.”<sup>[83]</sup> This claim was based on the proposition that large proportions of amorphous silica in the clay substantially degrade impact strength and elongation, increase opacity or haze levels, and increase gas permeability.

A study of the requirements for preparing exfoliated TPO/C<sub>18</sub>-mmt nanocomposites was reported.<sup>[88]</sup> It was noted that nanocomposite properties were dependent not only on exfoliation of the clay, but also on the structure and properties of the silicate / polymer matrix interface. The optimization of the organoclay structure for the maximum enhancement of TPO/clay nanocomposite mechanical properties was discussed.

The effect of varying clay loading on the morphology of TPO/clay nanocomposites was studied using atomic force microscopy, transmission electron microscopy, and X-ray diffraction.<sup>[89]</sup> Thermoplastic olefin/clay nanocomposites were made at clay loadings varying from 0.6 to 6.7 wt.%. The morphology of these TPO/clay nanocomposites was investigated with atomic force microscopy (AFM), transmission electron microscopy (TEM), and X-ray diffraction (XRD). The ethylene-propylene rubber (EPR) particle morphology in the TPO was found to undergo progressive particle breakup and decrease in particle size, as clay loading increased in the range from 0.6 to 5.6 wt.% clay. Transmission electron micrographs showed that the clay platelets preferentially segregate to the rubber–particle interface. The breakup of the EPR particles was suspected to be a result of the increasing melt viscosity observed as clay loading increased and/or the accompanying chemical modifiers on the clay, acting as interfacial agents, reducing the interfacial tension with concomitant reduction in particle size. The clay

morphology was mainly as intercalated tactoids with a minor amount of exfoliated and dispersed clay platelets evident in the TEM photomicrographs. Flexural modulus increased monotonically as clay loading increased. Impact strength was maintained or decreased modestly as clay loading increased.

## CONCLUSION

Polypropylene is one of the most widely used thermoplastics not only because of its balance of physical and mechanical properties, but also because of its environmental friendliness (e.g., recyclability) and low cost. Although the addition of mineral fillers to polypropylenes enhances the stiffness properties, the concomitant effect is typically a decrease in toughness properties because the inorganic filler particles act as stress concentrators. Therefore the formation of propylene-based polymer/clay nanocomposites is an area of intensive investigation.

Considering that clay is composed of platelets that are about 1 nm in thickness and around 1000 nm in lateral dimensions and assuming a density of 2.65 g/cm<sup>3</sup> yields an upper limit of about 750 m<sup>2</sup>/g surface area per gram for fully exfoliated clay. This is 5 to 10 times the surface area per gram achievable with ordinary mineral fillers. Exfoliated clay in polymers has been shown to endow unique properties to the system, such as increased T<sub>g</sub>, increased stiffness, maintenance of impact strength, increased barrier to gases and liquids, increased flame retardancy, etc.

The tightly bound stacks of clay platelets in natural clay may be readily separated by simple dissolution in a polar solvent; however, separation of the clay platelets in a nonpolar polymer is difficult. Therefore organic modification of natural clay minerals is required to disperse the clay in polypropylenes. This typically involves exchange of cations on the natural clay with alkyl ammonium cations with alkyl chains of varying lengths. However, the vast majority of experimental studies and commercial developments employ polypropylene with maleated polypropylene (PP-MA), or more rarely another functionalized PP, as a compatibilizer to form PP/clay nanocomposites with reasonable dispersion of the clay.

These polypropylene nanocomposites have exhibited enhancements in mechanical properties, rheological properties, barrier to gases and liquids, flammability, thermal stability, heat deflection temperature, and electrical properties. Although the majority of work that has been published, relative to propylene-based polymers, concerns the development of polypropylene nanocomposites, there has been little incentive to commercially produce these compositions because polypropylene is a very low cost commodity

thermoplastic and the improvements in the properties so far demonstrated have not justified the increased cost to produce nanocomposites commercially.

On the other hand, far more interest has been generated in developing thermoplastic olefin (TPO) nanocomposites. The applications of TPOs, especially targeted for nanocomposite development, are those in the automotive sector. The major initiative in the development of TPO nanocomposites was that of General Motors Research and Basell Polyolefins to develop TPO nanocomposites for injection-molded automotive components. Automotive TPOs are usually reinforced with large quantities (up to 50 vol.%) of mineral fillers, such as talc and calcium carbonate. Replacing these conventional composites with lighter weight and better-performing TPO nanocomposites has driven these efforts. Because of the much higher cost basis of TPOs, relative to polypropylene homopolymer, this objective appears to be much easier to achieve. The processability advantages of a TPO/clay nanocomposite over a conventional TPO/talc composite have been reported, but no reports on the morphology and the specific degree of intercalation and exfoliation of the clay in the material developed by General Motors Research and Basell Polyolefins have been published.

Therefore the state of development of polypropylene homopolymer or TPO nanocomposites is currently in an early stage. From the technical standpoint, the formation of nanocomposites with uniformly dispersed clay remains a daunting challenge. From the commercial standpoint, the production of economically viable nanocomposites, i.e., with properties enhanced to the extent that the increased cost of production is justified, also remains a daunting challenge. Certainly, the research that is progressively reported, which better defines and innovates upon the structure and properties of polypropylene and TPO nanocomposites, continues to spur interest in commercial development. The outlook remains bright, but formidable challenges, both technical and commercial, abound.

# Porous Alumina Templates for Nanofabrication

**Latika Menon**

*Department of Physics and the Center for Nanotechnology,  
Texas Tech University, Lubbock, Texas, U.S.A.*

## INTRODUCTION

Currently, nanotechnology is concerned with fabrication of useful materials at the nanoscale level for applications in nanodevices. Several methods are being used for nanofabrication,<sup>[1–10]</sup> e-beam lithography, interference lithography, cluster method, etc. One commonly used method is the use of membranes with nanosized holes. When the holes are filled up with appropriate materials, it leads to formation of a self-assembled nanoarray. Some commonly used membranes are polycarbonate membranes and nanoporous alumina membranes. Use of porous alumina membranes is particularly noteworthy.<sup>[11]</sup> These are aluminum oxide membranes with nanosized cylindrical holes perpendicular to the surface of the film. The membranes are available commercially in some fixed sizes with specific pore diameters. They can also be prepared very easily in the laboratory using electrochemical means. Fabrication conditions can be controlled to achieve desired pore length and diameter, and they can be used in many different ways to prepare a variety of nanostructured materials, magnetic metals and alloys, semiconductor alloys and heterostructures, superconductors, carbon nanotubes, etc. This entry briefly reviews some of the ongoing research in the area of nanofabrication using porous alumina templates.

## FABRICATION OF NANOPOROUS ALUMINA TEMPLATE

It is well known that a thin (2–5 nm) film of aluminum oxide always forms on the surface of aluminum exposed to air. This is because of oxidation of aluminum in the presence of oxygen and water vapor. The reactions occurring during the process are

and

The oxidation process can be hastened by anodizing or oxidizing aluminum in the presence of an acid. Anodization in a weak acid leads to formation of a non-porous barrier layer of aluminum oxide. In contrast, a strong acid can partially dissolve aluminum oxide. Anodization in a strong acid (pH < 4) therefore results in a porous aluminum oxide film (commonly known as porous alumina) because of a competing mechanism of oxide growth and partial dissolution of aluminum oxide by hydrogen ions.<sup>[12,13]</sup>

In the laboratory, a commercially available aluminum foil is first electropolished to create a clean, shiny, flat surface (roughness ~5–10 nm). Electropolishing is carried out under d.c. conditions in an electrolyte commonly called the L1 electrolyte. It consists of 1050 mL ethyl alcohol, 150 mL butyl cellosolve, 93 mL perchloric acid, and 205 mL distilled water. The optimum voltage is of the order of 30–60 V, and the optimum electropolishing time is of the order of 10–30 sec.<sup>[14–16]</sup> The electropolished Al surface is then anodized in the presence of an acid. In this process, the Al foil is placed at the anode, while a Pt mesh is used as cathode (Fig. 1). A d.c. voltage is applied across the two electrodes. A moderately strong acid (for example, 15% sulfuric acid, 3% oxalic acid, or 5% phosphoric acid) is used as electrolyte. During the process of anodization, a thin film of nanoporous aluminum oxide forms at the surface of aluminum as shown in the schematic cross-section diagram in Fig. 2.

The pores are cylindrical, straight, and are open at the top. The pores do not grow all the way into the aluminum surface. There is a thin barrier layer of aluminum oxide separating the porous alumina layer from the bottom aluminum layer. The thickness of the barrier layer and the diameter of the pores are controlled by fabrication conditions, namely, the acid used and the voltage applied. Some commonly used acids are 3% oxalic, 15% sulfuric, and 5% phosphoric acid. The smallest pore diameters are obtained by anodization in 15% sulfuric acid at low voltages, and the largest pore diameters are obtained for anodization in 5% phosphoric acid at higher voltages. Pore densities are typically of the order of  $10^{10}$ – $10^{11}$  pores/cm<sup>2</sup>. Barrier layer thickness is in the range of tens of

**Fig. 1** Schematic diagram showing a typical anodization process.

nanometers. Pore diameters are in the range of 8–200 nm. Theoretical modeling of pore growth and dependence of pore parameters on fabrication conditions are discussed in detail in Refs.<sup>[17–19]</sup> The length of the pores is controlled by time of anodization. Increased time of anodization leads to longer pore lengths. Some typical AFM images of templates prepared by anodization under different conditions are shown in Figs. 3 and 4. The pores are highly ordered over length scales of the order of 5–10  $\mu\text{m}$ . The extent of ordering can be increased slightly by annealing the Al foil prior to anodization and also by carrying out a multistep anodization process.<sup>[20]</sup> In a multistep process, Al foil is first anodized for a very long time (typically 12–18 hr). Long time anodization causes the pores to rearrange and reduces the number of

**Fig. 3** Transmission Electron Microscope image of a template anodized in 15% sulfuric acid at 10 V showing an array of pores with diameter  $\sim 10$  nm.

defects and dislocations. It also leads to formation of a very thick alumina template. The thick template is dissolved away in a 0.2 M chromic–0.4 M phosphoric acid mixture at 60°C which leaves behind a textured Al surface consisting of an array of ordered bumps.

**Fig. 4** Atomic force microscopic image of a template anodized in 3% oxalic acid at 40 V showing an array of pores with diameter 50 nm.

**Fig. 2** Schematic cross-sectional diagram of a typical porous alumina template showing the nanoporous layer, the barrier layer and the aluminum layer ( $L$  is the pore length,  $d$  is the pore diameter,  $D$  is the interpore spacing, and  $B$  is the thickness of the barrier layer).

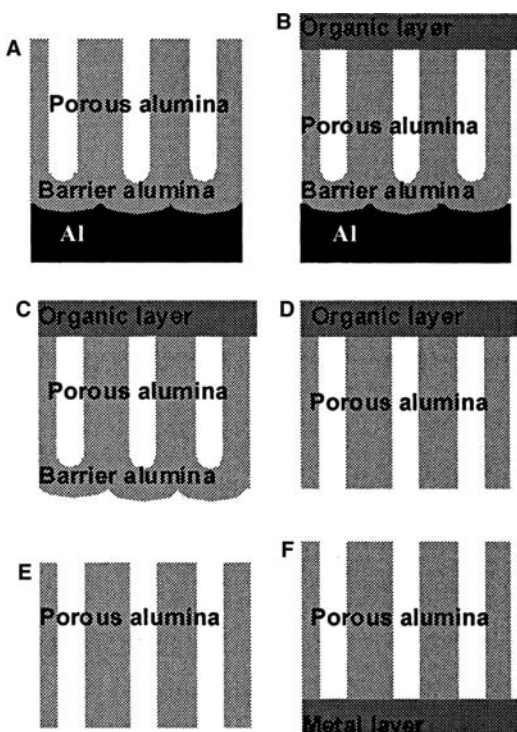

Reanodization of the textured Al surface for the desired length of time leads to a well-ordered nanoporous template (Fig. 4). Instead of a multistep anodization process, an initial ordered nanoindentation of the Al surface can also be used to improve the ordering of the subsequent pore array.<sup>[21]</sup>

## NANOFABRICATION METHODS USING POROUS ALUMINA

Once the templates are fabricated with the desired pore size, they can be used in many different ways to fabricate nanoarrays. Some of these methods are discussed in this section.

### Electrodeposition

Alternating current electrodeposition is the simplest way to fill the pores with the appropriate material. For example, to prepare an array of Fe nanowires inside the pores, a 0.1 M aqueous solution of  $\text{FeSO}_4$  can be used. Porous alumina and the Pt mesh are the electrodes. An a.c. voltage is applied across the two electrodes. The frequency and voltage are optimized. In the solution,  $\text{FeSO}_4$  dissociates into  $\text{Fe}^{2+}$  ions and  $(\text{SO}_4)^{2-}$  ions. During every negative half-cycle, Fe ions are reduced to Fe atoms and deposit inside the pores.

**Fig. 5** Sequence of steps to prepare a template in contact with a conducting substrate to achieve d.c. electrodeposition.

Fig. 5 shows a cross-section SEM image of a nanoporous alumina membrane containing Fe nanowires. Using a similar electrodeposition method, nanoarrays of other magnetic metals, for example, Co and Ni, can also be prepared. Alloys, for example, FeCo and CoNi, can be prepared by using an electrolyte containing the appropriate ratio of the constituent materials. The two materials are then subsequently electrodeposited into the pores under optimized a.c. conditions to create alloy nanoarrays. The magnetic properties of Fe, Co, Ni, and FeCo nanoarrays are discussed in “Magnetic Nanoarrays.” Other materials, for example, thermoelectric materials such as Bi,<sup>[22]</sup> superconducting Pb,<sup>[23]</sup> conducting materials Cu and Au,<sup>[24]</sup> and conducting polymers,<sup>[25]</sup> may also be synthesized inside the pores by using the appropriate electrolyte.

To carry out d.c. electrodeposition, the barrier layer below the pores must be removed. This can be achieved by following the sequence of steps shown in Fig. 6. The top nanoporous layer is first coated with a protective organic layer. The sample is then soaked in 3%  $\text{HgCl}_2$  solution to remove the bottom Al layer. This is followed by soaking in 5% phosphoric acid solution for a predetermined length of time to remove the alumina layer at the bottom. The top organic layer is finally removed by soaking in ethyl alcohol solution. This leaves behind a through-hole template. One side is coated with a thin conducting layer, e.g., Au. Using an appropriate electrolyte, nanowires can be deposited inside the pores under d.c. conditions, using a three-terminal setup and a potentiostat. The Pt mesh is used as the counterelectrode, porous alumina is used as the working electrode, and a third electrode, for example, calomel electrode, is used as reference electrode. The voltage between the reference electrode and the

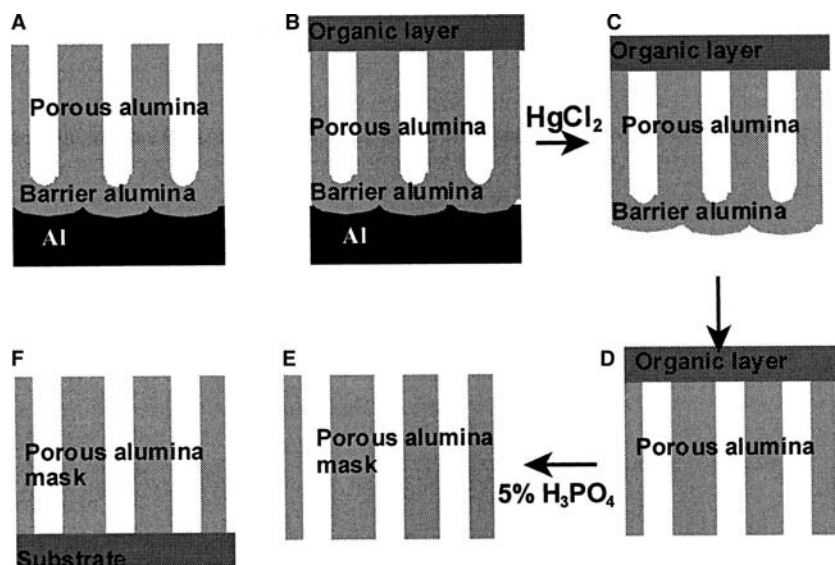

Fig. 7 Sequence of steps to process a nanoporous alumina template for transfer onto a substrate.

alumina is adjusted so that it is higher than the standard reduction potential of the element to be deposited. The standard reduction potentials are obtained from literature. Direct current electrodeposition is particularly useful in the deposition of multilayered nanowires for applications in Giant Magnetoresistance (GMR) devices and other semiconductor-based spintronic structures. Multilayer nanowires with layers as thin as a few angstroms may be fabricated in porous alumina using electrodeposition.<sup>[26]</sup> This is achieved using separate electrolytes for the two components or by using a single electrolyte. The electrolyte is prepared such that it consists of only a trace amount of the nobler element, A, in comparison with the second element, B. The deposition voltage is continually switched between two values, one at which only A is deposited and the other at which both A and B are deposited. By keeping only a trace amount of the nobler metal, A, in the electrolyte, it is ensured that the amount of metal in the AB layer is small, so that its deposition is diffusion-limited. The process may be carried out by adjustment of either the current density (galvanostatic) or the potential (potentiostatic).

#### Transfer of Porous Alumina onto Substrate

In this method, alumina template is transferred to an appropriate substrate, so that it is in direct contact with the substrate. Several processing steps are necessary to separate the template from the parent aluminum film. The sequence of steps is shown in Fig. 7. The sample is initially anodized for a very short time, sufficient to produce a thin nanoporous layer  $\sim 0.1$ – $0.5 \mu\text{m}$ . A protective organic coating is then applied to the top porous layer. The bottom Al and the barrier

alumina layer are etched away in  $\text{HgCl}_2$  solution and 5% phosphoric acid solution, respectively. Dry etching methods, for example, plasma etching or focused ion beam milling, may also be used to remove the barrier layer.<sup>[27,28]</sup> In the final stage, the organic coating is dissolved away in ethyl alcohol. This leaves behind a thin through-hole nanoporous alumina layer. The layer is carefully transferred onto a substrate, dried, and subsequently used as a mask for deposition of nanoarrays of various materials. Fig. 8 shows an AFM of an array of Co nanodots prepared in this manner on a Si substrate. One difficulty with this method is the very small area of the prepared masks.

Fig. 8 Atomic force microscopic image showing an array of Co nanodots on a Si substrate.

Fig. 9 Sequence of steps to deposit nanoporous alumina template on a substrate.

This is because of the very small thickness of the masks ( $\sim 0.1\text{--}0.5\ \mu\text{m}$ ) and the very brittle nature of aluminum oxide. This problem can be overcome if porous alumina is directly deposited (instead of being transferred) on a substrate.

### Direct Deposition of Porous Alumina on a Substrate

In our laboratory, we have recently demonstrated a novel method to deposit nanoporous alumina template on a substrate.<sup>[29]</sup> The method also allows transfer of the nanoporous template pattern onto the bottom substrate. The technique combines anodization process to produce template arrays and plasma etching through the pores. The sequence of steps is shown schematically in Fig. 9. We used silicon wafers as the starting substrate material, although in principle, the method can be extended to any other substrate, for example, epitaxial GaN.<sup>[30]</sup> A 5-nm-thick adhesion layer of Ti is deposited onto Si substrate by e-beam evaporation followed by a 1- $\mu\text{m}$ -thick layer of Al. Without the Ti layer, the subsequently deposited nanoporous alumina membrane is found to peel from the Si substrate. The aluminum film is anodized in an acid under d.c. conditions for 2–3 min. A cross-section SEM image of the as-deposited template is shown in Fig. 10. The remaining Al layer following anodization and the alumina layer produced by the anodization process are clearly seen. The presence of a thin barrier layer of alumina (U-shaped barrier) is also seen at the pore bottoms. The thickness of the barrier layer in this case is only of the order of 10–20 nm. One major problem for applications based on this method is posed by etching of this barrier layer to pattern layers directly below. Wet chemical etching methods, such as dilute phosphoric acid, although attempted in the past by other research groups,<sup>[31,32]</sup> are not particularly useful. In addition to removing the barrier layer, it also causes pore widening, thus increasing pore diameter and, in some cases, completely removing the alumina film.

We have used plasma etching to anisotropically remove the barrier layer without changing pore diameter. Plasma etching was carried out using a commercial inductively coupled plasma system with reactive ion etching (RIE).  $\text{Cl}_2$  diluted with Ar was used as etchant. The etch process required critical control over various parameters, in particular, etch power and etch time. Details of the process are described in Ref.<sup>[29]</sup> Cross-section image of the final product after a 60-sec etch at 200-W RIE power is shown in Fig. 11. The pores in the top nanoporous alumina layer can be clearly seen. In addition, the etch has penetrated through the barrier region and continued down through the Al to the Ti adhesion layer. Some of the Al nanotubes produced by the process have snapped in cleaving, showing the hexagonal shape of the parent hole template. Following breakthrough of the barrier layer, etch time can be varied to control the depth of the aluminum pores. In fact, with the appropriate

Fig. 10 Left: SEM cross-section image before plasma etch showing nanoporous alumina layer at the top, barrier layer followed by aluminum layer below.

**Fig. 11** Right: Cross-section image postplasma etch showing porous alumina layer and the porous aluminum layer below. *Source:* From J. Yun, M. Holtz, Texas Tech Univ.

etchant, the etch can even be continued through the Ti layer into the bottom substrate. In this manner, a nanoporous pattern, which mirrors the pattern on the initial nanoporous alumina template, can be created on any substrate. The top nanoporous alumina layer can easily be removed by soaking in a mixed solution of 0.2 M chromic/0.4 M phosphoric acid. Fig. 12 shows an AFM image of the top view of the aluminum template postremoval of the porous alumina layer. The pore diameter is of the order of 50–60 nm similar

**Fig. 12** Top view AFM image showing pores on aluminum layer.

to that of the initial alumina film. In the final stage, nanoarrays of various materials can be synthesized by depositing/growing them inside the pores.

## SELF-ASSEMBLED NANOARRAYS

Using the various methods discussed, nanoarrays of different materials have been successfully deposited. These include magnetic materials, semiconductor compounds, superconductors, and carbon nanotubes. A brief description of the properties of these nanoarrays is given below.

### Magnetic Nanoarrays

Current magnetic recording media are based on magnetic thin films where the information is stored on grains. To increase data storage density in such media, one must either reduce the size of the grains or reduce the number of grains that constitute each bit. Reducing the number of grains leads to increased noise and decreased size of grains leads to superparamagnetism where thermal energies alone are enough to flip the magnetization direction. These limits depend mainly on the anisotropy constant of the material and the aspect ratio of the grains. For present-day magnetic media, the superparamagnetic limit will be reached at densities of about 100 Gb/in<sup>2</sup>. Patterned media consisting of isolated single-domain islands where each island stores one bit of information are expected to overcome the above problem. It is thought that for such patterned media (with anisotropy constant equal to that of present-day magnetic media), storage densities as high as 1 Tb/in<sup>2</sup> will be achievable. For such large densities, the size of the islands will have to be around 10 nm. Using porous alumina, one can easily fabricate nanomagnetic islands with feature size down to 10 nm. Materials such as Fe, Co, and Ni electrodeposited into the nanopores serve as a model system for the study of magnetic properties, interactions, and thermal stability of nanometer-sized particles. Several research groups have carried out investigations on the magnetic properties of Fe, Co, and Ni nanowires electrodeposited in porous alumina.<sup>[33–37]</sup> The standard synthesis procedure has been to use a.c. electrodeposition. The wires are in the form of cylinders positioned perpendicular to the film plane in a regular array. The wires have been characterized using electron diffraction measurements. Fig. 13 shows a TEM image of Fe nanowires released from alumina template and dispersed onto a substrate. The wire diameter is of the order of 10 nm. High-resolution TEM images of the wires reveal that the wires are polycrystalline in nature with grain sizes ranging from ~5 to 50 nm.

**Fig. 13** Transmission electron microscopic image of Fe nanowires released from porous alumina.

Electron diffraction image for Fe nanowires is also shown in Fig. 14. Analysis of the image confirms a bcc crystal structure for these nanowires. Similar studies for Co and Ni nanowires reveal an hcp structure for Co and fcc structure for Ni nanowires.<sup>[38,39]</sup>

Magnetic properties of these nanowires exhibit strong perpendicular anisotropy. Fig. 15 shows a typical magnetization vs. field image for an array of

**Fig. 14** Electron diffraction image of Fe nanowires.

**Fig. 15** Magnetization vs. field for an array of Fe nanowires in the perpendicular and parallel direction.

Fe nanowires electrodeposited inside porous alumina. The diameter of the wires is around 10 nm, and the length is of the order of 1 μm. In the direction perpendicular to the film plane, the coercivity is very high, about 2341 Oe (remanence ratio 0.96), and in the parallel orientation, the coercivity is only about 300 Oe (remanence ratio 0.055). The nanowires thus possess uniaxial anisotropy with easy axis perpendicular to the film plane. The large anisotropy arises mostly from shape anisotropy because of the cylindrical shape of the nanowires. For a cylinder-shaped entity, the demagnetizing factor for field parallel and perpendicular to the cylinder axis are 0 and  $2\pi$ , respectively. The shape anisotropy therefore forces the magnetization to be in the axial direction and is given by  $2\pi M_s$ , where  $M_s$  is the saturation magnetization. The anisotropy field can be estimated by extrapolating the magnetization curves using the  $M_s$  values for bulk Fe ( $1710 \text{ emu/cm}^3$ ) and is estimated to be of the order of 8 kOe for Fe nanowires. These may be compared with theoretically predicted shape anisotropy field of  $2\pi M_s$  ( $\sim 10.7 \text{ kOe}$  for Fe nanowires) for an infinite cylinder. The large perpendicular coercivity suggests resistance to magnetization reversal. The large perpendicular squareness in comparison to the parallel squareness indicates large remanent magnetization. All of these factors, large perpendicular squareness, high remanence, and the large coercivities, may make these materials useful for magnetic recording media.<sup>[40,41]</sup> For such applications, it is necessary to investigate the dependence of magnetic properties on size of the nanostructure.

We have carried out a systematic investigation of the magnetic properties of Fe nanowires as a function of length and diameter of nanowires.<sup>[42]</sup> For large length of the nanowires, of the order of microns, the coercivity  $H_c$  was found to be somewhat independent of length for fixed wire diameter. The coercivity, however, depends critically on the diameter of the wires. In general, the coercivity is found to decrease with increasing wire diameter. For example, Fe nanowires of diameter 32 nm exhibit a coercivity of  $\sim 2158$  Oe which is about 200 Oe smaller than that for wires of diameter 9 nm. The decrease in coercivity is a result of development of multidomain structure in larger nanowires.

An interesting feature is observed for wires with very small diameter,  $<13$  nm. As seen in Fig. 16, for diameter  $<13$  nm, the coercivity is found to decrease. The maximum in coercivity therefore occurs at a wire diameter of about 13 nm and has a value of about 2640 Oe. In contrast to the behavior at 300 K, at 5 K, the coercivity exhibits a maximum for the smallest wire diameter investigated, namely, 9 nm (Fig. 16). The coercivity is around 3700 Oe at 5 K. Unlike the behavior at 300 K, for increasing wire diameter, the coercivity continually decreases. The non-monotonic behavior at 300 K, in contrast to that at 5 K, can be explained as follows. At such small sizes, the wire diameter is much smaller than a single domain. Ferromagnetic domains cannot form and superparamagnetism dominates. Accordingly, the coercivity is low. Indeed, Li and Metzger<sup>[43]</sup> reported very small activation volumes,  $\sim 1.0 \times 10^{-18} \text{ cm}^3$ , for small diameter Fe nanowires at room temperature. This value is very close to the theoretical superparamagnetic limit.<sup>[44]</sup> The superparamagnetic effect will contribute to

Fig. 16 Coercivity as a function of wire diameter for Fe nanoarrays, at room temperature and at 5 K.

magnetization at low temperature below blocking temperature leading to the increase of coercivity at 5 K. Magnetic interaction between the wires is an important factor in recording media and can be estimated by measuring the quantity defined as  $\Delta M$ .

$$\Delta M = I_d(H) - (1 - 2I_r(H)) \quad (3)$$

where  $I_r(H)$  is d.c. demagnetization remanence and  $I_r(H)$  is isothermal remanence. For isothermal remanent magnetization measurements, the sample was first demagnetized. A magnetic field was then applied and reset to zero and the remanent magnetization was measured. This was carried out for different field values, and the isothermal remanent magnetization curve was obtained as a function of the field. In the case of the d.c. demagnetization curve, the sample was first saturated in a high field of 13 kOe and the remanent magnetization was obtained at various values of the reversal field. Fig. 17 shows the  $\Delta M$  plots for Fe wires with different diameters. All of them show negative peaks, suggesting presence of magneto-static interaction.

Magnetic properties of Co and Ni nanoarrays electrodeposited in porous alumina have also been studied in great detail by various authors. The largest coercivities for Ni nanowires have been reported by Nielsch et al.<sup>[36]</sup> They obtained coercivity of  $\sim 1200$  Oe for highly ordered Ni wires of diameter 30 nm with remanence of the order of 100%. The diameter of the wires was varied in the range 30 to 55 nm while keeping the nanowire distance constant (100 nm) and found that the coercivity drops to 600 Oe (remanence  $\sim 30\%$ )

Fig. 17  $\Delta M$  plots for Fe nanowires of varying diameter.

for wires of diameter 55 nm. Magnetic measurements for Co nanowires in anodic alumina templates have been studied extensively by Zeng et al.<sup>[45]</sup> For a fixed wire diameter of about 10 nm, as the nanowire length is increased,  $H_c$  is found to increase steeply until a constant value of about 2300 Oe is approached at wire lengths of about 200 nm. For larger wire lengths, the coercivity is more or less independent of length. For wire lengths of the order of 500–1000 nm, the coercivity is found to decrease gradually with increasing nanowire diameter. This is accompanied by shearing of the hysteresis loop. Both the decrease of  $H_c$  and the shearing of the loop are attributed to magnetostatic interactions.

Time dependence of magnetic properties of Fe, Co, and Ni nanoarrays has been studied.<sup>[46–48]</sup> Quantities such as magnetic viscosity and activation volume have been calculated, and models for reversal mechanism in these nanowires have been extensively investigated. Typically, the activation volume for wires with diameter of the order of 10 nm is calculated to be of the order of  $\sim 4 \times 10^{-18} \text{ cm}^3$ . This value is much smaller than the physical wire volumes, which indicates that magnetization reversal starts in a small region of wires. Magnetic reversal mechanisms such as coherent rotation and curling treat the wires as perfect homogeneous cylinders. However, the coherent rotation and curling modes are delocalized and could lead to activation volumes much larger than those observed. A more reasonable explanation of the reduced coercivities and thermal activation volumes encountered in electrodeposited nanowires is morphological inhomogeneities. Transmission electron microscopic results indicate a considerable degree of polycrystallinity with crystallite diameter of about 5 nm. Polycrystalline wires can be interpreted as random-anisotropy ferromagnets where interatomic exchange tries to align the local spins, but the exchange stiffness has to compete against random-anisotropy forces associated with the local uniaxial anisotropy. As a consequence, the magnetization processes become localized.<sup>[49]</sup> The localization length or physical activation volume strongly depends on crystallite size.

As discussed earlier, in nanowires, magnetic anisotropy originates mainly from shape anisotropy. Large-shaped anisotropies can result from large saturation magnetization, which, in turn, can lead to large coercivity. This suggests that large coercivities are expected in FeCo nanowires because in bulk form, these alloys exhibit large saturation magnetization ( $1950 \text{ emu/cm}^3$  for 35 at.% Co) which is larger than both Fe and Co. We have successfully electrodeposited FeCo alloys into the pores.<sup>[50]</sup> For these arrays, we did observe coercivity for some FeCo nanowires to be larger than that of Fe and Co. The coercivity is found to be 2600 Oe for  $\text{Fe}_{0.93}\text{Co}_{0.07}$ , 2900 Oe for  $\text{Fe}_{0.67}\text{Co}_{0.33}$ ,

Fig. 18 Variation of coercivity as a function of wire diameter for FeCo alloys.

2850 Oe for  $\text{Fe}_{0.33}\text{Co}_{0.67}$ , and 2400 Oe for  $\text{Fe}_{0.07}\text{Co}_{0.93}$ . The coercivity is largest for  $\text{Fe}_{0.33}\text{Co}_{0.67}$  and  $\text{Fe}_{0.67}\text{Co}_{0.33}$  samples and is much higher than those obtained for Fe (2400 Oe) and Co (1900 Oe) prepared under similar conditions. As in the case of elemental Fe, Co, and Ni nanoarrays, we obtained very high squareness ratio ( $\sim 1$ ) for most of the samples, suggesting excellent perpendicular magnetization characteristics. Fig. 18 shows the variation of coercivity as a function of diameter of the nanowires for all the  $\text{Fe}_{1-x}\text{Co}_x$  alloys. Length of the nanowires is kept constant in all the samples ( $\sim 3 \mu\text{m}$ ). It is noted that contrary to the behavior of pure Fe, Fe–Co alloys show no maximum in coercivity as a function of wire diameter, suggesting that the superparamagnetic behavior is eliminated even for the smallest diameter wires (9 nm) used in this study. With increasing Co addition, the saturation magnetization and hence shape anisotropy constant of Fe–Co alloys are increased, which should result in higher energy barrier  $E$  (given by  $KV$ , where  $K$  is the anisotropy constant and  $V$  is the volume).

## Semiconductor Nanoarrays

Alternating current or direct current electrodeposition can be used to fabricate arrays of semiconducting nanowires/nanodots in porous alumina. Electrochemically, the most easily fabricated semiconductors are the II–VI semiconductors of the type CdS, CdSe, etc. This can be achieved using three different methods. In the first method used by Moskovits,<sup>[51]</sup> a metal capable of forming a semiconductor is first electrodeposited into the pores of alumina. The top surface of the porous aluminum oxide is then etched away in an acid to expose the ends of the metallic array of wires. The deposited metal is then allowed to react with a liquid

or gaseous reagent to convert them chemically to a semiconductor. For example, cadmium particles can be converted to CdS by reaction with sulfur vapor or hydrogen sulfide. Gallium particles may be converted to GaAs by reaction with arsine.

In the second method, sulfuric acid is a.c.-electrolyzed causing the sulfide atoms to be deposited in the pores. This is followed by a.c. electrodeposition of Cd into the pores, allowing the S atoms to react chemically with the Cd atoms, causing formation of CdS. Instead of a.c. electrodeposition of Cd, one may simply soak the porous template containing S atoms into a boiling solution of cadmium sulfate.

In the third method, the electrolyte used for the electrodeposition is non-aqueous unlike that used for magnetic materials.<sup>[52,53]</sup> For the preparation of semiconductor nanowires of MX (M = Cd, Pb, Zn and X = S, Se, Te), a solution of dimethylsulfoxide containing a salt of M (50 mM) and elemental X (S or Se) is used. For example, CdS is electrodeposited using a 50-mM solution of cadmium perchlorate and 50 mM S in a dimethylsulfate solution. A small amount of lithium perchlorate is also added to improve the conductivity.

We have successfully prepared nanowires of CdS, CdSe, PbSe, ZnSe, etc. using the deposition methods described above. Details of our studies on these nanoarrays and their possible device applications are discussed in detail in Ref. <sup>[54]</sup>. Such nanowire arrays can be used to study their electrical properties and thus investigate their potential applications in devices such as diodes, transistors, photodetectors, and light-emitting devices. Semiconductor nanodots and nanowire devices could be the building blocks for digital nanoelectronics, an integrated circuit technology which will permit downscaling to be carried beyond what is currently achievable.

## Energetic Nanocomposite Nanoarrays

Energetic materials are a class of substances consisting of an appropriate mixture of a fuel and oxidizer material. When ignited, they release a large amount of energy because of an exothermic reaction. Such materials have several applications, in explosives, propellants, etc. Recently, it has been found that when fabricated in the form of nanocomposites, the energetic properties are highly enhanced.<sup>[55]</sup>

Using porous alumina templates, we have developed two novel methods to fabricate these materials. In both methods, a thin film of Al is the fuel material and Fe oxide nanowires are the oxidizer material. Al film is prepared by means of thermal evaporation, while the nanowires are prepared by means of electrodeposition inside nanoporous alumina templates. We have found that presence of aluminum oxide around the wires inhibits direct interaction between Al and iron oxide. The aluminum oxide barrier layer and the aluminum oxide around the wires therefore need to be completely removed. Fig. 19 shows the sequence of steps that we followed to achieve this.<sup>[56]</sup> The electrodeposited sample is first coated with a thin organic layer. The sample is then soaked in 3% mercuric chloride solution, which removes the bottom Al layer. The top organic layer protects Fe wires inside the pores from being etched away by mercuric chloride solution. In the next step, the organic layer is removed in ethyl alcohol solution and the sample is dried. The sample is now soaked in a mixture of chromic-phosphoric acid at 60°C to partially etch the pores from the top revealing Fe wires. The sample is rinsed and dried, and a thin film of Al (50 nm) is coated on top by means of thermal evaporation. Al film is therefore in contact with the Fe nanowires. The sample is annealed at 100°C for a few minutes to improve the interface contact between Al

Fig. 19 Sequence of steps to prepare Al-Fe oxide nanocomposites (method 1).

and the Fe nanowires. It is then soaked in chromic-phosphoric acid mixture to etch away the remaining aluminum oxide film. This leaves behind an Al film attached to an array of Fe nanowires. The sample is cleaned, dried, and annealed to completely remove trace amounts of water vapor and also to convert Fe nanowires into Fe oxide. In method 2 (see Fig. 20 for sequence of steps), a thin film of photoresist material is deposited on a glass wafer followed by thermal evaporation of a thin layer of aluminum (50-nm thickness). A commercial Al foil is anodized separately under d.c. conditions at 40 V in 3% oxalic acid for 30 min, creating a nanoporous template with pore diameter of the order of 50 nm. Fe nanowires are electrodeposited inside the pores under a.c. conditions. The sample is then soaked in a mixed solution of 0.2 M chromic/0.4 M phosphoric acid at 60°C. The acid mixture dissolves aluminum oxide completely leaving behind the Fe wires in solution. This solution is poured onto the thermally evaporated Al film. The Al film is annealed at 100°C to improve adhesion of Fe nanowires, followed by rinsing and drying to remove traces of the acid. The sample is then soaked in a solution of acetone to dissolve the photoresist material. This leaves behind the final product, Al-Fe oxide nanocomposite film, which is rinsed in methanol followed by annealing at 100°C for a few minutes to remove all traces of water vapor. Al-Fe oxide nanocomposite prepared using these two methods is found to ignite readily under flame ignition, indicating several possible applications of these materials in explosives, propellants, and other military applications.

### Carbon Nanotube Arrays

Carbon nanotubes<sup>[57]</sup> can be viewed as rolled-up sheets of graphite with diameters approximately a few nanometers. They can be either metallic or semiconducting,

with band gaps that can be controlled by controlling the tube diameter. Several applications are envisioned for these materials. Carbon nanotube electronics are expected to provide a viable alternative to silicon when chip feature sizes cannot be made any smaller using silicon.<sup>[58]</sup> Nanotube electronics are also expected to provide great progress in computer miniaturization and computing power. They have potential applications in cold-cathode flat panel displays because of their excellent field emission properties.<sup>[59]</sup> Carbon nanotubes can be used to encapsulate other materials such as Fe, Co, etc.<sup>[60]</sup> They can be used in infrared imaging, inert membranes for biomedicine, etc. They can be placed on an Scanning Probe Microscopy (SPM) tip to manipulate molecules with sub-angstrom accuracy.<sup>[61]</sup> The tips are atomically precise with chemistry similar to C<sub>60</sub>, and thus serve as functional elements with a wide variety of molecular fragments. Functionalizing carbon nanotube tips will allow mechanical manipulation of many molecular systems on various surfaces with sub-angstrom accuracy.

For several of the applications described above, particularly in nanotube electronics, it is necessary to be able to control the growth of carbon nanotubes both with respect to size and orientation. Carbon nanotube arrays have been successfully synthesized in ordered porous alumina templates.<sup>[62-66]</sup> The diameter and spacing of the carbon nanotubes are controlled by controlling the diameter and interpore spacing in porous alumina. Most of the methods involve initial deposition of Co inside the pores which act as catalyst for the growth of carbon nanotubes. Earliest demonstration of carbon nanotube synthesis in porous alumina was provided by Li et al.<sup>[65,66]</sup> A small amount of Co is electrodeposited in the pores, and the templates are heated in a tube furnace at 600°C for 4-5 hr under CO flow (100 cm<sup>3</sup>/min). The CO flow is then replaced by a mixture of 10% acetylene in nitrogen at a flow rate of 100 cm<sup>3</sup>/min for about 2 hr at

Fig. 20 Sequence of steps to prepare Al-Fe oxide nanocomposite (method 2).

650°C. The samples are then annealed for 15 hr in nitrogen leading to formation of an array of carbon nanotubes. The carbon nanotubes produced in porous alumina templates have the following common characteristic features: they always grow perpendicular to film plane, are multiwalled, have uniform sizes, and are open-ended. The growth of carbon nanotubes inside pores by catalytic decomposition of organic vapors has been postulated as either base or tip growth.<sup>[67]</sup> Scanning electron microscopic studies indicate residual Co/Fe catalyst in the base of the tubes, indicating that a tip growth mechanism could be responsible for the tube growth. It is also thought that the surrounding alumina may also be acting as a catalyst in nanotube growth.<sup>[68]</sup>

Field emission characteristics of ordered carbon nanotubes have been investigated.<sup>[63–69]</sup> Yuan et al.<sup>[63]</sup> demonstrated excellent field emission characteristics for these nanotube arrays. In their measurements, they removed the barrier layer between the aluminum and the porous layer. Field emission was seen to begin at a relatively low electric field ( $\sim 2.8$  V/ $\mu$ ). They measured a very large emission current 0.08 mA/cm<sup>2</sup> at 3.6 V/mm, much greater than that reported by Davydov et al.<sup>[69]</sup> for as-prepared nanotube arrays (in presence of barrier layer). Over a period of 150 hr, no significant reduction in emission current was observed. In contrast, in the presence of the barrier layer, the current density was found to decrease rapidly with time over a period of a few minutes. Another reason for the enhanced field emission may be related to the open-ended nature of the carbon nanotubes, which results in smaller radius of curvature than the closed ends, thus causing electrons to be emitted more easily. In a similar study, Jeong et al.<sup>[70]</sup> measured a turn-on field of 1.9–2.1 V/ $\mu$ m and a field enhancement factor of 3360–5200. In their samples, the barrier layer is absent and the density of carbon nanotubes was very small,  $\sim 10^7$  tips/cm<sup>2</sup>. The intertube distance is therefore higher, minimizing field screening effect and, in turn, enhancing field emission effect.<sup>[71]</sup> Field emitter arrays with such high emitting efficiency are expected to have applications in flat panel displays in the near future. For application in nanoelectronics, it is sometimes necessary to be able to make connections between carbon nanotubes. One solution is to directly prepare T- or Y-junction carbon nanotubes. In general, pores inside nanoporous alumina are straight when the anodization voltage is kept fixed during anodization. However, one can create branched pores inside alumina by changing the anodization voltage during anodization. In particular, Y-shaped pore forms in porous alumina when the anodization voltage is reduced by a factor of 1/2 during the anodization. Li et al.<sup>[66]</sup> synthesized Y-junction carbon nanotubes in such templates by using Co as a catalyst and

by pyrolysis of acetylene at 650°C. Papadopoulos et al.<sup>[72]</sup> obtained electronic transport measurements on both individual and parallel arrays of Y-junction nanotubes synthesized in porous alumina. Non-linear transport and rectifying behavior was observed. This behavior can be explained in terms of a change in band gap across the junction caused by the change in diameter across the junction. Y-junction carbon nanotubes are thus a realization of semiconductor heterostructures in the nanometer scale. Y-shaped nanotubes and nanowires are expected to have possible applications in room-temperature single electron transistor and spintronic devices.

## CONCLUSION

In conclusion, porous alumina is indeed a versatile template. It allows fabrications of a variety of nanostructures in the form of nanoarrays with feature sizes as small as 10 nm. As described in this entry, characterization and measurement of appropriate properties of the nanoarrays can be easily carried out. It allows investigation of several fundamental phenomena at the nanoscale level and also allows for investigation of potential applications of nanostructures in future high-performance nanoscale devices.

## ACKNOWLEDGMENTS

Most of the work described in this entry (unless specified) has been carried out by the author and her colleagues at the University of Nebraska-Lincoln and at Texas Tech University, Lubbock. The author would like to thank S. Bandyopadhyay, N. Kouklin, X.Z. Li, P.F. Williams, M. Holtz, K. Zhu, and J. Yun for useful discussions, collaborations, and help with experiments. Several aspects of the work are supported by grants from National Science Foundation, Office of Naval Research, and the Department of Army.

## INTRODUCTION

For the foreseeable future, the vast majority of commercial electronics, photonics, and other devices will be in the solid state and incorporated onto or into a substrate—although there are substantial efforts to change this paradigm.<sup>[1]</sup> To date, most of these surface structures are manufactured by a “top-down” approach wherein various layers of a material are selectively added or removed. The formation of organic light-emitting diodes (OLEDs), for example, generally requires the careful deposition of several to several tens of layers of various organic and inorganic materials, and the thickness of each must be precisely controlled. An alternative “bottom-up” approach exploits knowledge of intermolecular interactions to self-assemble molecules into supramolecular structures, self-organize molecules into monolayers, or electrostatically deposit films layer by layer.<sup>[1–5]</sup> The degree of predictable and long-range molecular order decreases from self-assembly to self-organization to layer by layer. Notable applications of the second mode of bottom-up assembly are the deposition of thin films of liquid crystals and mesogens for various display applications.<sup>[6–9]</sup> Because exact alignment of molecules is not usually possible with the layer-by-layer approach, applications of this method to date have focused on modifications of large surface areas. This entry focuses on the methods and applications of self-assembled and self-organized porphyrinic materials on surfaces; however, many of the themes and methods discussed are applicable to a variety of other chromophores and other organic molecules. Porphyrinoids are tetrapyrrolic macrocycles that are excellent molecules for various commercial applications because of their remarkable stability, considering their rich photonic properties.

A crucial step toward the application of nanoscaled photonic devices is the ability to design and create increasingly larger architectures of interactive molecules and to incorporate these entities into device components.<sup>[2–5]</sup> For example, the tessellation of molecules into specific designs on surfaces<sup>[10,11]</sup> remains a significant challenge (Fig. 1). The efficiency of electronic and energy transfer in organic-based materials depends on both the molecule and the architecture of these molecules in the device. Other major considerations include the interconnections between the organic material and inorganic components as well as environmental factors. In addition to increasing the performance and efficiency of devices, the components of devices that are molecule-based will be more environmentally benign than much of the inorganic materials they replace.

## DEFINITIONS AND SCOPE

### Porphyrinoids

Porphyrins are tetrapyrrole macrocycles (Fig. 2) found in nature in systems such as hemoglobin, myoglobin, various cytochromes (*C*, *P*<sub>450</sub>, etc.), chlorophylls, methyl-Co-M reductase in methanogenic bacteria, and a plethora of other biological systems.<sup>[12]</sup> They function as transporters of small molecules such as dioxygen, mediators of electron transport, oxidation catalysts, light-harvesting and energy transport conduits, and catalysts for the reduction of a methyl thioether, respectively. Although porphyrins can bind virtually every metal in the periodic table (and a few nonmetals), in biological systems these metals are usually Mg, Fe, Co, and Ni—where the redox chemistry of the latter three provides the function. The limited flexibility and restricted aperture of the square planar

**Fig. 1** Although there has been substantial progress in the assembly of molecules on surfaces, the tessellation of even simple patterns such as the one on the left (from the New York City subway) is currently not feasible because of the large numbers of specific intermolecular interactions needed to distinguish and place the molecules in the pattern. The 21-particle nonamer of porphyrins on the right represents one of the best examples of molecular tessellation on a surface.

ligand modulate both the redox potential and the coordination geometry of bound metals, which in turn modulate the redox and photophysical properties of the macrocycle. The remarkable stability of the macrocycle (it is found in shale oils as a vanadium complex) and the wide distribution in nature have indicated to some researchers that porphyrins may be prebiotic.<sup>[12]</sup>

Because of their biological relevance and diverse functions, a large number of porphyrin derivatives

have been synthesized in the laboratory in the last decades using the methods of Adler, Longo, and Shergalis<sup>[13]</sup> and Lindsey<sup>[14]</sup> and, more recently, a solventless “green” synthesis.<sup>[15]</sup> These methods have allowed commercial applications of porphyrin derivatives that include oxidation catalysts, blood substitutes, therapeutics, sensors/actuators, photonic materials, dyes, and various forms of “toners” in photolithography. In the past decade, there has been substantial effort to create and characterize the properties of multiporphyrinic systems for materials applications.<sup>[16–18]</sup> Two related macrocycles—phthalocyanines and porphyrazines—have also been the subject of much research for similar applications, but multichromophoric systems of these dyes are less well developed at present.<sup>[19–22]</sup> Although all three types of macrocycles have related photophysical properties, the porphyrins have been the primary focus of research because of synthetic accessibility and greater solubility in organic solvents.

In the context of nanotechnology and materials chemistry, the aforementioned properties of porphyrinoids can be exploited for a variety of applications that include: [1] molecular electronics,<sup>[4,23–26]</sup> [2] components of nanoscaled sensors, actuators,<sup>[27–34]</sup> and photonics,<sup>[35–38]</sup> [3] both structural and chemically active elements in molecule-constructed molecular sieves,<sup>[39–45]</sup> [4] catalysts,<sup>[46]</sup> and [5] part of biomolecular encapsulating systems.<sup>[47,48]</sup> For many of these applications, the precise geometric alignment of the chromophores in the materials is essential for function. The problem, then, is how to make nanomaterials of organic compounds wherein a few to a few hundred molecules are brought together in a predefined or predictable geometry—as opposed to aggregates, colloids, and gels (all of which have important applications in nanotechnology as well). The remarkable progress in organic chemistry has provided many elegant molecular systems with more than one porphyrin linked by covalent bonds.<sup>[14,25,49–65]</sup> These include acetylene, phenylacetylene, bridged, fused, and other linkages. For many of these molecular systems, the interspatial

**Fig. 2** The three basic porphyrinoid pigments.

relationships of the macrocycle are well defined. However, the significant limitation of these molecular systems is that the product yield drops precipitously as the number of chromophores increases. There are a variety of polymeric systems bearing porphyrins, or with porphyrins as part of the polymeric chain where the dispersity varies from system to system, but the yields are generally better than for the above molecular system.<sup>[31,66–77]</sup> Both the molecular and polymeric systems have provided a wealth of information of the nature of energy and electron transport mediated by the porphyrins and the various linkers, as well as the means to gate these processes. Several functional materials have also been reported, *vide supra*. The focus of this review is on self-assembled and self-organized porphyrinic systems on surfaces.

## Supramolecular Chemistry

Self-assembly and self-organization are spontaneous processes that allow simple components to form more complex and more ordered systems.<sup>[78–85]</sup> In terms of molecules, the spontaneous *self-assembly* of a given set of molecules results in a discrete supramolecular entity or three-dimensional lattice, whereas the spontaneous *self-organization* of a set of molecules results in systems that are usually not discrete and ordered in only one or two dimensions. The former is usually less tolerant of defects or errors in structure than the latter. Much of the initial inspiration and concept for both self-processes comes from the study and observation of biological systems. For example, the self-assembly of a set of helical proteins into a discrete ion channel relies on the complex intermolecular interactions between the component molecules. One may observe the opening and closing of a single ion channel that gates ionic currents across a lipid membrane (which is an example of a self-organizing system). The intermolecular interactions are governed by the electron distributions in molecular orbitals and by complementary shapes or structures. For purposes of discussion, the intermolecular interactions are heuristically classified and include hydrogen bonding, electrostatic interactions, coordination chemistry, and van der Waals forces acting in concert. The “lock-and-key” concept for shape complementarity has a long history.<sup>[78,79]</sup> Thus nature provides a plethora of examples, which demonstrate that self-assembly and self-organization are effective means to build complex, functional structures in good yields. The self-assembly of discrete supramolecular systems generally relies on the use of component molecules designed with specific intermolecular interactions such as H-bonds, metal ion coordination, and sometimes electrostatics because these noncovalent bonds are directional and stronger than

other intermolecular forces.<sup>[1]</sup> However, the self-organization of materials generally relies on a greater number of weaker, nonspecific interactions such as dipolar, van der Waals, and hydrophobic/hydrophilic forces. Crystals of supramolecular systems are an example of structures that arise from both directional and nondirectional intermolecular interactions.<sup>[39,40,82,84,86,87]</sup> In most cases, the architectures of molecules arising from both self-processes are the thermodynamic products.

## Supramolecular Systems on Surfaces

The advantages of using supramolecular chemistry to construct materials that can serve as components of nanoscaled devices include the ability to construct complex structures efficiently, but there are several significant technical challenges. The reversibility of the intermolecular interactions that allow self-assembly and self-organization to result in thermodynamic products in high yields also means that the structure of the system is sensitive to environmental factors such as concentration, temperature, ionic strength, etc.<sup>[10,11,17,88]</sup> Because the formation of the desired nanoarchitectures of organic molecules generally proceeds in solutions and these are to be incorporated onto surfaces as components of devices, the first challenge is to deposit the self-assembled or self-organized system onto an appropriate substrate. The inherent concentration changes during deposition and solvent evaporation may significantly alter the supramolecular structure, or result in undesirable aggregates. Other factors such as surface chemistry and surface energetics may also affect the structure of self-assembled or self-organized systems. The second challenge is to design supramolecular systems on surfaces that are stable to the operating conditions of the device. Device stability to thermal fluctuations, redox chemistry, environmental changes such as humidity, and dioxygen is crucial. But all of these factors can affect the equilibrium of self-assembled systems, thus also the structure and function. There are numerous examples of porphyrin-containing self-organized monolayers,<sup>[89–92]</sup> thin films,<sup>[20,93,94]</sup> and polymeric materials<sup>[95]</sup> on surfaces; however, there are only a few examples of self-assembled (discrete, monodispersed) systems that can be deposited onto surfaces with high structural fidelity that are stable at room temperature. These last constructs are the primary subject of this entry.

An important aspect of all types of nanoscaled materials on surfaces is the role of surface chemistry and surface energetics in determining the final structure/orientation of the molecules. This is especially true of self-assembled and self-organized systems because the surface properties may induce unanticipated

structural changes, or may be exploited as a further means of dictating the final structure.<sup>[10,11]</sup> A host of surface chemical preparations can be utilized to modify the surface chemistry, and hence the surface energetics of the substrate, which impacts the structure of adsorbing supramolecular materials. For example, Au surfaces can be modified by self-assembly of alkanethiol-based compounds. The chemistry of glass or mica surfaces can be readily changed by organosilanes, allowing for the generation of hydrophobic or hydrophilic surfaces. Chemical modification of the surface can even allow the direct assembly of species on surfaces by providing the appropriate anchor groups on which to build. Weakly bound aggregates, such as those organized by  $\pi$ -stacking, can be made to either retain or lose their initial solution structure depending on the competition between the interaggregate interactions, the interactions of the component molecules, and the interactions of the aggregates with the surface. This has been readily demonstrated by the adsorption of porphyrinic nanoparticles on surfaces.<sup>[10,11,96,97]</sup>

## Applications

Some of the applications of these porphyrinic materials are envisioned to be in the areas of molecular electronics<sup>[5,98]</sup> and photonic materials.<sup>[2,3,23,26]</sup> The latter applications exploit both the functionality and the rigid structure of porphyrins to make materials such as molecular sieves,<sup>[39,42]</sup> catalysts,<sup>[99]</sup> sensors,<sup>[100]</sup> actuators,<sup>[24]</sup> and non-linear optics.<sup>[101]</sup> Elegant synthetic organic work has yielded discrete multiporphyrinic systems held together by covalent bonds using a variety of linkers,<sup>[25,49–57,61,102–111]</sup> or by direct fusion of the porphyrin macrocycles.<sup>[58–62,112,113]</sup> In addition to the development of new synthetic methods, these types of molecules have provided insights into the complexities of photo-induced electron/energy transfer processes<sup>[51,104,105]</sup> in terms of chromophore geometry, role of the linker, and dynamics of the molecule. However, the overall yield of discrete molecular systems containing more than a few porphyrins is too low to be commercially viable for all but the most specialized applications. Similarly, numerous polymers of/with porphyrins have also yielded interesting materials that have a distribution of polymeric and photonic properties because of polydispersity and the subtly different environments of the chromophores.<sup>[70–73,114]</sup> For many of the aforementioned applications, control of both the relative positions of the macrocycles and the nano-scaled size of the system is necessary for the function.<sup>[1]</sup> Since the first publications on self-organizing<sup>[115,116]</sup> and self-assembling porphyrins via H-bonds<sup>[117]</sup> and coordination chemistry,<sup>[118]</sup> there has been an exponential annual increase in the number or reports of

multiporphyrinic systems made by these methods.<sup>[10,11,17,23,52,81,88,96,97,115–127]</sup> The primary focus of this entry will be on the developments of the last few years because there are several reviews and entries that cover a large body of work on the chemistry, properties, and applications of porphyrins up to early 2000.<sup>[52,81,85,126]</sup> There are also a variety of reviews on both self-assembly and multiporphyrin systems.<sup>[16,43,65,125,126,128–132]</sup>

## SELF-ORGANIZED PORPHYRINIC FILMS ON SURFACES

Because self-organized systems are generally less ordered and more tolerant of defects both in solution and on surfaces than self-assembled systems, these types of systems are generally easier to make. Thus the majority of work on porphyrinic materials on surfaces use self-organizing systems, which can be divided into two categories: [1] thin films<sup>[93,94]</sup> deposited as polymers or by layer-by-layer methods,<sup>[133–135]</sup> and [2] monolayers chemically attached via covalent<sup>[89,136–138]</sup> or coordination bonds to the surface,<sup>[139]</sup> or as (mono)-layers adsorbed onto the surface. To date, most of the demonstrated applications for nanoscaled porphyrinic materials on surfaces have been in the area of electrodes, wherein these types of layered films are used to modify electrodes to make them selective for various analytes, and/or to modify surface/electrode chemistry. Other applications in molecular electronics are in the early stages of development.

## Polymers and Layer-by-Layer Adsorption

The deposition of polymers and molecules onto surfaces via the layer-by-layer technique can be summarized as follows. Dipping a charged substrate into a solution containing an organic molecule or polymer of the opposite charge results in a thin film or layer of the material on the surface. After annealing and rinsing, the coated substrate is dipped into a second solution that has molecules or polymer(s) with the charge opposite to the first layer. This alternate layering can be repeated, but the structural fidelity generally decreases with increasing number of layers. The density of defects in each layer and the interpenetration of the layers are major issues for most layer-by-layer systems, but these are difficult to quantify on the molecular scale and may not be important for some applications. An early example of this technique used the tetraanionic tetra-4-sulfonatophenylporphyrin (TSPP) and a tetra-4-pyridylporphyrin (TPyP), where each of the four pyridyl groups coordinates with cationic RuBiPy<sub>2</sub> units (BiPy = 2,2'-bipyridine).<sup>[133]</sup> Other methods to make layers of porphyrins include the use

**Fig. 3** Chemical attachment of a hydrocarbon bearing a porphyrin at one end to a surface can be accomplished in a variety of ways by matching the reactivity of the substrate to the functional group on the opposite end. Some examples:  $x = \text{S}$  on gold,  $x = \text{PO}_3^{2-}$  on zirconium, and  $x = \text{O}$  on glass. The orientation of the porphyrin depends on the number and location of the reactive groups, as well as the nature of the hydrocarbon linker. The planes of the macrocycles are at an angle to the substrate surface in (A) and (C), and nearly parallel in (B). Some two-dimensional order can be found in small domains, but not globally.

of TPyP and Pd(II) in a layer-by-layer method wherein the first porphyrin is attached to a glass surface via an alkane linker (Fig. 3A). The substrate is then dipped in a solution of Pd(II), rinsed, and dipped in a solution of TPyP.<sup>[140]</sup> Again the defect density is not well established.

The stepwise self-organization of a bis-bipyridinium–porphyrin dyad and gold nanoparticles on a conductive indium tin oxide (ITO) surface results in a system where the redox properties are significantly different than the component molecules.<sup>[141]</sup> A cationic polyamine adsorbed onto glass promotes adsorption of anionic TSPP.<sup>[142]</sup> The electrostatic association of cobalt TPyP coordinated to four cationic Ru(BiPy)<sub>2</sub> moieties with anionic Zn(II)TSPP in layer-by-layer films on electrodes has been used to examine nitrite oxidation as an analytical application.<sup>[143]</sup> Indium tin oxide electrodes modified with porphyrin–fullerene dyads as the active layer give rise to improved light-harvesting properties in the visible region.<sup>[134,144]</sup> The synthesis and characterization of electropolymerized thin films of tetra(4-aminophenyl)porphyrin from an aqueous solution onto electrodes to form an emeraldine-type polymer was reported,<sup>[31]</sup> although the morphology of the film was not well defined. A five-component light-harvesting and electron transfer system using this alternating cationic/anionic porphyrin system was also reported.<sup>[145]</sup>

## Monolayers

The formation of uniform molecular films of porphyrins on solid surfaces can be accomplished by a variety of means, ranging from covalent attachment, to

coordination chemistry, to adsorption. The formation and properties of Langmuir–Blodgett films of porphyrin derivatives at the air–water interface have been well studied but are beyond the scope of the present discussion unless these films are then transferred to a solid support. Historically, the chemical, electrostatic, or adsorptive attachment of hydrocarbons to an appropriate surface to yield a uniform molecular layer is referred to as self-assembled monolayers (SAMs); however, these materials are more accurately described as self-organizing systems because they result in dynamic two-dimensional systems and generally do not exhibit specific intermolecular interactions. There has been considerable research on SAMs; some of the concepts found in numerous reports on porphyrin-containing monolayers are discussed below.

## Chemically Bound

One of the most common routes to monolayered materials on surfaces is to chemically bind (Fig. 3) a hydrocarbon bearing a reactive functional group to an appropriate surface. Most often, this method uses a thiol group (or its precursors) to react with gold surface, and there are numerous examples with porphyrins.<sup>[89,91,137,146–148]</sup> The gold–sulfur bond is reasonably strong, but there is some mobility along the surface. Other substrates such as ITO<sup>[147]</sup> and polypyrrole<sup>[149]</sup> have also been used. Using standard reactions for the derivitization of glass yields porphyrins on transparent supports, but the order of these systems is generally less than similar gold constructs. The nature of the hydrocarbon linker modulates the

physical properties, and therefore the photonic activity, of the monolayer. Carboxylate moieties have been used to organize monolayers of porphyrinic materials on surfaces such as gold<sup>[92,150–152]</sup> and mica,<sup>[93]</sup> and at the air–water interface<sup>[153]</sup> for later transfer to a solid support. The weaker substrate–molecule interactions of these systems allow more facile modification of the surface after formation of the monolayer, but it also results in less well-defined structures. A hybrid system with octacarboxylate porphyrins adsorbed facedown onto a gold surface surrounded by a bolaamphiphile monolayer has been reported.<sup>[154,155]</sup> The motivation behind this work is to make nanoscaled test tubes on the surface for catalytic or sensing applications. Phosphates are well known to bind to zirconium, and this system has been used to form porphyrin monolayers.<sup>[17,83,156–158]</sup>

Monothiolated porphyrins covalently bound to gold surfaces (shown schematically in Fig. 3A) have been formed with a variety of orientations relative to the surface plane. Control of such orientation has been the subject of many investigations. For instance, it has been shown that the length of alkane linkers between the porphyrin and gold surfaces affects their relative orientations. For smaller chains, odd numbers of methylene groups exhibit a more perpendicular orientation, whereas an even number results in a more parallel arrangement.<sup>[159]</sup> In addition, post-assembly metal insertion has been shown to avoid unexpected disorder in the monolayer.<sup>[137]</sup> Structural control of the monolayer is needed for various applications that require defined chromophore architectures. Surface catalysis requires such a condition, and porphyrinic monolayers attached to gold surfaces have been shown to better control the rate and selectivity of the electrocatalytic oxidation of ascorbic acid.<sup>[46]</sup> Other applications include biorecognition surfaces for attaching cells, proteins, and other biomolecules, which also require rigid, enzyme-like clefts on the surface for biomolecule attachment.<sup>[160]</sup> Artificial photosynthesis, photocatalysis,<sup>[136,138,147,161]</sup> and molecular photonics<sup>[147,159]</sup> using porphyrinoids are also under development. Well-defined aggregates are better able to harvest light<sup>[91,159]</sup> than the lone metal/composite surface, and these dyes are used to increase the absorption of near-infrared (IR) light for photocatalysis.<sup>[91]</sup> Furthermore, three-dimensional architectures of nanosize particles provide even more light-harvesting efficiency than the two-dimensional layers. This has been demonstrated by the synthesis of an air-stable alkanethiolate monolayer-protected gold cluster.<sup>[136]</sup> Porphyrin monolayers have also been the subject of surface plasmon excitation studies.<sup>[89,163]</sup> Gold surfaces have proven to be an effective excitation source for porphyrin monolayers. Although gold is the most commonly studied solid substrate, other possible

surfaces continue to be explored. Porphyrins have been attached through a silane bond to glass<sup>[163,164]</sup> and ITO.<sup>[147]</sup> In the former case,<sup>[164]</sup> instead of directly linking the porphyrin to the surface, the glass was silylated beforehand and the porphyrin was connected via amide coupling. For example, a freebase porphyrin monolayer on glass was designed for heavy metal detection in environmental applications. In the latter case,<sup>[147]</sup> ITO was chosen to increase the quantum yield because of its semiconducting properties. The ITO exhibited remarkably better photocurrent generation than a similar system on gold because gold introduces an undesirable electron transfer quenching not observed with semiconductors. More complex (structural, redox, and optical) photonic triple-decker molecules containing porphyrins, phthalocyanines, and both porphyrins and phthalocyanines have been used to form monolayers with more complex redox and optical properties.<sup>[148,165–169]</sup> The increased physical chemical complexity affords an opportunity to design and characterize devices that act as multistate counters for molecular electronics applications.

Hipps et al. have carried out extensive scanning tunneling microscopy (STM) studies of porphyrin and phthalocyanine monolayers on metal surfaces. Scanning tunneling microscopy studies revealed that well-ordered two-dimensional arrays form from vapor-deposited films on Au(111) and that the atomic structure of the rings could be observed. Contrast differences were readily obtained for metalation of the macrocycle, and the differing chemical properties of the pendent groups could be used to vary the surface structure.<sup>[170–172]</sup> Other surfaces such as Cu(100) have been used for STM studies as well.<sup>[157]</sup> The electrochemical potential of an electrode surface can also modulate the self-assembly of porphyrinic systems.<sup>[173]</sup>

Another means to organize two different chromophores—one per layer—is to use porphyrins bearing two different functional groups. By these means, one functional group is used to attach the porphyrin to the surface, which poises the second functional group on the opposite side of the macrocycle to form supramolecular or covalent bonds with a second chromophore in a second step. The subsequent layers are added with varying degrees of structural fidelity to the initial layer. Because of the increasing propensity for defects with increasing number of layers, characterization of multilayer systems is often more difficult.

## Coordination Chemistry

There have been numerous reports on systems where exocyclic ligands such as pyridine on the porphyrins coordinate to metal ions bound to the surface by

**Fig. 4** Organization of monolayers on surfaces using coordination chemistry. As in Fig. 3, the relative orientation of the porphyrin plane to the surface depends on the mode and topology (number of bonds between the macrocycle and the surface). (A)–(C) use ligands on the porphyrin to coordinate to metal ions attached to the surface by ligands chemically bound to the surface. (D) and (E) use chemically attached ligands that coordinate to metalloporphyrins either at one or two axial positions. X can be a variety of organic or inorganic functional groups and depends on the surface chemistry. The arrowheads indicate the connectivity mediated by ligand coordination. Not all surface-bound ligands are used.

ligands, which are chemically attached to the surface (Fig. 4A–C). Conceptually, this approach (e.g., Refs.<sup>[95,150,174]</sup>) is similar to the chemically attached self-organized monolayers. Surfaces modified with covalently bound ligands can also directly bind metalloporphyrins in the axial position(s) (e.g., Ref.<sup>[175]</sup>) (Fig. 4D and E). The chemistry used to attach these various ligands is essentially the same as that used for the self-organized monolayers where the nature of the surface dictates the range of suitable functional groups. This method affords a great deal of design flexibility in terms of porphyrin orientation and placement of functional groups. The linkers most commonly used contain pyridine, which ligates to the metal center,<sup>[174,176,177]</sup> or carboxylic acid-terminated hydrocarbon chain, which hydrogen-bonds

to complementary groups on the macrocycle.<sup>[150]</sup> An advantage of using hydrogen bonding is that the center of the porphyrin remains functionally available for applications such as catalysis or molecular recognition,<sup>[178]</sup> and allows the use of freebase porphyrins. For coordination bonds, a variety of metals can be used, although zinc<sup>[174,176]</sup> and cobalt<sup>[176,177,179]</sup> are the most common. Systems using metalloporphyrins allow for the utilization of the metal center for catalysis<sup>[176,177]</sup> and nanoscaled optical devices.<sup>[174,177]</sup> In special cases, a single type of linker can symmetrically ligate the metal on both axial positions of a metalloporphyrin,<sup>[33,180]</sup> such as pyridine ligands coordinating an iron or cobalt center. These types of assemblies (Fig. 4E) can be used to study electronic changes involved in the reversible binding of dioxygen,<sup>[33]</sup> or

to study the optical spectroscopy of metalloporphyrins on surfaces.<sup>[180]</sup>

There are several examples of two-dimensional monolayers where a ligand is covalently attached to the substrate and this binds to an axial position of a metalloporphyrin.<sup>[160,175–177,179,181,182]</sup> This method to make monolayers on surfaces generally orients the plane of the porphyrin parallel to the plane of the surface, but there is sufficient room for the macrocycle to tilt such that a range of orientations is possible. These may be investigated by surface plasmon resonance, surface-enhanced Raman scattering, and surface-enhanced IR absorption.<sup>[37,89,146,162]</sup> Interactions of analytes with these porphyrin-modified surfaces may be exploited as a means of chemical identification and sensing. As mentioned above, the relative orientation of the porphyrin rings with respect to each other and with respect to the surface is of paramount importance to the photonic properties of the system. An elegant way to use coordination chemistry to orient metalloporphyrins perpendicular to the surface is to make monolayers with flexible linkers and ligands that generally are poised to bind 6-coordinate metalloporphyrins in both axial positions (Fig. 4E), resulting in layers with the plane of the macrocycle generally perpendicular to the surface.<sup>[139,180]</sup>

### Adsorption of Liquid Crystalline and Mesogenic Materials

One of the early successes in the self-organization of a porphyrin-based device utilized liquid crystal-type

interactions to form thin films of a photoconducting zinc porphyrin with eight dodecyloxy groups on the pyrroles.<sup>[4,183,184]</sup> Electron–hole pairs are generated on irradiation of a section of a device that has this porphyrin derivative placed between two optically transparent electrodes with an applied electric field. The device then performs as a high-density nanosecond charge trap that can be used as an optical memory device. Similar porphyrins were used to make liquid crystal thin films between ITO-coated glass slides, which displayed electric field-modulated near-field photoluminescence.<sup>[185]</sup> These studies show that there is a correlation between the device's physical properties and the morphology of the self-organized, photoactive, organic layer. Other liquid crystal-forming porphyrins with properties dependent on the nature and position of the hydrocarbon have also been reported.<sup>[186–188]</sup> The attachment of long-chain hydrocarbons allows for the two-dimensional organization of porphyrins (Fig. 5)<sup>[92]</sup> and phthalocyanines<sup>[189–191]</sup> on surfaces, which can be characterized by scanning probe microscopy.<sup>[192,193]</sup>

There are several examples of discrete multiporphyrin arrays with long-chain hydrocarbons appended on the periphery that induce the formation of monolayers by the Langmuir–Blodgett method. Then, these can be transferred to surfaces such as glass with reasonable structural integrity.<sup>[64,194,195]</sup> These films are early examples of using a secondary procedure to self-organize self-assembled supermolecules. A good example of an alternating current light-emitting device based on Langmuir–Blodgett films of porphyrins was

**Fig. 5** Porphyrins bearing long-chain hydrocarbons that serve as liquid crystal-forming motifs can be adsorbed on surfaces. The R-group can be a variety of polar and non-polar functional groups. The number and topology of the hydrocarbon chains and the nature of R-groups govern the molecule–surface and molecule–molecule interactions thus the resulting organization on the surface.

reported,<sup>[196]</sup> where the transient character of electroluminescence is explained in terms of a space charge-assisted electron injection.

Solid vesicle membranes made of bixin–porphyrin derivatives have been reported to form stable colloidal solutions, which can be photopolymerized to yield 30- to 120-nm spheres<sup>[197]</sup> and cast onto surfaces. Self-assembled fibrillar networks are formed from porphyrins bearing two lipid groups on the same side of the macrocycle.<sup>[198]</sup>

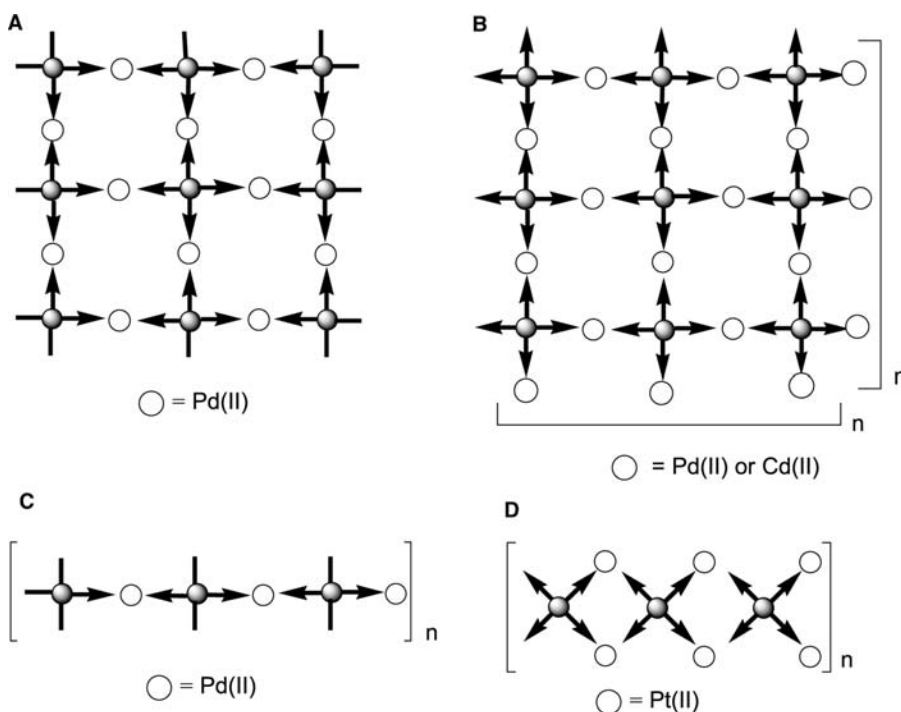

## Outlook

The self-organization of porphyrins on a variety of surfaces can be accomplished via covalent attachment, coordination chemistry, and electrostatic interactions. The choice of substrate and mode of attachment is dictated by the desired function of the surface-bound photonic material. In general, the relative orientation of the macrocycle to the plane of the substrate can be reasonably designed, but the horizontal two-dimensional structure of the porphyrins is usually much less ordered or organized than simple SAMs. The two-dimensional order that is observed results from weak porphyrin–porphyrin interactions and is generally found only in small domains, rather than globally. The extent of these organized domains varies with the mode of surface assembly found in Figs. 3–5. This does not imply that these systems are not well suited for some purposes, but rather that long-range surface organization is not easily achieved by these

approaches. The applications of these systems can be as diverse as the mode of assembly, the nature of the porphyrin, the choice of substrate, and the properties of the linkage. All of these parameters can be systematically changed to modulate the material/device properties and to optimize catalytic, sensor, and photonic functions.

## SELF-ASSEMBLED PORPHYRINIC MATERIALS ON SURFACES

As discussed in the “Introduction,” there are several challenges to using self-assembled and self-organized structures in commercial devices, which can be generally ascribed to issues of structural and chemical stability. One of the first examples of self-assembled porphyrin arrays that address the above issues is a self-assembled nonamer (Fig. 6A). The  $3 \times 3$  tessellation of nine porphyrins of three topologies (+, T, and L-shaped) is mediated by the *trans* coordination geometry of Pd(II) in a variety of organic solvents. These non-amers (which are the third generation of self-assembled porphyrin arrays mediated by metal ion coordination) can then self-organize into columnar stacks of 1 to ~20 layers to form  $6.5 \times 0.5$ –10 nm nanoscaled aggregates.<sup>[122]</sup> The length of the columnar stack can be fine-tuned by the choice of appended alkane, solvent, metalloporphyrin, and by kinetics.<sup>[11,88]</sup> These stacks can be deposited onto glass surfaces without any observable change in structure or function because of the weak interactions between the

**Fig. 6** Self-assembled porphyrinic arrays and polymers. (A) A 21-particle porphyrin non-amer can be placed on Au(111) surfaces with high structural fidelity, or nanoscaled aggregates can be placed on a variety of surfaces. (B) Two-dimensional polymers with an as yet unspecified defect density are formed using a similar chemistry. (C, D) Short one-dimensional polymers can also be made with a distribution of lengths depending on the thermodynamics of the coordination bonds and topology. The arrowheads indicate the connectivity mediated by ligand coordination.

aggregate and the substrate and the strength of the intermolecular forces holding the nonamer and the stack together. Conversely, the individual (non-aggregated) non-amer can be deposited on an Au(111) surface—an example of a purely self-assembled structure deposited on a surface. Most importantly for applications, all of these constructs and their photonic functions are stable in air at room temperature for years.<sup>[10]</sup> The next challenge will be to self-organize the self-assembled non-amers into two-dimensional arrays on surfaces.

The ability to control the size of the nanoscale aggregates of porphyrin nonamers is an important consideration for many applications, *vide supra*. This can be accomplished by a variety of means. The nature of the peripheral R-group affects the solubility of the non-amer and thus the heights of the nanoaggregates can be varied from  $\sim 10$  nm, where R = H, to  $\sim 7$  nm, where R = methyl, to  $\sim 5$  nm, where R = *tert*-butyl as observed by atomic force microscopy (AFM) on glass.<sup>[10,11]</sup> The metalation state of the porphyrin and the choice of metal affect the internonamer interactions both by electrostatics and by altering the  $\pi$ -stacking energetics. The average height for the R = *tert*-butyl freebase is  $\sim 5$  nm, for the Zn(II) derivative is  $\sim 7$  nm, and the Co(II) is about 11 nm, as observed by AFM on glass.<sup>[10,11]</sup> The surface–non-amer interactions also play a role in the size of the nanoparticle found on a substrate; thus single non-amers are observed by AFM and STM on Au(111). The average columnar height is  $\sim 3$  nm on mica, and the average height is  $\sim 5$  nm for the freebase R = *tert*-butyl on glass. During the equilibration process, 20- to 150-nm aggregates are observed, which ultimately result in the above  $< 15$  nm columnar stacks, although the structural arrangement of the non-amers within these is not known at this time. These large aggregates can be deposited on surfaces, and after solvent evaporation, they are trapped in this aggregation state. These samples are as stable as the smaller  $\sim 5$ -nm particles. In addition to influencing the height of the columnar nanoaggregates, the R-groups that constitute the side surfaces also play a role in determining interaggregate associations. Thus non-amers bearing dodecyloxyphenyl groups were constructed in the expectation that these long hydrocarbon chains would assist in the organization of the non-amers, and the columnar aggregates on surfaces. UV–visible spectroscopy, dynamic light scattering (DLS), and  $^1\text{H}$  nuclear magnetic resonance (NMR) spectroscopy indicate that this non-amer is indeed formed in solution. However, neither the non-amers nor the columnar aggregates are observed by AFM on gold or glass, respectively. These results indicate that the additional surface–non-amer interactions arising from the 12 hydrocarbon chains is sufficient to break apart the non-amer on

**Fig. 7** Scanning tunneling microscopy indicates that the 12 dodecyloxyphenyl groups interact strongly with an Au surface and break apart the nonamer to yield individual nonassembled porphyrins. Area,  $20 \times 20$  nm;  $\delta z$ ,  $\sim 0.5$  nm.

gold (Fig. 7), and to form amorphous films on glass. This is clear evidence that there is a careful balance between the intermolecular interactions in self-assembled supramolecular systems and the energetics of binding these systems to surfaces.

Using similar design strategies, several two-dimensional arrays/polymers (Fig. 6B) are formed from TPyP and Cd(II) using Langmuir–Blodgett methods, which then can be deposited on surfaces,<sup>[199]</sup> or the equivalent Pd(II) linked array can be made with the layer-by-layer method.<sup>[135]</sup> These are two examples of methods to make self-organized two-dimensional monolayers using specific intermolecular interactions, but the long-range order (or defect density) is not well established in either case.

When deposited on a variety of surfaces, small one-dimensional porphyrinic tapes (Fig. 6C and D) result in a variety of aggregates and little organization. To obtain better surface organization of these types of systems, long-chain hydrocarbons have been placed on the peripheral phenyl groups of a Pd(II)-linked dimer.<sup>[200]</sup> However, this system tends to form non-uniform films and rings of varying heights, radii, and thickness largely because of solvent evaporation during the deposition process. One likely explanation for this variation in surface topology of this particular dimer is that there is substantial flexibility in the relative orientations of the two macrocycles. As a result, both the dimer–dimer and dimer–surface interactions are not well defined.

To construct self-assembled arrays that then self-organize into reasonably uniform films on surfaces, two porphyrinic squares bearing dodecyloxyphenyl groups on the periphery were constructed, as shown

**Fig. 8** Two porphyrinic supramolecular tetramers: (A) square results from the  $90^\circ$  topology of the pyridyl groups on these porphyrins and the architecturally complementary  $180^\circ$  coordination geometry of  $\text{Pd(II)Cl}_2$ ; and (B) cube results from the  $180^\circ$  topology of the pyridyl groups on the isomeric porphyrins and the architecturally complementary  $90^\circ$  coordination geometry of  $\text{Pt(II)Cl}_2$ . The eight remaining substituents are dodecyloxyphenyl groups. The arrowheads indicate the connectivity mediated by ligand coordination.

schematically in Fig. 8. The intent was that there would be much less conformational flexibility, compared to the above dimer; therefore the intersupramolecular forces would be more defined, and a more ordered film would result. These squares are constructed using the same design strategy as the first discrete porphyrin assemblies reported—pyridyl porphyrins with  $\text{Pd(II)}$  and  $\text{Pt(II)}$ .<sup>[118]</sup> Because the  $\text{Pt-Py}$  bond is stronger than the  $\text{Pd-Py}$  bond, assemblies using  $\text{Pt}$  as a linker are more robust. Consistent with previous findings, these supramolecular squares with dodecyloxy groups are all well characterized in solution by NMR, UV-visible, and mass spectral analyses. The conformation of **8A** is largely planar as illustrated because the  $90^\circ$  topology of the rigid corner macrocycles prevents much twisting about the pyridyl- $\text{Pd(II)}$  bond, but the conformation of **8B** is boxlike or parallelogram-like because there can be substantial rotation about the pyridyl- $\text{Pt(II)}$  bonds. The calculated structure showing the bond rotations is shown in Fig. 9. This means that the dodecyloxyphenyl groups of **8A** are essentially coplanar with the plane of the supramolecular square, but in **8B**, these groups are directed along two faces of the box. The orientation of these liquid crystal-forming groups has a significant influence on the resultant structure of the films on glass surfaces, such that films from **8B**-type squares are reasonably uniform, whereas those from **8A**-type squares are much less so. The relative number/strength of the van der Waals forces per supermolecule may be largely responsible for these observations. Although both **8A** and **8B** have eight alkane groups, only two per side of Fig. 8A can interact with a coplanar neighbor, but four alkanes interact with the neighbors of **8B**. This hypothesis is born out by AFM studies of these two supramolecular squares

**Fig. 9** MM2-calculated structure of a porphyrinic cube using  $\text{Pt(II)Cl}_2$  corners. The H and dodecyloxyphenyl groups are left out for clarity.

deposited on glass. **8B** tends to form thin films that are 2–5 nm thick, whereas Fig. 8A forms small islands of variable thickness. An **8B**-type square with *tert*-butylphenyl groups was made for comparison with the supermolecule with dodecyloxyphenyl groups. As expected, the *tert*-butylphenyl-substituted square does not form films but rather small aggregates similar to those observed for the non-amer discussed above. This is a clear indication that the number, position, and nature of the R-groups are of paramount importance to the self-organization of self-assembled arrays of porphyrins. Comparisons between the non-amer and the tetrameric species reveal that the size and conformational flexibility of the supermolecule also dictate the organization of these entities on surfaces. Further studies on the interactions of all of these systems on different surfaces will reveal the role of surface chemistry/energetics in the organization of supramolecular porphyrinic systems.

Adsorption of the dodecyloxyphenyl-functionalized porphyrin square on glass shows that a thin ( $\sim 2$  nm) film is formed. The thickness of this film is in general agreement with the dimensions of a single central square unit, as shown schematically in Fig. 10. The film is composed of both nanoparticles of these subunits and larger domains/islands (Fig. 11), which are found to be much more uniform in height than those of the porphyrin rings using a  $\text{Pd}$ -linked dimer.<sup>[200,201]</sup> Annealing of the samples may yield more organized structures, and temperature-dependent studies are currently underway.

**Fig. 10** Two possible conformations of the tetramer in Fig. 8B (top) and possible interactions between the supramolecular tetramers in Fig. 8B (bottom).

## Outlook

The ability to deposit specifically designed self-assembled (discrete) supramolecular structures onto surfaces without change in structure or function remains a significant challenge for the exploitation of this methodology in real-world applications and devices. However, self-organized monolayer systems are more accessible because of the tolerance for local defects, but the horizontal dimensions of these are generally quite large. The layer-by-layer method has both advantages (ease of preparation) and disadvantages (greater defect density than SAMs), but may find

**Fig. 11** Topographic AFM image of the dodecyloxyphenyl-functionalized porphyrin square **8B** on glass formed by drop casting and evaporation of solvent. The film is composed of nanoscale particles  $\sim 2$  nm in height. The uncovered regions are glass (dark open circles). A bright (indicating higher topography) spot appears where multiple particles have stacked together and were not removed by rinsing.

numerous applications as sensors, and other systems requiring surface modification. The adsorption of a  $\text{La(III)(TPyP)}_2$  sandwich compound onto a liquid Hg surface can provide access to two-dimensional arrays on this and other surfaces when they are chemically cross-linked with a dibromohydrocarbon.<sup>[202,203]</sup> The overall structure of these systems is likely a grid, but because the cross-linking step results in kinetic rather than thermodynamic products, the degree or order is likely not comparable to self-assembled/organized systems. This work is notable because it is an attempt to organize porphyrin sandwich compounds on surfaces with greater structural stability and a degree of order different from monolayers of similar compounds.

## CONCLUSION

The use of porphyrins and porphyrinoids for self-assembly and self-organization of molecules and ions to create functional, photonic materials has been the cornerstone of much research because of their structural rigidity, chemical stability, and rich photochemical and electrochemical properties. The facile modulation of the photonic properties of porphyrins<sup>[27,36,51,204,205]</sup> is accomplished both by the choice of metal ion and by the choice of substituents on the macrocycle. Steric crowding and distortions of the macrocycle can alter the excited state lifetimes of some nickel porphyrins by six orders of magnitude.<sup>[206,207]</sup> The placement of self-assembled/organized porphyrinoids on surfaces<sup>[89–92,95,146,150,152,173,174,182,208,209]</sup> remains a key issue toward the use of these systems in materials and devices,<sup>[10,11]</sup> and scanning probe methods for both discerning functional properties and organization have been used.<sup>[208–210]</sup> Although the focus of much of the research discussed herein is on nanoscaled materials<sup>[3,5,10,11,23,68,93,97,125,134,141,146,152,154,158,183,193,201,210–220]</sup> in which at least one dimension is less than a few nanometers, some applications of porphyrinoids require larger, less defined structures such as nanoscaled colloids between about 100 and 600 nm for catalysis, or less well-defined or controllable surface structures.<sup>[210–220]</sup> To date, the methods to self-assemble discrete multiporphyrinic systems of this size are limited, but aggregates of this size have been made and deposited on surfaces.<sup>[97]</sup> These particles exhibit enhanced catalytic activity and have novel photonic properties. The rapid advances in supramolecular chemistry, surface chemistry, and physical chemistry indicate that molecule-based materials have a bright future.

# Printed and Molded Nanostructures: Photonic Applications

**John A. Rogers**

*Department of Materials Science and Engineering and Beckman Institute,  
University of Illinois at Urbana–Champaign, Urbana, Illinois, U.S.A.*

## INTRODUCTION

Many classes of components for integrated optics and optoelectronics rely on structures with nanometer features sizes (typically a fraction of the optical wavelength at which they operate) for couplers, filters, laser resonators, etc.<sup>[1]</sup> Similar but more advanced devices that use photonic crystals<sup>[2]</sup> as well as a variety of subwavelength elements<sup>[3,4]</sup> for bulk optics also make use of arrays of nanostructures to achieve desired optical effects. Traditionally, techniques borrowed from the microelectronics industry, such as photolithography and electron beam lithography, have been employed for these applications. The operational complexity of these methods, their high capital costs, and certain inherent limitations associated with them create research interest in alternative fabrication techniques.<sup>[5,6]</sup> Two relatively recent approaches to patterning photonic nanostructures use advanced forms of printing and molding, two of the conceptually oldest forms of lithography. These methods offer sub-micron resolution along with patterning capabilities that are well suited to this class of application. This entry summarizes these methods and demonstrates their use in fabricating a range of components for integrated optics.

## HIGH-RESOLUTION STAMPS AND MOLDS

High-resolution stamps and molds can be formed with electron beam lithography or photolithography according to the procedures illustrated in Fig. 1. Casting and curing a polymer against a pattern of resist formed with these techniques (known as the “master”) yields polymeric elements that can serve as stamps and molds. Many elements can be produced from a single master and each element can be used many times. Similar molds and stamps can be made out of the material that serves as the substrate for the master by using the resist to generate surface relief, through selective etching. There are currently two classes of printing techniques that use these stamps for patterning with

submicron resolution—microcontact printing ( $\mu$ CP)<sup>[7,8]</sup> and nanotransfer printing (nTP).<sup>[9,10]</sup> In  $\mu$ CP, an elastomeric stamp [usually poly(dimethylsiloxane), PDMS; Dow Corning, Inc.] is used to print patterns of chemical inks. In nTP, a hard or an elastomeric stamp delivers a solid ink material to a substrate.  $\mu$ CP offers typical edge resolution of 50–200 nm depending on the inks and substrates. Demonstrated resolution in nTP is in the range of 5–20 nm. The stamps for these techniques can also be used as high resolution molds for embossing relief structures into polymers and other soft materials.<sup>[5]</sup>

## Microcontact Printing

It was mainly developed for use with inks that form self-assembled monolayers (SAMs) of alkanethiolates on gold and silver. The procedures for carrying out  $\mu$ CP in these systems are simple: A stamp, inked with a solution of alkanethiol, is brought into contact with the surface of a substrate to transfer ink molecules to regions where the stamp and substrate contact. The resolution and effectiveness of this method relies on conformal contact between the stamp and the surface of the substrate, rapid formation of highly ordered monolayers,<sup>[11]</sup> and autophobicity of the SAM,<sup>[12]</sup> which effectively blocks the reactive spreading of the ink across the surface. It can pattern SAMs over relatively large areas (up to  $\sim 0.25$  ft<sup>2</sup> have been demonstrated in prototype electronic devices)<sup>[13]</sup> in a single impression.

Fig. 2 schematically illustrates the use of  $\mu$ CP and wet etching to pattern a thin film of Au. Fig. 3 shows scanning electron microscope (SEM) images of representative nanopatterns of gold (20-nm thick, thermally evaporated with a 2.5-nm layer of Ti as an adhesion promoter) that were fabricated on silicon wafers using this approach. In both of these examples, the masters for the stamps consist of photoresist patterned on silicon wafers with projection-mode photolithography. Placing a few drops of a  $\sim 1$  mM solution of hexadecanethiol (HDT) in ethanol on the surface of the stamps, and then blowing them dry with a stream of nitrogen

**Fig. 1** Schematic illustration of two representative methods for producing high-resolution stamps and molds. Both begin with photolithography to pattern a thin layer of resist on a flat substrate, such as a silicon wafer. This structure, known as the master, is converted to a stamp or mold either by etching or by molding. In the first case, the resist acts as a mask for etching the underlying substrate. Removing the resist yields a stamp or a mold. In the molding approach, a pre-polymer is cast against the relief structure formed by the patterned resist on the substrate. Curing (thermally or optically) and then peeling the resulting solid polymer away from the substrate completes the process.

prepares them for printing. Contacting the metal film for a few seconds with the stamp produces a patterned self-assembled monolayer (SAM) of HDT. An aqueous etchant removes the unprinted regions of the gold.<sup>[14]</sup> The patterns in Fig. 3 have edge roughness of  $\sim 50$ – $100$  nm. This resolution, which is typical for  $\mu$ CP, is determined by the grain size of the metal films, the isotropic etching process, slight reactive spreading of the inks and edge disorder in the patterned SAMs. Patterns with these feature sizes are useful for many applications in integrated optics, and especially those at the infrared wavelengths ( $1.5 \mu\text{m}$ ) that are predominant in communication systems.

### Nanotransfer Printing

Nanotransfer printing (nTP) is a more recent high-resolution printing technique that uses surface chemistries as interfacial “glues” and “release” layers to control the transfer of solid material layers from relief features on a stamp to a substrate.<sup>[9,10]</sup> This approach, which is illustrated in Fig. 4, is purely additive (i.e., material is only deposited in locations where it is needed) and it can generate complex patterns of single

**Fig. 2** Schematic illustration of an example of microcontact printing. The first step involves “inking” a “stamp” with a solution of hexadecanethiol (HDT) in ethanol. Contacting the stamp to a thin film of gold on a substrate produces a patterned SAM of HDT. The printed SAM can act as a resist for the aqueous-based wet etching of the exposed regions of the Au. The resulting pattern of conducting gold can be used to build devices of various types.

or multiple layers of materials with nanometer resolution over large areas in a single process step. It does not suffer from surface diffusion or edge disorder in the patterned “inks” of  $\mu$ CP nor does it require post-printing etching or deposition steps to produce structures of functional materials. The method involves four components: 1) a stamp (rigid, flexible, or elastomeric) with relief features in the geometry of the desired pattern; 2) a method for depositing a thin layer of solid material onto the raised features of this stamp; 3) a means for bringing the stamp into intimate

**Fig. 3** Scanning electron micrographs of typical structures formed by microcontact printing a self-assembled monolayer ink of hexadecanethiol onto thin gold films followed by etching of the unprinted areas. The left frame shows an array of Au (20-nm thick) dots with  $\sim 500$ -nm diameters. The right frame shows printed lines of Au (20-nm thick). The edge resolution of features in both of these patterns is  $\sim 50$ – $100$  nm.

**Fig. 4** Schematic illustration of procedures for nanotransfer printing a pattern of Au on a GaAs substrate. A uniform monolayer of 1,8-octanedithiol molecules is formed on the GaAs using vapor or solution phase deposition. Evaporating a collimated flux of Au (20 nm) onto an elastomeric stamp forms layers on the recessed and raised regions but not on the sidewalls. Contacting this stamp with the substrate leads to Au–S bonds. Removing the stamp leaves a pattern of gold on the substrate in the geometry of relief on the stamp. The transferred gold patterns are effectively “glued” to the surface by strong Ga–S, As–S, and S–Au bonds at the interface. The insets highlight the idealized orientation of the dithiol molecule on GaAs surface; control experiments indicate that the unreacted thiol endgroups are generally oriented away from the wafer surface.

physical contact with a substrate; and 4) surface chemistries that prevent adhesion of the deposited material to the stamp and promote its strong adhesion to the substrate. nTP has been demonstrated with SAMs and other surface chemistries for printing onto flexible and rigid substrates with hard inorganic and soft polymer stamps.<sup>[9,10,15]</sup> Fig. 4 presents a set of procedures for using nTP to pattern a thin layer of Au with a surface transfer chemistry that relies on Au–S bonding and self-assembled monolayers.<sup>[15]</sup> The process begins with fabrication of rigid or elastomeric stamps using the procedures of Fig. 1. Careful control of the processing steps yields features of relief with nearly vertical or slightly reentrant sidewalls. Directional deposition of Au (or other materials) onto the surfaces of such stamps yields coatings only on the raised and recessed regions and not on the sidewalls. The depth of relief on the stamps is typically  $>200$  nm for patterning metal films with thicknesses  $<50$  nm.

In the case of Fig. 4, contacting a gold-coated PDMS stamp to a GaAs substrate that has a self-assembled dithiol monolayer on its surface leads to thiol-gold linkages at the interface. Removing the stamp (to which the gold does not adhere) leaves behind a pattern of gold in the geometry of the raised regions of the stamp.<sup>[15]</sup> Similar procedures can be used with a wide range of stamps, patterned materials, substrates, and surface chemistries. Fig. 5 shows some representative examples. The resolution of nTP is limited mainly by the roughness at the edges of the films that are deposited on the stamps and by the stamps themselves. This edge roughness is less than 5–20 nm for evaporated gold and stamps fabricated by electron beam lithography. There is no observable degradation in feature sharpness or resolution because of the transfer process. Care must be taken to use optimized deposition and printing conditions in order to avoid nanocracking in the transferred layer, especially when patterns of rigid materials are printed from deformable stamps onto deformable surfaces. In the applications that we have explored, even when they might exist, the nanocracks (which are not visible with conventional optical or scanning electron microscopes) do not significantly affect the functional properties of the devices (e.g., resistivity test structures, organic transistors and simple circuits, photonic structures, thin film capacitors, etc.).

**Fig. 5** Optical micrographs of patterns of Au (15-nm thick) formed on plastic (top left and bottom left frames), silicon (top right frame), and GaAs (bottom right frame) substrates with nanotransfer printing. The transfer chemistry in the top left case relies on silane self-assembled monolayers with exposed thiol groups. The chemistry for the patterns in the top and bottom right cases relies on surface dehydration reactions. The bottom right pattern used a dithiol chemistry. The minimum feature sizes and the edge resolution are limited, in all cases, by the stamps.

**Fig. 6** Schematic illustration of molding procedures for defining distributed feedback gratings for lasers. The gratings are formed by exposing a thin film of a photocurable polymer to ultraviolet light through an elastomeric mold.

### Nanomolding

The stamps used for  $\mu$ CP and nTP can also serve as molds for generating relief surface relief features in other materials. Nanoimprint lithography and related embossing methods represent one class of such techniques that use hard stamps and thermally softened polymers or photocurable liquids.<sup>[5]</sup> The use of elastomeric materials for “soft” molds yields a related type of

**Fig. 7** Atomic force micrographs of distributed feedback grating structures. The right frame was collected from a photolithographically defined pattern in a thin layer of SiO<sub>2</sub> on a silicon wafer. The left frame was collected from a polymer replica generated with an elastomeric mold produced from the structure illustrated on the right.

**Fig. 8** Scanning electron micrographs of 200 nm period distributed feedback gratings in a thin layer of SiO<sub>2</sub> on a silicon wafer (left frame) and in a thin layer of a photocurable polymer on a glass slide (right frame). The structure in silica was formed by direct write electron beam lithography and etching. The structure in the photopolymer was defined by molding using an elastomeric mold formed by casting and curing against the silica structure.

technique which, because of the flexibility of the molding elements, can be used for large-area patterning of nanostructures even in fragile materials.<sup>[6]</sup> Fig. 6 shows procedures for using this approach to generate features of relief in a thin photocurable polymer. The transparent PDMS mold allows the photopolymer to be cured by exposure to ultraviolet light passing through the mold. In the case illustrated here, the pattern consists of a distributed feedback grating for a laser that emits in the visible spectrum. Fig. 7 presents atomic force microscope images of a relief pattern generated by photolithography and etching of a thin layer of SiO<sub>2</sub> on a silicon substrate (left frame) and a fifth generation replica grating (right frame) in a photocurable polyurethane (NOA 72, Norland) formed by using the procedures of Fig. 6 with a PDMS mold generated from the SiO<sub>2</sub> structure.<sup>[16]</sup> These procedures are effective for pattern replication down to the 50–100-nm scale. Fig. 8 shows scanning electron micrographs of 100 nm lines and spaces fabricated by

**Fig. 9** Images of a large-area master (6-in. silicon wafer with patterned photoresist; left frame), a large-area mold formed from this master (middle frame), and a molded thin film (2  $\mu$ m thick) of photopolymer formed using this mold (right frame). The mechanical flexibility and elastomeric nature of the mold are key features that allow this type of large-area replication. The lateral feature sizes in this pattern range from 200 nm to 1 cm. The relief depth ranges from 1 to 0.25  $\mu$ m.

**Fig. 10** Scanning electron micrographs showing molded features of relief in a thin polymer film before (top frame) and after (bottom frame) reactive ion etching to remove the thin regions.

electron beam lithography and etching in  $\text{SiO}_2$  (left frame) and a replica grating structure in a molded polymer (right frame).<sup>[17]</sup> Below these sizes, the mechanical properties of the mold can be limiting;<sup>[18–21]</sup> newer elastomers with comparatively high modulus and physical toughness can extend the resolution of these procedures deep into the sub-100-nm regime.<sup>[18,20]</sup>

The resolution and replication fidelity illustrated in Figs. 7 and 8 can be achieved over large areas. Fig. 9 shows a master, a mold, and a replicated pattern in a thin polymer film carried out with and on 6-in. silicon wafers. The ability to flex and bend the mold allows contact with the thin spin cast photopolymer to be initiated at the center of the wafer. As the contact line is gradually allowed to move toward the edges of the substrate, air is pushed out, thereby eliminating trapped air pockets of the type that are difficult to avoid in more conventional embossing and

**Fig. 11** Scanning electron micrographs of nanopatterns of tungsten (left frame) and gold (right frame) formed by etching through a sacrificial polymer resist defined by molding and etching.

imprinting techniques that use rigid molds. The mechanical flexibility of the mold is also important for release because it allows the mold to be removed from the substrate by bending and peeling, in way that avoids damage to the substrate or the mold.

The wafer-scale results illustrated in Fig. 9 incorporate features with lateral dimensions down to 200 nm. This relief can be converted into isolated polymer nanostructures by etching to remove the thin regions of the molded films. Fig. 10 shows SEMs of a molded thin polymer film before and after exposure to an oxygen reactive ion etch. Careful control of the etching conditions can enable removal of the thin regions of the molded films without significant changes in the lateral dimensions of the features. The isolated polymer lines that are generated by these procedures can be used in the same way that patterned photoresist is used in conventional semiconductor processing. In the examples illustrated in Fig. 11, similar polymer structures were used for dry etching a pattern into underlying films of tungsten and gold. This molding and etching approach provides an alternative route to building the types of structures that can be formed by  $\mu\text{CP}$  and  $\text{nTP}$ .

**Fig. 12** Schematic illustrations and emission spectra of plastic lasers that use molded resonators based on surface relief distributed Bragg reflectors (DBRs) and distributed feedback gratings (DFBs) on glass substrates. The grating periods are  $\sim 600$  nm in both cases. The lasers use thin-film plastic gain media deposited onto the printed gratings. The emission profiles, the lasing thresholds, and other characteristics of these devices are comparable to similar lasers that use resonators formed by high-resolution projection-mode photolithography.

**Fig. 13** Scanning electron micrographs of four photonic crystal structures ( $\sim 50$ -nm deep) molded onto the surfaces of sol-gel-derived glass films. [The slight “graininess” in these images is due to a thin coating of gold ( $\sim 5$  nm) deposited to eliminate charging.]

## APPLICATIONS

Nanopatterns such as those described in the preceding discussion can be used for a variety of photonic devices. To build lasers out of molded or printed surface relief structures (which not only yields functional devices but also demonstrates the quality of these structures—defect density, spatial coherence, uniformity, etc.—for other applications), a thin layer of organic gain media is deposited on top of the structure to define a planar waveguide that confines light to the surface. The thickness of this layer is chosen to support a single transverse mode. Photopumping the structure generates lasing as a result of feedback associated with reflections from the grating. A lower-order interaction couples light out of the waveguide. For the examples described in this article, a third-order interaction with the grating provides the feedback and a first-order interaction leads to output coupling.

**Fig. 12** shows the typical performance of plastic lasers that use printed and molded distributed feedback (DFB) and distributed Bragg (DBR) resonators with spin-coated thin film (150–200-nm thick) gain media of 2-(4-biphenyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole doped with 1 wt.% Coumarin 490 and DCMII (Exciton, Inc.).<sup>[16]</sup> Photopumping these structures with 2-nsec pulses from a nitrogen laser with intensities  $>5$  kW/cm<sup>2</sup> leads to multimode lasing at resolution-limited linewidths and wavelengths corresponding to the third harmonic of the gratings. The spectra and the threshold intensities for lasing are similar to those observed in lasers that use SiO<sub>2</sub> gratings generated with photolithography. They are better than those that we observed from gratings formed by pressing heated thin polymer films against rigid templates.<sup>[22]</sup>

The same printing and molding techniques can be used with more unusual materials and laser structures. **Fig. 13** shows images of some two-dimensional photonic crystal structures molded into a type of sol-gel derived glass<sup>[23]</sup> as examples. This class of material, known as an organically modified silicate, consists of interpenetrating organic and inorganic networks prepared by using a metal alkoxide with a reactive organic moiety. This hybrid matrix forms, at relatively low temperatures, thick, mechanically hard coatings with good optical properties. To generate fine patterns of surface relief in these films, the curing is carried out while the film is in contact with a PDMS mold.<sup>[23]</sup> The structures in **Fig. 13** are molded in organically modified silicate films several microns thick and consist of periodic arrays of cylindrical posts or holes with submicron diameters, arrayed in triangular, square, and honeycomb lattices. The images suggest that the structures are replicated with a spatial resolution that comfortably exceeds both the smallest dimensions of the features ( $\sim 150$  nm) in these sol-gel-derived photonic crystals and in structures ( $\sim 250$  nm) that are useful for applications in telecommunications.

**Fig. 14** Schematic illustration (left frame) and optical image (right frame) of emission from a photopumped photonic crystal laser that uses a molded resonator of cylindrical depressions  $\sim 50$ -nm deep, with 400-nm diameters and center-to-center separations of 600 nm in a layer of an organically modified silicate glass film on glass slide. In this device, the crystal acts both as the resonator to provide feedback for the laser and the output coupler.

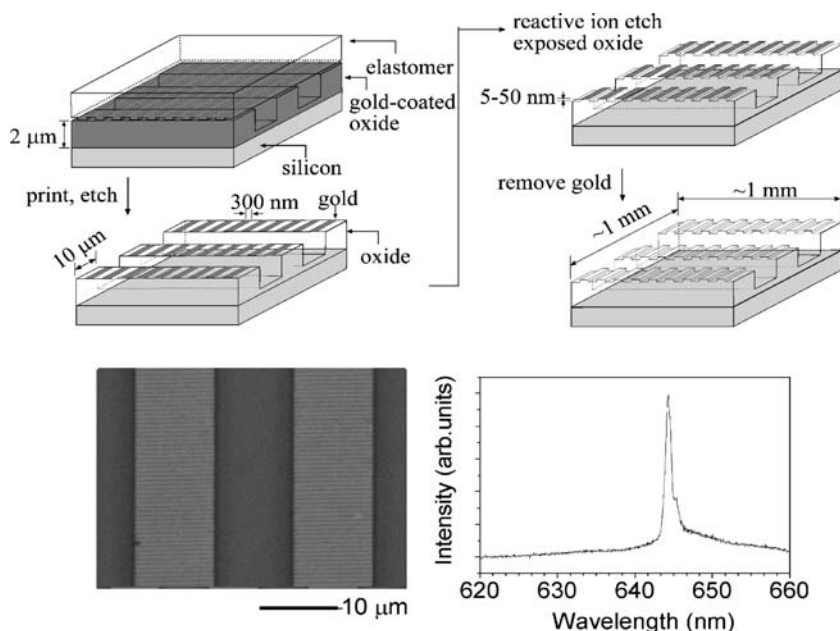

**Fig. 15** Emission spectrum (left frame) and output intensity as a function of pump intensity (right frame) for a photopumped laser that uses a molded two-dimensional photonic crystal as a resonator. The narrow emission linewidth (instrument limited), the well-defined emission spots and the relatively low lasing threshold provide evidence that the quality of the molded resonator is high (i.e., spatially uniform and free of defects).

Depositing thin films (150–200-nm thick) of organic gain materials [8-hydroxyquinolino aluminum (Alq) and the laser dye, DCMII] onto these molded patterns produces lasers that operate due to Bragg reflections induced by the photonic lattice.<sup>[23]</sup> Fig. 14 illustrates the photopumping geometry (left frame) and an image of the spatial pattern of laser emission (right frame). A typical spectrum (left frame) and the measured dependence of the output intensity on the intensity of the pump light (right frame) are shown in Fig. 15. The lasing threshold ( $\sim 50 \text{ kW}/\text{cm}^2$ ) and the emission spectra are, to within device-to-device variations, identical to those of similar lasers that use photolithographically defined resonators in  $\text{SiO}_2$ .<sup>[24]</sup>

Printing and molding procedures not only provide a simple, low-cost route to structures that can be fabricated with other approaches, but they also enable some unique patterning capabilities. For example,  $\mu\text{CP}$  can be used to form DFB resonators directly on the top surfaces ridge waveguides.<sup>[25]</sup> In certain cases, there are

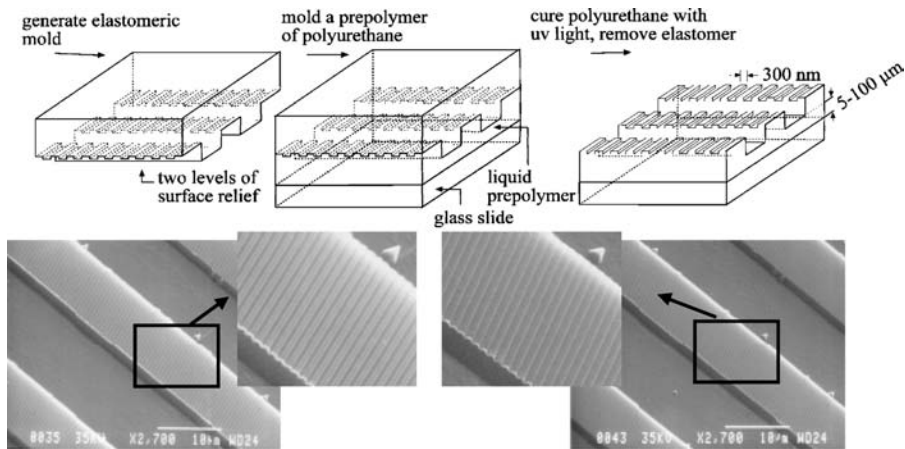

manufacturing advantages to forming the gratings after defining the waveguides. Achieving this process sequence with photolithography is challenging because spin cast layers of photoresist develop large and undesired thickness variations due to dewetting at the sharp edges of relief associated with the waveguides. Fig. 16 illustrates the procedures for using  $\mu\text{CP}$  for this patterning task.<sup>[25]</sup> The bottom left frame shows an optical micrograph of the printed gold lines. Sublimation of a  $\sim 200$ -nm film of Alq doped with 0.5–5.0 wt.% DCMII onto the resonators produces waveguide DFB lasers. The bottom right frame of Fig. 16 shows the emission profile. Once the ridge waveguide DFB structure has been fabricated, it can be used as a master for producing a mold with two levels of relief.<sup>[17]</sup> The structure can then be rapidly replicated by molding in a single step. Fig. 17 shows the procedures and micrographs of the master and a typical replica in a photopolymer.

This basic type of laser can also be produced by molding the relief structure directly into the organic

**Fig. 16** Schematic illustration (top frames) of steps for microcontact printing high-resolution gratings directly onto the top surfaces of ridge waveguides. The printing defines a sacrificial etch mask of gold, which is subsequently removed. The bottom left frame shows a top-view optical micrograph of printed gold lines on the ridge waveguides. The bottom right frame shows the emission output of a plastic photopumped laser that uses the printed structure and a thin evaporated layer of gain media.

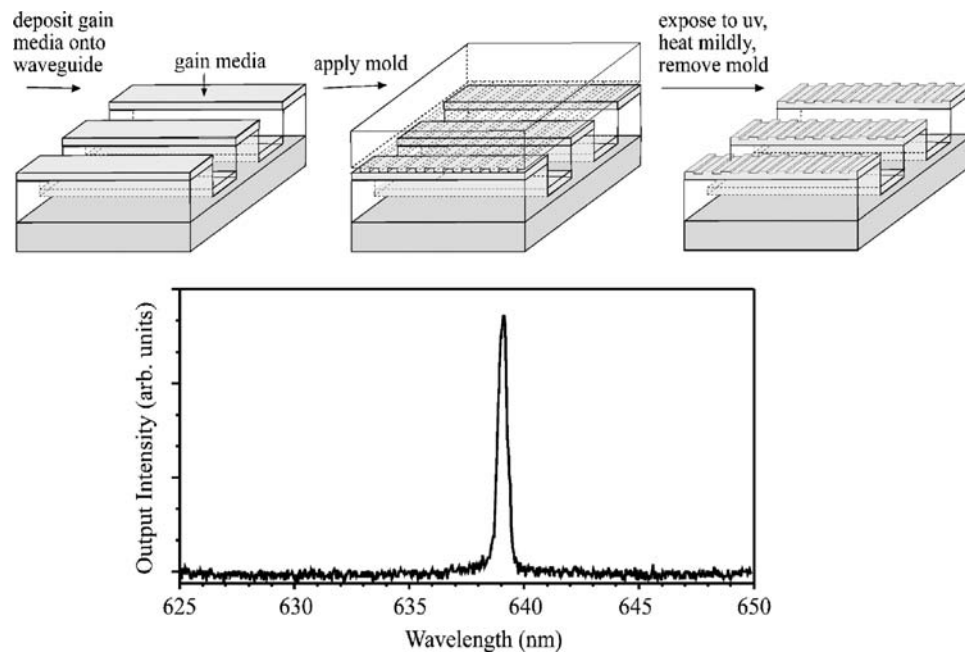

**Fig. 17** Schematic illustration (top frames) of the use of a two-level mold to produce, in a single step, distributed feedback ridge waveguide laser resonators. The scanning electron micrographs on the right show the silica master that was used for the mold (top frame) and a molded replica in a photocurable polymer (bottom frame).

gain material.<sup>[25]</sup> Fig. 18 shows the procedures. In this case, a PDMS mold is placed in contact with a thin layer of gain material that is evaporated onto the waveguides. Exposing this film to ultraviolet laser light while in contact with the mold softens the material and causes it to conform to the relief of the mold. Removing the PDMS mold after this procedure leaves a surface relief DFB grating embossed onto the gain material itself. Photopumping this structure leads to lasing; a typical spectrum is shown in Fig. 18. We have also used this same basic soft molding approach to pattern relief features into thin films of the polymer poly(*p*-phenylene vinylene) (PPV) to structure light emission in polymer light-emitting diodes (Figure 19).

A PPV film cast on top of a piece of glass coated with indium tin oxide was molded during solvent evaporation using a PDMS mold. A uniform top electrode consisted of a uniform bilayer of Al/Ca. Here thickness relief produced by the molding leads to light output from only the thin regions of the film at certain voltages.<sup>[26]</sup> This sort of direct patterning of thin layers of electroactive organics could have important applications in the emerging field of active organic optoelectronics. These classes of mechanically and chemically fragile materials are difficult or impossible to pattern with conventional approaches because of their chemical incompatibility with the required photoresists, developers, and solvents.

**Fig. 18** Schematic illustration (top frames) of procedures for molding high-resolution gratings directly onto the surface of a thin layer or organic gain material. Photopumping this structure leads to lasing. The bottom frame shows a typical emission spectra.

**Fig. 19** Atomic force micrographs (left frames) of surface relief structure molded into a thin film of poly(*p*-phenylene vinylene) on a thin film of indium tin oxide on a glass slide. The right frames show optical micrographs of the patterns of emission that results from diodes that are formed by depositing Al/Ca on top of the molded films.

## CONCLUSION

This entry summarizes some of our recent work in the development and application of unconventional methods for fabricating photonic nanostructures, with examples of their use in organic optoelectronics. Integrated optics represents a field where new or emerging techniques for nanofabrication could find important niche applications. The dimensional requirements for registration and alignment (2–500 μm typically) in these systems is much less demanding than the requirements on the minimum feature sizes (~100–300 nm for the devices described here). As a result, the complex and highly engineered systems that are required for nanoscale registration are not needed, and the challenges associated with achieving nanoscale overlay accuracy with deformable molds and stamps can be avoided.<sup>[27]</sup> These features greatly simplify the potential introduction of these new lithographic methods into realistic manufacturing settings. Compared to other types of unconventional approaches that have nanometer resolution (e.g., imprint lithography, embossing, etc.) the printing and molding methods described here are attractive, in part because they are directly compatible with classes of organic active materials. The technologies that emerge from the combined use of soft materials and soft patterning methods for photonics have a strong potential to yield important classes of devices for future optical communication networks, information displays, and other systems.

# Protein Adsorption Kinetics under an Applied Electric Field

Paul R. Van Tassel

Department of Chemical Engineering, Yale University,  
New Haven, Connecticut, U.S.A.

## INTRODUCTION

The dimensions of the largest naturally occurring molecular species and those of the smallest manmade features converge at the nanoscale. Proteins, the basic building blocks of living organisms, are among the larger molecules in nature with dimensions ranging from 1 to 100 nm. Materials incorporating proteins are therefore true nanomaterials. Of particular importance are thin films of proteins immobilized at a solid substrate. Biosensing, tissue engineering, enzymatic catalysis, and bioelectronics are just a few of the areas in which immobilized layers of proteins play a key role.

The tendency of proteins to attach to interfacial regions is well documented.<sup>[1–4]</sup> Ionic, van der Waals, solvation, and donor–acceptor interactions all play important roles in rendering the interfacially adsorbed state to be thermodynamically favored over the solution state.<sup>[1]</sup> Proteins are colloidal objects, possessing a distribution of surface charge and, in an electrolytic solution, a distribution of weakly associated counterions. Their interaction with a solid substrate is thus expected to be sensitive to the substrate's charge distribution. By controlling the polarization of an adsorbing surface (i.e., applying an electric field), one alters this charge distribution and therefore the surface–protein interaction. This possibility is understandably appealing to those wishing to control the adsorption process, perhaps desiring adsorbed layers of preferred orientation or spatial distribution. However, the interaction between proteins and surfaces is complex and predicting adsorbed layer properties by considering the contributions from the interaction modes listed above remains a significant challenge. Adding an electric field makes the problem even more complex. Thus while influencing an adsorbed protein layer with an electric field is both possible and desirable, the outcome is as yet poorly understood.

In this contribution, we review the field of protein adsorption kinetics under an applied electric field. By focusing on kinetics, we limit ourselves to studies where adsorbed layer properties are measured in situ during the electroformation process. We begin with a brief presentation of certain basic theoretical

considerations. We then introduce the methods employed to measure protein adsorption kinetics under an applied electric field. Next, we introduce some of the key results, grouping our presentation by investigator. A perspective on future directions is then given and this is followed by a conclusion. By summarizing some of the key accomplishments and open questions, we hope to guide future efforts to produce nanoscale devices employing adsorbed protein layers formed under an electric field.

## THEORY

An applied electric field may affect protein adsorption in two ways. The first of these deals with transport. Proteins are composed of amino acids, some of which contain acidic/basic sites. Thus at all but the isoelectric pH, the protein will possess a net charge and thus migrate in response to an electric field. Because the charge distribution is generally not spherically symmetric, the electric field also imposes a torque on the molecule, causing it to rotate. Of course, electric-field-induced migration and rotation must compete against the molecule's thermal diffusive motion, so these influences are only observed in excess of some threshold field strength. The second principal effect of an applied electric field involves the direct interaction between the electrode and the protein upon close approach. The alteration of electrode potential brings about various physicochemical changes in the surface itself and alters the counterion distribution away from the surface; these two effects influence the protein–surface interaction and affect such properties as the rate of attachment, protein orientation, and the rate and extent of subsequent post-adsorption changes in orientation and conformation.

The transport of protein in a (assumedly laminar) flowing solution to the surface may be described by the general transport relation

$$\frac{\partial c}{\partial t} + \vec{v} \cdot \vec{\nabla} c = \vec{\nabla} \cdot \left( D \vec{\nabla} c + \frac{cq\vec{E}}{\zeta} \right) \quad (1)$$

where  $c$  is the protein concentration,  $t$  is the time,  $\vec{v}$  is the fluid flow velocity vector,  $D$  is the diffusivity,  $q$  is the effective protein charge,  $\vec{E}$  is the electric field vector, and  $\zeta$  is the friction coefficient (a measure of the viscous drag on the protein). The flow field must be known in advance to solve Eq. (1). So long as the concentration is quite low, one may neglect the influence of the migrating proteins on the fluid and solve for the flow field using the standard Navier–Stokes equation.

The two terms on the right side of Eq. (1) represent the contributions from thermal diffusion and electric-field-induced migration, respectively. It is interesting to consider the limiting cases where one is much larger than the other. Neglecting the second term gives pure convective diffusion. One may approximate the flux to the surface by assuming steady shear flow and a perfect sink boundary condition at the adsorbing surface. In this case, the flux may be approximated by  $J(x, t) = Dc_b/\delta(x, t)$ , where  $c_b$  is the bulk protein concentration and

$$\delta(x, t) = \frac{(45Dx/2a)^{1/3}}{f\left(\frac{4Dt}{(45Dx/2a)^{2/3}}\right)} \quad (2)$$

is the convective diffusion boundary layer, a function of the diffusivity ( $D$ ), the distance along the surface in the direction of the flow ( $x$ ), the shear rate ( $a$ ), and the time ( $t$ ).<sup>[5,6]</sup> The function  $f(\tau)$  is the inverse of  $\tau(f) = [1 - (1 - f^3)^{2/3}]/2f^2$  for  $\tau < 1/2$  and  $f(\tau) = 1$  for  $\tau > 1/2$ . Pure convective diffusion is therefore characterized by an initially zero flux that increases steadily to a steady flux at dimensionless time,  $\tau$ , equals 1/2.

Neglecting the first term in Eq. (1) is equivalent to ignoring diffusive motion. In this case, assuming an electric field normal to the surface of magnitude  $E$ , fully developed shear flow, and a no-slip, perfect sink boundary condition, the concentration profile is given by

$$c(x, z, t) = c_b H\left(azt + \frac{aqEt^2}{2\zeta} - x\right) \quad (3)$$

where  $z$  is the height above the surface and  $H$  is the Heaviside function [i.e.,  $H(\xi) = 1$  for  $\xi > 0$  and  $H(\xi) = 0$  for  $\xi < 0$ ].<sup>[6]</sup> The flux to the surface is thus

$$J(x, t) = \frac{c_b q E}{\zeta} H\left(\frac{aqEt^2}{2\zeta x} - 1\right) \quad (4)$$

Pure electrophoretic migration is therefore characterized by an initial period of zero flux, during a time of  $\sqrt{2\zeta x/aqE}$ , followed by a steady flux.

In the absence of transport limitations, the rate of adsorption may be expressed as

$$\frac{d\Gamma}{dt} = k_a c_b \Phi - \sum_i k_{d,i} \Gamma_i \quad (5)$$

where  $\Gamma$  is the density of adsorbed protein (mass per area),  $k_a$  is the adsorption rate constant,  $\Phi$  is the one-body cavity function, and  $k_{d,i}$  and  $\Gamma_i$  are the desorption rate constant and the density of protein in the  $i$ th structural state, respectively (these states may denote various conformations, orientations, or states of aggregation).<sup>[7]</sup> The cavity function is defined as  $\Phi = \langle e^{-u/kT} \rangle_{\Gamma, T}$ , where  $u$  is the potential energy of a single molecule interacting with the surface and with all of the previously adsorbed molecules ( $u$  depends on position and orientation),  $k$  is the Boltzmann constant,  $T$  is the absolute temperature, and the brackets represent an averaged quantity, over all representations of the adsorbed layer at density  $\Gamma$  and temperature  $T$ , according to their appropriate weights, and over all orientations and positions of the single “reference” molecule. All of the quantities on the right of Eq. (5) (except  $c_b$ ) may be altered by application of an electric field.

To make quantitative predictions, the potential energy of interaction between protein molecules and the charged surface must be calculated. The electrostatic contribution to this energy may be determined using Poisson–Boltzmann<sup>[8–12]</sup> or density functional<sup>[13,14]</sup> approaches.

## EXPERIMENTAL METHODS

In this section, we review the experimental methods used to measure protein adsorption kinetics, in situ, under an applied electric field.

### Impedance Measurements

Impedance measurements involve the application of an alternating voltage across an electrode/solution interface.<sup>[15–17]</sup> The solution is modeled as a resistor and the interface as an impedor and a capacitor in series. The capacitance is simply the imaginary part of the measured impedance. Adsorbed molecules (e.g., organics and proteins) displace ions and solvent from the interface; this changes the charge distribution and thereby the interfacial capacitance. The capacitance is thus an indirect measure of the extent of adsorption and structure of the adsorbed layer.

## Reflectometry

Reflectometry involves measuring the reflection of polarized light at the interface between two optical media. In fact, two reflections are measured: one for the electric field component perpendicular to the plane of incidence (transverse electric or s-wave) and one for the electric field component parallel to the plane of incidence (transverse magnetic or p-wave). At a certain angle of incidence (the Brewster angle), the p-wave reflection vanishes and around this angle, the reflectivity, or square of the amplitude of the p-wave reflection, and ellipticity, or ratio of p- and s-wave reflections, become very sensitive to interfacial heterogeneity, as brought about, for example, by adsorption of biomolecules. By assuming the adsorbed layer to be uniform in refractive index, both its thickness and refractive index may be determined. By further assuming a linear dependence of refractive index on concentration, the adsorbed density is calculable. Silica is typically used as the adsorbing substrate; thus to apply an electric field, a conducting coating is needed. Bos et al.<sup>[18]</sup> have developed a reflectometry method using silica coated with a ca. 100-nm layer of indium tin oxide (ITO). An important caveat is that the intensity ratio changes in the presence of an applied voltage and this must be considered when calculating the amount of adsorbed protein.

## Quartz Crystal Microbalance

A quartz crystal microbalance (QCM) consists of a thin disk of (piezoelectric) crystalline quartz sandwiched between thin film metal electrodes. Upon application of an alternating voltage, the crystal undergoes thickness shear mode vibration. The mass adsorbed to the electrode surface, including the trapped solvent, is simply proportional to the frequency shift. In addition, the dissipation of energy following voltage removal, as measured by the decay of the oscillation amplitude, is a sensitive measure of the viscoelastic properties of an adsorbed layer. Khan and Wernet<sup>[19]</sup> have developed a QCM method in which a voltage is applied between an electroconductive polymer film-coated adsorbing surface and a counterelectrode.

## Optical Waveguide Lightmode Spectroscopy

Optical waveguide lightmode spectroscopy (OWLS) is based on the phase shift associated with multiple interfacial reflections: when either the s- or p-wave undergoes a total phase shift equal to an integral multiple of  $2\pi$  upon one complete traversal of a planar, dielectric waveguide sandwiched between media of lower refractive index, a standing wave is excited in

the waveguiding film. Because of their dependence on reflection, the phase shifts are sensitive to interfacial heterogeneity—and the thickness, refractive index, and density of an adsorbed biomolecular layer can be readily determined. Optical waveguide lightmode spectroscopy is normally applied to non-conductive substrates. To allow for detection in the presence of an electric field, Brusatori et al.<sup>[6,20]</sup> and Bearinger et al.<sup>[21]</sup> have developed OWLS methods employing an indium tin oxide coating.

## Total Internal Reflection Fluorescence

When light traversing an optically dense medium approaches an interface with a more optically rare medium at an angle exceeding a critical value of  $\theta_{\text{crit}} = \sin^{-1}(n_{\text{rare}}/n_{\text{dens}})$ , a total internal reflection occurs and an evanescent wave of exponentially decaying intensity penetrates the rarer medium. In total internal reflection fluorescence (TIRF) spectroscopy, the evanescent wave excites fluorescent probes attached to the biomolecules and detection of the emission associated with their decay provides information on the density, composition, and conformation of adsorbed molecules. Fraaije et al.<sup>[22]</sup> and Asanov et al.<sup>[23,24]</sup> have extended TIRF methods to measure protein adsorption under an applied electric field.

## RESULTS

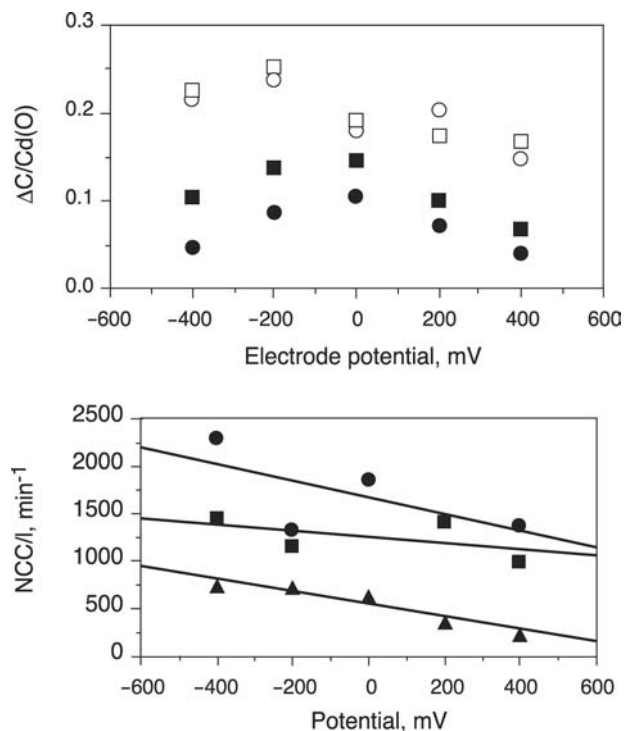

Bernabeu and Caprani<sup>[15]</sup> have measured the adsorption of fibrinogen and albumin to a carbon electrode using an impedance method. They observed the initial rate and the overall extent of adsorption of these two negatively charged proteins to decrease with increasing voltage, in apparent violation of electrostatic rules [Fig. 1](#). The authors explained this in terms of adsorbed counterions. On a platinum (i.e., more hydrophilic) surface, the rate and overall extent yielded minima at an intermediate electrode potential.

Feng and Andrade<sup>[16]</sup> have investigated the adsorption of several proteins on low-temperature isotropic carbon electrodes, also using an impedance method. They generally find the extent and initial rate of adsorption to decrease with increasing electrode potential, irrespective of protein charge and solution ionic strength [Fig. 2](#). In contrast, on a gold electrode, the extent and initial rate varied according to electrostatics. At higher pH, they did note a maximum in adsorbed amount at an intermediate potential—consistent with behavior of organics at metal surfaces—and surmised that similar behavior may hold at other pH values, provided a sufficiently large potential range. This non-monotonic behavior is explained by

**Fig. 1** (A) The characteristic time of adsorption and (B) the amount adsorbed at saturation in the initially adsorbed state (bottom line) and the conformationally altered state (upper line) vs. electrode potential for fibrinogen adsorbing to a carbon electrode as measured using an impedance method. *Source:* From Ref.<sup>[15]</sup>.

the hydrophobic effect: at a hydrophobic surface of near-zero charge, the contacting water is highly ordered and thus its displacement is highly favored entropically, whereas at a more charged hydrophobic

**Fig. 2** (A) Normalized capacitance change because of adsorption of 0.5 g/L human serum albumin (circles) and 0.1 g/L lysozyme (squares) from acidic (pH = 4.0, open) and basic (pH = 10.6, solid) solutions as functions of carbon electrode potential as measured by an impedance method. (B) Initial rates of normalized capacitance change for 0.50 g/L human serum albumin (circles), 0.05 g/L human plasma fibrinogen, 0.50 g/L superoxide dismutase, and 0.10 g/L lysozyme onto a carbon electrode as a function of electrode potential. The change in interfacial capacitance is a measure of the extent of surface coverage. *Source:* From Ref.<sup>[16]</sup>.

surface, the contacting water is less ordered and thus more difficult to displace by adsorbing molecules.

Fievet et al.<sup>[17]</sup> have also used impedance methods to measure protein adsorption onto a carbon electrode. They observed both the adsorbed amount and the initial adsorption rate to exhibit a maximum at an intermediate electrode potential and attributed this as well to a hydrophobic effect.

Bos et al.,<sup>[18]</sup> using reflectometry, observed a modest influence of an applied electric field on the adsorption of several proteins onto indium tin oxide under most conditions. Most observations followed electrostatic arguments, but an exception was lysozyme at pH = 9.9 Fig. 3, where a significant increase in adsorbed amount of this positively charged protein was observed at ITO potentials exceeding 300 mV (vs. Ag/AgCl). This was explained by a local pH effect: the  $\text{H}^+$  concentration decreased with increasing electrode potential, thereby causing the protein to become less positive (or even slightly negative).

**Fig. 3** The amount of lysozyme (open symbols) and ribonuclease (closed symbols) from a solution at  $\text{pH} = 9.9$ , following 15 min of exposure to an indium tin oxide surface, as a function of applied voltage as measured using reflectometry. *Source:* From Ref.<sup>[18]</sup>.

Khan and Wernet<sup>[19]</sup> used a quartz crystal microbalance to investigate the adsorption of glucose oxidase onto an electroconducting polyanion-doped polypyrrole film. Although the study focused on enzymatic activity following adsorption, of particular significance was the demonstration of a kinetic isotherm under an applied potential Fig. 4.

Fraaije et al.<sup>[22]</sup> have used total internal reflection fluorescence to investigate the voltage dependence of the amount and mean orientation of cytochrome *c* adsorbed onto tin oxide. The fluorescent intensity as a result of absorption of both the p-wave and the s-wave of the incident light was measured, and it was

**Fig. 4** The amount of glucose oxidase adsorbed to a sulfated poly  $\beta$  hydroxyether-doped polypyrrole film vs. time at an open circuit potential and under an applied potential difference of 0.4 V as measured using a quartz crystal microbalance. *Source:* From Ref.<sup>[19]</sup>.

determined that over a fairly significant voltage range (from 0 to 1 V vs. Ag/AgCl), little change in adsorbed amount or mean orientation occurs. In contrast, changing the pH or the surface coverage of the adsorbed protein resulted in changes in mean orientation angle  $7^\circ$  and  $4^\circ$ , respectively.

Asanov et al.<sup>[23]</sup> have used TIRF to measure the adsorption of bovine serum albumin onto tin oxide under an applied electric field. They find little effect on adsorption at anodic potentials (negative surface charge) but a significant increase in adsorption at increasingly cathodic potentials. This behavior again contradicts one's expectations based on electrostatics. However, it was noted that the adsorption behavior correlates strongly with the adsorbing substrate's water contact angle; thus it appears that hydrophobic forces are at play. These authors have also investigated the voltage-induced desorption of biospecifically bound species, with a goal of developing a regenerable biosensing platform.<sup>[24]</sup> Their findings are impressive: the rate and extent of desorption could be greatly enhanced by the application of an oscillating voltage Fig. 5. In particular, the desorption time constant was decreased from  $10^5$  sec in the absence of an applied potential to 300 sec in the presence of a square wave potential alternating from  $-0.7$  to  $+1.1$  V.

Brusatori et al.<sup>[6,20]</sup> have investigated the adsorption of albumin and cytochrome *c* onto ITO using OWLS. The raw data of a typical experiment appear in Fig. 6. Following a baseline measured under flowing solvent

**Fig. 5** The fluorescence detected (a measure of the adsorbed amount) from labeled antibiotin adsorbing onto a biotinylated indium tin oxide electrode. At the first arrow, the protein solution is replaced by a pure PBS buffer solution. At the second arrow, the open circuit potential is replaced by a saw tooth polarization from  $-0.7$  to  $+1.1$  V at  $0.1$  V/sec. At the third arrow, the potential is changed to a square wave polarization from  $-0.7$  to  $+1.1$  V at a time period of 5 sec. *Source:* From Ref.<sup>[24]</sup>.

**Fig. 6** The effective refractive index (a measure of the adsorbed amount from optical waveguide lightmode spectroscopy) and the current during cytochrome *c* adsorption from water onto indium tin oxide as a function of time. At point i, a voltage difference of 1.0 V is applied. At point ii, the protein solution is introduced. At point iii, the protein solution is replaced by a buffer solution. At point iv, the system is returned to an open circuit potential, and at point v, the 1.0-V voltage difference is reapplied. At point vi, the protein solution is reintroduced. *Source:* Taken from Ref.<sup>[6]</sup>.

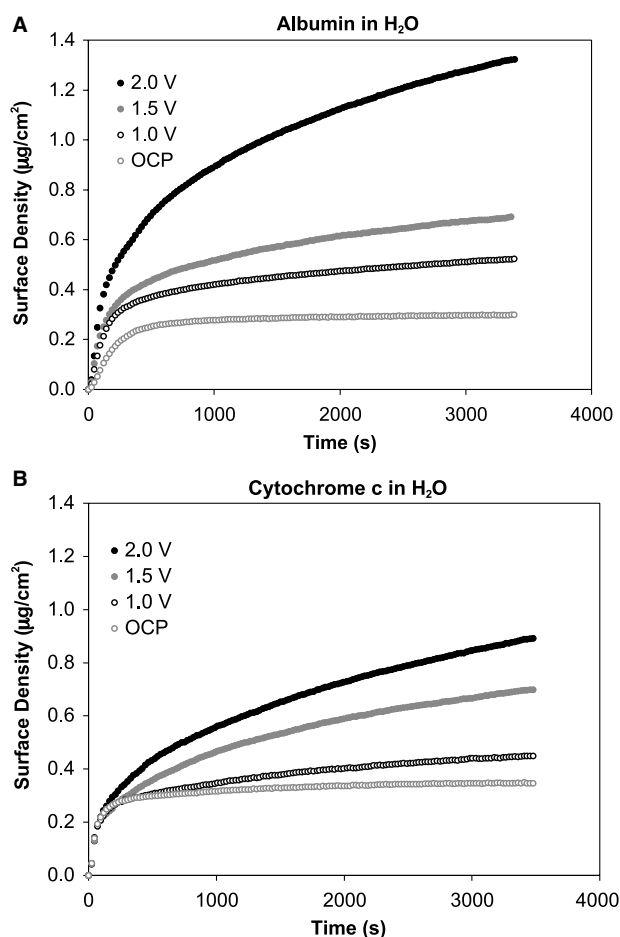

(deionized water in this case), application of an electric field (1.0 V over a 1.0-mm distance) between the adsorbing substrate and a platinum counterelectrode (i) yields an increase in the measured effective refractive index, the fundamental output signal of OWLS. This increase is not fully understood, but is likely a result of interfacial double-layer charging, to penetration of small ions into the ITO and/or the underlying silicon titanium oxide films (even in deionized water, carbonate and other ionic impurities are present), or to mild oxidation of the ITO. The current increases initially but then decreases, as would occur for a resistor and capacitor in series. Upon addition of cytochrome *c* in water (ii), the signal greatly increases because of optical changes at the interface brought about by adsorption. A return to the deionized water (iii) causes only a small signal reduction, indicating that only a small quantity of protein desorbs. When the electric field is removed (iv), a decreased signal results. However, this is not a result of further desorption as a reapplication of the field (v) returns the signal to its previous level. Finally, a reintroduction of the protein (vi) yields an additional signal increase. This additional adsorption is likely a result of an increased amount of area on the surface open for adsorption. The cause of this increased available area is likely aggregation among the adsorbed molecules.

The surface density vs. time for albumin and cytochrome *c*, in a water solvent, adsorbing to ITO under a range of applied voltage appears in Fig. 7. Clearly, adsorption is significantly enhanced under an applied electric field. In fact, at voltages exceeding 1.0 V, no true adsorption plateau is reached. If a rectangular array of adsorbed proteins is assumed, the saturated monolayer density would be  $0.46 \mu\text{g}/\text{cm}^2$ . Thus

multilayer adsorption is occurring, at least to some extent, in all but the open circuit potential curve of Fig. 7. In Fig. 8, the adsorption rate vs. adsorbed amount is shown. In all curves, an initial increase in adsorption rate is noted, reflecting transport limitations. The subsequent decrease in adsorption rate is a result of surface filling. Thus the initial surface limited kinetics of albumin increase significantly with applied voltage, while those of cytochrome *c* are not affected. At longer times, however, the rate of adsorption for cytochrome *c* also is increased by the presence of the electric field. The transport-limited adsorption rate vs. time (insets) shows that only albumin transport is directly influenced by the field, likely because of its greater overall (negative) charge. While solvent and local pH effects could be influencing these results, the major contributing factor is the preferential adsorption, under an applied field, at patches on the protein surface of complementary charge.

## PERSPECTIVES

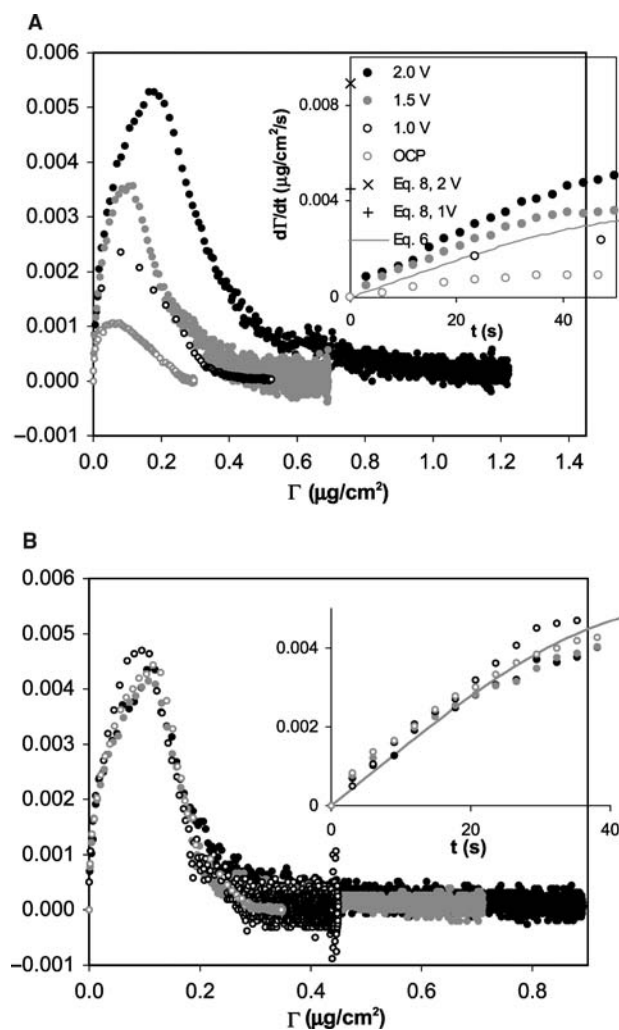

An applied electric field offers an opportunity to influence the structure and formation kinetics of an adsorbed protein layer. The literature now contains several examples of this.<sup>[6,15–20,22–24]</sup> However, it is striking the extent to which observed behavior deviates from that expected by basic electrostatics. There is little agreement on the cause of such behavior and therefore on the very nature of the electric field's influence on protein adsorption. Explanations put forth invoke surface-bound counterions, local pH effects, interfacial solvent structure, and protein charge heterogeneity. Below, we comment upon each of these effects.

**Fig. 7** The amount of (A) albumin and (B) cytochrome *c* from a water solution adsorbed to an indium tin oxide surface as a function of time for various applied voltages as measured by optical waveguide lightmode spectroscopy. *Source:* Taken from Ref.<sup>[6]</sup>.

### Surface-Bound Counterions

Could similarly charged surfaces be attracted to one another given the presence of a third, oppositely charged species? At first glance, this would seem unlikely because counterions would at most completely compensate the charge, leaving two neutral surfaces. The classic Poisson–Boltzmann approach, in which solvated electrolytic species are assumed uncorrelated, predicts only repulsion between like charged objects in an electrolytic solution. However, there are examples where charge overcompensation may occur. A spectacular recent example of this is the layer-by-layer method of growing thin films by exposing a substrate alternatively to solutions of polyanions and polycations.<sup>[25]</sup> Although not fully understood theoretically, the idea is that charged sites on the polyions exchange nearly completely with smaller ions at the surface for entropic reasons. However, in addition to sites contacting

**Fig. 8** The rate of adsorption vs. amount adsorbed for (A) albumin and (B) cytochrome *c* from water onto indium tin oxide as a function of adsorbed amount (and, in the insets, as a function of time) for various applied voltages as measured by optical waveguide lightmode spectroscopy. *Source:* Taken from Ref.<sup>[6]</sup>.

the surface, the polyions generally contain additional charged sites that extend away from the surface, thus resulting in a charge overcompensation. However, this type of charge overcompensation would not be expected from the relatively small ionic species present in most protein adsorption systems.

### Local pH Effects

Proteins are amphoteric, i.e., possess a number of acid/base sites whose charge is pH-dependent. Because a positively (negatively) charged surface will repel solvated protons (hydroxide ions) and thus raise (lower) the pH near to the surface, the sign of a protein's

overall change could change upon approach to the surface. In this case, attraction that is indeed electrostatic in origin may follow. Could this effect explain the antielectrostatic behavior reported in the literature? Evidence to suggest otherwise lies in the following observation: the degree of buffering has been shown to have little effect on these antielectrostatic adsorption trends.<sup>[20]</sup>

### Solvent Interfacial Structure

Solvent molecules (typically water) at or near a solid substrate often experience a hindered rotation relative to those far from the interfacial region. If liberated from the surface via, for example, displacement by an adsorbed protein, a net entropy gain results. An estimation of the rotational contribution to the entropy is given by the statistical mechanical result for an ideal gas rigid rotor,  $S_{\text{rot}} = Nk \ln q_{\text{rot}}$ , where  $N$  is the number of molecules,  $k$  is the Boltzmann constant, and  $q_{\text{rot}}$  is the rotational partition function. For water at 300 K,  $q_{\text{rot}} \approx 30$ , so the contribution per mole of water liberated from the surface is about 28 J/K mol. An average-sized protein might result in the liberation of 50 water molecules, so the contribution to the overall free energy of adsorption at 300 K from the solvent rotation would be about  $-420$  kJ/mol. Of course, this is an upper bound because the molecules at the surface do possess some rotational freedom. This estimate would most accurately apply to water at a neutral, hydrophobic surface, where the molecules are expected to be very ordered. As the magnitude of surface charge is increased, the water becomes more disordered, i.e., may experience enhanced rotation, and the free energy gain from its liberation is thus diminished. As several of the above-mentioned studies show trends consistent with these thoughts, the role of solvent structure in the overall influence of an applied electric field cannot be discounted.

### Protein Charge Heterogeneity

Based on electrostatics, can a positively (negatively) charged protein be attracted to a positively (negatively) charged surface? Within the Poisson–Boltzmann approach, the answer is yes, according to Asthagiri and Lenhoff,<sup>[10]</sup> so long as both protein and surface contain charge heterogeneity. The idea is that regions of complementary charge may come into close contact, while overall repulsion is sufficiently screened by counterions so that a net attraction occurs. Brusatori, Tie, and Van Tassel invoke this reasoning to explain the increase in adsorption observed for positively charged cytochrome *c* with increasing adsorbent potential.<sup>[6]</sup>

### CONCLUSION

An applied electric field offers the possibility of controlling the structure of an adsorbed protein layer. This represents a powerful method of producing nanostructured coatings for biosensing and biomaterials applications. Only in the past few years have techniques become available to measure the adsorbed layer properties in situ during formation. While it remains to fully resolve a number of puzzling observations—and while quantitative prediction of the effects of the electric field, such as counterion binding, local pH enhancement, solvent structure, and charge heterogeneity, remains sparse—the prospects are strong for a general understanding, in the not-to-distant future, of the influence of an electric field on protein adsorption, and the engineering of protein coatings to near-exact specifications using voltage-based methods is certainly a realistic and laudable goal.

# Protein Nanotubes as Building Blocks

Hiroshi Matsui

Department of Chemistry, Hunter College, City University of New York,  
New York, New York, U.S.A.

## INTRODUCTION

Nanometer scale self-assemblies of biological molecules, such as protein nanotubes, play important roles in nature to regulate biological activities. It is a natural progress to synthesize protein nanotubes in order to mimic those biological functions and apply for medical applications such as drug delivery and medical imaging. Although it appears to be unlikely, peptide nanotubes are also applied to non-biological fields such as electronics, sensors, catalysis, and optics because those smart, selective peptide functions can be applied in various device fabrication processes. Those new types of building blocks with smart biological functions may offer more economical, reproducible, accurate, and simpler methods in device fabrications. In this entry, various examples of natural and synthetic protein nanotubes and their functionalizations for particular applications are discussed.<sup>[1–32]</sup>

## OVERVIEW

Protein nanotubes are tubular assemblies of proteins. The production of protein nanotubes can be synthetic or natural. They are generally produced via their direct self-assemblies into tubular structures<sup>[33]</sup> or their self-assemblies on template nanotubes.<sup>[34–37]</sup> While the direct nanotube assemblies from protein monomers without templates are normally achieved in vitro,<sup>[38,39]</sup> there are some examples that protein nanotubes are self-assembled in solutions in the presence of divalent metal ions.<sup>[40]</sup> With the aid of surfactants, some proteins were also demonstrated to be assembled as a tubular form.<sup>[41]</sup> Molecular self-assembly is robust and reproducible under the controlled experimental conditions.<sup>[42,43]</sup> For example, protein nanotubes are grown in solution via self-assembly with high reproducibility and monodispersity.<sup>[40]</sup> Thermodynamics controls chemical structures and dimensions of self-assembled nanotubes<sup>[44]</sup> and it can be determined by external experimental conditions such as pH, temperature, solvents, and pressure.<sup>[45]</sup> Protein nanotubes such as virus, phages, and microtubules are also produced via natural self-assembly with high reproducibility and monodispersity inside cells. The chemical structures of natural protein nanotubes can be modified

via mutations, which gives flexibility to design protein nanotubes.<sup>[46]</sup> Therefore the use of self-assemblies either synthetically or naturally has an advantage to mass-produce monodisperse and chemically identical nanotubes. Because protein nanotubes are water-soluble, it makes their size separation easier if necessary.

While the self-assembly nature offers some interesting features in protein nanotubes, they may not display useful physical properties as shown in metal and semiconductor nanowires for particular devices such as electronics and sensors. Then what makes protein nanotubes special compared with other inorganic nanotubes/nanowires? I believe that features of protein nanotubes distinguished from other nanotubes are their flexibility in the functionality and their molecular recognition. All proteins have some functions and those functions can be used to introduce new properties into protein nanotubes, desired for particular building blocks in specific nanodevices. For example, proteins can mineralize various metals and semiconductors selectively via their molecular recognition and biomineralization, which are routinely operated in living systems.<sup>[47,48]</sup> Positioning of protein nanotubes can be achieved through biological recognitions of proteins toward their complementary ligands.

In this entry, I would like to categorize the features of protein nanotubes into four characteristic functions: 1) coating, 2) arrangement, 3) sensing, and 4) mechanical motion. In the coating section, biomineralization of protein nanotubes is discussed. In the placement section, organization and location-specific immobilization of protein nanotubes are explained via biological recognitions such as inorganic-protein and protein-protein interactions. Physical property changes of protein nanotubes via biological recognition-induced adsorption of target molecules can be used for their detections and quantitative analysis, as explained in the “Sensing” section. In the “Mechanical motion” section, motor functions of protein nanotubes by converting chemical energy into mechanical force are summarized.

## COATING

To apply protein nanotubes as building blocks for various nanodevices, functionalizations of protein nanotubes via coatings are very effective. Choices of

proteins are dependent upon what types of materials to be coated. Tobacco mosaic virus (TMV) was used to mineralize CdS, PbS, silica, and iron oxides on the outer surfaces of TMV.<sup>[49,50]</sup> Tobacco mosaic virus, a hollow protein nanotube, is a stable virion with 18 nm in diameter and 300 nm in length, self-assembled from the protein monomers. The repeated protein subunits on the nanotubes offer the nucleation sites to produce highly crystalline semiconductor coatings. Figure 1A shows CdS nanotubes fabricated by exposing a buffered suspension of TMV in 10 mM CdCl<sub>2</sub> to H<sub>2</sub>S gas for up to 6 hr. High-resolution transmission electron micrograph (HRTEM) of the CdS nanotubes in Fig. 1B indicates that the CdS coating consists of aggregates of crystalline CdS nanoparticles with 5 nm in diameter, whose fringe space matches a (111) lattice plane of the zinc-blende structure. Modified TMV nanotubes at the C-terminus via a single site mutation were also synthesized as template nanotubes to

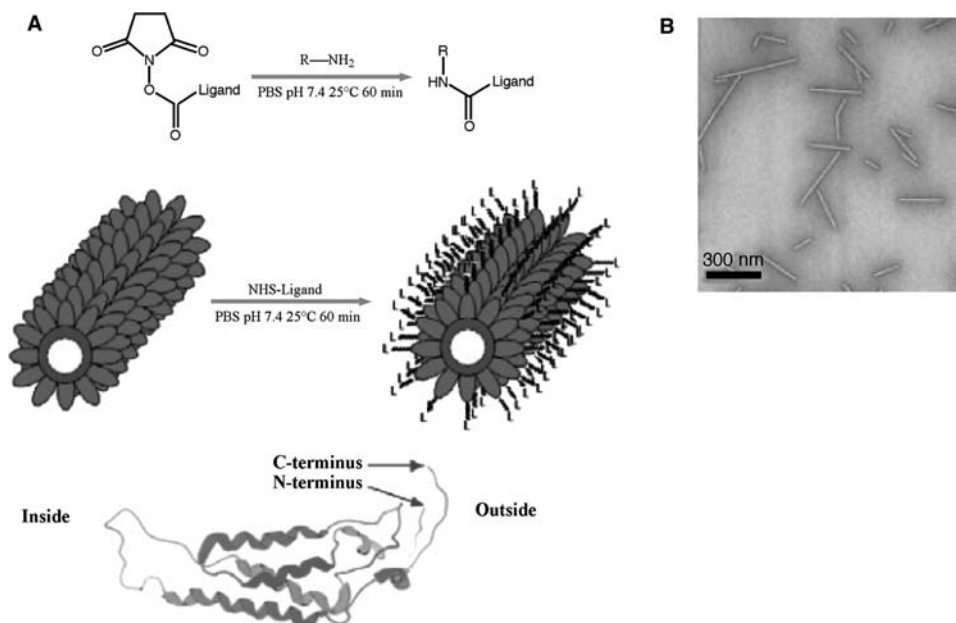

**Fig. 1** TEM images of (A) CdS-coated TMV nanotubes, scale bar=50 nm, inset: corresponding EDX spectrum (Ni and Cu peaks arise from TEM grid and sample holder). (B) CdS nanocrystals (white arrows) on the TMV nanotube in high magnification, scale bar = 10 nm. Source: From Ref.<sup>[49]</sup>. © (1999) Wiley-VCH Verlag GmbH.

improve their selectable chemospecificity.<sup>[46]</sup> The modified TMV nanotubes have lysine units on the outer surfaces of the nanotubes and these sites can be used to immobilize functional molecules via *N*-hydroxy succinamide chemistry (Fig. 2). This mutant TMV nanotube functionalized with fluorophor selectively mineralized Cu via photoreduction of Cu ions. Another example of biomineralization of protein nanotubes is to produce magnetic nanofibers by using rod-shaped bacterium as templates.<sup>[51]</sup> A single *bacillus subtilis* bacterium is an organism with cells of approximately 0.7 μm in diameter and up to 4 μm in length. Two types of iron oxide nanoparticles, magnetite (Fe<sub>3</sub>O<sub>4</sub>) and maghaemite (γ-Fe<sub>2</sub>O<sub>3</sub>), were mineralized on the bacterial threads. The magnetization data showed that the magnetic field-dependent switching behavior was markedly sharp when single domains of iron oxide nanoparticles were aligned to the easy axes of the nanotubes. This alignment was achieved when the magnetic nanotube synthesis was conducted within an external magnetic field.

Microtubules, self-assembled from cytoskeletal proteins in vitro, were used as template nanotubes to coat Pd.<sup>[38]</sup> The subunits of purified porcine brain tubulin were cross-linked by glutaric dialdehyde and this process yielded stabilized microtubules, whose diameter is 4–5 nm and length is about 8 μm. This resulting microtubule remained intact up to 90°C for approximately 1 hr in the pH range from 4 to 9. The improved microtubule mineralized Pd with trisodium citrate or dimethylamine borane at 90°C. The trisodium citrate produced smaller Pd nanocrystals with a mean diameter of 1.9 nm and the dimethylamine borane produced larger Pd nanocrystals with a mean diameter of 3.1 nm (Fig. 3A). HRTEM micrograph of the highly monodisperse Pd nanocrystals on the nanotubes imaged the (111) plane of a pure metallic Pd phase (Fig. 3B). Pd nanocrystals were found to grow on both α- and β-tubulin subunits of the protein nanotubes and the histidine residues likely serve as nucleation sites for the Pd biomineralization on the nanotubes.

Improved metal nanocrystal coatings were demonstrated on the biological nanotubes incorporating sequenced peptides that can mineralize specific metals via biological recognitions.<sup>[52]</sup> This sequence consisting of histidine and alanine residues not only produced monodisperse Au nanocrystals on the nanotube surfaces but also controlled the density and the size of nanocrystals by tuning the sequenced peptide conformations (Fig. 4).<sup>[53]</sup> The histidine residue captured Au ions (ClAuPMe<sub>3</sub>) and the reduction of those trapped Au ions led to monodisperse nanocrystal formation with an average diameter of 5 nm on the nanotubes. The change in experimental conditions such as pHs and ion concentrations in the nanocrystal growth solution induced the ion-peptide conformation change

**Fig. 2** (A) The upper panel: the facile NHS chemical reaction; the middle panel: the structure of TMV nanotube and a schematic to introduce ligands on the TMV nanotube surface via the NHS chemistry; the lower panel: the structure of the protein monomer for the TMV nanotube and the relative positions of the monomer in the TMV nanotube. and this structural transformation controlled the size and the distribution of Au nanocrystals on the nanotubes. It should be noted that metallic nanocrystals with a diameter below 6 nm are in the size domain to observe significant conductivity change by changing the packing density.<sup>[54]</sup> Therefore this system may be useful as a conductivity-tunable building block by controlling the nanocrystal size and the distribution.

## ARRANGEMENT

There are several techniques to align nanotubes by using electronic fields, magnetic fields, microfluidics,

and hydrophobic interactions.<sup>[26–30]</sup> But when multiple types of nanotubes are necessary to be aligned respectively in more complex device configurations, the above methods may not be sufficient. For example, consider fabricating a nanodevice whose configuration has two nanotubes crossing perpendicular to each other (Fig. 5). In this configuration, when one nanotube is coated by a metal and the other nanotube is coated by a semiconductor, this nanodevice will function as a switch in memory circuits for reading and writing information.<sup>[6,55]</sup> Whereas these device elements can be switched between well-defined on-and-off states by transiently charging the coated nanotubes to produce

attractive and repulsive electrostatic forces,<sup>[55]</sup> aligning two or more types of nanotubes in desired directions precisely is not an easy task by the techniques described above.

By functionalizing circuit elements and connecting wires with biomolecular recognition of complementary connecting units while in solution, we can mimic biological systems, in which organic/inorganic nanoscale building blocks are routinely and precisely turned into complex structures for biological function with almost perfect reproducibility. In theory, protein nanotubes, which can recognize and selectively bind a well-defined region on complementary protein-patterned substrates, can be used as building blocks to assemble three-dimensional nanoscale architectures by placing them at the uniquely defined positions. As shown in Fig. 5, an antigen 1 nanotube can be aligned on antibody 1 areas while an antigen 2 nanotube recognizes and immobilizes on antibody 2 surfaces. Therefore the immobilization of protein nanotubes onto the antibody self-assembled monolayers (SAMs) will be “programmed” (i.e., protein nanotubes recognize binding sites and attach automatically) in aqueous solution without any complicated multistep fabrication procedures. To demonstrate the feasibility of this scheme, the streptavidin-coated nanotubes were dispersed on

biotin-incorporated SAMs in solution, and their selective immobilization onto the biotin-incorporated SAMs was observed after 1 day (Fig. 6).<sup>[56]</sup> Protein-functionalized nanotubes were positioned to interconnect patterned complementary protein-SAM/Au surfaces via protein-protein interactions; however, uniform coverage of proteins on template nanotubes also caused the nanotube aggregations on the complementary protein-SAM surfaces.<sup>[56]</sup> One solution to produce the nanotube-bridge configurations with minimum nanotube aggregations could be selective protein immobilization at the ends of nanotubes. We recently demonstrate that this location-specific protein immobilization on nanotubes was established by using Au nanocrystal masks.<sup>[57]</sup> As a proof-of-principle, avidin was used to be immobilized only at the ends of peptide nanotubes with the nanotube end-fabrication method, as outlined in Fig. 7. The approach involves thiolation of the nanotube sidewalls [step (i)] and Au nanocrystal coating to mask the sidewalls of nanotubes [step (ii)], followed by incubating nanotubes with sulforhodamine-labeled avidin [step (iii)]. After avidin molecules were immobilized at the ends (with no Au nanocrystals) and the sidewalls (with Au nanocrystals) of the nanotubes, the Au nanocrystals on the sidewalls were chemically etched and the proteins at the ends remained attached

**Fig. 5** Illustration of proposed scheme to assemble multiple protein nanotubes into device configurations via biological recognitions between the protein nanotubes and the complementary protein-patterned surfaces.

**Fig. 6** Illustration and SEM image of a streptavidin-functionalized nanotube immobilized onto the complimentary biotin SAMs/Au substrates. *Source:* From Ref.<sup>[56]</sup>.

without denaturing [step (iv)]. The chemical etching of the Au nanocrystal masks on the sidewalls of nanotubes removed avidin molecules from the sidewalls; however, avidin molecules at the nanotube ends remained bound.<sup>[57]</sup> After sulforhodamine-labeled avidin was incubated into the Au nanocrystal-masked nanotube solution for 36 hr [step (iii) in Fig. 7], the protein was immobilized on the entire nanotube surface shown by fluorescence micrograph of the resulting nanotube (Fig. 8A). This fluorescence image was dramatically changed after the Au nanocrystals on the nanotube sidewall were etched by iodine in step (iv). After etching the Au nanocrystals from the nanotube surface, fluorescing areas of the sulforhodamine-labeled avidin were limited to the ends of the

nanotube and fluorescence at the nanotube sidewall was diminished, as shown in Fig. 8B. These fluorescence micrographs confirm that the protein remained bound to the peptide nanotube ends after the chemical Au nanocrystal etching. This chemical etching process did not denature the avidin on the nanotubes and the nanotube ends could still recognize the complementary biotin after the etching process.<sup>[57]</sup> This result is particularly important to this proposed research because denaturing proteins at the nanotube ends via the chemical etching process could prevent the use of this protein nanotube as building blocks for nanodevices due to the loss of the biological recognition function. Our preliminary result indicates that these end-functionalized nanotubes reduced the nanotube aggregation about five times on

**Fig. 7** Procedure to immobilize proteins at the ends of nanotubes using Au nanocrystals as protective masks. *Source:* From Ref.<sup>[57]</sup>.

the biotin-SAMs compared to the nanotubes whose entire surfaces were coated by avidin.<sup>[57]</sup>

The location-specific assembly of protein nanotubes was also achieved via biological recognitions between inorganic surfaces and phages.<sup>[58]</sup> Phages and natural protein nanotubes with 6.6 nm in diameter and approximately 880 nm in length (Fig. 9A) can be modified to have specific peptide sequences on the surfaces to recognize and bind specific inorganic surface after multiple cycles of the peptide selection processes. To identify appropriate peptide sequences of phages to recognize specific inorganic surfaces, Whaley and coworkers used a combinatorial library of genetically engineered bacteriophage.<sup>[58]</sup> For example, this peptide combinatory approach identified proteins that specifically bind GaAs (100) and they were self-assembled on the patterned GaAs surfaces (Fig. 10).<sup>[59]</sup> The specificity of binding exerted the level over the recognition of crystal orientations.

**Fig. 9** (A) Illustration of phage and ZnS nanocrystals (the PIII peptide unit and the ZnS nanocrystal bound to the phage are not drawn in scale). (B) TEM image of an individual phage and ZnS nanocrystals. (C) HRTEM image of 0.01% phage-ZnS suspension, showing lattice fringe images of ZnS nanocrystals. **Fig. 10** Fluorescence image of tetramethyl rhodamine-labeled phages selectively assembled on the patterned (100) GaAs surfaces. The red lines (1 μm across) correspond to GaAs and the black spaces (4 μm across) are SiO<sub>2</sub>. *Source:* From Ref.<sup>[59]</sup>. © (2002) National Academy of Science, U.S.A.

Those genetically engineered bacteriophage-nanocrystal complexes can also be arranged into ordered films.<sup>[60]</sup> For example, when phages were engineered to recognize ZnS, they mineralized highly crystalline ZnS nanocrystals at the end of the tubules in ZnCl<sub>2</sub>/Na<sub>2</sub>S solutions (Fig. 9B,C). Under the optimized experimental conditions, those phages with ZnS nanocrystals were spontaneously assembled into self-supporting hybrid films whose order structures were maintained over a centimeter-length scale (Fig. 9D). These films showed the liquid crystalline phase behaviors and they could be modulated by solvent concentrations and an external magnetic field.<sup>[60]</sup> The monodispersity of the genetically engineered phages and the ease in incorporating and aligning various types of inorganic nanocrystals by molecular cloning techniques and genetic selections are advantageous to apply the protein nanotube-based materials in the field of liquid crystals.

## SENSING

As pointed out above, one of the key functions of proteins is to recognize specific molecules and ions. The molecular recognitions of proteins are dependent on the shapes of target molecules because multiple hydrogen bonds, electrostatic interactions, and hydrophobic interactions between target molecules and proteins in a well-defined spatial pattern provide the excellent selectivity of protein bindings.<sup>[61]</sup> Therefore it is natural to apply the molecular recognition of protein nanotubes to sense and diagnose target molecules.

A planar field effect transistor (FET) has been used mostly as a nanotube-based sensor configuration. Modification of the gate oxide in the carbon nanotube-based FET allowed monitoring a conductance change due to the adsorption of analytes.<sup>[62]</sup> The practical aspect of the FET is that the FET can serve as a highly sensitive real-time electrically based sensor. The sensitivity of carbon nanotube-based FET sensors was in the regime of single-molecule detection.<sup>[62]</sup>

Cui and coworkers assembled antigen nanowires, antigen-coated silicon nanowires, as building blocks into the FET sensors.<sup>[63]</sup> The single-crystal boron-doped (p-type) silicon nanowires, prepared by a nanocluster-mediated vapor-liquid-solid growth method,<sup>[64]</sup> were aligned by a microfluidic technique between two electrodes, a source and a drain (Fig. 11).<sup>[29]</sup> The reversible, real-time antigen-nanowire sensor was fabricated by functionalizing the silicon nanowire template with biotin via the drop deposition, and this sensor system could detect conductivity changes under m-antibiotin adsorption on the functionalized nanowires.<sup>[63]</sup> A linear change in the nanowire conductance as a function of m-antibiotin concentration was observed as shown in

**Fig. 11** Plot of the conductance change of a biotin-modified Si nanowire vs. m-antibiotin concentration. (Inset) SEM image of a typical FET configuration: a Si nanowire connecting two electrodes, a source and a drain. *Source:* From Ref.<sup>[63]</sup>. © (2001) American Association for the Advancement of Science.

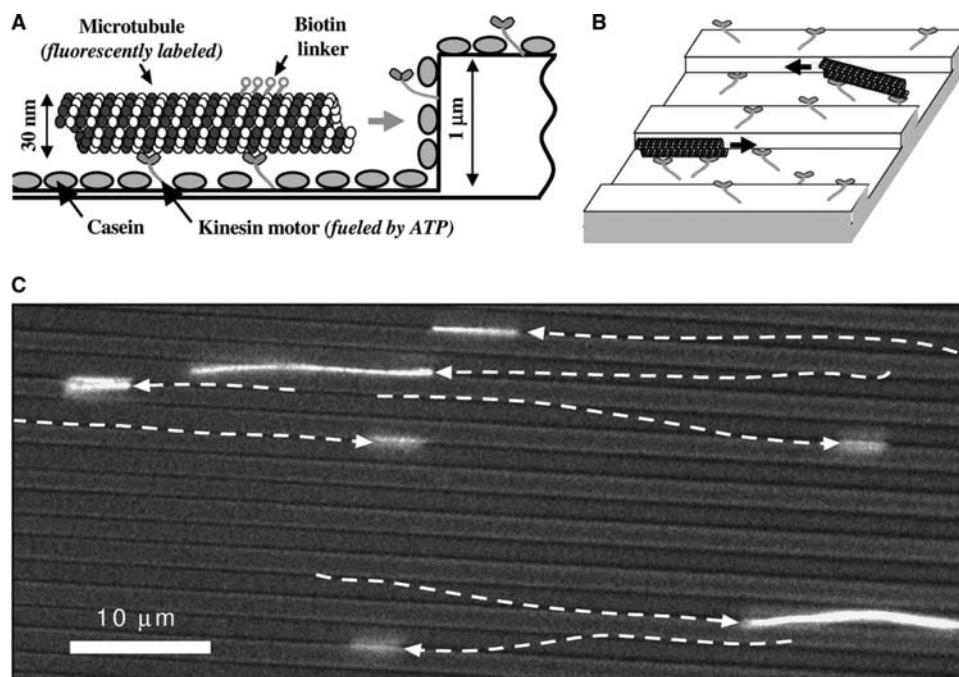

Fig. 11. The correlation between linear current ( $I$ ) vs. voltage ( $V$ ) was transformed to the conductance ( $dI/dV$ ). The detection of m-antibiotin in this sensor system was achieved below 10 nM, while the detection limit for streptavidin could reach in the order of pM.<sup>[63]</sup>

## MECHANICAL MOTION

There have been major attempts to synthesize chemically powered nanoscale engines driven by light or chemical energy.<sup>[65,66]</sup> The weaknesses of the synthetic nanoscale motors are as follows: 1) they often stall when operated under load; and 2) they have a low cycle time.<sup>[61]</sup> In contrast, motor proteins are better engines at this point as the man-made motors are fueled by electrical or thermal energy with an efficiency of around 30% while protein motors are driven by direct conversion from chemical energy with an efficiency as high as 90%.<sup>[67]</sup> Therefore motor proteins have been studied extensively not only to understand the mechanism for their mechanical motions regulating cell activities but also to fabricate high-performance nanoscale engines. There are two types of well-studied protein motors, translational motors and rotary motors. Translation protein motors transport on the complimentary protein nanotubes. While development of rotary protein-based nanodevices has also been very active,<sup>[68]</sup> rotary protein motors are not discussed in this entry.

Conformational changes of motor proteins produce mechanical forces and motions fueled by the interconversion of chemical energy.<sup>[69]</sup> Translational motor proteins move along their complementary nanotubes via the energy conversion. Microtubules, protein nanotubes in diameter of 25 nm, are tracks to guide a translational motor protein, kinesin. Kinesins transport vesicles, chromosomes, and protein complexes using these tracks throughout the intracellular environment.<sup>[70]</sup> For example, kinesins transfer encapsulated neurotransmitters from cores of nerve cells to synaptic clefts in order to excite next nerve cells.<sup>[61]</sup>

Kinesins are elongated heterotetrameric proteins and contain adenosine triphosphate (ATP) and microtubule binding sites.<sup>[30]</sup> The side-by-side motor domains alternately bind and release the tubulin subunits of a microtubule,  $\alpha$ - and  $\beta$ -tubulins, in a walking type of motion.<sup>[71]</sup> The walking motion is fueled by the hydrolysis of ATP from adenosine diphosphate (ADP), initiated by a proton gradient across a cell membrane. The kinetically more dynamic end of the microtubule is terminated with the  $\beta$ -tubulin (black circles in Fig. 12A) whose relative polarity is positive, whereas the opposite end is terminated with  $\alpha$ -tubulin (white circles in Fig. 12A) whose relative polarity is negative. The overall structural polarity of microtubules is recognized by motor proteins, which determine the

**Fig. 12** (A) Illustration of the microtubule transport on kinesin motor surfaces. (B) Illustration of a typical geometry of the kinesin motor track. (C) Micrograph of photolabeled microtubules moving in channels ( $2\ \mu\text{m}$  wide) on a patterned polyurethane substrate. The dotted lines are the paths of individual microtubules. *Source:* From Ref.<sup>[61]</sup>. © (2002) the Materials Research Society.

direction of their motion along the microtubule surface as kinesin steps only toward the plus end.<sup>[72]</sup> Myosins are another family of translational protein motors that move along actin nanotubes for cell motility and muscle contraction.<sup>[61]</sup>

While there have been extensive effort to manipulate this molecular transport machinery outside cells and fabricate as moving building blocks of nanodevices driven by kinesin/myosin motor proteins,<sup>[71]</sup> their applications require to overcome technical problems such as the orientation of force generation toward the desired direction, the optimization of surface conditions and geometries, and the stability of the motor protein–protein nanotube systems.<sup>[73]</sup>

Motor protein–protein nanotube integrated systems have been fabricated in two configurations: 1) moving motor proteins on protein nanotube tracks; and 2) moving protein nanotubes on motor protein-patterned surfaces. The first configuration is analogous to the geometry found in cells.<sup>[70]</sup> When kinesins and microtubules were integrated to develop nanodevices, the majority of effort has been focused on positioning and alignment of microtubules.<sup>[30,70,71,73]</sup> The microtubules must be aligned precisely in order to transport cargoes attached to motor proteins toward the proper destinations. For example, Limberis and Stewart transported silicon microchips with genetically engineered kinesin motors to particular locations guided by patterned microtubules on substrates.<sup>[71]</sup>

The second configuration is the inversed geometry used in nature. Various surface topologies with lithographically fabricated ridges and valleys were examined as motor protein tracks to guide protein nanotubes inside the ridges or valleys (Fig. 12B). The difficulty in this scheme is that microtubules tend to escape from the valleys by binding the sidewalls of valleys, slowly climb up, and then move toward different directions.<sup>[74]</sup> This escaping motion of microtubules on a kinesin-coated polyurethane surface patterned with  $2\text{-}\mu\text{m}$ -wide and  $1\text{-}\mu\text{m}$ -deep channels is shown in Fig. 12C. In this figure, the bottom of the channels is in focus and the plateaus in between are out of focus. Some microtubules were staying in the channels but most of them moved up and down in the grooves.<sup>[74]</sup> The patterned myosin surfaces were shown to direct the actin nanotube movement in one direction more effectively.<sup>[75]</sup> Recently, the myosin gel substrate also appeared to regulate the movement of the cross-linked actin nanofibers in one direction (Fig. 13).<sup>[67]</sup> The optimal solution to engineer motor protein/protein nanotube tracks seems to be an optimized combination of chemical and topological track patterns,<sup>[74]</sup> and the myosin/actin system may be chemically favorable to reduce the nanotube sliding motions.

Those motor protein/protein nanotube systems have potential to be applied in the fields of mechanical engineering, biomedical engineering, and electronics. Coupling motors/nanotubes with gears or rotors

**Fig. 13** (A) Sequential fluorescence images of the cross-linked actin gel movement on the oriented myosin gels. (B) Illustration of the actin gel movement on the myosin gels. *Source:* From Ref.<sup>[67]</sup>. © (2002) Wiley-VCH Verlag GmbH.

may be used as switches or valves in microfluidic channels.<sup>[70]</sup> It is encouraging that recently motion of microtubules can be turned on and off sequentially on patterned motor protein substrates triggered by UV-induced release of caged ATP via the enzymatic ATP degradation, which is a crucial feature to develop the switches and the valves.<sup>[74]</sup> Motor protein-based microgenerators, pumps, and biosensors can be applied in medical implants.<sup>[71]</sup> For example, the motor protein-based microgenerators can power implanted microdevices for monitoring physiological processes because the mechanochemical energy of motor proteins is transduced to an electrical current. In any applications described above, alignments and chemical controls of protein nanotubes will be crucial to develop nanodevices from these smart components.

## CONCLUSION

Protein nanotubes have distinguished characters compared with other nanotubes. Obviously, protein-assembled nanotubes are biocompatible and broad biological applications can be expected. Molecular recognition is another unique function in protein nanotubes. The molecular recognition, such as an antibody–antigen recognition, images the complementarity of a lock and a key—the lock being antibody and the key being antigen that is recognized via the spatial fit and non-covalent interactions to form the specific antibody–antigen complex. This specificity will make protein nanotubes smart building blocks for high-performance chemical sensors. When multiple antibodies are patterned wisely on surfaces, resulting device configurations, after antigen–nanotubes recognize and position onto their complementary regions, will be achieved via their robust self-assembling processes. This approach may build certain device configurations in an economical and simple manner. Coupling between protein nanotubes and motor proteins certainly offers intriguing potential to build nanodevices powered by converting chemical energy into mechanical force. When physical properties of protein nanotubes are not suitable to certain applications, protein nanotubes can be functionalized to add the desired physical properties. For example, if conductive nanotubes need to be placed at a certain position, protein nanotubes can be coated with

conductive metals via biomineralization after protein nanotubes are positioned at the desired position via molecular recognitions. To date, fabrication of protein nanotubes and organization of protein nanotubes have been investigated, respectively. Applications of protein nanotubes as building blocks in real-world nanodevices will be accelerated once those two outcomes are integrated.

Of course, this field is still extremely young and there are many concerns and hurdles to overcome. For example, proteins typically lose their functions within days or weeks unless they are frozen.<sup>[61]</sup> They degrade by various and often competing mechanisms, including thermal and enzymatic degradation as well as precipitation. For the applications in the coating and the arrangement of nanotubes, proteins need to be active during the nanotube assembly, which is normally achieved in a short time because of robust self-assembly. Therefore the protein degradation may not be a crucial issue for these applications. But when protein nanotubes are applied to the devices necessary to transform one structure to the other repeatedly or to detect target molecules over and over again, proteins must be evolved to survive under harsh environmental conditions.<sup>[76,77]</sup>

Various difficulties in applying protein nanotubes as building blocks of nanodevices will be overcome if we keep learning from nature. There are many natural protein nanotubes/nanofibers whose excellent properties are known, but their chemical structures remain unsolved. For example, a tensile strength of spider dragline silk is comparable with steel and its elasticity is comparable with rubber.<sup>[78]</sup> This unique combination makes the spider dragline silk mechanically superior to any other man-made materials. But it was just recently that the protein sequences and structures of the spider dragline silk were understood.<sup>[78]</sup> Progress in understanding unsolved natural protein nanotubes and mimicking those nanotubes will make protein nanotubes more attractive to apply them as building blocks for various nanometer-scaled devices.

## ACKNOWLEDGMENT

I would like to thank my co-workers for the past four years for their hard work in the development of protein nanotubes and their applications: S. Pan,

G.E. Douberly, P. Porrata, Yung-fou Chen, Lingtao Yu, Ramin Djalali, and Ipsita Banerjee. I also would like to acknowledge the financial supports from the National Science Foundation CAREER Award (EIA-0133493), the National Science Foundation NER program (ECS-0103430), and the U.S. Department of Energy (DE-FG-02-01ER45935).

# Proteins: Structure and Interaction Patterns to Solid Surfaces

Thomas J. Webster

Department of Biomedical Engineering, Purdue University, West Lafayette, Indiana, U.S.A.

## INTRODUCTION

Advances in several critical research fields (processing, catalytic, optical, actuation, electrical, mechanical fields, etc.) have started to benefit from new technological advancements in the area of nanotechnology.<sup>[1–22]</sup> Nanotechnology can be broadly defined as the use of materials and systems whose structures and components exhibit novel and significantly changed properties when control is gained at the atomic, molecular, and supramolecular levels. Specifically, such advances have been found for materials when particulate size is decreased to below 100 nm. However, to date, relatively few advantages have been described for biological applications (specifically, those involving protein interactions). This entry elucidates several promising examples of the control nanophase materials have in manipulating interactions with proteins to improve traditional biological applications (such as for improving implantable devices, filtration systems, bioMEMS, etc.). Such advances were previously unimaginable with conventional materials possessing large micron size particulates. To describe the promise nanophase materials have in revolutionizing interactions with biology, this entry will start with a review of protein structure and interaction with solid surfaces. The entry will then continue with reports from the literature providing evidence of unique interactions proteins can have with nanophase materials.

## PROTEIN STRUCTURE

Proteins are essential to health and, in fact, mean “of first importance” in Greek. This is for a very good reason because initial protein interactions with material surfaces control subsequent cell functions essential for tissue engineering/implant applications, antibody interactions for immunoassays and/or biodegradation devices, and bacteria interactions involved in problems such as marine fouling and infection. Clearly, understanding protein size and structure will aid investigators in either maximizing or minimizing protein interactions with surfaces to improve these technologies.

Proteins are polyamides formed by a step reaction polymerization between the amino and carboxyl groups of amino acids:

where R is a characteristic side group and  $n$  is the number of repeating units. Depending on the side group, the molecular structure of the protein will drastically change. The simplest side group in protein structure is hydrogen, which will form the amino acid glycine (abbreviated Gly). The geometry of Gly is shown in Fig. 1 as a hypothetical flat sheet with a repeating distance of 0.72 nm.<sup>[23]</sup> Although the R side group in proteins can be diverse (as will soon be discussed), there are many commonalities between proteins, namely, size and structure in the nanometer regime. To date, the fundamental nanometer size of proteins has been largely ignored and not appreciated when considering approaches to control initial protein interactions with surfaces. Thus it is first important to describe protein structure to discuss how nanotechnology can be utilized to influence protein interactions. There are four important levels of protein structure to consider: primary, secondary, tertiary, and quaternary; these will be discussed in the sections that follow.

## Primary Protein Structure

The primary structure of a protein is its linear sequence of amino acids. Each amino acid is linked to another through peptide bonds (Fig. 2).<sup>[23]</sup> Because there are 20 amino acids found in man (11 of which are synthesized in the human body: Ala, Arg, Asn, Asp, Cys, Glu, Gln, Gly, Pro, Ser, and Tyr; and 9 of which are synthesized elsewhere but are essential to human diet: His, Ile, Leu, Lys, Met, Phe, Thr, Trp, and Val) (Fig. 3),<sup>[24]</sup> many sequences are possible to create numerous proteins with diverse properties. Moreover, these 20 amino acids are themselves diverse (Table 1)<sup>[25–27]</sup>

**Fig. 1** The geometry of proteins as a hypothetical flat sheet with a repeating distance of 0.72 nm. *Source:* From Ref.<sup>[23]</sup>.

and may be classified according to a number of categories: such as either aliphatic amino acids, amino acids with hydroxyl-containing or sulfur-containing side chains, aromatic amino acids, basic amino acids, cyclic amino acids, or acidic amino acids and their amides, as presented in Fig. 3. Other amino acid classifications that are often utilized when considering initial protein interactions with material surfaces are either non-polar, polar, or ionized, labeled as either N, P, or I in Fig. 3, respectively.

Some amino acids have side chains (or residues) that carry no charge at any pH yet exhibit strong polar character (e.g., Ser and Thr).<sup>[23]</sup> Ionizable side chains vary from fairly acidic ones (such as Asp and Glu, which are fully negative at the physiological pH of 7.4) to more basic amino acids (such as the imidazole group in His, which has a positive charge at a pH of 7.4) and the still more basic amino acids that carry full charges at a pH of 7.4 (specifically, Lys and Arg).<sup>[23]</sup> Yet another group of amino acids has no acid, base, or polar character in their residues as shown by their generally much lower solubility in water (such as Ala, Val, Leu, Ile, Met, Trp, and Pro). For these reasons, it should not be surprising why proteins exist with a wide range of properties, as

shown in Table 2, and this is just from considering protein primary structure.<sup>[25,26,28–32]</sup>

## Secondary Structure

The secondary structure of proteins consists of regions of ordered structures in the protein chain (Fig. 4A and B).<sup>[23]</sup> Two main secondary structures of proteins are very common: the  $\alpha$ -helix (Fig. 4A) and the  $\beta$ -pleated sheet (Fig. 4B). The degree of secondary structures in proteins varies to a large amount. For example, in structural proteins such as silk and wool, secondary structures are extensive and thus determine the overall shape of such proteins.<sup>[23]</sup> In addition, myoglobin and hemoglobin (proteins involved in oxygen transport and storage) have extensive  $\alpha$ -helical secondary structure. In contrast, some proteins possess very little secondary structure such as the digestive enzyme chymotrypsin.

Both the  $\alpha$ -helix and  $\beta$ -pleated sheet secondary protein structures are controlled by hydrogen bonding mechanisms, as illustrated in Fig. 4. Hydrogen bonding mechanisms are electrostatic attractions between oxygen of one chemical group and hydrogen of another chemical group. The  $\alpha$ -helix results from the coiling of the protein chain such that the peptide bonds making up the backbone are able to form hydrogen bonds with each other (presented as curved lines in Fig. 4A). These hydrogen bonds are directed along the axis of the helix, and thus amino acid residues (portions of the amino acid not participating in the peptide bond) extend at right angles from the helix with minimal steric hindrance that further stabilizes the  $\alpha$ -helix. The  $\beta$ -pleated sheet is a layering of protein chains in which each layer is held together by hydrogen bonds between the peptide links (presented as curved lines in Fig. 4B). The amino acid residues are situated at right angles to the sheets with, again, minimal steric hindrance that further stabilizes the  $\beta$ -pleated sheet.

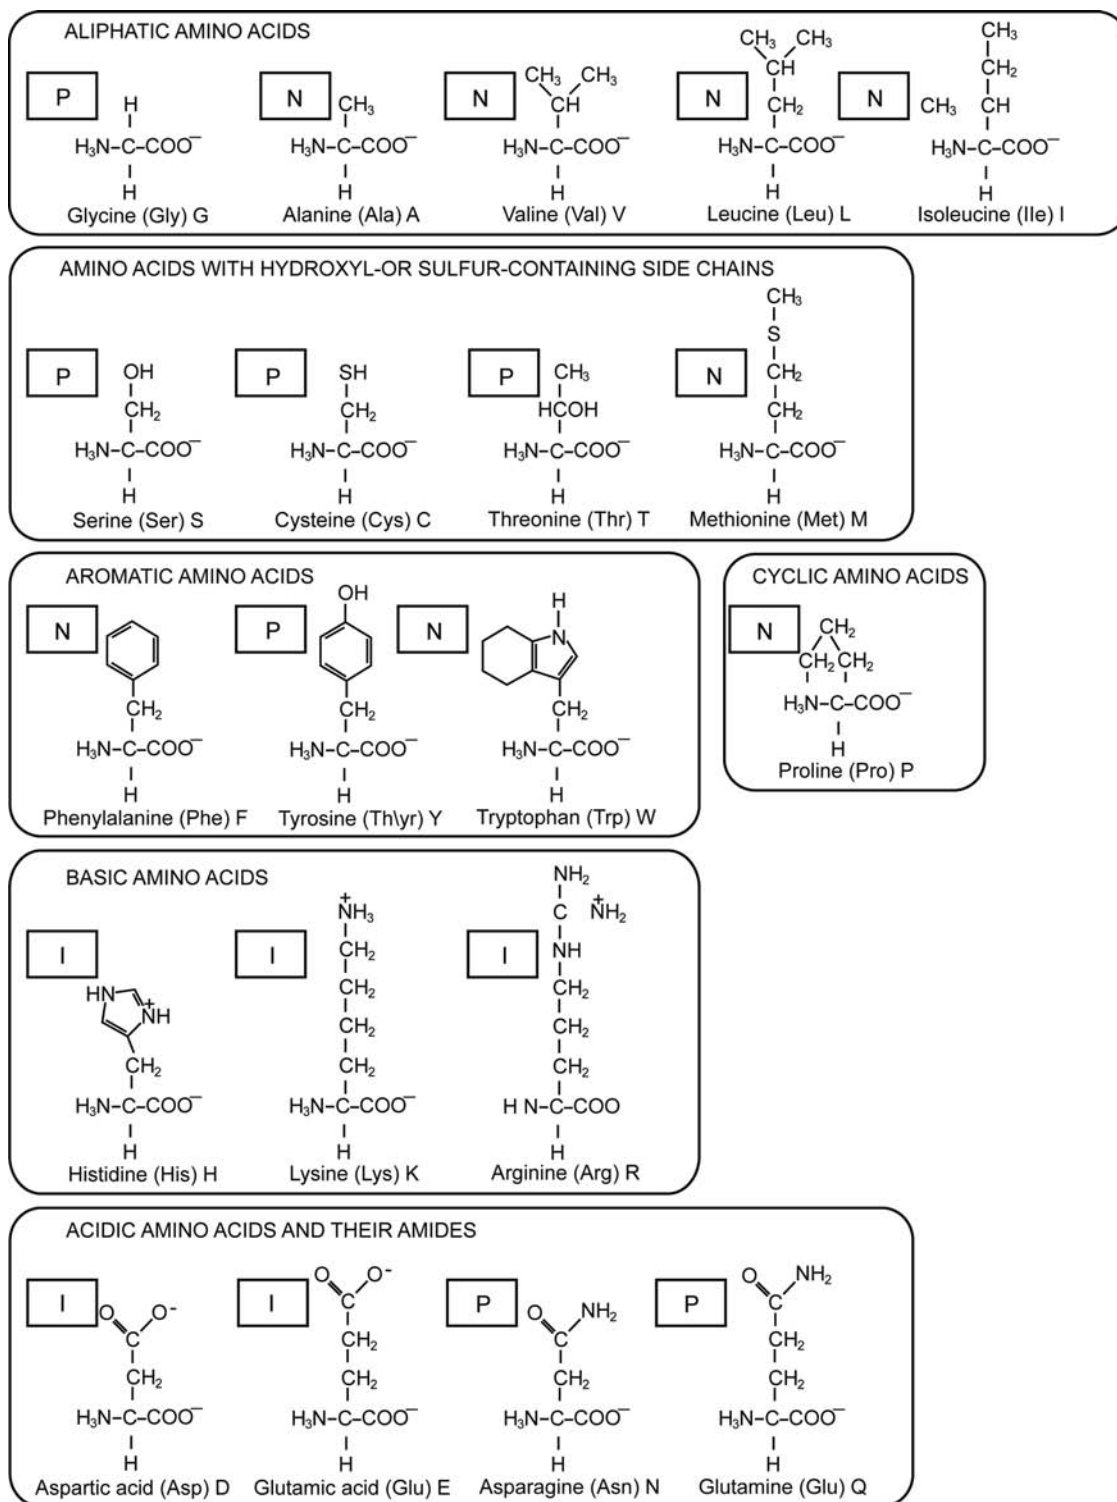

## Tertiary Structure

The tertiary structure of proteins is the overall three-dimensional shape of the protein (Fig. 5).<sup>[23]</sup> Protein

**Fig. 2** Each amino acid is linked to another in proteins through peptide bonds. Note that the R group characteristic of each amino acid is often referred to as an amino acid residue. *Source:* From Ref.<sup>[23]</sup>.

**Fig. 3** Twenty common amino acids. N, P, and I are non-polar, polar, and ionized residue categories, respectively, that appear to the left of each amino acid. *Source:* From Refs.<sup>[23]</sup> and <sup>[24]</sup>.

tertiary structure can either possess little order for many structural proteins, or be extremely complicated for other proteins such as enzymes that fold up on themselves to form more complex structures. Clearly,

the tertiary structure of proteins is a consequence of primary structure as it depends on spontaneous interactions between different amino acids and, under aqueous conditions, spontaneous interactions between

**Table 1** Diverse properties of amino acid residues

Amino acid (three-letter and one-letter abbreviations)	Charge	Hydrophobicity (kcal/mol) <sup>a</sup>	Surface tension (erg/cm <sup>2</sup> /mol/l lowering of the surface tension of water)
Isoleucine (Ile or I)	Neutral	0.73	-15.2
Phenylalanine (Phe or F)	Neutral	0.61	-17.3
Valine (Val or V)	Neutral	0.54	-3.74
Leucine (Leu or L)	Neutral	0.53	-21.9
Tryptophan (Trp or W)	Neutral	0.37	-9.6
Methionine (Met or M)	Neutral	0.26	-3.01
Alanine (Ala or A)	Neutral	0.25	0.96
Glycine (Gly or G)	Neutral	0.16	1.12
Cysteine (Cys or C)	0 to -1	0.04	0.69
Tyrosine (Tyr or Y)	0 to -1	0.02	-15.1
Proline (Pro or P)	Neutral	-0.07	-0.49
Threonine (Thr or T)	Neutral	-0.18	0.59
Serine (Ser or S)	Neutral	-0.26	0.76
Histidine (His or H)	0 to 1	-0.40	1.03
Glutamic acid (Glu or E)	0 to -1	-0.62	0.86
Asparagine (Asn or N)	Neutral	-0.64	1.17
Glutamine (Gln or Q)	Neutral	-0.69	1.21
Aspartic acid (Asp or D)	0 to -1	-0.72	0.96
Lysine (Lys or K)	0 to 1	-1.1	0.92
Arginine (Arg or R)	0 to 1	-1.8	1.03

<sup>a</sup>Transfer from hydrophobic to more hydrophilic phase; increased positive value means more hydrophobic.  
Source: Refs.<sup>[25-27]</sup>.

amino acids and water as will be discussed. Because of the properties of the amino acids and the order in which amino acids are bonded (i.e., protein primary structure), select electrostatic interactions will be created for predictable tertiary structures. This automatic folding of proteins occurs even as proteins are synthesized within ribosomes of cells. As individual proteins are synthesized, residues of each amino acid will either attract, repel, or remain indifferent to residues of another amino acid. Thus regions of the protein will twist and turn to minimize unfavorable and to maximize favorable interactions to form a consistent shape or three-dimensional tertiary structure, as illustrated in Fig. 5 (please note repulsive and attracting forces resulting in a favorable protein shape).

There are four main interactions among residues of amino acids that contribute to the tertiary structure of proteins, each with different strengths: covalent, ionic, hydrogen, and van der Waals bonds. Of these interactions, covalent bonds are the strongest, as indicated in Table 3.<sup>[23]</sup> For example, when two Cys amino acids come in close proximity, a covalent bond between sulfur in each residue can be formed as a result of oxidation (Fig. 6A).<sup>[23]</sup> This covalent bond can have

a strength approaching 250 kJ/mol.<sup>[23]</sup> Ionic bonds are also a strong interaction force (approximately 20 kJ/mol),<sup>[23]</sup> which occurs between chemical groups having opposite charges. For example, ionic bonds are often formed between the carboxylate ion of an acidic residue (such as Asp) and the ammonium ion of a basic residue (such as Lys), as presented in Fig. 6B.<sup>[23]</sup> As previously mentioned, hydrogen bonds are formed between electronegative atoms, such as oxygen, and protons attached to electronegative atoms. Hydrogen bonding between two Ser amino acids is illustrated in Fig. 6C.<sup>[23]</sup> The forces can be quite strong in the range of 7–40 kJ/mol.<sup>[23]</sup> Lastly, van der Waals forces result from interactions between hydrophobic molecules (e.g., between two aromatic residues such as Phe, as presented in Fig. 6D). They result from unequal distributions of electrons between residues such that an area of high electron density on one residue has an attraction for an area of low electron density on another residue. These forces are the weakest of those discussed (1.9 kJ/mol).

Based on Table 3, one might expect that the most important or influential binding forces are those with the highest strength. On the contrary, generally

**Table 2** Diverse properties of proteins

Protein	Function	Location	Size (kDa)	Shape (Å)	Stability	Surface activity
Albumin	Carrier	Blood	65	42 × 141	Denatures at 60°C	Low on polyethylene
Fibrinogen	Clotting	Blood	340	460 × 60 (trinodular string)	Denatures at 56°C	High on polyethylene
IgG	Antibody	Blood	165	T-shaped		Low on polyethylene
Lysozyme	Bacterial lysis	Tear; hen egg	14.6	45 × 30 (globular)	$\Delta G_n = -14$ kcal/mol	High on negatively charged surfaces
Hemoglobin	Oxygen carrier	Red blood cells	65	55 (spherical)	Normal form	Very high on polyethylene
Hemoglobin S	Oxygen carrier	Sickle red blood cells	65	55 (spherical)	Less than hemoglobin	Much higher air-water activity than hemoglobin
Myoglobin	Oxygen carrier	Muscle	16.7	45 × 35 × 25 (spherical)	$\Delta G_n = -12$ kcal/mol	
Collagen	Matrix factor	Tissue	285	3000 × 15 (triple helical rod)	Melts at 39°C	
Bacteriorhodopsin	Membrane protein		26	30–40 long		High at cell membrane
Tryptophan synthase $\alpha$ subunit (wild type)	Enzyme		27		$\Delta G_n = -8.8$ kcal/mol; denatures at 55°C	High air-water activity compared to ovalbumin
Tryptophan synthase variant $\alpha$ subunit	Enzyme		27		$\Delta G_n = -16.8$ kcal/mol	Much less active at air-water interface than wild type

Source: Refs.<sup>[25,26,28–32]</sup>

speaking, the most important binding forces for the tertiary structure of proteins are those with the weakest strength (i.e., van der Waals and hydrogen bonding forces), whereas the least important forces are those with the highest strength (specifically, covalent and ionic bonding forces). One reason for this is because, compared with ionic and covalent bonding, there are many more opportunities for van der Waals and hydrogen bonding interactions in protein tertiary structure. A simple reexamination of amino acid chemical structures, as given in Fig. 3, can provide the answer as to why this is true. For example, the only covalent bond that is readily seen in protein tertiary structure is the disulfide bond.<sup>[23]</sup> The only amino acid capable of creating such a bond, when in juxtaposition to itself, is Cys.<sup>[23]</sup> In contrast, there are eight amino acids capable of promoting van der Waals interactions (specifically, Gly, Ala, Val, Leu, Ile, Phe, Pro, and Met).<sup>[23]</sup> However, it is important to note that for some proteins (small polypeptides such as the hormones vasopressin and oxytocin), covalent bonding mechanisms are more important, but for the majority of proteins, these bonds play a minor role in mediating

tertiary structure compared with the other bonding mechanisms listed in Table 3. The same is true for ionic and hydrogen bonding mechanisms. Specifically, significantly more amino acids are capable of forming hydrogen bonds (eight: Ser, Thr, Cys, Asn, Gln, His, Tyr, and Trp) than ionic bonds (four: Asp, Glu, Lys, and Arg).<sup>[23]</sup>

Another reason for the increased importance of the weaker-strength interactions in controlling tertiary structure is the fact that proteins exist in aqueous media. Thus residues of amino acids must interact with water, which is a highly polar compound that forms strong hydrogen bonds (as presented in Fig. 5). In addition, water can also accept a proton to become positively charged and can form ionic bonds to several amino acids including Asp and Glu. This makes water an important medium for influencing the tertiary structure of proteins because it can form either hydrogen or ionic bonds with the following groups of amino acids: Ser, Thr, Cys, Asn, Gln, His, Tyr, Asp, Glu, Lys, and Arg.<sup>[23]</sup> These hydrophilic amino acids are either polar or ionizable, as given in Fig. 3. The remaining non-polar amino acids (Ala, Val, Leu, Ile, Phe, Pro, and Met)

**Fig. 4** Secondary protein structures: (A)  $\alpha$ -helix and (B)  $\beta$ -pleated sheet. *Source:* From Ref.<sup>[23]</sup>.

are hydrophobic and thus are repelled by water. In this manner, it can be expected that the most stable tertiary structures of proteins in aqueous media are those where most of the hydrophobic and hydrophilic amino acids are on the inside and outside of the protein, respectively (Fig. 5). This is why most soluble proteins exhibit spherical or globular tertiary shapes, although fibrinogen (an important protein for blood clotting) does not follow this trend as it is more elongated than spherical.

Globular tertiary protein structures have several consequences in terms of amino acid interactions. The hydrophobic amino acids on the inside of the protein tertiary structure (avoiding interaction with water) are forced to interact with each other because of this tertiary structure. However, the number of ionic and hydrogen bonds contributing to the tertiary structure is reduced because the hydrophilic amino acids on the exterior of the protein form ionic and/or hydrogen bonds with water. For these reasons, hydrophobic—not

**Fig. 5** Tertiary protein structure. *Source:* From Ref.<sup>[23]</sup>.

hydrophilic—interactions control the tertiary structure of proteins. However, as will be discussed, hydrophilic and hydrophobic amino acid locations on the outer and inner cores of the protein, respectively, will drastically change as proteins initially come in contact with solid surfaces.

Of course, repulsion forces between amino acid residues in close proximity can also aid in protein tertiary

structure. For example, residues that are hydrophilic (such as amino functional groups in Gln) would repel amino acid residues that are hydrophobic (such as an aromatic ring in Phe) when in close position. Similarly, two residues that are identical in charge will repel each other until a more favorable interaction between residues is created.

### Quaternary Structure

Only proteins that possess numerous subunits have quaternary structure. How these subunits interact will determine the quaternary structure of that protein. An example of a well-studied quaternary protein structure is hemoglobin, which is composed of four protein subunits as described by secondary structure: two identical  $\alpha$  subunits and two identical  $\beta$  subunits (Fig. 7).<sup>[24]</sup> Of course, interactions between amino acid

**Table 3** Strengths of bonds controlling tertiary protein structure

Type of bond	Strength (kJ/mol)

residues on the exterior of the protein's tertiary structure will control quaternary structure. Thus ionic bonding mechanisms, which control the placement of hydrophilic amino acids on the exterior of protein tertiary structure in an aqueous environment, now play another important role in determining quaternary structure. Similarly, hydrophobic interactions have an essential role in determining quaternary structure.

For example, it is clearly not possible for all hydrophobic amino acids to be placed on the interior of proteins; some may be present on the exterior. Thus a small hydrophobic area between adjacent subunits in the quaternary structure of proteins may be formed through hydrophobic interactions because these groups would have a preferred interaction of facing each other, rather than being exposed to the aqueous

**Fig. 7** Quaternary structure of hemoglobin. *Source:* From Ref.<sup>[24]</sup>.

environment. This is another example of how important hydrophobic interactions are in controlling protein structure.

Although the structure of proteins has been well studied for a number of years, only in the past several decades have investigators begun to elucidate mechanisms of protein interactions with solid substrates. Knowledge of protein structure has certainly aided these researchers in understanding properties of surfaces that mediate protein interactions. “Protein Interactions with Surfaces” will describe some of these findings.

## PROTEIN INTERACTIONS WITH SURFACES

Although proteins may interact in a wide range of media, such as at the air–water interface in the case of interfacial coagulation/foaming, this section will primarily discuss interactions at the solid–liquid interface because the most promising applications of nanophase materials in a biological context have been observed at this intersection.<sup>[33–42]</sup> Because proteins can interact with surfaces in two main ways—adsorption and orientation (or conformation)—the next sections will focus on these aspects beginning with adsorption.

### Principles of Protein Adsorption

A great deal of attention has been focused on protein structure in aqueous media in this entry. This is because soluble proteins present in biological fluids (e.g., blood plasma) are the type of proteins that are involved in immediate adsorption to surfaces.<sup>[43]</sup> In contrast, insoluble proteins that comprise tissues (such as collagen and elastin) are not normally free to diffuse

to a solid surface; however, these proteins may appear on solid surfaces of implantable devices because of synthesis and deposition by cells.<sup>[25]</sup>

In as short a time that can be measured (i.e., less than 1 sec), soluble proteins become adsorbed to surfaces.<sup>[25]</sup> This is true for applications incorporating implants (such as orthopedic, vascular, etc.), bioseparation devices, immunoassays, catheters, and biosensors, or for any device involved in protein contact from a liquid surface to a solid surface. In seconds to minutes, a monolayer of adsorbed protein will form on solid surfaces.<sup>[25]</sup> Typical values for protein adsorption on solid surfaces are in the range of  $1 \mu\text{g}/\text{cm}^2$  and exhibit a plateau with respect to initial protein concentration.<sup>[25]</sup> That is, protein adsorption will reach a maximum and will not be influenced by higher initial bulk protein concentrations. Moreover, the surface concentration of proteins adsorbed on a material surface is often 1000 times more concentrated than in the bulk phase.<sup>[25]</sup> It is apparent that because there is a limited amount of space on a material surface, extreme competition exists for protein adsorption to solid surfaces. Depending on the two major driving forces for protein adsorption from liquid to solid surfaces (specifically, the relative bulk concentration of each protein in solution and the properties of the surface that control protein reactivity), the outcome of this competitive adsorption process is that the surface will be rich in some proteins while poor in others. Because proteins have vastly different properties and thus reaction to surfaces, as shown in Table 2,<sup>[25,26,28–32]</sup> protein adsorption will clearly be different depending on material chemistry, wettability, roughness, charge, etc.

It is also imperative to note that with some exceptions, protein adsorption to material surfaces is irreversible and thus leads to “immobilization” of specific proteins because they are, for the most part, not free to diffuse away.<sup>[44]</sup> Harsh treatments, such as using detergents (such as sodium dodecyl sulfate [SDS]), are usually required to remove adsorbed proteins from a material surface.<sup>[40]</sup> Clearly, because of this efficiency, proteins have an inherent tendency to adsorb on surfaces as a tightly bound adsorbate, and removing unwanted protein adsorption (or fouling) from surfaces has consequently become an active area of research.<sup>[45–47]</sup>

### Kinetics of Protein Adsorption

The kinetics of protein adsorption to solid surfaces can be described as a very fast initial phase that is diffusion-limited followed by a slower phase until steady state is realized.<sup>[25]</sup> A plot of the initial amount of protein adsorbed vs. the square root of time results

**Table 4** Positive enthalpy change of protein adsorption to surfaces

Protein	Surface	Enthalpy change of adsorption (mJ/m <sup>2</sup> )
Horse serum albumin	$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	+1.9 at pH = 5
		+7.0 at pH = 7
RNase	Negatively charged polystyrene with high surface charge density	+4 at pH = 5
		-2 at pH = 11

Source: Refs.<sup>[25,31,41]</sup>

in a linear characteristic typical of diffusion-controlled processes.<sup>[25]</sup> It can be speculated that during the later phase, protein adsorption is slowed because of the competition to locate a position sterically unhindered on the surface.<sup>[25]</sup>

### Thermodynamics of Protein Adsorption

Because protein adsorption appears to be irreversible,<sup>[25,40,44]</sup> the thermodynamics of protein adsorption is difficult to characterize. However, there have been several studies providing insights into the thermodynamics of protein adsorption.<sup>[25,31,41]</sup> For example, some studies have determined direct measurements of the heat of adsorption for several proteins on a variety of surfaces, as indicated in Table 4.<sup>[25,31,41]</sup> Positive enthalpies have been documented on spontaneous adsorption, thus providing evidence that protein adsorption is entropically driven under certain circumstances. [Remembering that  $\Delta G = \Delta H - T\Delta S$ , with a positive  $\Delta H$  (enthalpy),  $\Delta S$  (entropy) must be positive to keep  $\Delta G$  (free energy) negative to provide for a spontaneous reaction.] It is now generally agreed on that all protein adsorption processes are strongly driven by entropic changes.<sup>[25]</sup> The presence of entropic factors in protein adsorption to solid surfaces could arise because of the thermodynamics of water binding to the surface and the limited protein unfolding that occurs once adsorbed.<sup>[25]</sup>

### Principles of Protein Orientation

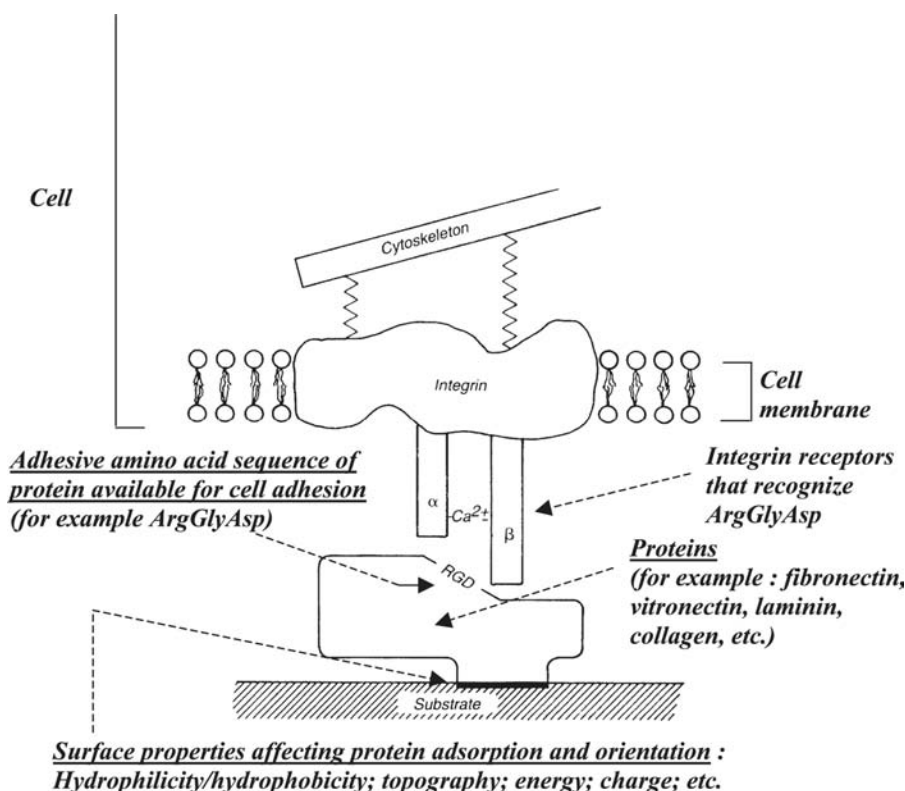

As previously mentioned, protein adsorption is only one manner in which proteins interact with solid surfaces. The orientation of proteins in the adsorbed monolayer must also be considered because this interaction leads to extreme consequences in the ultimate function of a device.<sup>[36,44]</sup> For example, for implant, biosensor, or immunoassay applications, particular amino acids in proteins are well known to bind to a

variety of cells, antibodies, or other agents that drastically influence device function. An example of the importance of protein orientation for the capture of cells is illustrated in Fig. 8.<sup>[48]</sup> Protein orientation will alter from surface to surface because proteins are not uniform in properties (Table 2) or structure. The existence of regions that are largely acidic/basic and hydrophobic/hydrophilic, and with select amino acids exposed to the aqueous media will greatly influence how that protein will adsorb to a surface, and thus its orientation, once adsorbed. As previously mentioned, proteins are not free to rotate once adsorbed because of multiple bonding mechanisms and thus immediately on adsorption, proteins are fixed in a preferred orientation or bioactivity.<sup>[25]</sup>

Under certain extreme conditions (e.g., conditions that are outside of the physiological range, or outside the range of 0–45°C and pH 5–8, and in aqueous solutions of about 0.15 M ionic strength), proteins may lose their normal structure.<sup>[25]</sup> In other words, under such conditions, the spherical or globular tertiary structure most soluble proteins assume in aqueous media will unfold or denature. The structure of denatured proteins has been described as a random coil structure similar to those found in synthetic polymers.<sup>[25]</sup> Because the structure of the protein has changed from that of a hydrophilic/hydrophobic exterior/interior to a more random arrangement, often times denatured proteins lose their solubility, become less dense (folded protein structures have densities of approximately 1.4 g/cm<sup>3</sup>), and ultimately lose their bioactivity.<sup>[25]</sup> Although there have been many examples of protein denaturation in solution, in general, there have been few reports of full protein denaturation on material surfaces.<sup>[25]</sup> That is, generally, proteins adsorbed at the solid-liquid interface are not fully denatured and retain some degree of structure.

### Properties that Influence Protein Interactions

Not only do properties of proteins determine the degree of protein interaction with surfaces, but properties of the media and the surface (specifically, wettability, surface energy, chemistry, roughness, etc.) also influence the degree of protein interactions.<sup>[48]</sup> This is true because proteins are relatively large in size and have correspondingly great numbers of charged amino acid residues of varying acidity/basicity well distributed on the exterior of the protein. Therefore the inherent polyelectrolytic behavior of proteins becomes increasingly important depending on conditions of the aqueous media (such as alterations in pH and ionic strength). The polyelectrolytic property of proteins provides for exciting design criteria to engineer surfaces to either maximize or minimize protein

**Fig. 8** Control of surface-protein interactions for capture of cells. Source: From Ref.<sup>[48]</sup>.

interactions. Not surprisingly, at a neutral or slightly charged surface and at a pH in which the net charge on the protein is minimal (i.e., near the isoelectric pH), most proteins will exhibit maximum adsorption.<sup>[25]</sup> For surfaces with a large net charge, initial protein interactions will be dominated by the degree of the opposite charge on the surface.<sup>[25,48]</sup> Thus to develop a surface to maximize interactions with a protein displaying a large positive charge, one needs to design a surface with a large negative charge (such as one with numerous hydroxyl groups).

Simple consideration of the spatial organization of amino acids can also be used in the design of surfaces to enhance protein interactions.<sup>[39]</sup> As previously discussed, hydrophilic and hydrophobic amino acids are present primarily on the exterior and the interior of soluble proteins, respectively. This spatial arrangement has a direct consequence on the initial interaction of proteins with surfaces. For example, for the most part, a surface that initiates interactions with the exterior hydrophilic amino acid residues can promote adsorption. In contrast, for the interior hydrophobic amino acid residues to interact with a material surface, the soluble protein would have to unfold or lose tertiary structure, which is unlikely under normal conditions. For this reason, it can be reasoned that the types of amino acid residues that will initially react with a material surface are only those that exhibit largely polar properties (Fig. 3). Thus to minimize interactions with hydrophobic regions of proteins, one could design a surface

with a large degree of hydrophobicity (such as polymers with numerous nonfunctionalized benzene rings).

Several studies have confirmed speculations that properties (such as chemistry, charge, topography, etc.) of surfaces dictate select interactions (specifically, the type, concentration, and conformation/bioactivity) of proteins.<sup>[43,49-53]</sup> It has been reported in the literature that changes in the type and concentration (up to 2100%, 74%, and 53% for albumin,<sup>[52]</sup> fibronectin,<sup>[54]</sup> and vitronectin,<sup>[55,56]</sup> respectively) of protein adsorption on materials depend on surface properties such as chemistry (i.e., either polymer, metal, or ceramic), hydrophilicity/hydrophobicity, roughness, and surface energy. Specifically, maximum vitronectin,<sup>[56]</sup> fibronectin,<sup>[54]</sup> and albumin<sup>[43,52]</sup> adsorption was noted on hydrophilic ceramic surfaces with high surface roughness and/or energies. Despite these promising studies providing some level of understanding between material properties and protein adsorption, few (if any) studies have accurately correlated material properties to protein orientation. This lack of correlation may be because of a previous failure to create surfaces with features similar in size to those of proteins (i.e., at the nanometer level).

## THE PROMISE OF NANOPHASE MATERIALS FOR ENHANCING PROTEIN INTERACTIONS

Nanophase materials are new formulations of materials that are composed of particulates of the same

**Fig. 9** Representative atomic force images of (A) conventional materials compared to (B) nanophase materials (specifically, titania is depicted here). *Source:* From Ref.<sup>[35]</sup>.

atoms but are fewer (less than tens of thousands) and smaller (less than 100 nm in diameter) than conventional forms (which contain several billions of atoms and have particulate sizes in microns to millimeters in diameter).<sup>[15]</sup> Representative images of nanophase compared with conventional materials are presented in Fig. 9.<sup>[35]</sup> The rationale, followed by experimental evidence that surface properties of nanophase materials enhance initial protein interactions, is expounded in the sections that follow.

### Rationale

Surface properties (such as area, charge, and topography) depend on the particulate (such as grain) size of a material.<sup>[1,4,7,15,21,22]</sup> In this respect, nanophase materials that, by their very nature, possess higher surface areas with increased portions of surface defects (such as edge/corner sites) and/or grain boundaries<sup>[1,7]</sup> have special advantageous properties that remain largely unexplored for applications involving biology. To date, the increased surface reactivity of nanomaterials has been utilized for catalytic applications exclusively;<sup>[1,7]</sup> for example, compared with conventional (greater than 100 nm in average grain size) magnesium oxide (MgO),

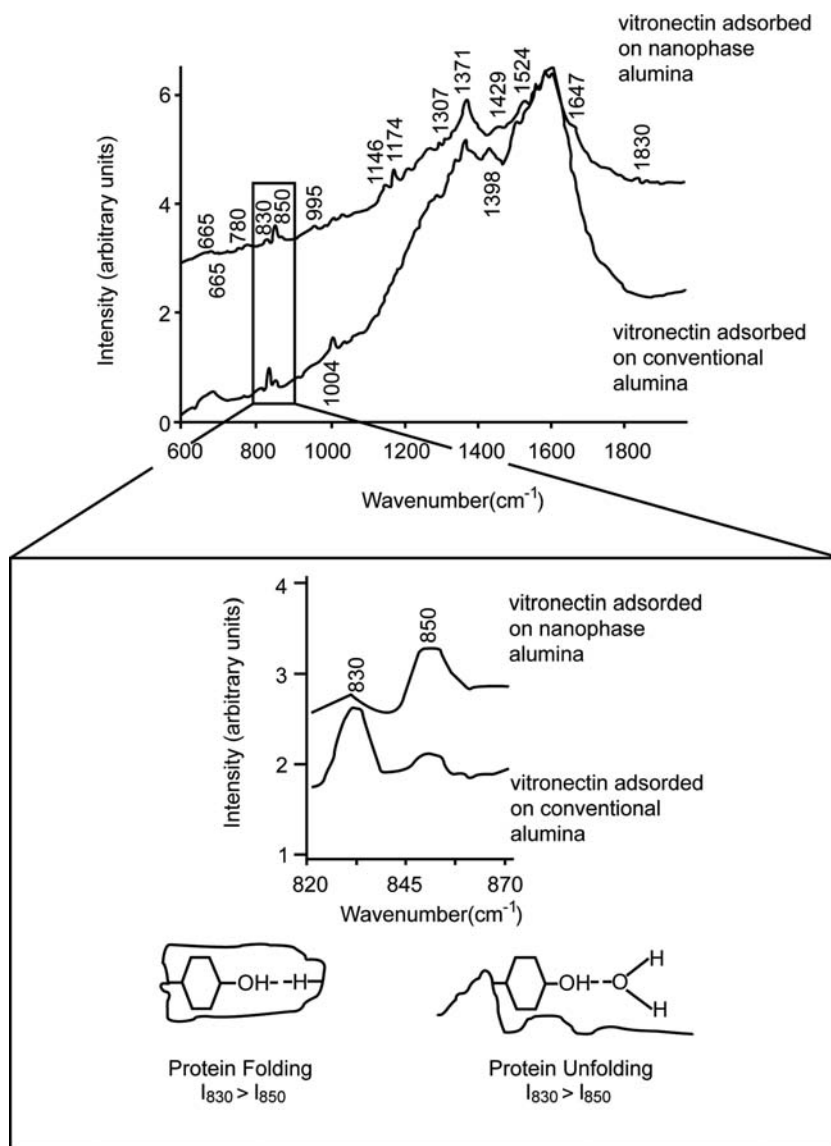

nanophase (i.e., 4 nm average grain size) MgO possessed an increased number of atoms at the surface, higher surface area (100–160 m<sup>2</sup>/g compared with 200–500 m<sup>2</sup>/g, respectively), less acidic OH<sup>-</sup> groups (because of a much higher proportion of edge sites for the nanophase MgO to cause delocalization of electrons) (Fig. 10), increased adsorption of acidic species, and increased destructive adsorption of organophosphorous and chlorocarbons.<sup>[1,7]</sup> Because such promising results have been found when utilizing nanophase materials in catalytic applications, it is intriguing to ponder what promise these materials may have in applications involving protein interactions.

### Experimental Evidence

Some of the best examples of how nanophase—compared with conventional—materials alter interactions with proteins are outlined in investigations of the potential use of nanostructured materials as the next generation of bone implants.<sup>[33–42]</sup> Reports in the literature have determined that new bone synthesis is enhanced on materials with grain sizes less than 100 nm.<sup>[33–42]</sup> Investigations of the underlying mechanisms revealed that the initial adsorbed

**Fig. 10** Special surface properties of nanophase materials pertinent for protein interactions. Compared to (A) conventional materials, (B) nanophase materials possess a greater number of atoms at the surface, higher surface areas, and less acidic OH<sup>-</sup> groups (because of an increase in electron delocalization) in the hydroxide layer. *Source:* From Refs.<sup>[1]</sup> and <sup>[7]</sup>.

**Fig. 11** Surface-enhanced Raman scattering technique provided evidence of increased unfolding of the proteins (specifically, vitronectin in this example) adsorbed on nanophase compared to conventional grain-sized ceramics. *Source:* From Ref.<sup>[40]</sup>.

concentration,<sup>[36]</sup> conformation,<sup>[40]</sup> and bioactivity<sup>[40]</sup> of proteins contained in blood serum were responsible for the select enhanced functions of osteoblasts (or bone-forming cells) on nanophase materials. Of first importance, the cumulative adsorption of proteins contained in serum was significantly higher on smaller, nanometer grain-sized ceramics.<sup>[36]</sup> In particular, the interaction of four proteins (fibronectin, vitronectin, laminin, and collagen—proteins all known to enhance osteoblast function)<sup>[36]</sup> increased greatly on nanophase compared with conventional ceramics.<sup>[36]</sup> For example, by just decreasing grain size to below 100 nm, select competitive vitronectin adsorption increased by 10% on alumina formulations. These studies demonstrated that initial enhanced calcium adsorption on nanophase ceramics was a key mechanism for increased protein interactions.<sup>[36]</sup>

Calcium-mediated protein adsorption affected the orientation of proteins adsorbed on nanophase ceramics as well.<sup>[40]</sup> Specifically, a novel adaptation of the standard surface-enhanced Raman scattering (SERS) technique provided evidence of increased unfolding of the aforementioned proteins adsorbed on nanophase compared with conventionally grain-sized ceramics (Fig. 11).<sup>[40]</sup> Unfolding of these proteins promoted the availability of specific cell-adhesive epitopes (such as the amino acid sequence Arg-Gly-Asp) that undoubtedly increased bone cell adhesion and function (this interaction is depicted in Fig. 8); evidence supporting this claim was further provided by these investigators through competitive cell adhesion inhibition studies.<sup>[40]</sup> These studies were the first to demonstrate that by decreasing grain size (or, in effect, decreasing the size of surface features) to below 100 nm (thus becoming closer to the fundamental size of

proteins), interactions of proteins were altered in ways previously unobserved on conventional formulations.

It is interesting to consider what properties of nanophase ceramics manipulated protein adsorption and orientation to benefit new bone formation needed for orthopedic implant applications. Select adsorption of proteins important for bone cell function was enhanced by simply decreasing the grain size of the ceramics into the nanometer regime. Equally as important, the tertiary structure of the proteins (namely, the positioning of the Arg–Gly–Asp amino acid sequence in the interior of some of these proteins)<sup>[57]</sup> was manipulated and partially unfolded to expose cell-adhesive epitopes. Because of these novel observations, the investigators characterized several key material properties of nanophase ceramics to find some insights into these interactions.

One may speculate that increased surface area (up to 30% for alumina)<sup>[35]</sup> of nanophase materials is the only property leading to increased adsorption of proteins. However, although this property certainly holds promise for biofiltration, bioseparation applications, etc., literature reports have normalized increased protein adsorption to the increased surface area observed on nanophase ceramics, and have still found enhanced protein adsorption.<sup>[36]</sup> Thus it is clear that the greater surface area that results from nanostructured surface features compared with conventionally structured surface features is not the only property promoting interactions with proteins.

Increased protein adsorption may be directly related to the reported increased surface wettability of nanophase over conventional ceramics.<sup>[35]</sup> It was previously suspected that nanophase ceramics have much greater surface reactivity because of an increased number of atoms at the surface, greater amounts of grain boundaries at the surface, and higher proportions of edge sites (Fig. 10).<sup>[7]</sup> This was confirmed by studies that provided evidence of aqueous contact angles three times smaller than when alumina grain size was reduced from 167 to 24 nm.<sup>[35]</sup> As previously discussed, because proteins assume a tertiary structure with mostly hydrophilic amino acid residues on the exterior of globular shapes, a material surface with increased wettability (or hydrophilic) properties should increase interactions with hydrophilic regions of proteins to, subsequently, enhance unfolding of that protein to expose interior amino acids important for cell adhesion.

In addition, large topographical differences resulting from grain size as well as pore size differences were found between nanophase and conventional ceramics as expected (Fig. 9).<sup>[35]</sup> Specifically, surface roughness increased by 35–50% on nanophase compared with conventional grain size ceramics.<sup>[35]</sup> These investigators hypothesized that, for the first time, because of

the ability to create surface topographies with features that approximate the size of proteins, extreme control over protein orientation can result. For example, because of protein stereochemical structure and ceramic pore size dimensions (in angstrom regime compared with micron regime for nanophase and conventional ceramics, respectively), many of these nanostructured proteins important for bone cell function adsorbed in preferential orientations to smaller pores sizes in nanophase ceramics.<sup>[36,42]</sup> Some of the larger proteins contained in blood plasma (such as albumin not important for bone cell function) were preferentially sterically excluded from angstrom-sized pores of nanostructured ceramics.<sup>[36,42]</sup> In addition, variations in ceramic surface topography on the same order of magnitude as the size of proteins influenced adsorbed protein orientation, and thus the availability of select amino acid sequences, to promote bone-forming cell function. Because of protein dimension in the nanometer regime, through the use of nanostructured topographies, scientists can now modify a surface to control and manipulate adsorbed protein conformation; this is, most likely, the largest unexplored and promising potential at the intersection of protein interactions and nanophase materials. These studies demonstrate that the reported high surface reactivity nanophase materials have in enhancing catalytic applications can be transferred to benefit applications involving protein interactions.

## CONCLUSION

Nanostructured materials provide alternatives not yet fully explored for controlling interactions with proteins. Because technologies now exist to manipulate materials at the atomic, molecular, and supramolecular levels, surfaces can be designed at a dimension similar to that of proteins—the nanometer level. Moreover, in conjunction with this promise, nanophase materials have special surface properties because of an inherent increased number of atoms at the surface, large surface areas, higher proportions of edge sites, and a greater number of material defects (such as grain boundaries for ceramics) at the surface. When these concepts are fully appreciated and realized, it will be possible to design highly engineered surfaces for improving implantable devices, filtration systems, bioseparations, bioMEMS, etc. Such advances were previously unimaginable with conventional materials. Fundamental knowledge of protein dimension, structure, and organization is essential toward this goal. As the disciplines of protein biology and nanophase material science develop and mature, the design criteria mentioned in this chapter for controlling protein interactions will be expanded and refined. Undoubtedly, nanophase

materials have the potential to become the next generation-of-choice proactive materials for innovative biotechnology and biomedical applications that could have profound impact in many diverse fields that involve interactions with proteins.

## INTRODUCTION

A fundamental breakthrough in semiconductor device physics is connected with the recent progress in the synthesis of sheets of nanoscale narrow-gap insertions in a host semiconductor—quantum dots (QDs). The key peculiarity of QDs is related to the spatial confinement of charge carriers and their discrete energy levels determined by QD size and shape. The shape is dictated by the growth kinetics and the parameters of the materials governing the thermodynamics of growth. The large body of recent results on the physical properties of QDs and their utilization for the QD laser design has been discussed in Ref.<sup>[1]</sup>.

Apart from charge carrier confinement, there exists a class of effects governed by the intrinsic spatial inhomogeneity of the QD heterostructures. Transparent and dissipative heterogeneous media with small inclusions of one material into another material, conventionally referred to as composite materials, exhibit, in general, new mechanical, electronic, as well as optical properties, which are not inherent to each individual component.<sup>[2]</sup> In the case of QD heterostructures, a conventional picture is modified because of specific properties of excitons, coupled electron–hole states, which define the QD response. First, excitonic composite is constituted by resonant particles and, consequently, is characterized by resonant response; moreover, inverse population is possible owing to the discrete energy spectrum of excitons. Thus a QD-based composite is a resonant active system. Another specific property of QD composites appears owing to the quantum nature of excitons: the exciton Bohr radius  $a_B$  can either exceed the QD linear extension (strong confinement regime), or be much less (weak confinement regime). In the latter case, often realized in experiments, the QD electromagnetic response becomes nonlocal<sup>[3]</sup> (i.e., constitutive relations for polarization of the QD medium take the form of integral operators). Electromagnetic properties of QD-based composites are the focus of the present paper. Consideration is based on earlier published articles of various authors.<sup>[4–10]</sup>

## BASIC RELATIONS

### Effective Permittivity Tensor for Three-Dimensional Structures

Electromagnetic properties of composites are usually modelled in the framework of the effective medium approach,<sup>[2]</sup> which implies electromagnetic field averaging over material inhomogeneities. Thus a homogeneous medium with effective constitutive parameters (ECPs), such as conductivity, susceptibility, and permittivity, instead of a composite, is being considered. The effective parameters are expressed in terms of the generic and the geometrical parameters of the inclusions and the host medium. The general approach for estimating the effective parameters of a composite material is as follows: First, the field scattered by a single inclusion in the host medium is found; then, the scattering contributions from all inclusions are summed and averaged over a vanishingly small region. For this approach to hold, all inclusions must be electrically small (i.e., their linear size must be small compared with the wavelength). Quantum dot-based structures completely satisfy that condition in the visible range.

There are a large number of different modifications of the effective medium theory. Among them, we choose the Maxwell Garnett approach as it is based on rigorous solutions of the integral equations of macroscopic electrodynamics<sup>[11]</sup> for composites with small volume fractions of inclusions ( $f_V < 0.4$ – $0.5$ ) (i.e., a weak modification of the electronic spectrum and the gain of QD ensemble are assumed as compared with that of individual QDs). In the framework of the Maxwell Garnett approach, rigorous derivation of the effective permittivity tensor has been first presented in Refs.<sup>[12]</sup> and<sup>[13]</sup> (also Ref.<sup>[2]</sup>) where it has been shown that a composite medium comprising a regular ensemble of uniform-sized, electrically small, dielectric inclusions dispersed in a host dielectric material is characterized by the effective permittivity tensor as follows:

$$\hat{\epsilon}(\omega) = \epsilon_h + f_V \epsilon_h \hat{\alpha}(\omega) [1 + f_V \hat{\delta} \hat{\alpha}(\omega)]^{-1} \quad (1)$$

where  $\hat{\alpha}(\omega)$  is the polarizability tensor of a single QD and  $\hat{\delta}$  is the lattice tensor completely determined by the array

geometry. Furthermore, the dielectric constant of the host material  $\epsilon_h$  is assumed to be real, frequency-independent, and equal to the permittivity of the QD material far away from the exciton resonance.

Eq. (1) states that the QD ensemble comprises an optically anisotropic medium even if both the QD and host materials are isotropic. Thus we predict electromagnetic anisotropy of the gain in QD arrays because of the diffraction of the electromagnetic field by inclusions. The diffraction manifests itself in two ways. First, the effective permittivity tensor depends on the array geometry involving the electromagnetic interaction between inclusions. Second, the polarizability of a single QD depends on its shape because of the depolarizing field. Assuming the linear size of the lattice elementary cell to be much less than the wavelength, it has been shown that components of the lattice tensor are given by integrals as follows:

$$\begin{aligned}\delta_{ij} &= \frac{1}{4\pi} \int_{\Omega} \frac{r_i r_j}{r^5} d^3 r \text{ if } i \neq j \text{ and} \\ \delta_{ii} &= \frac{1}{4\pi} \int_{\Omega} \frac{3r_i^2 - r^2}{r^5} d^3 r\end{aligned}\quad (2)$$

where  $\Omega$  is the elementary cell volume,  $r$  is the radius vector of a point inside the elementary cell,  $r = |r|$ ; indices stand for Cartesian components. Note that lattice tensor (2) is found without any reference to specific properties of QDs as quantum-mechanical objects.

### Effective Boundary Conditions for Planar Structures

In many cases, a planar array of QDs with intrinsic two-dimensional (2-D) periodicity of characteristic period much less than the optical wavelength can be treated as a more adequate and realistic model.<sup>[1]</sup> Below we present a general method for the evaluation of the electromagnetic response of planar arrays of QDs. This method, conventionally referred to as the effective boundary condition (EBC) method, has been originally developed for microwaves and antenna theory,<sup>[14–16]</sup> and has found a wide application in these fields. Similar approaches have also been developed in acoustics, hydrodynamics, and elasticity theory. Recently, the EBC method has been extended to low-dimensional nanostructures, such as quantum wells,<sup>[17,18]</sup> carbon nanotubes,<sup>[19,20]</sup> and semicontinuous metal films.<sup>[21]</sup> The basic idea of the EBC method is that a smooth homogeneous surface is considered instead of the initial structure, and appropriate EBCs for the electromagnetic field are stated for this surface. These conditions are chosen in such a way that the spatial structures of the electromagnetic field, because of an effective current induced on the homogeneous

surface, and the electromagnetic field of the real current in the initial structure turn out to be identical at some distance away from the surface. Material characteristics of the structure as well as its geometrical parameters are included in coefficients of EBCs. In essence, the EBC method is a modification of the effective medium theory as applied to 2-D confined structures. A detail description of the EBC method as applied to planar QD structures has been presented in Ref.<sup>[7]</sup>

Effective boundary conditions, in the form of two-sided impedance boundary conditions, were first formulated for the linear electrodynamics of single-shell and multishell carbon nanotubes.<sup>[19]</sup> Using this analysis, the EBC method has been extended to planar QD structures and corresponding EBCs have been derived.<sup>[7]</sup>

$$\begin{aligned}\mathbf{n} \times \mathbf{n} \times (\mathbf{H}^I - \mathbf{H}^{II}) &= -\frac{2\pi}{c} \mathbf{n} \times \hat{\sigma}(\mathbf{E}^I + \mathbf{E}^{II}) \\ \mathbf{n} \times (\mathbf{E}^I - \mathbf{E}^{II}) &= -\xi \mathbf{n} \times \nabla[\mathbf{n} \cdot (\mathbf{E}^I + \mathbf{E}^{II})]\end{aligned}\quad (3)$$

where  $\mathbf{n} \parallel \mathbf{e}_z$  is the normal to the QD layer, and  $\hat{\sigma}$  and  $\xi$  are coefficients completely determined by the shape and size of QDs. Nonzero components of the tensor  $\hat{\sigma}$ ,  $\sigma_{ij}$  ( $i, j = x, y$ ), constitute  $2 \times 2$  surface conductivity tensor  $\hat{\sigma}_{\parallel}$ . For quadratic lattice with period  $d$ , it can easily be found that:

$$\hat{\sigma}_{\parallel} = i \frac{\epsilon_h \omega}{d^2} \left[ \hat{\mathbf{I}}_{\parallel} + \frac{\delta_x}{d^2} \hat{\alpha}_{\parallel} \right]^{-1}, \quad \xi = \frac{2\pi \alpha_{zz}}{d^2 + \delta_z \alpha_{zz}} \quad (4)$$

Here  $\hat{\mathbf{I}}_{\parallel}$  is the  $2 \times 2$  unit tensor, and  $\hat{\alpha}_{\parallel}$  is given by the in-plane components  $\alpha_{ij}$  ( $i, j = x, y$ ) of the QD polarizability tensor. Coefficients  $\delta_{x,z}$  are derived from Eq. (2) for planar quadratic elementary cell.<sup>[7]</sup>

Eq. (3) constitutes the complete system of EBCs for electromagnetic field in low-dimensional nanostructures. They have been obtained in an ordinary way, by the averaging of a microscopic field over a physically infinitesimal volume. The technique of macroscopic averaging is similar to that which introduces the constitutive parameters for bulk media, but differs in that the averaging occurs in boundary conditions rather than in field equations. Correspondingly, the averaging was carried out over the 2-D surface but not over the three-dimensional (3-D) spatial element. Thus in electrodynamics of low-dimensional structures, EBCs play the same role as constitutive relations in the electrodynamics of bulk media. A theory is applicable in both strong and weak confinement regimes. Although EBCs have been derived for 2-D periodical structures with quadratic lattices, they keep validity for the arbitrary configuration of elementary cell and for planar layers with random distributions

of QDs. The derived EBCs turn out to be analogous to well-known boundary conditions for quantum wells (QWs)<sup>[17]</sup> if spatial dispersion in the latter can be neglected (i.e., in the limit of infinitely large exciton mass). Thus a planar layer comprising a 2-D array of QDs can be treated as an effective QW.

## POLARIZABILITY OF A SINGLE QUANTUM DOT

For practical utilization of the derived ECPs (Eq. (1)) or EBCs (Eq. (3)), the polarizability tensor of an isolated QD requires to be known. For the simplest configuration of QDs (spheres, disks), this tensor can be found analytically whereas direct numerical simulation is required for more complicated configurations. A conventional phenomenological model of gain in a QD is based on a semiclassical theory of two-level systems, which gives the equation of motion for the mean polarization  $\mathbf{P}$  caused by transitions between levels:<sup>[22]</sup>

$$\left[ \frac{\partial^2}{\partial t^2} + \frac{2}{\tau} \frac{\partial}{\partial t} + \omega_0^2 \right] \mathbf{P} = -\frac{\omega_0}{2\pi\epsilon_h} \hat{\mathbf{g}}_0 \mathbf{E}_L \quad (5)$$

Here  $\omega_0$  is the resonant frequency of the transition,  $\tau$  is the exciton dephasing time, and  $\mathbf{E}_L$  is the macroscopic local field inside the QD. The tensor  $\hat{\mathbf{g}}_0$  is a phenomenological parameter expressed in terms of the QD dipole moment  $\boldsymbol{\mu}$  diadic:

$$\hat{\mathbf{g}}_0 = \mp \frac{4\pi}{\hbar V} \boldsymbol{\mu} \boldsymbol{\mu}$$

Here,  $V$  is the QD volume, and upper and bottom signs correspond to ground and excited states, respectively, so that  $\|\hat{\mathbf{g}}_0\| > 0$  in an inverted medium. If QD comprises an isotropic material, orientational averaging leads to the change  $\boldsymbol{\mu} \boldsymbol{\mu} \rightarrow |\boldsymbol{\mu}_0|^2 \hat{\mathbf{I}}/3$ , where  $\boldsymbol{\mu}_0$  is the matrix element of the dipole moment of the corresponding bulk sample.

For time-harmonic fields, the solution of Eq. (5) in the vicinity of the resonance gives the well-known Lorentz contribution to medium polarizability:

$$\hat{\alpha}(\omega) = \frac{1}{\epsilon_h} \frac{\hat{\mathbf{g}}_0}{\omega - \omega_0 + i/\tau} \quad (6)$$

This dependence on the isotropic  $\hat{\mathbf{g}}_0$  is commonly used as a phenomenological model of the dispersion and the gain of a single QD. However, relation (6) assumes an infinite, isotropic, homogeneous medium and can serve only as a rough approximation to the case under consideration: the polarizability of a single QD turns out to be distinct from that given by Eq. (6). Indeed, the

**Fig. 1** Schematic picture of correlation between acting and local fields in electrically small scatterer. The local field is assumed to be homogeneous.

local field  $\mathbf{E}_L$  inside the QD is different from the external acting field  $\mathbf{E}_0$  (Fig. 1). The depolarization field determines this difference by:<sup>[23]</sup>

$$\mathbf{E}_L = \mathbf{E}_0 - 4\pi \hat{\mathbf{N}} \mathbf{P} \quad (7)$$

where  $\hat{\mathbf{N}}$  is the depolarization tensor. This tensor is symmetrical<sup>[24]</sup> (also Ref.<sup>[10]</sup>) and depends only on the shape of the scattering object:

$$N_{\alpha\beta} = -\frac{1}{4\pi V} \int_V \int_V \frac{\partial^2}{\partial r_\alpha \partial r_\beta} \frac{1}{|\mathbf{r} - \mathbf{r}'|} d^3\mathbf{r} d^3\mathbf{r}'$$

Here  $r_{\alpha,\beta} = x, y, z$ . For a sphere,  $\hat{\mathbf{N}} = \hat{\mathbf{I}}/3$ ; for an ellipsoid, this tensor is diagonal on a basis related to the ellipsoid's axes.<sup>[23]</sup> For more complex objects, its elements can be found only numerically.

Substitution of Eq. (7) into Eq. (5) results in a set of equations for three coupled oscillators, which describe the tensorial polarizability of QD in the vicinity of resonance:

$$\hat{\alpha}(\omega) = \frac{1}{\epsilon_h} \frac{1}{(\omega - \omega_0 + i/\tau) \hat{\mathbf{I}} + \hat{\mathbf{g}}_0 \hat{\mathbf{N}}/\epsilon_h} \hat{\mathbf{g}}_0 \quad (8)$$

In this equation, we neglect the linewidth change provided by depolarization.<sup>[5]</sup> Thus one can conclude that the QD's shape reflects itself as a fine structure of the resonance, which itself is a superposition of three bands with frequencies  $\omega_0 - \Delta\omega_j$ , where  $\Delta\omega_j$  are the eigenvalues of the inner tensor product  $\hat{\mathbf{g}}_0 \hat{\mathbf{N}}/\epsilon_h$ . Note

that this diffraction-induced shift is analogous to that which occurs in ferromagnetic resonance, where the resonance frequencies of small-sized grains and infinite continuous media are different because of the effects of demagnetization.<sup>[23]</sup> Depolarization shift has been ignored in Ref.<sup>[25]</sup> under the construction of the electromagnetic response theory of QD arrays. For spherical isotropic QDs, the tensors  $\hat{\mathbf{N}}$  and  $\hat{\mathbf{g}}_0$  are isotropic and the fine structure manifests itself as a polarization-independent shift of the resonance line.<sup>[26,27]</sup> Let us estimate the shift using well-known data for QD characteristics and relations for the exciton radiative lifetime in a medium  $\hbar/\tau_{\text{rad}} = 4k_1^3|\mu_0|^2/3$ , where  $k_1 = \sqrt{\epsilon_h}\omega_0/c$ . Then, the depolarization shift can be written by:

$$\Delta\omega = \pm \frac{4\pi}{9\hbar V} |\mu_0|^2 = \pm \frac{1}{\tau_{\text{rad}}} \frac{\pi}{Vk_1^3} \quad (9)$$

For GaAs spherical QDs with radius in the range  $R = 2\text{--}4$  nm, dielectric constant  $\epsilon_h = 12.25$ , and radiative lifetime  $\tau_{\text{rad}} \cong 1$  nsec,<sup>[1]</sup> at the wavelength  $\lambda = 1.3$   $\mu\text{m}$ , formula (9) gives  $\hbar\Delta\omega \sim 10\text{--}1$  meV, respectively. This estimate correlates well with the theoretical predictions given in Refs.<sup>[4,5,28]</sup> Note that the Bohr radius for such QDs is about 10 nm,<sup>[1]</sup> so that the strong confinement approximation used above is valid. For experimental detection of the predicted fine structure, the value  $\Delta\omega$  must exceed the linewidth provided by radiative decay and homogeneous broadening because of dephasing. From Eq. (9), it follows that the inequality  $\Delta\omega \gg 1/\tau_{\text{rad}}$  holds true for any realistic arbitrary-shaped QDs. Analysis shows that the dominant contribution to the homogeneous broadening gives exciton–phonon interactions. Recent low-temperature ( $T = 20\text{--}40$  K) measurements<sup>[29–31]</sup> give the homogeneous linewidth  $\sim 1\text{--}20$   $\mu\text{eV}$ . Analogous estimates follow from calculations presented in Ref.<sup>[32]</sup> at  $T = 77$  K. Thus at low temperatures, the predicted value of the shift turns out to be sufficiently large to be measured. At room temperature, the homogeneous linewidth grows up to  $\sim 0.2\text{--}1$  meV.<sup>[1,31,32]</sup> This magnitude is comparable to the depolarization shift. However, even in that case, local field effects are of importance for adequate prediction of spectral line shape. Note that the optical absorption and gain of an isolated QD could be distinguished owing to the depolarization shift—blue in the former case and red in the latter one.<sup>[27]</sup>

### Physical Interpretation

Physical interpretation of the depolarization field effect can be given by an analogy with the  $\mathbf{k} \cdot \mathbf{p}$  theory of bulk crystals<sup>[33]</sup> utilizing the concept of electron–hole

effective mass. For spherical QD, using the standard expression for  $\omega_0$  and the given expression for  $\Delta\omega$ , we obtain:

$$\hbar(\omega_0 + \Delta\omega) = \epsilon_g + \frac{\hbar^2\kappa_{nl}^2}{2R^2M} \pm \frac{|\mu|^2}{R^3} \quad (10)$$

where  $M$  is the mass of electron–hole pair in QD,  $\epsilon_g$  is the width of the forbidden bandgap,  $\kappa_{nl}$  is the  $n$ th root of the Bessel function  $J_{l+1/2}(\cdot)$ , and indices  $n$  and  $l$  define the working mode in the oscillator spectrum. The third term in the right-hand part of this equation describes the depolarization field contribution. The right-hand part of the equation can be rewritten as:

$$\epsilon_g + \hbar^2\kappa_{nl}^2/2R^2M_{\text{eff}}$$

with  $M_{\text{eff}}$  given by:

$$M_{\text{eff}} = M \left[ 1 \pm \frac{|\mu|^2 M}{\hbar^2\kappa_{nl}^2 R} \right]^{-1}$$

The quantity  $M_{\text{eff}}$  can be interpreted as effective mass of the electron–hole pair in the QD. Thus electromagnetic effects at the QD boundary (QD depolarization) change the exciton effective mass. Analogous consideration for the case of asymmetrically shaped QDs leads to the tensorial effective mass, which gives rise to the polarization-dependent splitting of the gain band.<sup>[4,5]</sup>

### The Role of Nonlocality

In the weak confinement regime, when the exciton Bohr radius is much less than the QD linear extension, the QD electromagnetic response becomes nonlocal: The constitutive relation for medium polarization takes the form of the integral operator as follows:<sup>[34]</sup>

$$\mathbf{P}(\mathbf{r}) = \frac{DF(\mathbf{r})}{\omega - \omega_0 + i/\tau} \Lambda \quad (11)$$

where

$$\Lambda = \int_V F(\mathbf{r}') \mathbf{E}_L(\mathbf{r}') d^3\mathbf{r}', \quad D = -2|\mu|^2\Phi^2(0)/\hbar \quad (12)$$

The function  $F(\mathbf{r})$  is the envelope function of the exciton ground state whereas the function  $\Phi(r) = \exp(-r/a_B)/\sqrt{\pi a_B^3}$ <sup>[35]</sup> describes the electron–hole relative motion. Inside, QD retardation can be neglected and thus local and acting fields are coupled by:

$$\mathbf{E}_L(\mathbf{r}) = \mathbf{E}_0(\mathbf{r}) + \nabla \nabla \cdot \int_V \frac{\mathbf{P}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d^3\mathbf{r}' \quad (13)$$

Assuming polarization to be constant over the QD volume, Eq. (13) is reduced to relation (7). Eq. (13) allows us to find vector  $\Lambda$  by omitting the procedure of evaluation of the local electromagnetic field  $\mathbf{E}_L(\mathbf{r})$ ; to do this, let us multiply this equation by the function  $F(\mathbf{r})$  and integrate it over the QD volume. As a result, we obtain:

$$\Lambda \approx F_0 \mathbf{E}_0 + \frac{\tilde{\mathbf{g}}_0}{\omega - \omega_0 + i/\tau} \hat{\mathbf{N}}' \Lambda$$

where

$$F_0 = \int_V F(\mathbf{r}') d^3 \mathbf{r}', \quad \tilde{\mathbf{g}}_0 = \frac{4\pi\epsilon_h}{V} F_0^2 D \quad (14)$$

and the 3-D tensor  $\hat{\mathbf{N}}'$  is given by its components:

$$N'_{\alpha\beta} = -\frac{V}{4\pi F_0^2} \int_V \int_V F(\mathbf{r}) F(\mathbf{r}') \frac{\partial^2}{\partial r_\alpha \partial r_\beta} \times \frac{1}{|\mathbf{r} - \mathbf{r}'|} d^3 \mathbf{r} d^3 \mathbf{r}' \quad (15)$$

In the far zone, the electromagnetic field scattered by QD is characterized by the Hertz potential:

$$\Pi^e = \frac{e^{ik_1 r}}{r} \int_V \mathbf{P}(\mathbf{r}') d^3 \mathbf{r}' = \frac{e^{ik_1 r}}{r} D F_0 \Lambda$$

Substituting the above relation for  $\Lambda$  into this formula and taking into account the relation:<sup>[23]</sup>

$$\Pi^e = \frac{V}{4\pi r} e^{ik_1 r} \hat{\alpha} \mathbf{E}_0$$

we come to Eq. (8) for the polarizability tensor of an isolated QD with the change  $\hat{\mathbf{g}}_0 \rightarrow \tilde{\mathbf{g}}_0 \hat{\mathbf{I}}$  and  $\hat{\mathbf{N}} \rightarrow \hat{\mathbf{N}}'$ . Thus the special law of nonlocality (Eq. (11)) inherent to an isolated QD admits the description of the electromagnetic field scattering by the QD using the polarizability tensor independent of the incident field structure. In other words, the nonlocality changes the values of the polarizability tensor components but does not change the general representation of the scattering operators compared with the strong confinement regime. The above result admits extension of the Maxwell Garnett approach to 3-D composites constituted by QDs in weak confinement regimes.

Let us estimate depolarization shift in the weak confinement regime for a spherical QD of the radius  $R$ . Exciton wavefunction for an isolated spherical QD is as follows (e.g., Ref.<sup>[26]</sup>):

$$F(r) \equiv F_{nlm} = C_{nl} Y_{lm}(\vartheta, \varphi) J_{l+1/2}(\kappa_{nl} \rho / R) / \sqrt{\rho}$$

where  $Y_{lm}(\theta, \varphi)$  is the spherical harmonics;  $J_{l+1/2}(x)$  is the Bessel function;  $\kappa_{nl}$  is its  $n$ th root;  $\rho$ ,  $\theta$ , and  $\varphi$  are

the spherical coordinates; and indices  $n$  and  $l$  define the working mode in the oscillator spectrum. Coefficient  $C_{nl} = \sqrt{2} [R J_{l+3/2}(\kappa_{nl})]^{-1}$  provides orthonormalization of functions  $F_{nlm}$ . Furthermore, we restrict ourselves to the case  $l = m = 0$ . By integrating Eqs. (14) and (15), we obtain  $F_0^2 = 32\pi R^3 / \kappa_{n0}^2$ ,  $N_{xx} = N_{yy} = N_{zz} = \kappa_{n0}^2 / 72$ . This allows us to evaluate the depolarization shift of the exciton resonance in the weak confinement regime:

$$\Delta\omega = \pm \frac{4}{3\tau_{\text{rad}}} \frac{\pi}{V k_1^3} \left( \frac{R}{a_B} \right)^3 \quad (16)$$

This shift is different from that given by Eq. (9) for spherical QDs in the strong confinement regime. Because  $V \sim R^3$ , formula (16) states the independence of the depolarization shift on the QD radius in the weak confinement regime. Choosing excitonic modes with another set of numbers  $n, l, m$ , we obviously obtain another magnitude of components  $\hat{\mathbf{N}}'$  and, consequently, another magnitude of the polarizability tensor  $\hat{\alpha}$  (Eq. 8). Thus we come to a peculiar property of the weak confinement regime: Depolarization depends on the excitonic mode number. This property follows from the nonlocality of the exciton polarization. Unlike that, in the strong confinement regime, the depolarization tensor  $\hat{\mathbf{N}}$  is completely determined by the QD geometry.

## BIREFRINGENCE IN QUANTUM DOT ARRAYS

In this section, the general consideration developed above applies to the tetragonal lattice composed of certainly shaped identical QDs. The tetragonal lattice serves as a geometrical model for an ensemble of separated QDs vertically stacked with finite period.<sup>[1]</sup> Let QD be a spheroid with the axis of symmetry directed along the lattice vector  $\mathbf{e}_z$  (Fig. 2). This model admits analytical treatment in the framework of the effective medium theory presented above. Indeed, for the chosen QD shape and the lattice geometry, the depolarization tensor  $\hat{\mathbf{N}}$  and the lattice tensor  $\hat{\delta}$  turn out to be diagonal in the Cartesian basis depicted in Fig. 2,<sup>[13]</sup> and eigenvalues of these tensors corresponding to the basis vectors  $\mathbf{e}_x$  and  $\mathbf{e}_y$  are degenerated. Furthermore, the tensor  $\hat{\mathbf{g}}_0$  must also show the same properties in these coordinates by reasoning of symmetry. In such a situation, the effective permittivity tensor  $\hat{\epsilon}(\omega)$  (Eq. 1) of a composite can be expressed in terms of Cartesian basis diadics by:

$$\hat{\epsilon}(\omega) = \epsilon_H (\mathbf{e}_x \mathbf{e}_x + \mathbf{e}_y \mathbf{e}_y) + \epsilon_E \mathbf{e}_z \mathbf{e}_z \quad (17)$$

where

$$\epsilon_\sigma(\omega) = \epsilon_h + \frac{f_V \alpha_\sigma(\omega)}{1 + f_V \delta_\sigma \alpha_\sigma(\omega)} \quad (18)$$

**Fig. 2** Array of vertically stacked disklike QDs arranged on a tetragonal lattice.

and  $\sigma = E, H$  refers to light polarized along ( $E$ -polarization) or normal ( $H$ -polarization) to the  $z$ -axis. The polarizability components  $\alpha_\sigma$  follow from Eq. (8) and have the form:

$$\alpha_\sigma(\omega) = \frac{1/\varepsilon_h}{\omega - (\omega_0 - g_0^\sigma N_\sigma / \varepsilon_h) + i/\tau} \quad (19)$$

In accordance with Ref.<sup>[23]</sup>, for spheroid, the depolarization factors  $N_\sigma$  are as follows:

$$\begin{aligned} N_E &= \frac{e^2 + 1}{e^3} (e - \arctan e), \\ N_H &= \frac{1}{2} (1 - N_E) \end{aligned} \quad (20)$$

where  $e = [a^2/b^2 - 1]^{1/2}$  is the spheroid eccentricity, and  $a$  and  $b$  are the spheroid semi-axes in the  $xy$ -plane and the  $z$ -direction, respectively. These formulae hold true for both disklike ( $a > b$ ) and cigarlike ( $a < b$ ) spheroids. Infinite stretching of the spheroids ( $a/b \rightarrow 0$ ) results in  $N_E \rightarrow 0$  and  $N_H \rightarrow 1/2$ , and Eq. (19) reproduces the polarizabilities of cylinders (e.g., Ref.<sup>[4]</sup>). The geometrical coefficients  $\delta_\sigma$  for a tetragonal lattice have been derived in Ref.<sup>[13]</sup> (also Refs.<sup>[4]</sup> and<sup>[5]</sup>):

$$\begin{aligned} \delta_E &= \frac{1}{4\pi} \left[ \left( 18 - \frac{10}{\beta^2} \right) \arctan \frac{Q}{\beta^2} + 30 \frac{1 - \beta^2}{\beta^4} \right. \\ &\quad \left. \times \left( 2 \arctan Q - \ln \frac{1 + Q}{1 - Q} \right) \right] \\ \delta_H &= \frac{1}{4\pi} \left[ \left( 18 + \frac{20}{\beta^2} - \frac{30}{\beta^4} \right) \arctan Q \right. \\ &\quad \left. + 15 \frac{1 - \beta^2}{\beta^4} \ln \frac{1 + Q}{1 - Q} \right] \end{aligned} \quad (21)$$

where  $\beta = d_z/d$  is the ratio of lattice periods in the  $z$ -direction and in the  $x$ -direction or  $y$ -direction,  $Q = \beta/\sqrt{2 + \beta^2}$ . The above expressions are not valid for  $\beta \ll 1$  or  $\beta \gg 1$ . For a cubic lattice,  $\beta = 1$  and the electromagnetic interaction of QDs

becomes isotropic:  $\delta_E = \delta_H = 1/3$ . Thus for the chosen QD shape and array configuration, we have found the geometrical coefficients  $N_\sigma, \delta_\sigma$  needed for the evaluation of the array effective dielectric function. These two coefficients correspond to two different mechanisms responsible for the modification of the gain in the array. The first mechanism is related to diffraction at individual QDs. Although QDs are assumed to be electrically small and, by this reason, the diffraction can be described within the dipole approximation, its role turns out to be essential owing to the resonant nature of the exciton. It is obvious that the diffraction-induced shift does not depend on the exciton dephasing time  $\tau$  and the volume fraction  $f_V$  of QDs. The second mechanism inducing a frequency shift is a collective effect and is defined by electromagnetic interaction between QDs in the ensemble. This contribution depends on lattice type. The combined effect of both mechanisms can easily be obtained from Eq. (19):

$$\Delta\omega_\sigma = \frac{g_0^\sigma}{\varepsilon_h} (N_\sigma + f_V \delta_\sigma) \quad (22)$$

Different from the geometrical coefficients  $N_\sigma, \delta_\sigma$ , the quantities  $g_0^\sigma$  are phenomenological parameters, which must be invoked with consideration of the outside.

Eq. (17) shows that, in the language of crystal optics,<sup>[11]</sup> the QD composite being considered is effectively a uniaxial dielectric continuum with the  $z$ -axis as its preferred axis. The phenomenon of birefringence is characteristic for this medium: Both ordinary and extraordinary planewave propagations can occur in it.<sup>[36]</sup> The refractive indices of these waves ( $n_H$  and  $n_E$ , respectively) are given by:<sup>[36]</sup>

$$n_H = \sqrt{\varepsilon_H}, \quad n_E = \sqrt{\frac{\varepsilon_E \varepsilon_H}{\varepsilon_H + (\varepsilon_E - \varepsilon_H) \cos^2 \theta}} \quad (23)$$

where  $\theta$  is the angle between the  $z$ -axis and the propagation direction. The polarization vector of the ordinary wave is normally directed to the plane constituted by the  $z$ -axis and the propagation direction. Eq. (23) shows that  $n_H = n_E$  when the propagation direction coincides with the  $z$ -axis ( $\theta = 0$ ), and  $n_E = \sqrt{\varepsilon_E}$  when the propagation occurs in the  $xy$ -plane ( $\theta = \pi/2$ ). Substitution of Eqs. 19–21 into Eq. (18) and then into Eq. (23) allows us to evaluate the anisotropic macroscopic gain for QD arrays for both polarizations:

$$g_{H,E} = \text{Im}(n_{H,E}) \quad (24)$$

Below we discuss the computation of  $g_{H,E}$  by Eqs. (18), (23), and (24).

## Numerical Estimates and Discussion

The analytics presented above implies composite medium constituted by uniform two-level insertions in the host. Actually, QDs in ensemble are characterized by essential size dispersion and multilevel structure of the exciton spectrum. These factors provide inhomogeneous line broadening, which is beyond the above consideration. As a first step to take the effect into account, we introduce into analytics phenomenological parameters  $g_0 = |\hat{g}_0|$  and  $\tau$  as collective characteristics of the ensemble. A simple estimate of  $g_0$  using experimental data can be given in the following way. The parameter  $g_0$  is related to the material gain per dot  $g_{\text{mat}}$  by  $g_{\text{mat}} \approx kg_0/2\Gamma_{\text{inh}}\sqrt{\epsilon_h}$ , where  $\Gamma_{\text{inh}}$  is the inhomogeneous broadening width in the measured QD sample. The value of  $g_{\text{mat}}$  is extracted from experimental measurements of the QD ensemble gain. Letting  $g_{\text{mat}} \cong 10^5 \text{ cm}^{-1}$  and  $\Gamma_{\text{inh}} \cong 10^{13} \text{ sec}^{-1}$ ,<sup>[1]</sup> for  $\lambda = 1300 \text{ nm}$ , one can obtain  $|g_0| \cong 10^{14} \text{ sec}^{-1}$ . The value of the experimentally estimated maximum material gain correlates with theoretical predictions.<sup>[37,38]</sup> The above estimate is used further for calculations.

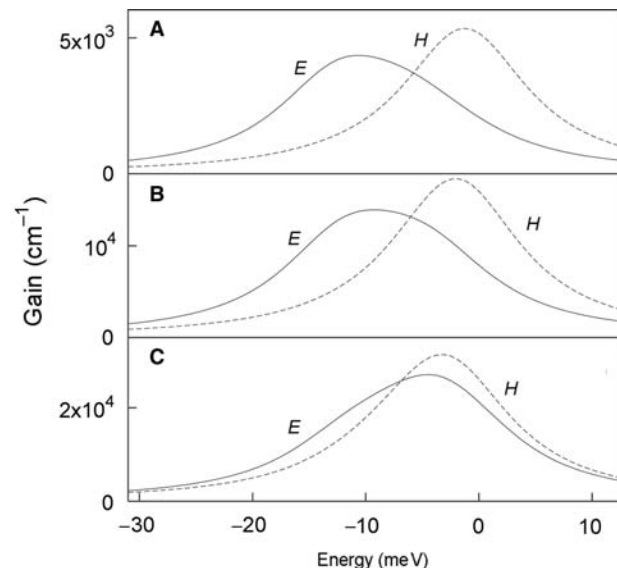

Fig. 3 demonstrates the polarization-dependent shift of the resonance energy of macroscopic gain for the case  $g_0^E = g_0^H$  at different magnitudes of the effective dephasing time and  $\theta = \pi/2$ . In the case of disklike QDs, the gain band for  $H$ -polarized field directed

**Fig. 3** Macroscopic gain bands for  $E$ -polarized and  $H$ -polarized fields (solid and dashed lines, respectively) for an array of disk QDs arranged on a cubic (A) and tetragonal (B, C) lattice and different dephasing times  $\tau = 0.1$  psec (A, B) and  $\tau = 1$  psec (C). Vertical stacking period  $\beta = 1$  (A), 0.3 (B, C); QD's volume fraction  $f_V = 0.02$  (A), 0.07 (B, C);  $B/A = 0.33$ ;  $A/D = 0.25$ ; host dielectric constant  $\epsilon_h = 12.25$ ; and wavelength  $\lambda = 1 \mu\text{m}$ . Also shown by dotted lines are the gain bands of QD ensembles defined by Eq. (6) with isotropic  $\hat{g}_0$ . Source: From Ref.<sup>[5]</sup>.

toward the long axis of the disc possesses the smaller shift. The polarization dependence of the shift results in an appreciable polarization splitting of the gain bands for  $E$ -polarization and  $H$ -polarization, which become completely resolved for sufficiently large dephasing times (Fig. 3C). Thus radiation from an active composite must be linearly polarized at a given frequency.

As it has been pointed out above, the analytical treatment illustrated by Fig. 3 is invalid at  $\beta \ll 1$  and  $\beta \gg 1$ . Fig. 4 demonstrates polarization splitting of the gain band for cubic (Fig. 4A) and tetragonal lattices (Fig. 4B and C) of disklike QDs, obtained via direct numerical simulation by the minimal autonomic block (MAB) method.<sup>[5]</sup> Comparison with Fig. 3 shows that for cubic lattices (Figs. 3A and 4A), the polarization splitting effect manifests itself in the same manner, distinguished only in that the peak gains for  $E$ -polarized and  $H$ -polarized waves are slightly different in the last case. The situation is changed as  $\beta$  decreases (i.e., disks approach each other along the  $z$ -axis as far as they are in contact). Instead of the splitting increase demonstrated by Fig. 3B, we see a reverse tendency (Fig. 4B) up to the interchange of the  $E$ -polarized and  $H$ -polarized peaks for closely stacked pyramids (Fig. 4C). Note that the relative location of the  $E$ -polarized and  $H$ -polarized peaks in last case correlates with analytical results for quantum wires presented in Ref.<sup>[4]</sup>. Thus from an electrodynamic point

**Fig. 4** Macroscopic gain bands for  $E$ -polarized and  $H$ -polarized fields (solid and dashed lines, respectively) for an array of disklike QDs arranged on a cubic (A) and tetragonal (B, C) lattice. The input parameters  $\epsilon_h$ ,  $\lambda$ ,  $B/A$ , and  $A/D$  are the same as in Fig. 3. Dephasing time is  $\tau = 0.1$  psec. Vertical stacking period  $\beta = 1$  (A), 0.3 (B), and 0.2 (C). QD's volume fraction  $f_V = 0.02$  (A), 0.07 (B), and 0.1 (C). Source: From Ref.<sup>[5]</sup>.

of view, closely stacked QDs form a corrugated quantum wire. The corrugation is responsible for the quantitative difference in the polarization splitting for closely stacked QDs (Fig. 4B) and cylindrical quantum wires.<sup>[4]</sup> Numerical results for slablike QDs at  $\beta \rightarrow 0$  correlate well with the analytics. The fact that the tendency inherent in the polarization splitting for closely stacked QDs cannot be derived from analytical treatment reflects both the restrictiveness of the Maxwell Garnet formalism of the effective medium approach utilized in our paper and the use of approximate expressions (Eq. (21)) for the geometrical coefficients  $\delta_\sigma$ .

Fig. 5 demonstrates the formation of the gain band fine structure in tetragonal lattices of disklike QDs for the  $E$ -polarized field (extraordinary wave; Eq. (23)) at oblique propagation with respect to the  $z$ -axis. As is predicted by Eq. (23), the  $H$ -polarized field exhibits single resonance coinciding with that for  $E$ -polarization at  $\theta = 0$ . Owing to the high symmetry of pyramids, the MAB method simulation for arrays of disklike and pyramidal QDs shows that both models of the QD shape manifest qualitatively similar behavior differing in the shift values and peak amplitudes. It should be noted that the band fine structure illustrated in the particular case given by Fig. 5 must be involved in considering the interpretation of any polarization effects in QD arrays.

In general, also the anisotropic shape of QD causes different oscillator strengths for transitions involving  $E$ -polarized and  $H$ -polarized fields.<sup>[37]</sup> To estimate the influence of different gains for different polarizations, we considered the case when the gain for  $E$ -polariza-

**Fig. 5** Macroscopic gain of  $E$ -polarized field by disk DQs arranged on a tetragonal lattice for different  $\theta$  from  $\pi/2$  to 0 as indicated. Lattice and individual QD parameters are as in Fig. 3. (B). *Source:* From Ref.<sup>[5]</sup>.

tion is lower and the case when the gain for  $H$ -polarization is higher (Fig. 6) compared with the case of equal gains in Fig. 3A and B (parameter  $g_0$  in Eq. (8) is the diagonal tensor). To make the effect clearer, we select also a longer exciton dephasing time. The remarkable result is that the gain peak of  $E$ -polarization locates closer to the QD resonance energy because the decrease of the gain peak dominates over the corresponding depolarization coefficient and results in smaller shifts than follow from Eq. (9).

To verify the predicted effects experimentally, a structure with a dense array of QDs was fabricated at the Abram Ioffe Physical Technical Institute (St. Petersburg). The structure represented 12 stacks of arrays of ZnCdSe disklike QDs formed in a self-organized way. The growth, structural, and basic optical properties of the structure are given in Ref.<sup>[39]</sup>. The areal density of QDs in a single sheet was about  $10^{12} \text{ cm}^{-2}$ ; the ZnCdSe dots had a lateral size of  $\sim 4 \text{ nm}$  and a height of  $\sim 1.2 \text{ nm}$ . The dots were incorporated in a ZnSe matrix and separated with 5-nm ZnSe spaces.<sup>[39,40]</sup> At low excitation density in edge geometry, QD photoluminescence (PL) is linearly polarized<sup>[5,40]</sup> throughout the PL band with a degree of polarization of 50% of the  $H$ -component (alignment as in Fig. 1). This effect is related to the anisotropy in optical transition matrix elements for  $H$ -polarizations and  $E$ -polarizations originating from the disklike shape of the QDs and the heavy-hole-like nature of

**Fig. 6** Macroscopic gain of  $H$ -polarized field (solid curves) by disklike QDs arranged on a tetragonal lattice for different anisotropic gains with  $g^E/g^H = 1.0(1), 4.0(2), 12.0(3)$ , normal incidence  $\theta = \pi/2$ ,  $\tau = 0.5 \text{ psec}$ , and other parameters as in Fig. 5. Dashed curve = a gain band for  $E$ -polarization; dotted curve = a gain band of a QD ensemble defined by Eq. (6) with isotropic  $\hat{g}_0$ . (From Ref.<sup>[5]</sup>.)

**Fig. 7** Photoluminescence (PL) and photoluminescence excitation (PLE) spectra (A) and *E*-polarized and *H*-polarized spectra of stimulated emission in edge geometry (B) for the observation temperature = 7 K, excitation density = 1 MW/cm<sup>2</sup>, and energy of exciting photon  $E_{ex} = 2.88$  eV. Source: From Ref.<sup>[4]</sup>.

the QD exciton. The light-hole-like exciton QD state is also seen in the PL excitation spectrum and is shifted significantly away from the spectral range of interest. With increase in excitation density, gain develops<sup>[39]</sup> and causes a strong superlinear growth of the PL intensity. Spectra of the *H*-components and *E*-components of stimulated emission are shown in Fig. 7B. The predominantly *H*-polarized component is shifted from the QD resonance revealed in the PL excitation and optical reflectance spectra (Fig. 7A). The degree of polarization of this component strongly increases with excitation density. At the same time, we distinctly observe an appearance of a second separate peak in the *E*-component at energies closer to the QD resonance. The intensity of the *E*-polarized peak is much smaller, pointing to a smaller gain coefficient as compared with that for the *H*-polarized peak at lower photon energy. Therefore the peak location of the *E*-component corresponds to the predictions of the calculations for the case of different gain coefficients for *E*-polarizations and *H*-polarizations (Fig. 6).

### Reflectance of Planar Array of Quantum Dots

As was pointed out above, a planar layer comprising a 2-D ensemble of QDs can be treated as an effective QW. As a result, the formalism of investigation of QWs can be extended to QD arrays by introducing effective integral parameters of the array defined by Eq. (4). In particular, it can easily be shown that EBCs (Eq. (3)) describe a QW of the thickness  $L_{QW}$  with the

tensorial dielectric function given by Eq. (17):

$$\begin{aligned}\varepsilon_H(\omega) &= \varepsilon_h - \frac{4\pi i}{\omega} \sigma_{xx} L_{QW}, \\ \varepsilon_E(\omega) &= \frac{\varepsilon_h}{1 + 2\xi/L_{QW}}\end{aligned}$$

Reflection coefficients for such a QW are given by:<sup>[17]</sup>

$$\begin{aligned}r_H(\omega) &= \frac{ik\eta_H}{2\sqrt{\varepsilon_h} \cos \theta - ik\eta_H}, \\ r_E(\omega) &= \frac{ik[\eta_H \cos^2 \theta + \varepsilon_h^2 \eta_E \sin^2 \theta]}{2\sqrt{\varepsilon_h} \cos \theta - ik[\eta_H \cos^2 \theta - \varepsilon_h^2 \eta_E \sin^2 \theta]}\end{aligned}\quad (25)$$

where  $\theta$  is the angle of incidence and:

$$\begin{aligned}\eta_H &= L_{QW}[\varepsilon_H(\omega) - \varepsilon_h], \\ \eta_E &= L_{QW} \left[ \frac{1}{\varepsilon_E(\omega)} - \frac{1}{\varepsilon_h} \right]\end{aligned}$$

For spherical particles, after substituting  $L_{QW} \rightarrow 2R$ ,<sup>[7]</sup> Eq. (25) describes the reflection from the planar array of QDs. Thus we state the mathematical equivalence of optical properties of a 2-D periodical layer of QDs and an isolated quantum well. It should be stressed that the mechanisms of electron transport processes and oscillator strengths in each case are essentially different. Nevertheless, the equivalence makes it possible to extend to QD-based planar structures with more complicated configurations (finite-sized QD layer, QD layer in microcavity, several QD layers, etc.) the well-developed mathematical formalism of investigation of quantum wells.<sup>[41]</sup> Namely this equivalence provides promising potentiality of the derived EBCs for particular electrodynamic problems in QD-based structures. In particular, the threshold current for QD-based lasers can be evaluated by analogy with solutions of corresponding problems for the QW lasers; the EBC method allows us to analyze electromagnetic responses of a QD layer (or a multilayer structure) placed in microcavity—this is very important for the design of QD-based semiconductor lasers.<sup>[1]</sup>

### CONCLUSION

In our paper, we have discussed the electromagnetic response properties of 2-D and 3-D inhomogeneous semiconductor heterostructures—excitonic composites—constituted by QDs imbedded in a transparent host medium. The Maxwell Garnett approach of the effective medium theory and its modification—impedance

boundary conditions—have been applied to study 3-D and 2-D structures, respectively. The depolarization shift of the QD gain band and, in anisotropically shaped QDs, the polarization-dependent splitting of this band have been predicted to exist as manifestation of the local field effects. Both types of the exciton localization—strong and weak confinement regimes—with a pronounced non-locality in the latter regime have been addressed. The basic result is that in both cases, spatially local constitutive relations describe QD composites although the electromagnetic response of an isolated QD in the weak confinement regime is spatially nonlocal. The nonlocality manifests itself in specific dependence of the effective constitutive parameters on the geometry and electronic properties of a single QD.

In our consideration, we have restricted ourselves to the simplest model of excitonic composites—the perfect lattice of identical QDs—whereas experimentally, available structures show intrinsic size dispersion and periodicity violation. These effects may be characterized by a distribution function and taken into account by a theory of irregular excitonic composites. Elaboration of such a theory is the topical question. Another essential restriction of the analysis presented is that nonclassical light–matter interactions have been left beyond the analysis. The quantum nature of light interacting with an excitonic composite is expected to be of importance for many problems where collections of excitons are involved: quantum computing, electromagnetic fluctuations, etc. Both topical questions will be addressed elsewhere in the future.

## INTRODUCTION

Quantum dot (QD) lasers emerged about decade ago and now they are one of the most rapidly developing and exciting areas in the field of semiconductor optoelectronics. Properly optimized QD lasers show better performance than conventional quantum well (QW) lasers: low threshold current, enhanced temperature stability, high differential efficiency, increased differential gain, and small linewidth enhancement factor resulting in reduced filamentation and chirp. Self-organized QDs offer the possibility to reach emission wavelengths that are larger than those obtainable with quantum wells of the same material system.

In this entry we discuss the fundamentals of QD lasers. The criteria for the optimization of QD lasers for different applications are considered. Experimental demonstrations of the advantages of QD lasers are presented. The latest experimental results on edge-emitting and vertical cavity surface emitting QD lasers are reviewed. Possible short-term commercial applications of QD lasers are also discussed.

## ADVANTAGES OF QUANTUM DOT LASERS

The concept of carrier confinement has been of primary importance in the development of semiconductor laser. The invention of the double heterostructure,<sup>[1,2]</sup> in which carriers in a narrow-gap material are confined by wide bandgap barriers, made possible the first continuous wave (CW) operation of semiconductor lasers at room temperature and their practical implementation. The next breakthrough occurred when Dingle and Henry proposed the idea to “exploit quantum effects in heterostructure semiconductor lasers to produce wavelength tunability” and to achieve “lower lasing thresholds” via “the change in the density of states which results from reducing the number of translational degrees of freedom of the carriers”.<sup>[3]</sup> It was also shown that if the number of translational degrees of freedom of charge carriers is decreased below two, a

singularity occurs in the density of states (Fig. 1). This singularity increases light absorption or light amplification (gain). An ultimate case of size quantization is realized in QDs. A QD is a coherent inclusion of a narrow-gap material in a wide-gap matrix in which electrons are quantized in all three spatial directions. Thus a single semiconductor QD exhibits a discrete  $\delta$ -function-like energy spectrum similar to that in a real atom, keeping the advantage of direct current injection, impossible in other types of lasers based on atomic transitions.

The physical advantages of QD lasers resulting from  $\delta$ -function-like density of states are:

- Low threshold current
- High material gain
- High temperature stability of the threshold current (characterized by characteristic temperature  $T_0$ )
- High differential efficiency
- High differential gain
- Small  $\alpha$ -factor and correspondingly reduced filamentation and chirp (shift of the lasing wavelength with current)

In addition, QD medium has some advantages, which are not directly related to size quantization effects:

- The possibility to reach emission wavelengths that are larger than those obtainable with quantum wells of the same material system. For instance, lasing at wavelengths up to 1.32  $\mu\text{m}$  is demonstrated for InAs QDs on GaAs substrate, in contrast to QW devices, in which lasing is limited to approximately 1.15  $\mu\text{m}$ .
- Dramatically reduced carrier lateral transport. Carrier capture in QDs is very fast and carrier localization in QDs is very efficient. This leads to a number of advantages of using QD medium in laser applications: larger catastrophic optical damage threshold due to decreased facet overheating, increased lifetime, enhanced radiation hardness, and the possibility to fabricate narrow stripes via

**Fig. 1** A schematic sketch of the density of states (dashed curves) and gain spectra (solid curves) in bulk material, quantum well, quantum wires, and quantum dots. Schematic morphology is shown on the right.

etching through active area without increase in surface recombination.

Some of the basic advantages of QD lasers such as improvement in the temperature stability of the threshold current,<sup>[4]</sup> high material gain,<sup>[5]</sup> and the possibility of remarkable reduction in the laser threshold were already described in the first theoretical works on QD lasers. These works, however, were generally based on simplified assumptions such as infinite barriers, no QD size fluctuations, one confined electron and hole level, and ultrafast energy relaxation of injected carriers. More recent theoretical models had to take into account such complications as finite barriers, many electron and hole levels (effect of excited states), QD size fluctuations, many body effects, radiative and non-radiative recombination in the optical confinement layer (OCL; wide-gap matrix), charge neutrality violation in QDs, etc. It was shown that the characteristics

of QD lasers depend dramatically on the parameters characterizing QD array (QD lateral size, height and corresponding position of energy levels, QD density, and size dispersion) as well as on the structure design: thickness of the OCL, doping profiles in the cladding layers and in the OCL, the band offsets at the interface between the OCL and the cladding layers. Depending on the abovementioned parameters the performance of QD lasers can be very good or poor. To get the best performance, an optimization of QD array parameters should be done consistently with the optimization of the structure design. Optimization for certain applications (low threshold current, high output power, etc.) should be done according to different criteria, and in many applications a combination of these criteria needs to be taken into account.

High temperature stability of the threshold current as the main fingerprint of QD lasers was demonstrated already in the first injection laser based on self-organized QDs.<sup>[6]</sup> Further realization of the advantages of QD lasers was associated with the improvement in QD growth and the development of more sophisticated QD growth techniques. At present, all the advantages of QD lasers are basically experimentally proved. At the same time we believe that there is still room for improvement in the characteristics of QD lasers. Experimental and theoretical studies of QD lasers are exploding in scientific areas and further progress in the field of QD lasers can be foreseen. Recently, the first commercial QD lasers have been announced.<sup>[7]</sup>

## QUANTUM DOTS GROWTH

Realization of QD lasers became possible owing to the progress in self-organized growth. The deposition of a material with a lattice constant different from that of the substrate was shown to result in a spontaneous formation of three-dimensional (3-D) islands (for a review, see Ref.<sup>[8]</sup>). In most practical cases, for instance for the deposition of InGaAs on GaAs, first a 2-D layer grows on the substrate and island formation occurs only after a certain critical thickness is exceeded. Thus QD array is situated on top of a thin initial planar layer (so-called wetting layer). This growth mode is referred to as Stranski–Krastanow growth mode. Under certain growth parameters, arrays of highly uniform coherent islands can be formed. Each island generates long-range strain fields in the substrate and interaction of the island via these fields favors island lateral ordering in a 2-D lattice.

The characteristics of QD lasers depend dramatically on the parameters characterizing QD array.<sup>[9]</sup> Already in the first injection QD laser based on QDs formed in simple Stranski–Krastanow growth mode, insufficient carrier localization in QDs and their

thermal escape to the wetting layer and the OCL were shown to be a disadvantage, deteriorating the device performance at high temperatures.<sup>[6]</sup> As simple Stranski–Krastanow growth provides only limited control of the interrelated size and density of the islands, extensive investigations have been conducted to overcome these limitations and to optimize the properties of QD arrays. Novel advanced approaches such as vertically coupled QDs<sup>[10]</sup> lead to a considerable improvement in the performance of QD lasers.

Present best performance QD lasers are based on QDs formed by the technological approach that we refer to as activated alloy phase separation (AAPS).<sup>[11,12]</sup> In this approach the original Stranski–Krastanow InAs islands are formed by depositing a certain amount ( $D_{IS}$ ) of InAs ( $D_{IS} = 1.7\text{--}3$  ML). The original islands are then overgrown with an average thickness  $H$  of  $\text{In}_x\text{Ga}_{1-x}$  As alloy layer ( $H = 0\text{--}6$  nm,  $x = 0\text{--}0.20$ ). The strain field induced by each island leads to a migration of In atoms toward it and, correspondingly, to an increase in its effective volume. The increase in the original island volume as well as partial strain relaxation in such QDs embedded in an  $\text{In}_x\text{Ga}_{1-x}$  As layer and a narrowing of the matrix bandgap results in a higher confinement of electron and hole levels with a corresponding red-shift of the photoluminescence (PL) emission.<sup>[12,13]</sup> Lasers based on QDs formed by the AAPS enable it to reach lasing wavelengths above  $1.3\ \mu\text{m}$  for the structures grown on GaAs substrates, which is not possible with the use of InGaAs QWs. The AASP process sensitively depends on the size and density of the InAs nanostressors, i.e., the InAs deposition amount ( $D_{IS}$ ), as well as on the thickness ( $H$ ), and on the composition ( $x$ ) of the  $\text{In}_x\text{Ga}_{1-x}$  As alloy layer. To achieve high QD confinement energy (long emission wavelength), narrow QD size distribution, and simultaneously prevent formation of dislocations and large dislocated clusters, a careful optimization of growth parameters is required and described in detail in Ref.<sup>[12]</sup>

A growth sequence very similar to AAPS is referred to by the authors as a “dots in a well” (DWELL) design.<sup>[14]</sup> In the DWELL design the original Stranski–Krastanow islands are formed on a several-nanometer-thick  $\text{In}_x\text{Ga}_{1-x}$  As buffer layer. To the best of our knowledge QDs formed by AAPS and DWELL have very similar properties. More details on the growth and optical properties of InAs–GaAs QDs emitting in long-wavelength optical region can be found in review.<sup>[15]</sup>

### EQUILIBRIUM VS. NONEQUILIBRIUM CARRIER DISTRIBUTION IN QUANTUM DOT ARRAY

Depending on the sample temperature and the confinement of electron and hole energy levels with respect to

the continuum, the carrier distribution within the QD array can be either equilibrium or non-equilibrium.<sup>[9]</sup> At high temperatures or (and) low confinement energies the characteristic times of thermally excited escapes of electrons and holes from a QD are small compared to the radiative lifetime in QDs. Thermal carrier emission, lateral transport via the wetting layer and matrix, and then recapture result in the quasi-equilibrium distribution of carriers in the array with the corresponding quasi-Fermi levels determined by the pumping level. As a consequence of such carrier redistribution, the level occupancies (and numbers of carriers) in various QDs will differ.

At low temperatures or (and) efficient confinement of electron and hole energy levels, the radiative lifetime in QDs is small compared with the characteristic times of thermally excited escapes of the carriers from a QD. A carrier captured by a QD having no time to leave a QD recombines in the same QD. The redistribution of carriers from one QD to another and establishment of quasi-Fermi levels for the conduction and valence bands do not occur. As the initial numbers of carriers injected into various QDs are the same, the level occupancies are also the same there.

Carrier distribution dramatically affects the dependence of gain spectra on the injection current.<sup>[9]</sup> In case of non-equilibrium distribution, the gain spectrum copies the shape of the curve corresponding to the dispersion of QD ground-state transition energies (Gaussian). The spectra are scaled along the vertical axis by a factor equal to the mean population inversion in QDs (Fig. 2A). In case of quasi-equilibrium the “gradual” filling of the curve occurs with the increase in pumping level (Fig. 2B).

### SPONTANEOUS EMISSION AND GAIN

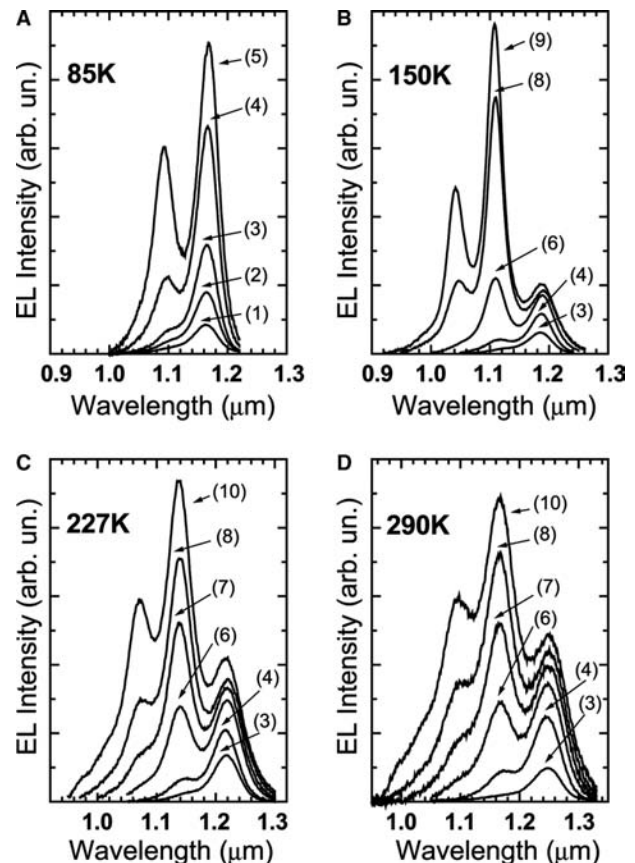

The first theoretical simulations of QD lasers were based on the assumption of one electron and one hole level in a QD. In actual QDs the energy level structure is much more complex.<sup>[13,16]</sup> In a pyramidal QD with base length larger than 14 nm there are several electron and hole levels.<sup>[16]</sup> Because of piezoelectric effect and Coulomb interaction there is no degeneracy, even accidental, of the excited states. However, several excited-state transitions may act as one “effective” transition if their energies are close. The absorption (gain) spectrum of the “effective” transition will be a superposition of absorption (gain) spectra corresponding to individual excited-state transitions with close energies. The maximal absorption (gain) of this superposition can be higher than that of the ground-state transition.<sup>[17]</sup>

Typical electroluminescence (EL) spectra of a laser based on QDs with narrow size distribution are

**Fig. 2** Gain spectra for the cases corresponding to non-equilibrium (A) and equilibrium (B) filling of QDs. The curves are numbered in ascending order of population inversion in a QD. The dashed curve corresponds to the population inversion equal to unity.  $E_0$  is the energy of the ground state transition in an average sized QD. *Source:* From Ref.<sup>[9]</sup>.

shown in Fig. 3. A 200- $\mu\text{m}$ -long stripe was used. Short stripes are essential to measuring the EL spectrum shape correctly. The longer the stripe the higher the probability of high energy photons corresponding to the emission from excited states to be reabsorbed and contribute to the final emission from lower energy levels. By contrast, lower energy photons corresponding to the emission from the ground state easily leave the structure. The reabsorption effect can modify the EL spectra. Moreover, in short stripes, the spontaneous emission can be studied even at high current densities. At the lowest excitation density, the emission mainly originates from the ground-state transition. At higher excitation densities, the first and the second short wavelength peaks become apparent. Strong level filling occurs at high injection currents because of the limited number of QD energy states. At all temperatures, EL lines from the ground- and excited-state transitions are relatively narrow (40–60 nm) and well resolved. Emission due to the wetting layer/InGaAs layer is also seen in the spectra at 0.97  $\mu\text{m}$  at room temperature (the QDs are embedded in a QW formed by

**Fig. 3** Electroluminescence spectra from a 200- $\mu\text{m}$ -long stripe at different injection currents and temperatures: (1) 12.5, (2) 25, (3) 50, (4) 125, (5) 250, (6) 500, (7) 1250, (8) 2500, (9) 3750, and (10) 5000  $\text{A}/\text{cm}^2$ .

the wetting layer and InGaAs layer with nominal thickness  $H$ ). Each of the two short wavelength QD peaks is likely to be a superposition of two or more closely located peaks from transitions involving different electron and hole sublevels. At 80 K, the lasing starts at a current density of 500  $\text{A}/\text{cm}^2$ , whereas at 290 K the device is in the spontaneous emission mode up to 5  $\text{kA}/\text{cm}^2$ .

Modal gain spectra of a laser structure based on three sheets of QDs formed by the AAPS are shown in Fig. 4. The surface density of QDs estimated from TEM images was  $4\text{--}5 \times 10^{10} \text{cm}^{-2}$ . The spectra are measured by the variable-stripe length method with varying current injection. The maxima at 1.254 and 1.18  $\mu\text{m}$  correspond to the ground- and first excited-state transitions. At current densities of about 900  $\text{A}/\text{cm}^2$  the gain of the ground-state transition saturates. The gain saturation effect is a consequence of the limited surface density of QDs, inhomogeneous broadening of the QD array, and the limited QD radiative emission rate. The maximum modal gain for the transition from the  $i$ th electron level to the  $j$ th hole

**Fig. 4** Modal gain spectra at different injection currents: (1) 98, (2) 195, (3) 487, (4) 975, (5) 1950, and (6) 2925 A/cm<sup>2</sup>.

level is:<sup>[17]</sup>

$$g_{ij}^{\max} = \frac{\xi}{4} \left[ \frac{\bar{\lambda}_{ij}}{\sqrt{\bar{\epsilon}_{ij}}} \right]^2 d_{ij} \frac{1}{\tau_{ij}^{\text{QD}}} \frac{\hbar}{(\Delta\epsilon)_{\text{inhom},ij}} \frac{\bar{\Gamma}_{ij}}{\bar{a}} N_S Z_L \quad (1)$$

where

$\xi$  is a numerical constant ( $\xi = 1/\pi$  and  $\xi = 1/\sqrt{2\pi}$  for Lorentzian and Gaussian QD-size distribution functions, respectively);

$\bar{\lambda}_{ij} = 2\pi\hbar c/\bar{E}_{ij}$  (a wavelength at transition  $\bar{E}_{ij}$ );

$d_{ij}$  is the degeneracy of the transition;

$\bar{a}$  is the mean size of QDs;

$Z_L$  is the number of QD layers;

$N_S$  is the surface density of QDs in a layer;

$\bar{\epsilon}_{ij}$  is a dielectric constant;

$\tau_{ij}^{\text{QD}}$  is the spontaneous radiative lifetime for the  $i \rightarrow j$  transition;

$(\Delta\epsilon)_{\text{inhom},ij}$  is the inhomogeneous line broadening for the  $i \rightarrow j$  transition;

$\bar{\Gamma}_{ij}$  is the modal optical confinement factor in a QD layer (along the transverse direction in the waveguide) for the  $i \rightarrow j$  transition.

The measured maximum (saturated) modal gain of the ground-state transition is 12 cm<sup>-3</sup> (4 cm<sup>-1</sup> per

QD sheet). For a laser structure based on 10 stacks of similar QDs the measured maximum modal gain was above 25 cm<sup>-1</sup>.<sup>[11]</sup>

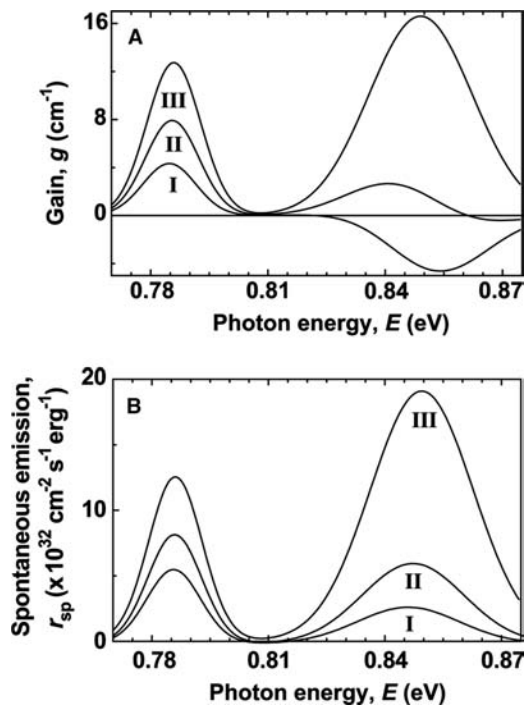

In equilibrium filling of QDs, the general relationship between the gain and spontaneous emission spectra has been shown to hold for an arbitrary number of radiative transitions and an arbitrary QD-size distribution.<sup>[17]</sup> Thus gain spectrum can be derived from the measured spontaneous emission spectrum (and vice versa).

### EFFECT OF EXCITED-STATE TRANSITIONS ON THE THRESHOLD CHARACTERISTICS OF A QUANTUM DOT LASER

Depending on the relationship between the separation of the ground- and excited-state transition energies and the inhomogeneous broadening, either a smooth or a step-like change in the lasing wavelength with losses occurs.<sup>[18,19]</sup> The multiple transition effect on threshold characteristics, in particular on the lasing wavelength, was theoretically studied in Ref.<sup>[17]</sup>. We consider two optical transitions and assume that maximal gain for the “effective” excited-state transition is higher than that for the ground-state transition. The following situations can arise:<sup>[17]</sup>

1. Large separation of the mean transition energies and small inhomogeneous broadening. The gain and the spontaneous emission spectra for different injection current levels are shown in Fig. 5A and B, respectively. As the injection current density at the lasing threshold is a monotonically increasing function of the losses  $\beta$ , the dependence of the laser characteristics on the injection current density will also represent the dependence on the losses, and vice versa. At  $\beta < g_1^{\max}$ , the gain peak is near the energy of the ground-state transition ( $\bar{E}_1$ ) and, hence, lasing occurs via this transition ( $\lambda \approx \bar{\lambda}_1$ , where  $\lambda$  is the lasing wavelength and  $\bar{\lambda}_1$  is the wavelength of the ground-state transition). For  $\beta$ , somewhat less than  $g_1^{\max}$ , there is a shift in the peak position, and for  $g_1^{\max} < \beta < g_2^{\max}$ , the peak is seen near the energy of the excited-state transition ( $\bar{E}_2$ ). Lasing then occurs via the excited-state transition ( $\lambda \approx \bar{\lambda}_2$ , where  $\lambda$  is the lasing wavelength and  $\bar{\lambda}_2$  is the wavelength of the excited-state transition). The lasing wavelength and threshold current density  $j_{\text{th}}$  are shown in Fig. 6 as a function of losses. The break in  $\partial j_{\text{th}}/\partial\beta$  at  $\beta \approx g_1^{\max}$  reflects the shift of the lasing wavelength. As the modal gain peak is equal to the losses at lasing threshold, it is obvious that the curve for the threshold

**Fig. 5** Gain (A) and spontaneous emission spectra (B) at different injection currents for a model structure in case of large separation of the mean transition energies and small inhomogeneous broadening. I:  $j = 6.8 \text{ A cm}^{-2}$ , II:  $j = 18 \text{ A cm}^{-2}$ ,  $j_3 = \infty$  (saturated  $g$  and  $r_{sp}$ ). Source: From Ref.<sup>[17]</sup>.

current density against losses also represents the gain peak vs. the injection current density (the gain-current curve) if the abscissa and the ordinate are interchanged.

2. Small separation of the mean transition energies and large inhomogeneous broadening. The character of the change in the gain and the

The vertical dashed lines are for  $g_1^{\text{max}}$  and  $g_2^{\text{max}}$ . The horizontal dashed and dotted lines in the inset are for  $\bar{\lambda}_1$  and  $\bar{\lambda}_2$ . Source: From Ref.<sup>[17]</sup>.

**Fig. 7** Gain (A) and spontaneous emission (B) spectra at different injection currents for a model structure in case of small separation of the mean transition energies and large inhomogeneous broadening, I:  $j = 20.7 \text{ A cm}^{-2}$ , II:  $j = 39.7 \text{ A cm}^{-2}$ ,  $j_3 = \infty$  (saturated  $g$  and  $r_{sp}$ ). Source: From Ref.<sup>[17]</sup>.

spontaneous emission spectra with injection current as well as the lasing wavelength dependence on losses are shown in Figs. 7 and 8, respectively. There is a smooth change in  $\lambda$  with  $\beta$ . The lasing wavelength  $\lambda$  can be significantly below  $\bar{\lambda}_1$  for high losses. Nevertheless, it is hard to construct a situation where  $\lambda$  approaches

**Fig. 8** Threshold current density and lasing wavelength (the inset) against losses. The parameters are the same as in Fig. 7. The vertical dashed lines are for  $g_1^{\text{max}}$  and  $g_2^{\text{max}}$ . The horizontal dashed and dotted lines in the inset are for  $\bar{\lambda}_1$  and  $\bar{\lambda}_2$ . Source: From Ref.<sup>[17]</sup>.

$\bar{\lambda}_2$ . This is because the position of the gain spectrum peak is determined by the overlap of the transition lines, and the inhomogeneous broadening of the excited-state transition is always larger than that of the ground-state transition. Thus the position of the gain spectrum peak is closer to that of the ground-state transition. Therefore when the lasing wavelength changes smoothly with losses, it is impossible to derive information on the energy of the excited-state transition directly from this dependence.

Near-threshold lasing and EL spectra of a laser structure based on three sheets of QDs formed by the AAPS (the same as was used to measure spontaneous emission and gain spectra; Figs. 3 and 4) are shown in Fig. 9. The inhomogeneous broadening is less than the separation of the mean transition energies (situation 1 takes place). For a long stripe, where the external loss is small, the gain of the ground-state transition is sufficient to overcome the total loss, and lasing occurs via the ground-state transition (Fig. 9A). In shorter stripes, with larger external loss, the gain of the ground-state transition is not sufficient to

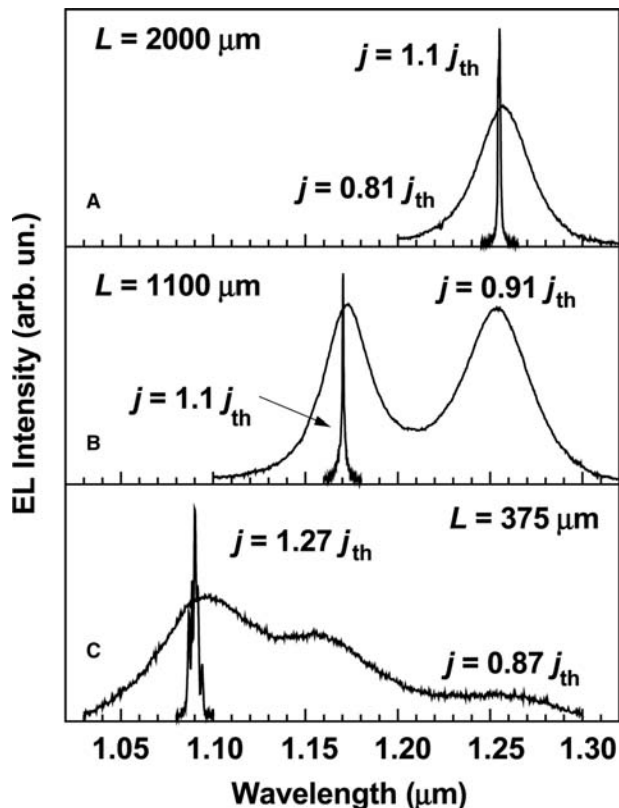

Fig. 9 Electroluminescence spectra showing spontaneous emission and lasing. Different stripe lengths are used.

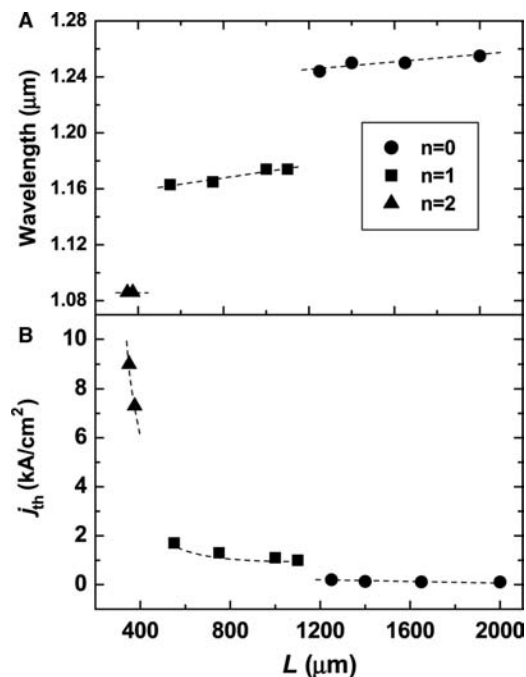

Fig. 10 Dependence of the lasing wavelength (A) and the threshold current density (B) on the cavity length.  $n = 0$ , 1, and 2 denote the ground, first, and second excited states, respectively.

overcome the total loss, and the lasing proceeds via the first excited-state transition (Fig. 9B); the threshold current density increases dramatically. The shortest devices lase via the second excited-state transition (Fig. 9C) at a very high threshold current density. The dependence of the lasing wavelength and the threshold current density on the cavity length is summarized in Fig. 10. When the lasing occurs via the ground-state transition (for cavities longer than 1.2 mm) the threshold current density increases only slightly as the cavity length decreases.

## THRESHOLD CURRENT DENSITY

Lower threshold current density in QD lasers as compared to those based on quantum wires and QWs was predicted in early theoretical works and greatly motivated experimental and theoretical research in the field of QD lasers. More detailed theoretical studies revealed dramatic dependence of threshold current on the parameters of QD array among which the most important are the QD density and the inhomogeneous broadening.<sup>[9]</sup> Thus, for instance, it was shown that lasing could never be achieved if QD density is less than certain critical density or inhomogeneous broadening exceeds the critical value. In Ref.<sup>[20]</sup>, the following inequality for interrelated tolerable values of structure

parameters was obtained:

$$\frac{4}{\xi} \left[ \frac{\sqrt{\varepsilon}}{\lambda_0} \right]^2 \tau_{\text{QD}} \frac{a}{\Gamma} \frac{(\Delta\varepsilon)_{\text{inhom}}}{\hbar} \frac{1}{N_S} \frac{1}{L} \ln \frac{1}{R} \leq 1 \quad (2)$$

where most values are defined in Eq. (1), and where  $R$  is the facet reflectivity and  $L$  is the cavity length.

Hence Eq. (2) relates the tolerable values of the three parameters,  $N_S$ ,  $(\Delta\varepsilon)_{\text{inhom}}$ , and  $L$ , to each other. The critical tolerable value of each of the three parameters is related to the given values of the other two. The more perfect the QD array [the less the  $(\Delta\varepsilon)_{\text{inhom}}$ ] or the longer the cavity the less is the minimum surface density of QDs  $N_S^{\text{min}}$ . The denser the QD ensemble (the greater the  $N_S$ ) or the longer the cavity the greater is  $(\Delta\varepsilon)_{\text{inhom}}^{\text{max}}$ . The more perfect the QD array or the denser the QD ensemble the less is the minimum cavity length  $L^{\text{min}}$ .

When one of the structure parameters is close to its critical tolerable value, the mean (averaged over the lateral direction) electron and hole level occupancies in QDs tend to unity—the electron and hole levels are fully occupied. This demands infinitely high free-carrier densities in the OCL and, correspondingly, infinitely high injection current. For the advantages of a QD laser to be attained in practice, structure parameters should be well away from the critical values. Fig. 11 shows the dependence of the normalized threshold current on the normalized surface QD density for a model structure.<sup>[9,20]</sup> There is an optimal surface QD density minimizing threshold current. For  $N_S < N_S^{\text{min}}$ , the lasing is impossible to attain (the gain cannot overcome losses).

**Fig. 11** Normalized threshold current density vs. the normalized surface QD density for a model structure. *Source:* From Ref.<sup>[9]</sup>.

Recent progress in crystal growth has resulted in arrays of In(Ga,As)–GaAs QD with a relatively small ( $< 10\%$ ) inhomogeneous broadening. Low threshold current densities of  $26 \text{ A/cm}^2$ <sup>[14]</sup> and  $19 \text{ A/cm}^2$ <sup>[21]</sup> at  $300 \text{ K}$ , and  $6 \text{ A/cm}^2$  at  $4 \text{ K}$ <sup>[22]</sup> for long devices with HR facet coatings based on a single sheet of QDs have been achieved. However, differential efficiency of such lasers was low. In commercial lasers, high differential efficiency is required and, thus, HR coatings cannot be applied to the front facet. Here the measure of quality is the value of threshold current density per single QW or QD layer. The best values of  $7\text{--}10 \text{ A/cm}^2$  per QD layer were realized in devices with a large number of QD stacks<sup>[11]</sup> and high differential efficiency. A record low transparency current of  $6 \text{ A/cm}^2$  per dot layer, an internal quantum efficiency of  $98\%$ , and an internal loss below  $1.5 \text{ cm}^{-1}$  have been demonstrated in a QD laser grown by MOCVD.<sup>[23]</sup>

## DEFECT REDUCTION TECHNIQUES

Growth of QDs especially large-sized ones with high confinement energy for electrons and holes may be accompanied by the formation of defects and large dislocated clusters. This problem can be eliminated by applying specially developed in situ defect-reduction techniques, which permits selective elimination of dislocated objects without affecting coherent QDs.<sup>[24]</sup> A schematic diagram illustrating the reduction of dislocation density is shown in Fig. 12. The QDs are overgrown with a thin (1 nm) GaAs layer (Fig. 12B) at a temperature corresponding to that of QD formation ( $480^\circ\text{C}$ ). Then the substrate temperature is raised to  $600^\circ\text{C}$ . The thin cap layer only partly covers the large dislocated InAs clusters allowing the InAs to evaporate in the annealing step (Fig. 12C). The smaller coherent QDs, being completely covered, are only weakly affected. Fig. 13 shows transmission electron microscopy (TEM) images for the samples grown with and without the annealing step. The density of dislocated islands in the sample grown without the annealing step is  $\sim 10^9 \text{ cm}^{-2}$ . No dislocated islands are revealed in the structure grown with the annealing step.

**Fig. 12** A schematic illustrating reduction of dislocation density.

**Fig. 13** Plan view bright field (220) TEM images of the structures grown without (A) and with (B) the annealing step. DI denotes dislocated islands.

The application of defect reduction techniques is especially important in case of lasers based on multiple QD stacks. Even small density of dislocations and large dislocated clusters in the first QD sheet result in a drastic deterioration of the properties of upper QD sheets. The use of defect reduction techniques results in a dramatic improvement in the characteristics of QD lasers (Fig. 14). More than sevenfold decrease in the threshold current is observed for a structure based on 10 QD stacks.

## TEMPERATURE CHARACTERISTICS

Ultrahigh temperature stability of threshold current was predicted for ideal QD lasers (infinite barriers,

**Fig. 14** Threshold current densities for the structures with various numbers of QD stacks grown without and with defect reduction. A design with negligible external losses is used.

no fluctuation of QD sizes, etc.) to be one of the main advantages over conventional (QW lasers.<sup>[4]</sup> Usually, the temperature dependence of the threshold current density ( $j_{th}$ ) is described by the characteristic temperature defined as

$$\frac{1}{T_0} = \frac{1}{j_{th}} \frac{\partial j_{th}}{\partial T}$$

In actual laser structures there are several reasons for  $j_{th}$  to be temperature dependent:

- The presence of carriers in the OCL and their radiative and nonradiative recombination processes give rise to an additional component of the threshold current, which is governed by the thermal escape of carriers from QDs and depends exponentially on temperature.<sup>[9]</sup>
- Inhomogeneous broadening of QD array. This effect is similar to that due to recombination in the OCL in the sense that the inhomogeneous line broadening is associated with undesired pumping of non-lasing QDs. So long as the electron and hole populations in the nonlasing QDs are in equilibrium with those in the active QDs, the fraction of threshold current arising from the recombination in non-lasing QDs depends on temperature, and the characteristic temperature is no longer infinite.<sup>[25]</sup>
- The charge neutrality violation in QDs makes the threshold current component, associated with the recombination in QDs, to be also temperature dependent.<sup>[26]</sup>
- Small energy separation between the discrete hole levels.<sup>[27]</sup>
- Temperature dependence of free carrier absorption.

Because of these effects the threshold current and its temperature stability depend dramatically on the parameters characterizing the QD array (surface density of QDs, QD size dispersion, and carrier localization energies in QDs) as well as on the structure design (p-type modulation doping in the active region, thickness of the OCL, doping profiles in the cladding layers and in the OCL, the band offsets at the interface between the OCL and the cladding layers, and the cavity length).

Most of the theoretical works simulate temperature dependence of the threshold current under the assumption of either equilibrium or nonequilibrium carrier distribution in the QD array. Recently, it has been shown that transition from non-equilibrium to equilibrium distribution can result in a very unusual behavior of temperature dependence of the threshold current unique for QD lasers. Fig. 15 shows the temperature dependence of the threshold current density for a

**Fig. 15** N-shape temperature dependence of the threshold current density for a laser with narrow QD size dispersion and low threshold current density. Cavity length is 2 mm.

high-performance QD laser.<sup>[28]</sup> At  $T < T_1$  ( $T_1 = 150$  K in our case), threshold current density  $j_{th}$  only weakly increases with the temperature. This increase can be attributed to the presence of carriers in the OCL and their radiative and non-radiative recombination. Then at  $T > T_1$ , threshold current density decreases with the temperature. Thus at  $T_1 < T < T_2$  ( $T_2 = 200$  K in our case), the temperature dependence of the threshold current is described by a negative  $T_0$ .<sup>[29]</sup> Finally, at  $T > T_2$ , threshold current density starts to increase, with the temperature steeper as compared to low temperature range. Temperatures  $T_1$  and  $T_2$  depend on the confinement of electron and hole energy levels with respect to the continuum and inhomogeneous broadening of QD arrays. For QD arrays with weak confinement and larger inhomogeneous broadening,  $T_1$  can be very low and was not observed in the early experiments.<sup>[29]</sup>

For commercial applications it is essential to have a high value of  $T_0$  at temperatures above 300 K. Several approaches have been proposed to improve the  $T_0$  values such as placing of QDs in a QW,<sup>[30]</sup> increasing the bandgap of the matrix,<sup>[29]</sup> etc. However, even in some cases the  $T_0$  values were increased (up to 350 K in Ref.<sup>[30]</sup>) threshold current density was also high. First high characteristic temperature operation (160 K) at ambient temperature (below 40°C (313 K)) together with low threshold current density (70 A/cm<sup>2</sup> for 3-fold stacked QDs) was realized in Ref.<sup>[31]</sup> for a design with negligible external losses in pulsed mode.

Very high characteristic temperature in QD lasers ( $T_0 = 230$  K up to 80°C (353 K)) was recently demonstrated by applying a QD p-modulation doping technique;<sup>[32]</sup> the approach, which was earlier proposed to improve the performance of QW lasers.<sup>[33]</sup> The penalty of p-doping was reduced differential efficiency

**Fig. 16** High-temperature stability of the threshold current for a high-performance QD laser emitting at 1.3 μm. The active area is based on five QD stacks.

(<20% in Ref.<sup>[32]</sup>). Recently, using undoped 5 fold-stacked QDs, it became possible to increase the  $T_0$  value to 170 K (Fig. 16) between 10°C (283 K) and 65°C (338 K) without paying a penalty of increased internal losses.<sup>[34]</sup> Remarkably, this device simultaneously showed low threshold current density (100 A/cm<sup>2</sup>, 1.5 mm cavity length, uncoated) and high differential efficiency (85%).

## TIME-RESPONSE

The modulation bandwidth of QD lasers was measured by different groups and is typically 5–10 GHz.<sup>[35–39]</sup> The high-speed performance of QD lasers was shown to be limited by the long “quantum capture” time of injected carriers.<sup>[40]</sup> The value of this parameter, which includes transport through the heterostructure, continuum to bound capture time, and intersubband carrier relaxation, varies with injection current and the number of dot levels in the active region. The carrier capture time measured in Refs.<sup>[40]</sup> and<sup>[41]</sup> quantitatively agrees with the modulation bandwidth value of 5 GHz. More direct femtosecond differential transmission measurements have been made by using the pump-probe technique.<sup>[35]</sup> These measurements have been done as a function of temperature (4–300 K) and excitation level (number of carriers per dot). It was shown that, in addition to intersubband electron relaxation in the dots, carrier reemission to the barrier and wetting layers and the density of available states in these regions also play significant roles in determining the carrier dynamics, particularly at elevated temperatures. It is therefore worthwhile to use QD with high confinement energy to suppress carrier reemission from QDs to the WL and OCL. Indeed, in QD amplifiers the use of QDs with high confinement energy (large-sized

QDs) resulted in a significant improvement in gain dynamic.<sup>[42]</sup>

The “hot-carrier” problem (or gain compression) can be overcome by injecting electrons directly to the lasing states<sup>[43,44]</sup> and thus bypassing the usual injection process over the heterojunction barriers. By tunnel injection, “cold” electrons are introduced into the lasing subband of the active (gain) region (resonantly or phonon assisted) at or near the Fermi level at a rate higher than the stimulated emission rate, and the electron distribution remains quasi-Fermi even at large drive currents. The hole thermalization rates are usually very large because of the high density of states and band mixing. Hot-carrier effects, mentioned earlier, can therefore be minimized. By utilizing tunnel injection of electrons, enhanced small-signal modulation bandwidth,  $f_{-3\text{ dB}}$ , and reduced temperature sensitivity of the threshold current, characterized by  $T_0$ , were measured in  $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}/\text{GaAs}$  self-organized quantum dot ridge waveguide lasers. Values of  $f_{-3\text{ dB}} = 15\text{ GHz}$  at  $283\text{ K}$  and  $T_0 = 237\text{ K}$  for  $278\text{ K} < T < 318\text{ K}$  are measured in these devices.<sup>[45]</sup> However, threshold current density of the laser was high.

Passive mode locking was achieved at  $1.3\text{ }\mu\text{m}$  in oxide-confined, two-section, bistable QD lasers with an integrated intracavity QD saturable absorber.<sup>[46]</sup> Fully mode-locked pulses at a repetition rate of  $7.4\text{ GHz}$  with a duration of  $17\text{ psec}$  were observed under appropriate bias conditions. No self-pulsation accompanied the mode locking. These results suggest that a carefully designed QD laser is a candidate for ultrashort pulse generation.

## LINewidth ENHANCEMENT FACTOR

The linewidth enhancement factor  $\alpha$  is a key parameter to characterize the dynamic behavior of semiconductor lasers. It is usually defined as  $\alpha = 4\pi/\lambda(dn/dN)(dg/dN)^{-1}$ , where  $N$  is the carrier density,  $n$  is the refractive index, and  $g$  is the optical gain. In narrow stripe lasers, large values of  $\alpha$  can result in antiguiding, whereas in broad area devices this leads to self-focusing, filamentation, and chirp under modulation. Typically,  $\alpha$  is about 2 for InGaAs single QW lasers at carrier densities corresponding to threshold.<sup>[47]</sup> A record low value of  $\alpha = 0.5$  has been reported.<sup>[48]</sup>

The linewidth enhancement factor can be calculated from the gain spectrum using the Kramers–Kronig relations. In the case of a QD laser with a dot ensemble showing a perfect Gaussian energy distribution and only one energy level for electrons and holes, the gain spectrum is perfectly symmetric around the peak gain energy. In this case, the differential gain is also symmetric about the peak gain energy at which lasing occurs. Thus the differential refractive index change

calculated using the Kramers–Kronig relations is exactly zero at the lasing energy, and the QD laser with a quasi ideally distributed (symmetric) ensemble of QDs exhibits a chirp-free operation.<sup>[49]</sup> Participation of excited states might cause a nonsymmetric gain curve, which increases the linewidth enhancement factor. A narrow QD distribution and well-resolved energy levels of  $1.3\text{-}\mu\text{m}$  QD lasers favor substantial reduction in  $\alpha$ . The linewidth enhancement factor below the onset of gain saturation has been measured to be as small as 0.1 in QD lasers,<sup>[50]</sup> which is significantly lower than values reported for QW lasers.

For nearly all applications large spatial coherence of the laser light is needed to focus the beam. Narrow stripe devices with index guiding that gives rise to fundamental transverse mode operation are limited in the output power by the onset of catastrophic optical mirror damage (COMD).<sup>[51]</sup> The solution of gain-guided broader area devices has been fraught with the problem of filamentation and higher order modes, which destroy the spatial coherence.<sup>[52]</sup> As beam filamentation strongly depends on the linewidth enhancement factor ( $\alpha$ -factor),<sup>[53]</sup> QD-lasers, which are conjectured to show a reduced  $\alpha$ -factor, are expected to show suppressed filamentation compared to QW lasers.

**Fig. 17** Near field cross sections in horizontal direction (slow axis) for  $6\text{-}\mu\text{m}$  stripe QW laser emitting at  $1.1\text{ }\mu\text{m}$  (A), QD laser emitting at  $1.1\text{ }\mu\text{m}$  (B), and QD laser emitting at  $1.3\text{ }\mu\text{m}$  (C). Cavity length is  $1.3\text{ mm}$  in all cases.

Recently, near-fields and beam-qualities ( $M^2$ ) were compared for a narrow stripe 1.1- $\mu\text{m}$  emitting QW laser, a 1.1- $\mu\text{m}$  emitting QD laser, and a 1.3- $\mu\text{m}$  emitting QD laser.<sup>[54]</sup> The cross section in the lateral direction (slow axis) of the near fields for output powers of 20, 40, and 60 mW is shown in Fig. 17A for the QW laser and in Fig. 17B and C for the QD lasers emitting at 1.1 and 1.3  $\mu\text{m}$ , respectively. The near fields of the QD lasers are Gaussian for all output powers up to 60 mW. In the QW laser, filamentation is present already at an output power of 20 mW. With increasing output power, filamentation increases with more sharp peaks appearing in the beam profile. Additionally, for higher drive currents side lobes next to the laser ridge emerge, too. The beam qualities ( $M^2$ ) were studied as a function of stripe width for QW and QD lasers.<sup>[54]</sup> At an output power of 20 mW,  $M^2$  increases for the QW laser from a value of 2.6 for a 3- $\mu\text{m}$  stripe laser to 4.7 for a 10- $\mu\text{m}$  stripe laser. Thus even for a narrow stripe width of 3  $\mu\text{m}$  no lateral fundamental mode emission could be achieved for this gain-guided QW laser. In the case of the QD lasers the situation is quite different. Lateral fundamental mode emission ( $M^2 \leq 2$ ) is demonstrated up to a stripe width of 8  $\mu\text{m}$  for the 1.1- $\mu\text{m}$  QD laser and up to 9  $\mu\text{m}$  for the 1.3- $\mu\text{m}$  QD laser at an output power of 20 and 45 mW, respectively.

## REDUCED CARRIER LATERAL TRANSPORT

Three-dimensional carrier localization in QDs leads to a dramatically reduced lateral carrier spreading in the active area of QD lasers. Carrier capture time from the GaAs matrix to the wetting layer was measured to be less than 1 psec for QDs emitting at long wavelengths.<sup>[55]</sup> The capture from the wetting layer into the QDs is also very efficient.<sup>[56]</sup> The fabrication of single-mode lasers may require etching through an active region. For QW devices this would lead to non-radiative recombination of carriers within a diffusion length at the processed surfaces. In contrast, in a QD structure, carrier transport in the lateral direction is suppressed, which makes the surface recombination insignificant. Thus leakage currents in narrow stripe QD lasers are expected to be lower than those in QW devices. In Ref.<sup>[56]</sup>, bright photoluminescence at 300 K was demonstrated from very small 0.2- $\mu\text{m}$  mesas at room temperature, indicating that using QDs as an active medium indeed permits a dramatic reduction of the surface recombination in deeply etched devices.

In QD lasers, lateral transport toward defects in the active area and, correspondingly, non-radiative recombination are also suppressed. This results in reduced sensitivity of the performance of QD lasers to defects in the active area. The influence of high-energy proton

irradiation on the device properties of QD lasers was investigated in Ref.<sup>[57]</sup>. Quantum dot lasers demonstrated enhanced radiation hardness in contrast to QW devices, which indicates that using QDs is promising for lasers in hard radiation environment. First degradation experiments on QD lasers demonstrated the potential of QD lasers for increased operation lifetime.<sup>[58,59]</sup>

## HIGH-POWER OPERATION

High differential efficiency, low threshold current, and suppression of filamentation make QD lasers very promising for high-power applications. Recently, light-current characteristics in QW, quantum wire, and QD lasers have been theoretically treated.<sup>[60]</sup> Quantum dot lasers were shown to have a major advantage over conventional QW laser from the viewpoint of high-power operation. According to Ref.<sup>[60]</sup>, in properly optimized QD lasers the light-current characteristic is linear with both the internal and external quantum efficiency being close to unity up to very high injection current densities (15 kA/cm<sup>2</sup>). Output power in excess of 10 W at an internal quantum efficiency higher than 95% was shown to be attainable in broad area devices.

Present broad-area QD lasers emitting in a spectral range of 0.94–1.3  $\mu\text{m}$  show CW output powers of 3–6 W.<sup>[61–64]</sup> Fig. 18 shows the pulsed performance of QD lasers based on 10-fold stacked QDs. The cavity length is 1.45 mm and uncoated facets are used. Differential efficiency as high as 85% and a threshold current density as low as 90 A/cm<sup>2</sup> are realized. The characteristic temperature is 150 K in a temperature range of 0–70°C. All the key numbers are better than those for commercial InP-based 1.3- $\mu\text{m}$  devices. Narrow

**Fig. 18** Pulsed light-current characteristic at room temperature of a broad area QD laser emitting at 1.3  $\mu\text{m}$ . Stripe width is 100  $\mu\text{m}$ , stripe length is 1.5 mm.

7- $\mu\text{m}$ -wide stripes demonstrated single-transverse-mode kink-free CW operation up to 330 mW for uncoated facets.<sup>[65]</sup>

### VERTICAL CAVITY SURFACE EMITTING LASERS BASED ON QUANTUM DOTS

Vertical cavity surface emitting lasers (VCSELs) emitting at 1.3  $\mu\text{m}$  are very promising for use in high-bit-rate transmission lines for telecommunications. Until recently only the InP/InGaAsP material system has been utilized to fabricate long-wavelength semiconductor lasers because the crystal composition of InGaAsP can be adjusted to produce emitters in the required wavelength region. However, the performance of current long-wavelength lasers still lags behind that of their shorter-wavelength counterparts. The problem limiting the performance of InP-based QW devices is a strong temperature dependence of their characteristics caused by insufficient electron confinement in the active region.<sup>[66]</sup> This leads to poor temperature stability of the threshold current and emission wavelength, as well as to high values of threshold current densities. Besides, the cost of InP-based devices is substantially higher than that for GaAs-based ones.

An additional disadvantage as far as fabrication of commercial long-wavelength vertical cavity lasers based on traditional InGaAsP–InP heterostructures is concerned is the lack of adequate Bragg mirrors. Mirrors of InGaAsP–InP layers have a small refractive index difference. Thus a Bragg mirror with 50 or more periods is required to achieve the reflectivity value ( $>0.99$ ) needed for lasing. The introduction of wafer-bonded GaAs/AlGaAs Bragg mirrors to InP-based active regions has led to an improvement in device performance.<sup>[67]</sup> However, the wafer-fusion technique represents a complex technological process and therefore expensive for large-scale production. In addition,

bonded interfaces have low quality, resulting in, for example, increased resistance. Other recent approaches (using top metamorphic AlAs–GaAs DBR, or using AlGaAsSb-based DBRs on InP substrates) do not solve the problem of reliability and cost efficiency, and may be competitive only until the production-oriented GaAs-based technology is developed. Thus for the fabrication of commercial 1.3- $\mu\text{m}$  VCSELs it is essential that the whole structure, including the active area, is grown on the same GaAs substrate, which would enable it to use monolithic high-contrast lattice-matched GaAs–Al(Ga)As or oxidized GaAs–AlO Bragg mirrors.

Two approaches are successfully applied for long-wavelength GaAs-based VCSELs: using InGaAs–GaAs QDs and nitrogen doping of InGaAs layers.<sup>[68]</sup> Self-organized QDs are particularly advantageous for VCSELs as they offer the possibility to realize very low threshold current density and high temperature stability in properly optimized devices. Owing to suppressed carrier lateral transport very small VCSELs can be fabricated without a deterioration of operating characteristics.

The first 1.3- $\mu\text{m}$  VCSELs grown on GaAs substrate was realized in Ref.<sup>[69]</sup>. The VCSEL design is schematically shown in Fig. 19. The microcavity is surrounded by (p) and (n)  $\text{Al}_{0.98}\text{Ga}_{0.02}\text{As}$  layers (less than  $\lambda/4$ -thick) followed by  $1\lambda$ -thick (p) and (n)GaAs current spreading/intracavity contact spacer layers doped to  $10^{18}\text{ cm}^{-3}$ . Intracavity contacts are used. The spacer layers are followed by DBRs composed of alternating  $\text{Al}_{0.98}\text{Ga}_{0.02}\text{As}$  and  $\lambda/4$ -thick GaAs layers. The  $\text{Al}_{0.98}\text{Ga}_{0.02}\text{As}$  layers in the DBR, as well as those surrounding the optical cavity, are selectively oxidized to form Al(Ga)O. The QDs are centered in a  $1\lambda$ -thick GaAs optical microcavity, whose edges are doped to  $10^{17}\text{ cm}^{-3}$ . The ends of the microcavity are composed of  $\text{Al}_x\text{Ga}_{1-x}\text{As}$  linearly graded from  $x = 0.02$  up to 0.98. The CW light power–current–voltage ( $L$ – $I$ – $V$ )

**Fig. 19** A schematic cross section of vertical cavity surface emitting laser with QD active region, oxide current aperture, and oxide DBRs.

Fig. 20  $L$ - $I$ - $V$  curves of a 1.3- $\mu\text{m}$  emitting GaAs-based QD VCSEL at various temperatures.

characteristics of a QD VCSEL are shown in Fig. 20. The threshold current of the QD VCSEL remains practically unchanged with temperature increase. The electroluminescence measurements from a test structure indicate that the lasing proceeds via the QD ground-state transition. The maximum differential efficiency is 64%. The emission wavelength is near 1.3  $\mu\text{m}$  (1.28–1.306  $\mu\text{m}$  depending on the particular position on the wafer). Variation in the threshold current across the wafer is  $\sim 10\%$ . The lasing threshold (1.2 mA) is constant down to 0.5- $\mu\text{m}$  oxide apertures, due to reduced carrier lateral diffusion. During the lifetime test in excess of 700 hr CW at 35°C no change in the performance of the device is found.

## CONCLUSION

Since the first realization of injection lasing<sup>[6]</sup> via self-organized QDs, tremendous progress has been achieved in the field of QD lasers. Development of sophisticated growth techniques resulted in arrays of In(Ga,As)-GaAs QD with a relatively small (<10%) inhomogeneous broadening, large confinement energies of electrons and holes, and emission wavelength of about 1.3  $\mu\text{m}$ . Lasers based on such QD arrays demonstrated unique characteristics such as low threshold current density, high temperature stability of threshold current, high differential efficiency, and small linewidth enhancement factor ( $\alpha$ -factor). The QDs are also very promising as an active medium for high-performance, cost-efficient, 1.3- $\mu\text{m}$  VCSELs. We believe that further progress in QD growth as well as deeper understanding of the physics of QD lasers will result in the perfection of their characters, reveal new exciting properties, and finally lead to a new generation of high-performance commercial devices for different applications.

## INTRODUCTION

Current epitaxial crystal growth techniques, with their precise monolayer (ML) control, have led to abrupt heterointerfaces in III–V and group IV semiconductors. This remarkable heterointerface control is responsible for 1-D carrier confinement in the growth direction: When a thin layer is formed from a more narrow bandgap material in the larger bandgap host, a quantum well (QW) is formed. In the III–V material system, this QW has had a dramatic impact in both semiconductor research and mainstream semiconductor technology. Although significant effort has been concentrated toward extending this control to 2-D and 3-D confinement with quantum wires and quantum dots, the results have been encouraging but not resounding. This is generally because lithography techniques typically used to provide increased lateral confinement do not have the monolayer resolution that is available through epitaxial growth techniques. Furthermore, because of interfacial damage, it is difficult to directly pattern active regions using processing. Although useful structures can be fabricated using surface patterning,<sup>[1–4]</sup> these techniques are not suitable for all structures. In the 1990s, a purely epitaxial technique was developed to produce quantum dots in the InAs/GaAs and Ge/Si semiconductor systems. This technique utilizes the strain-induced islanding of the Stranski–Krastanow (SK) growth mode, in which the growth surface islands compensate for the increase in energy caused by extra interface surface with a decrease in accumulated strain energy.

The formation of quantum dots by strain-induced islanding has provided a simple, lithography-free method to produce dense ensembles of quantum dots. Unlike the classical self-assembly processes in non-epitaxial systems, in this system, the energies associated with the epitaxial growth process still dominate those that drive the nanostructure formation process. The result is nanostructure features that are not identical but still similar. Strain-induced island formation is perhaps more akin to other surface and interface phenomena such as surface spinodal decomposition,<sup>[5]</sup> surface reconstruction, and ledge-and-step formation.<sup>[6]</sup> In fact, our general observation is that the

ensemble uniformity and spatial periodicity of InAs islands follow more closely these processes than the self-organized formation of more classical structures such as carbon nanotubes<sup>[7]</sup> or self-assembled protein structures.<sup>[8]</sup> Unfortunately, the dominance of the epitaxial process and the large surface migration processes common in this growth lead to large inhomogeneous island size distributions: The spectral features are broadened with respect to QWs, and the narrow, atomic-like transitions are lost in the ensemble broadening. Nevertheless, the association of self-organization with strain-induced islanding, specifically with respect to direct bandgap semiconductors, has done much to focus attention on the possible utility of this system. Although the phenomenological process of strain-induced islanding was observed 60 years ago, the association of spectral features with these islands was made by Tabuchi et al.,<sup>[9]</sup> whereas the general possibilities of this system have been noted, developed, and championed by Leonard, Noda, and Sasaki<sup>[10]</sup> This research is encouraging and lively, and with further fine-tuning of the growth processes, as was needed in the development of the successful QW technology, inhomogeneous broadening can be reduced.

## OVERVIEW

The strain-induced quantum dot formation approach has been used effectively to investigate the 0-D structure in nanoscale systems leading to a rich array of results.<sup>[11–13]</sup> New devices, where the active regions are composed of these quantum dot ensembles, have demonstrated improved characteristics. However, except for the improved thermal stability of lasers demonstrated by Heinrichsdorff et al.,<sup>[14]</sup> most of these improvements result not from the 0-D confined system but from material compliance. For example, the useful wavelength range of light-emitting diodes (LEDs) and lasers based on GaAs substrates has been extended, but this is not a result of increased carrier confinement. In addition, nearly all of these results rely on the random arrays of islands with slightly varying sizes, and the quest for atomic-like ensembles, either ordered or random, has not been demonstrated to date. This is

clearly because of the less dominant, secondary role of the energies that drive this ordering process in epitaxial systems.

However, there are benefits to the integration of self-ordering processes with epitaxial deposition. Creating active regions away from processing interfaces and placing these regions within doping and barrier structures while utilizing semiconductor processing and fabrication techniques are attractive approaches to nanostructure fabrication. To this end, we have investigated ways in which vertical growth precision can be incorporated to develop new structures and improve the size and spatial distribution of the strain-induced quantum dot ensemble. In this chapter, we discuss the effect of epitaxially layering InAs islands with small spacer layers of the GaAs host crystal<sup>[15,16]</sup> as a technique to create either small, well-controlled, vertically coupled structures, or as a mechanism to create an ordered surface array of quantum dots. Because of the strain distribution present around the InAs islands, GaAs deposited on top of an InAs island layer preferentially migrates away from individual InAs dots, resulting in a planarized growth front. If the deposited GaAs is thin enough so that the strain field is still present on the GaAs surface, when subsequent InAs is deposited, there is preferential migration to regions above InAs islands. In this way, InAs island layers, separated by thin GaAs spacer layers, can be vertically aligned in columns.<sup>[17]</sup>

Two properties can be optimized using these columns. First, the confined energy states within the InAs quantum dots are no longer isolated when two InAs dots are vertically aligned and separated by only a thin GaAs spacer layer. The energy states couple or extend into the adjacent dots.<sup>[15]</sup> Second, in a subsurface dot layer, the strain distribution from adjacent InAs dots can interact so that a surface strain distribution results, which is a superposition of strain distribution of the subsurface InAs dots.<sup>[18]</sup> In regions where island density is larger than some equilibrium value, the strain from individual subsurface islands will interfere so that the surface strain will be a superposition of the subsurface distribution. In regions where the island density is smaller than some critical value, the adjacent strain fields from subsurface islands will not interfere as significantly and the resulting surface strain distribution will have regions unaffected by subsurface islands. By depositing multiple island layers, the surface strain distribution can, in theory, be made uniformly periodic. Because the surface strain distribution resulting from the superposition of subsurface island strain affects the surface diffusion, increased spatial ordering of InAs islands on the surface can result. Furthermore, because the size distribution of dots in a layer is affected by variations in the nutrient field surrounding a stable island by creating a more

uniform spatial distribution of nucleation sites, the island size distribution can be made more uniform. Thus subsurface layers of InAs dots can be used to create a more structurally and spatially uniform top layer of quantum dots. When optimized to enhance coupling between vertical dots, we call the structures “vertically coupled quantum dot columns.” When optimized to enhance surface quantum dot uniformity, we call the structures “subsurface island superlattices.”

Before discussing the details of the vertical quantum dot layers, we discuss two salient features of single-layer InAs quantum dot ensembles: the control of ensemble density and the state of in-plane localization. Both of these effects depend on molecular beam epitaxy (MBE) growth conditions. The “Introduction” provides a general introduction to the formation of single quantum dot layers by this technique, in addition to particular discussions of ensemble density and localization. The rest of the chapter is broken into two sections on multiply quantum dot layer growth. The vertical electronic coupling in quantum dot columns is first discussed, whereas ordering by subsurface island superlattices follows.

## SINGLE-LAYER InAs QUANTUM DOT ENSEMBLES

### Theory of Island Formation

In homoepitaxial crystal growth of cubic materials, the (100) growth surface is the lowest energy facet plane.<sup>[19]</sup> If the growth temperature and flux rates are appropriate, adatom attachment on the growth surface is to kink and ledge sites, or at island nucleation regions. Thus crystal growth proceeds by the lateral growth of kinks and ledges, or by the expansion of/at monolayer-scale high islands. Ideally, as one monolayer is filled, new monolayer-high nucleation sites are created, and the 2-D (100) growth surface propagates. In contrast, during heterogeneous crystal growth, as more adatoms are deposited onto the growing surface, this growth surface can go through structural changes that can be as dramatic as the complete loss of epitaxial coherency, or as small as changes in surface reconstruction, surface roughness, or abruptness of a heterointerface.<sup>[20–23]</sup> In the case of InAs on GaAs, the lattice mismatch is 7.2%. The critical thickness for relaxation by dislocation generation is 45 Å, or approximately 15 unstrained InAs monolayers according to the Matthews–Blakeslee model.<sup>[24]</sup> This critical thickness is based on the mechanical equilibrium of an existing interfacial dislocation. A more accurate theory, based only on the energy density required to generate (not propagate) an interfacial dislocation, indicates the complete absence of a critical

thickness.<sup>[25]</sup> Although this approach cannot be assumed accurate at such large misfit, it does suggest a significantly smaller critical thickness. Because of the similar InAs and GaAs crystal structures, at least one chemisorbed monolayer of InAs can be assumed to be stable on the GaAs substrate. Below the critical thickness or after a chemisorbed layer, a metastable phase can exist. This is phenomenologically known as the SK growth regime.<sup>[26]</sup> In the SK growth of InAs on GaAs, there is a thickness region where excess strain is partially accommodated by surface islanding. This growth regime is a transitional growth mode between a compliant planar growth regime that characterizes ideal MBE growth and a plastically relaxed growth, because as islands grow and merge, the surface area can no longer expand to accommodate the increasing strain energy.

Without kinetic effects, island size and shape are predominantly determined by the Gibbs free energy balance:

$$\mu = \mu_0 + \frac{1}{2} \mathbf{S}_{ijkl} \sigma_{ij}(x) \sigma_{kl}(x) V_0 + \gamma K V_0 \quad (1)$$

where  $V_0$  is the molecular volume,  $\gamma$  is the surface tension, and  $K$  is the surface curvature (the inverse of the radius of curvature).  $\mathbf{S}_{ijkl}$  is the compliance matrix and  $\sigma_{kl}(x)$  is the stress field at  $x$ .  $S_{ijkl} \sigma_{kl}(x) = \epsilon_{ij}$  is the strain, so that  $1/2 \epsilon_{ij}(x) \sigma_{kl}(x) V_0$  is the accumulated strain energy.  $\gamma K V_0$  is the extra surface energy and  $\mu_0$  is the total unstrained planar crystal energy. If the epitaxial lattice mismatch were not present, the strain would be absent and the curvature ( $K$ ) that minimizes the system energy would be zero—corresponding to a flat surface. Thus the lattice mismatch strain leads to a non-flat growth surface with an island size determined by the minimization of Eq. (1). Entropy-of-mixing terms and reduction in the strain energy because of alloy mixing in the near-surface region are not included in Eq. (1). Because of surface diffusion limitations, the surface curvature will take the form of a periodic roughness  $a \cos kx$ , where  $a$  is the roughness amplitude and  $k$  is the roughness wavenumber. If  $\tau$  and  $n$  are the local in-plane and surface normals, whereas  $x$  and  $y$  denote the global crystal in-plane and normal directions, then by geometry, the stresses on the traction free surface are:

$$\begin{aligned} \sigma_{\tau\tau} &= \sigma_{xx} \cos^2 \theta + \sigma_{yy} \sin^2 \theta + 2\sigma_{xy} \cos \theta \sin \theta, \\ \sigma_{\tau n} &= \sigma_{nn} = 0, \quad \text{along the surface} \end{aligned} \quad (2)$$

To solve for  $\sigma_{\tau\tau}$ , an Airy solution of the form:

$$\Phi = \frac{\sigma_y^2}{2} + (A + By)e^{-ky} \sin(kx) \quad (3)$$

is used. The stress on the islanding surface is:<sup>[27–29]</sup>

$$\sigma_{xx} = \sigma(1 - ka(ky - 2))e^{-ky} \sin(kx) \quad (4)$$

where the  $y$  origin is taken as the mean surface. As more materials are deposited, the amplitude  $a$  increases. When  $a$  approaches the thickness of the heteroepitaxial layer, the troughs of the roughened surface begin to impinge on the heterointerface and stop because the mismatch is no longer present. The trough regions become extended as more materials are transferred away from the interface region to the peaks of the roughened surface, resulting in distinct islands.<sup>[20]</sup> The island shape is determined by the details of the facet-dependent surface energy  $\gamma$ . In the InAs/GaAs system, the islands are formed from (136) facets.<sup>[30]</sup>

Based on Eq. (1), as heteroepitaxial material is deposited, the growth surface remains initially flat until the accumulated strain energy exceeds the energy associated with creating extra surface area. The flat region is called the wetting layer in SK growth, and is inherent in this growth mode. Although the concept of critical thickness mentioned previously is based on a continuum model, there has been theoretical<sup>[31–33]</sup> and experimental evidence<sup>[34]</sup> showing dislocation and crack nucleation at island edges, suggesting that the islands formed during growth play a more central role in the transition to relaxed heterogeneous crystal growth.

## Experimental Control of Quantum Dot Properties

### Growth of dislocation-free islands

Except where noted, the InAs dot structures described in this chapter were constructed from epitaxial layers deposited in a Varian Gen II MBE system. The system uses an As<sub>2</sub> flux that is produced by thermally decomposing the As<sub>4</sub> flux commonly used as the arsenic source in MBE. In addition, the As source has an adjustable valve, so that the V/III flux ratio can be precisely controlled. In this way, we can control the surface diffusivity of In. The V/III beam equivalent pressure ratio is kept at 9 for all layers, except where noted. Except where noted, the InAs island region and all subsequent depositions were conducted at 500°C, as measured by the substrate thermocouple, which corresponds to 457°C using a more accurate optical technique.<sup>[35]</sup> Where growth temperature is varied, it is reported as thermocouple temperature and is approximately 50°C higher than the actual temperature. Each InAs island layer is composed of the equivalent of 3 ML of planar InAs deposited at a rate varied between 0.1 and 0.2 μm/hr. The GaAs growth rate was 0.2 μm/hr. Photoluminescence (PL) spectra

**Fig. 1** AFM images of InAs islands formed from various amounts of InAs deposition at 500°C. (A) After 2 ML on InAs, (B) 3 ML of InAs, (C) 4 ML of InAs, and (D) after 6 ML of InAs. The InAs islands are not covered with GaAs, but left bare for AFM imaging. The AFM is conducted *ex situ*, under ambient conditions.

were obtained using an Ar<sup>+</sup> ion laser with samples mounted in a circulation He cryostat, except for the LEDs, which are measured at room temperature.

Atomic force microscopy (AFM) images of the islanding surface for different InAs coverages are shown in Fig. 1.<sup>[36]</sup> This figure shows the transition in the SK growth regime between isolated 3-D island growth and coalesced island growth at 500°C. Fig. 1A shows isolated islanding at 2 ML of surface coverage. Just below this coverage (2 ML) of InAs, the epitaxial surface is planar. This abrupt transition to island growth just below 2 ML has been observed by several groups.<sup>[9,36,37]</sup> With 2 ML of deposited InAs, the average island diameter is 150 Å. Transmission electron microscopy (TEM) investigations<sup>[9]</sup> indicate that these islands are defect-free. When the equivalent of three planar monolayers of InAs (Fig. 1B) has been deposited, the additional material is accommodated by an increase in island size and density. The island size increases because more materials have been deposited and migrate to the islands. The increase in island density is more complicated and is related to the local wetting layer structure. Because of the lattice mismatch, the wetting layer thickness is only 1.8 ML. Thus very small differences in thickness and strain energy at different sample positions, corresponding to the equivalent thickness on the order of 0.2 ML (0.6 Å), will result in regions that are still growing planarly because this critical wetting layer thickness has not

**Fig. 2** The 8-K PL of several samples, which contain InAs thicknesses that vary between 1.5 and 3.75 ML. There is a transition from planar growth to dot growth between 1.75 and 2 ML. The intensity decrease at 3 and 3.75 ML is because of non-radiative recombination.

been exceeded, and regions that contain islands because the critical wetting layer thickness has been exceeded. As more materials are deposited, the planar thickness is exceeded over more regions of the sample and the island density increases.

When an additional 1 ML of InAs is deposited, so that the total InAs deposited is 4 ML (Fig. 1C), a significant change in surface topology is evident. The distribution in island size increases significantly and it appears that there are two distinct types of islands. The larger islands are formed by the coalescing of initially isolated islands, which have plastically relaxed through dislocation generation.<sup>[34,38]</sup> By 6 ML of InAs deposition (Fig. 1D), the transition to a surface topology of plastically relaxed islands is complete.

Fig. 2 shows PL spectra corresponding to the structural transformations observed in Fig. 1. The PL measurements of InAs QWs and quantum dots formed with varying thicknesses of InAs were taken at 8 K using a lock-in technique with a cooled Ge detector for the quantum dot spectra and a Si detector for the QW spectra. The InAs layers have GaAs barriers and are located 500 Å below the sample surface. When 1.5 and 1.75 ML of InAs are deposited, the observed luminescence energy and linewidth are consistent with a uniform InAs (or InGaAs) QW. When the total deposited thickness increases from 1.5 to 1.75 ML, there is a red shift in the spectral peak position because the width of the QW increases. When an additional 0.25 ML is added so that the total deposited InAs is 2 ML, the spectral peak position and shape change dramatically. This is the transition to the quantum dot ensemble structure shown in Fig. 1. This shift occurs when only 0.25 ML (0.75 Å) is added to the surface. The correlation of luminescence structure with the

change in physical structure clearly shows that the luminescence originates from the InAs dot regions. In the QD ensembles, the average height is 40 Å and the dots are unalloyed, whereas in the QW, the thickness is less than 40 Å and the well is alloyed with GaAs because of vertical diffusion. It will be shown later in the entry that significant alloying is present in the QW region but absent in the quantum dot region, leading to a higher energy bandgap in the QW region than in the QD region. Both the bandgap shift and the change in confinement contribute to the red shift in QD luminescence with respect to the QW luminescence. The QD linewidth increases because of the size distribution in the dot ensemble. The luminescence is attributed to an ensemble of InAs dots of different sizes and shapes that each have very narrow, atomic-like spectral linewidths.<sup>[39,40]</sup> The integrated intensity also increases when the deposited thickness changes from 2 to 3 ML. This is because of an increase in InAs dot density, as seen in Fig. 1. When the amount of deposited InAs is increased from 3 to 3.75 ML, the spectral peak position again shifts to lower energy because of the increasing size of the InAs islands. However, the integrated intensity now begins to decrease because of defect generation, which acts as non-radiative recombination site.

One of the major issues in the fabrication of quantum dots by strain-induced islanding is that the narrow, atomic-like emission from single quantum dots is hidden in the inhomogeneously broadened ensemble luminescence. Although it is not the purpose of this chapter to investigate the characteristics of single quantum dots, it is instructive to briefly investigate the emission from the isolated quantum dots forming the ensemble. By reducing the number of quantum dots sampled, single quantum dot features can be observed. This can be accomplished by etching posts into the quantum dot sample and observing the luminescence from individual posts. In Fig. 3A, PL from a single InAs quantum dot layer sample is shown. The wetting layer position is 850 nm and the peak of the quantum dot ensemble emission is 885 nm (1.40 eV). Posts isolating the quantum dot layer were fabricated by electron beam lithography and dry etching, after which microphotoluminescence measurements were made on isolated posts. These measurements were made by G. S., M. Pelton, and Y. Yamamoto. In Fig. 3B, microphotoluminescence from a single 2000-nm post is shown. The spectrum shows luminescence from a large number of closely spaced quantum dot features. By reducing the post size, the number of quantum dots within a post is reduced. In Fig. 3C, the post size is reduced to 100 nm and emission from a single quantum dot can be observed. The typical linewidth is 0.9 Å (140 μeV) and is limited by the spectrometer resolution. The linewidth of the

wetting layer peak at 850 nm is not significantly reduced because it is a continuous 2-D feature, where the major contribution to luminescence broadening is the thickness variation in the growth direction that fluctuates on spatial scale much smaller than the post diameter.

### Substrate temperature

The substrate temperature also affects the InAs QD size and luminescence properties. Fig. 4 shows PL spectra from InAs QD samples where each sample consists of the equivalent of 3 ML of InAs, and only the growth temperature has been varied. The growth temperature was changed from 515°C to 455°C. As the growth temperature is decreased, the spectral peak representing the QD ensemble undergoes a blue shift and the linewidth is reduced. The blue shift in the spectral peak position is because of the reduction in the average dot size. In Fig. 5, an AFM image of the bare dot surface of two samples is shown. The two growth temperatures are 455°C and 500°C. The dot size is reduced from 200 Å to less than 150 Å because of the reduction in In surface diffusion. The dots formed at the lower temperature are less distinct than the dots formed at 500°C. Although the quantum dots are less uniform when grown at 455°C, the spectral linewidth is smaller than in the well-formed QDs grown at 500°C.

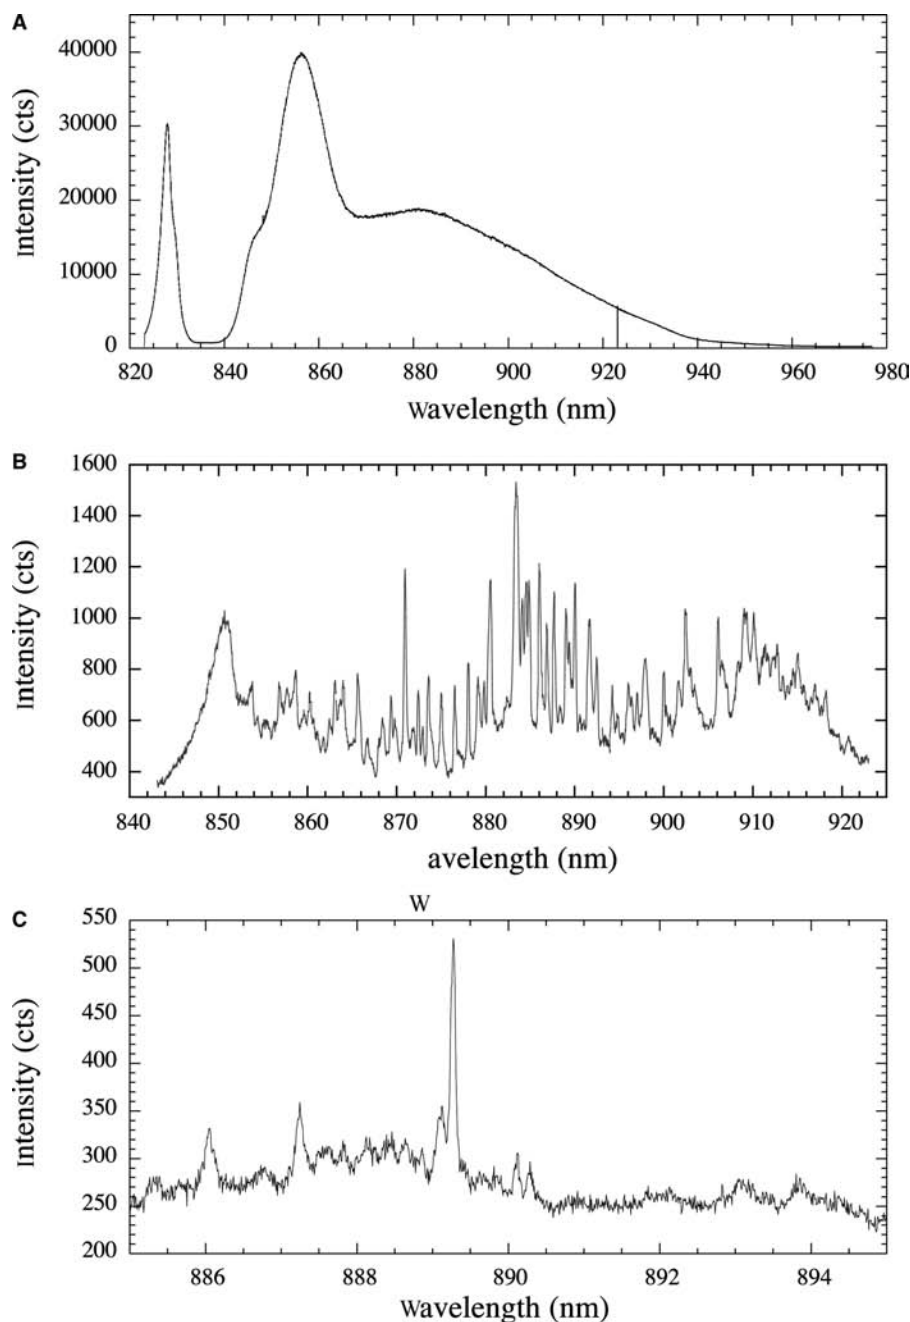

To explain this result, we first show that the small-scale roughness in the lower-temperature samples does not have a significant effect on luminescence broadening. Assume that a quantum dot exciton has a Hamiltonian of the form  $H = H_e + H_h + V_{eh} = H_{ex}$ , where  $H_e$  and  $H_h$  are the Hamiltonians for individual electrons and holes, and  $V_{eh}$  is the Coulomb attractive potential. Now assume that in a quantum dot, the individual electrons and holes have a Hamiltonian that is perturbed by roughness potentials  $V_{e,d}$  and  $V_{h,d}$ , respectively. If  $H_{e,0}$  and  $H_{h,0}$  are the unperturbed QD electron and hole Hamiltonians, the new Hamiltonian is  $H = H_{ex,0} + V_{e,d} + V_{h,d}$ . Assuming that the exciton is in the ground state, so that  $H_0|R_{cm},1s\rangle = E_{R_{cm}}|R_{cm},1s\rangle$ , the variation in the confining potential of the exciton is:

$$\Delta V_{exc,d} = \langle R, 1s | V_{e,d}(z) + V_{h,d}(z) | R, 1s \rangle \quad (5)$$

which we approximate by a combined potential energy component and a geometrical component, so that:

$$\Delta V_{exc} = \Delta V_{rough} \left( \frac{\lambda_c}{a_B} \right)^n \quad (6)$$

where  $\Delta V_{rough}$  is the change in Coulombic attraction because of local variations in confinement,  $\lambda_c$  is the wavelength of roughness perturbation,  $a_B$  is the exciton Bohr radius, and  $n$  is a geometrical factor that increases as

**Fig. 3** The 4-K microphotoluminescence of etched posts containing quantum dots. In (A), the unprocessed sample shows the inhomogeneously broadened luminescence from the QD ensemble. The wetting layer is at 850 nm. In (B), luminescence from many individual quantum dots in a 2- $\mu\text{m}$  post is shown. In (C), luminescence in a single quantum dot in a 100-nm post is shown.

the confinement goes from 1-D to 3-D.  $\Delta V_{\text{rough}}$  cannot be larger than the Coulomb binding energy, or new confinement regions are formed. In addition,  $\lambda_c$  values larger than  $a_B$  lead to inhomogeneous broadening. Thus the maximum broadening occurs when  $\lambda_c$  and  $\Delta V_{\text{rough}}$  are of the order of  $a_B$  and the Coulomb binding energy, respectively. This occurs for our case of InAs dots in GaAs when the dot radius equals the exciton radius, which is approximately 100 Å. Because the small-scale roughness that is dominant in the lower-temperature sample is much smaller than 100 Å, it does not significantly contribute to the ensemble luminescence broadening.

In fact, the structure of the lower-temperature dot sample reduces the broadening for a different reason. Because the barriers between the quantum dots are not well defined, the excitons (or electrons and holes) can become partially extended into adjacent quantum dots. This leads to reduced spectral broadening because these carriers interact with an average potential. If  $\bar{H}$  is the average Hamiltonian and  $\Delta H_i$  is the variation from this average seen by carrier  $i$ , then the energy variation in ground-state excitons is:

$$\Delta V = \sum_i \langle R_i, 1s | \Delta H_i | R_i, 1s \rangle \quad (7)$$

**Fig. 4** Spectra of dot structures grown at different growth temperatures. Each sample contains a dot layer composed of the planar equivalent of 3 ML of planar InAs with an undoped GaAs cap.

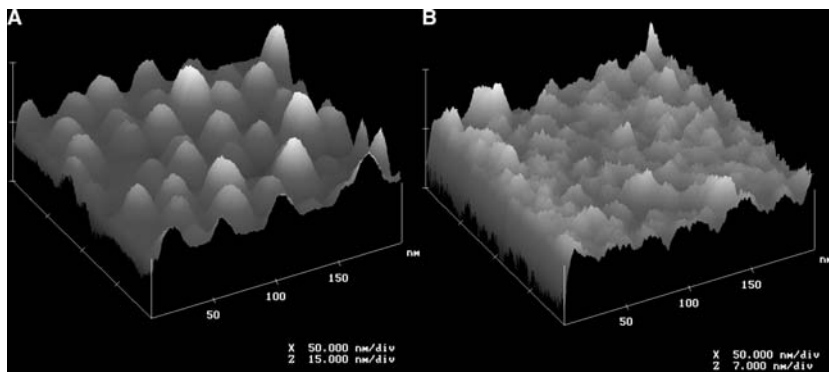

But this is reduced as the exciton samples more dots (and is eliminated completely in the trivial case when the exciton samples all of the dots). Therefore the broadening decreases as the dots become less defined and the carriers become less localized. The reduction in spectral broadening can be further enhanced if acoustic phonon scattering is present between the partially extended states of adjacent quantum dots. This scattering will allow carriers to move to the lowest energy state of the overlapping states. In such a case, the luminescence spectrum will no longer be Gaussian: The higher energy component of the Gaussian distribution will be reduced as carriers relax into the lower energies of the partially overlapping states. Evidence of this can be observed in Fig. 4, where the luminescence spectrum of the sample grown at 455°C is no longer symmetrical.

Although the PL linewidth is reduced and excitons become less localized in any particular dot, this is not coupling from overlapping identical states, nor is this complete delocalization and band formation. The observed narrowing is a result of the weakened in-plane localization, not a result of any increased

**Fig. 6** The spectral linewidth as a function of temperature for two samples fabricated at different growth temperatures. The narrowing in linewidth as the temperature initially increases is because of reduced localization.

uniformity in the dot ensemble. Additional confirmation of our model can be seen by investigating the variation in the spectral linewidth with sample (cryostat) temperature during measurement. At low temperatures, the spectral broadening is dominated by inhomogeneous broadening from the QD ensemble, whereas at high cryostat temperatures, the spectral broadening is dominated by thermal broadening. Fig. 6 shows the results of variable-temperature PL for the two cases described above. An unusual feature in the figure is the initial decrease in spectral linewidth observed in both samples with increasing sample temperature. The linewidth reduction is caused by a decrease in the inhomogeneous broadening as the sample temperature increases. The presence of further spectral linewidth narrowing confirms that complete delocalization is not present. We believe that the increased spectral linewidth reduction is because of variable range hopping between quantum dot regions. This is a thermally activated process involving states of varying energy. We note that thermionic

**Fig. 5** AFM images of the bare dot surface of two samples identically prepared, except for the growth temperature. In (A), the growth temperature is 500°C, whereas in (B), the growth temperature is 455°C, as measured by the substrate thermocouple. The vertical height scales are indicated and are different in these two images.

**Fig. 7** PL spectra of QWs grown at different growth temperatures with thickness of either 1.5 or 1.75 ML.

emission above the quantum dot barriers is an unlikely explanation because the barrier between the confined states and the QW wetting region is too large to be of issue at this temperature.

We have confirmed that the QDs formed at low growth temperatures are distinct from the wetting layer QW regions by fabricating QWs with 1.5 and 1.75 ML of InAs. Results of low-temperature PL measurements on these samples are shown in Fig. 7. The data in Figs. 4 and 7 have been combined into Fig. 8. A linear

**Fig. 8** PL spectra of QWs and quantum dots grown at different growth temperatures indicating that even at low temperature, the quantum dots luminescence is distinctly shifted from the QW luminescence.

fit is shown between the 1.5- and 1.75-ML QWs grown at 500°C and is extended to the 3-ML region of the figure. Although the 3-ML QD spectral peak position converges to approximately 1.25 eV, the linear fit from the QW region is at a much higher energy; it is clear that the PL peak of the QD ensemble is not converging to the QW (wetting layer) peak position. Although the QD luminescence blue shifts with decreasing growth temperature, the QW luminescence red shifts because of a combination of reduced In desorption and reduced alloying.

V/III flux ratio and quantum dot density

One of the largest determinants of the density of QDs formed using MBE is the V/III flux ratio.<sup>[41]</sup> Fig. 9 shows AFM images of surfaces where the V/III flux ratio has been varied while the InAs growth rate is maintained constant at 0.19 μm/hr. The V/III ratio is decreased from 36 in Fig. 9A to 18 in Fig. 9B, and finally to 9 in Fig. 9C. As the V/III ratio decreases, the 3-D island density increases, whereas the island diameter remains unchanged. The island density changes from 42% for a V/III ratio of 36, to 49% for a V/III ratio of 18, to 81% for a V/III ratio of 9. In MBE growth, decreasing the V/III ratio increases the In surface migration length. If the island density can be modulated by adjusting the In adatom surface diffusion on the islanding surface, then the island

**Fig. 9** AFM images of the difference in island density when the V/III flux ratio is changed from 36 in (A), to 18 in (B), and, finally, to 9 in (C). In all cases, the growth temperature was 500°C, the growth rate was 0.19 μm/hr, and 3 ML of InAs were deposited.

diameter should also change, but this is not observed. However, decreasing the V/III ratio also increases the In adatom surface diffusivity in the wetting layer, allowing it to approach a more equilibrium state with respect to uniform strain and uniform roughening. This situation allows for a more uniform and simultaneous transformation to an islanding surface, and hence a more dense island distribution on top of the wetting layer.

Decreasing the V/III flux ratio increases the concentration-dependent surface diffusion in the wetting layer and hence increases the 2-D island size (pill boxes) in the wetting layer. It is important to make clear the distinction between 3-D islands nucleating on top of the wetting layer and 2-D islands contributing to the layer-by-layer growth of the wetting layer. The 2-D islands nucleate between surface steps and coalesce into a layer. In typical MBE growth, their density and hence average size at which they coalesce are affected by surface diffusion: Increasing surface diffusion can lead to larger 2-D islands in the wetting layer. A layer composed of larger 2-D islands will have a more uniform strain distribution than one composed of smaller 2-D islands because of relaxation at island edges; thus this leads to a more uniform transition to an islanded surface and an increased 3-D island density. In addition, the increased surface diffusion will also allow the growth front to roughen more uniformly, and hence more uniformly develop into 3-D islands of increased density. Although two effects within the wetting layer that will increase the 3-D island density on top of this region have been described, it is not known whether one or both of these effects dominate.

## ELECTRONIC COUPLING IN VERTICALLY ALIGNED QUANTUM DOTS

### Quantum Dot Columns

In addition to the limitations of lithographically defined quantum dots described in the “Introduction,” currently, lithography can only be used to define in-plane features and cannot be used to form arbitrary 3-D quantum dot arrays. In this section, we show how arrays of InAs islands in a matrix of GaAs can be vertically stacked and vertically aligned, and we show that such a structure produces electronically coupled quantum dots in the growth direction. Vertical alignment of islands was demonstrated several years ago.<sup>[42]</sup> These results showed the vertical alignment of two layers in the context of a degenerative roughness process in InGaAs QWs in GaAs, and was believed to be associated with dislocation generation. Here we show the vertical alignment of up to 75 islanding layers

**Fig. 10** (A) TEM (110) cross-sectional image of several columns of vertically aligned InAs islands (dark regions). (B) Selected area diffraction pattern of TEM sample in (A) showing superlattice diffraction spots in the (001) growth direction.

with no associated dislocation generation. These vertically aligned islands have been designed to be electronically coupled by using a thin GaAs spacer layer so that the vertical barrier between dots is small. Although these vertical columns do not provide the freedom to make arbitrary 3-D arrays, this technique produces in situ vertical 1-D QD arrays.

In these structures, the thickness of the GaAs spacer layer between InAs islanding layers is defined as the thickness between adjacent wetting layers, and not the thickness between islands. For a 56-Å GaAs spacer layer, the separation between islands in adjacent islanding layers is approximately 15 Å. In Fig. 10A, a high-resolution TEM image of 10 layers of InAs dots shows several vertically aligned InAs dot columns. The sample is tilted slightly off the zone axis to reduce strain contrast, so that the dark regions in the layered structure are predominantly from the increased scattering of the heavier In atoms. The top InAs layer produces much larger, more rounded, and diffuse islands, which we believe are more heavily alloyed with GaAs than the InAs islands in the lower layers. The presence of a new InAs wetting layer close to the peak of the lower islands inhibits mixing of GaAs with the InAs islands. AFM measurements indicate that the

islands are approximately 180 Å in diameter, which is confirmed in Fig. 10A. AFM measurements also indicate that the in-plane island size does not change significantly when islanding layers of 10 or fewer are added.<sup>[16]</sup> Although the small spacer thickness impedes vertical alloying with GaAs, the island shape remains consistent with (113) sides, as observed by other workers.<sup>[43]</sup> Several TEM images made perpendicular to the zone axis to enhance the lattice contrast were investigated for dislocations in the layer island regions; none was observed. A search for dislocations at the upper interface between the InAs islands and the GaAs cap was done by tilting the sample up to 30° off the zone axis; again, no dislocations were observed.

A selected area diffraction (SAD) pattern is shown in Fig. 10B. Superlattice and InAs diffraction spots are present at all non-in-plane reciprocal lattice points. Of particular interest are the bright and faint reflections to the left of the GaAs reflections for non-in-plane reflections, such as the (004) reflection. Calculations indicate that the brighter secondary spots are because of the superlattice unit cell and are determined from the average composition and lattice constant of the superlattice. The faint reflections further to the left of the GaAs spot are because of InAs and a higher-order superlattice reflection. In reciprocal space directions that are not the growth direction or the in-plane direction, such as the [224] direction, the InAs reflections correspond to an in-plane InAs lattice constant that is pseudomorphically strained. Because the InAs islands form aligned columns, there are two separate diffracting regions that are structurally connected: the wetting layer regions without columns and the column regions. High-resolution X-ray diffraction (HRXRD) in the [001] direction will be discussed later and confirms that the superlattice diffraction results from the pseudomorphically strained wetting layer region. Because of the high island density, if the islands were relaxed through a dislocation mechanism, this relaxation should extend to the wetting layer region; however, this is not observed.

In Fig. 11, a high-resolution TEM cross section highlighting a single column of InAs islands is shown. It clearly indicates the individual InAs islands and their vertical alignment. The 1.8-ML InAs wetting layer<sup>[44]</sup> is not observed. X-ray diffraction (XRD) and cross-sectional STM results discussed in “Theory of Quantum Dot Vertical Alignment” show that the wetting layer diffuses vertically; therefore it is very difficult to image with the microscope. The island height is approximately 40 Å, but is difficult to accurately determine because, at the island peaks, only a small number of InAs atoms remain in cross section to contribute to the contrast, and the observed cross section may not intersect the island centers. The lower island interface

**Fig. 11** TEM image showing one column of vertically aligned InAs islands. The island height is approximately 40 Å, and the in-plane dimension is approximately 180 Å.

is flat and abrupt, indicating that the GaAs fills in and smoothes the islanding interface. As in Fig. 10, the island dimensions in the uppermost islanding layer are much larger and, from the contrast change, appear to be alloyed with GaAs. To the right of the island column in Fig. 11 is a four- or five-layer column that does not continue through the upper layers. This decrease in island density after five layers is also observed in our AFM results<sup>[16]</sup> and is consistent with predictions by Tersoff, Teichert, and Lagally<sup>[18]</sup>

### Theory of Quantum Dot Vertical Alignment

The vertical alignment of InAs islands is easily understood within the context of an energy balance between interface free energy terms and the lattice mismatch-induced strain energy. The islands form to reduce the large heteroepitaxial free energy component and allow the strain in InAs to partially relax. Because the InAs is partially relaxed, subsequent GaAs deposition is favored in the non-islanding regions, and the valleys between islands will be initially filled. When the islands are covered, the GaAs on top of the islands is locally more stressed than the GaAs in adjacent regions between the islands. When a new InAs islanding layer is initiated, the locally stressed GaAs regions above the

old InAs regions become favorable low-energy attachment sites.

The stress field on the islanding surface was described in Eq. (4) as:<sup>[27–29]</sup>

$$\sigma_{xx} = \sigma(1 - ka(ky - 2)e^{-ky} \sin(kx))$$

The strain is  $\epsilon_i = S_{ij}\sigma_{ij}$ , where  $S_{ij}$  is the compliance matrix. The surface strain is largest on the crest of the islands. Therefore Ga adatoms attaching to the crystal surface at island peaks are more strained than in non-island regions: There is a strain gradient toward the area between the islands. Thus In adatoms see a potential gradient in the opposite direction. The gradient is expressed as:

$$V = M\sigma_{\tau,\tau} \quad (8)$$

The mobility  $M$  is given by:

$$M = \frac{D}{kT} \quad (9)$$

where  $D$  is the diffusivity and  $kT$  is the thermal energy. The flux  $J$  along the surface is proportional to this gradient through the surface adatom concentration  $c$ . But if a concentration gradient develops, it also affects the surface flux, so that:

$$J = V\nabla c - D\nabla c = -D\left(\frac{c}{kT}\nabla V + \nabla c\right) \quad (10)$$

If the stress gradient exceeds the concentration gradient, Ga adatoms diffuse to the planar regions, whereas In adatoms diffuse to the island regions.

The local strain relaxation that occurs by islanding in one layer facilitates preferential island formation directly on top of islands in subsequent layers. The islanding process reduces the interface energy by limiting the contact of InAs with the GaAs underlayer, and allows the InAs free surface to partially relax. This partial relaxation is expected to be removed as the InAs island is covered by GaAs. However, if only a thin layer of GaAs is added to the islanding layer, the removal of the partial relaxation will not be complete and the strain field from the buried InAs island will extend to the surface, leaving the GaAs locally strained and possibly distorted. In such a case, the region above a buried InAs island will act as a preferential nucleation site for further islands. Note that the InAs wetting layer and islands form a coupled system, yet SAD and XRD indicate that the wetting layer is unchanged by this preferential islanding and stacking process. The TEM and AFM observations that there is only a marginally small change in the island size with the addition of 10 island layers implies that the

**Fig. 12** The 8-K PL of vertically stacked dot layers. The variation in spectral peak position and linewidth is shown when the number of stacked dot layers changes from 1 to 10.

modification of the local surface strain state by the buried InAs island is not yet pronounced enough to measurably change the lattice mismatch.

### Electronic Coupling in Quantum Dot Columns

Results from 8 K PL measurements are shown in Fig. 12. The single-layer sample is the 3-ML spectrum shown in Fig. 2. Again, the broad luminescence of the single-layer sample is a result of variations in the size of the InAs islands. It is observed that for increasing layers of InAs islands, the spectral peak position shifts to lower energies and the spectral linewidth decreases. In comparison to the single island layer centered at 1.22 eV, the PL peak shifts 73 meV for five layers of islands and an additional 19 meV for 10 layers of islands. Because TEM and AFM measurements show that the change in the island size is small, we attribute the shift in spectral peak position to vertical coupling between InAs islands within a column. There is a 25% reduction in the spectral linewidth between the single islanding layer and the 10 islanding layers. In all cases, the spectral lineshape is Gaussian.

The spectral peak shift and linewidth reduction result from vertical coupling of islands in a column. The tunneling between vertical islands allows carriers to migrate to the lowest energy dot in the column, resulting in a spectral peak shift to lower energy. However, because the number of dots contributing to the spectra is many orders of magnitude larger than the 10 dots in each column, this effect is not responsible for the spectra changes observed here. Vertical coupling also results in spectral peak shifts and linewidth

changes by reducing the ground-state confinement energy of each dot column. A miniband is formed; it is the sum of the bonding and antibonding states from the overlap of the individual wavefunctions in a column. The individual dot is approximated as either a sphere or a box with infinite potential barriers so that the linewidth of the ensemble is proportional to:

$$E \sum_i \left( \frac{\Delta\chi_i}{\chi_i} \right) \quad (11)$$

where  $E$  is the coupled energy level.  $\Delta\chi_i$  and  $\chi_i$  are the variation of the size and the average size of an island in the  $i$ th direction, respectively. The tight-binding formalism is used to model the coupling and resulting energy. In the tight-binding model for a superlattice:

$$E = E_i + S_i + 2T_i \cos(qd) \quad (12)$$

where  $E_i$  is the uncoupled energy in each dot,  $S_i$  is the energy change in each dot when an adjacent dot perturbs the barrier potential, and  $T_i \cos(qd)$  is the wave function overlap term, with dot spacing  $d$  and wavevector  $q$ . Here the bandwidth  $4T_i$  is approximated to increase as  $e^{-c(d-1)}$ , where  $c$  is a fitting parameter weighting the overlap and  $d$  is the number of coupled dots. In this analysis, the spectral peak position and spectral linewidth are fitted using the same coupling parameter, and it is assumed that conduction band coupling is dominant. The fit to the peak position and spectral linewidth is shown in Fig. 13. It is found that the peak shift and the reduction in linewidth can be fully attributed to the change in ground-state energy because of coupling.

The strongest coupling state results if all of the dots within a column have the same energy. This coupling will produce the largest spectral peak shift. However, such a state will not result in the largest reduction in

**Fig. 13** Changes in (A) spectral linewidth and (B) energy are shown as a function of the number of vertical islanding layers. Both exponential fits use the same fitting parameter.

the energy linewidth because if all of the dots within a column have the same energy, the in-plane size variations will insure a variation in the lowest miniband state in the ensemble of columns. The weak coupling state, where carriers tunnel through the vertical barriers in a dot column, produces small changes in spectral peak position and linewidth. These changes arise from the increased spatial extent of the dot wavefunctions and not from the strong overlap of coupled states. An interesting case is the intermediate coupling state, in which the vertical variation in the island size in a single column has the same distribution as the in-plane island size variation in an island layer. This coupling state produces the largest reduction in spectral linewidth because all of the dot columns now have the same size distribution. Because it has been shown that a significant element of the in-plane island size variation is caused by small spatial flux non-uniformities across the growth surface,<sup>[45]</sup> it is unlikely that the vertical distribution in island size can be made equal to the in-plane island distribution. Thus some significant inhomogeneous spectral broadening will always remain, as is the case here.

An additional source of spectral red shift and linewidth reduction is that as the number of island layers increases, the islands may be increasing in size or relaxing. This has not been observed in these 10-layer samples in our TEM or AFM characterization; however, changes in island size are observed in larger columns, as will be seen later in this chapter. If such changes were present here (yet too small to observe) and were responsible for the energy shift, we still do not observe spectral features from individual dot layers in the column, which would result in increased linewidths. Thus even in this scenario, weak coupling (tunneling) from islands in a column to the lowest energy state in the column would still be present.

The coupling in columns can be further investigated by varying the spacer layer thickness between the InAs island layers. The spacer layer thickness in a 10-islanding layer structure was changed between 40 and 50 Å, and 75 and 85 Å. Because these thicknesses are the approximate thicknesses between the wetting layer regions of adjacent islanding layers, the actual vertical spacing between islands varies between 0 and 45 Å. The 8-K PL results for these structures are shown in Fig. 14. The results indicate an increased spectral peak shift in the 40 Å spacer sample as compared with the 50-Å sample. This is consistent with the increased coupling that would be associated with a thinner spacer region. In addition, the spectral linewidth increases when the spacer layer thickness is reduced to 40 Å. The increased spectral linewidth is caused by a disruption in the island structure because the spacer layer is now approximately equal to the island height. However, the spectral peak shift is smaller in the sample with

**Fig. 14** The effect of varying the spacer layer thickness from 40 to 85 Å is shown. The energy shift is because of the change in electronic coupling. The narrowest linewidth is found in the sample with a 50-Å spacer layer.

the 85-Å GaAs spacer than the sample with the 50-Å GaAs spacer. Here the increased spacer thickness reduces the electronic coupling between islands. In addition, a broad, high-energy shoulder is also apparent in the spectrum with the 85-Å spacer. This shoulder is caused by isolated or only partially aligned islands, where coupling is either not present or is diminished. In Fig. 15, the sample composed of 10 QD layers with

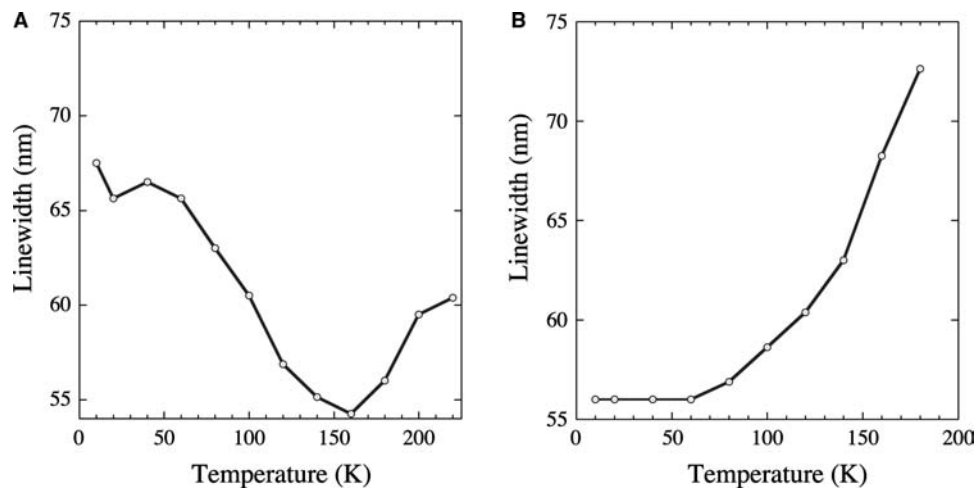

**Fig. 15** The 8-K PL of a 10-layer QD sample with an 85-Å spacer is compared to a single-layer sample to show how the larger spacer layer produces a broad high-energy spectral shoulder that indicates incomplete columns.

85-Å GaAs spacer regions is shown with the single-layer sample to further illustrate the how the high-energy shoulder corresponds with isolated or partially aligned columns.

We have shown that the wavefunctions of the isolated dots become vertically extended in the vertically aligned dot columns. When the states become vertically extended, the carriers occupying these states become delocalized and sample an average dot potential. This situation is similar to the in-plane delocalization that results when dots formed at low growth temperatures have rough, poorly defined structures (see “Single-Layer InAs Quantum Dot Ensembles” and Fig. 6) and there is in-plane delocalization when the PL temperature is raised, except that the vertical columns are a controlled 1-D chain of dots. We would not expect an increase in the PL measurement temperature to reduce the luminescence linewidth as with the single-layer samples. In Fig. 16, the variation in spectral linewidth with varying sample temperatures is shown for a single InAs QD ensemble sample and one with 10 InAs QD layers. Although the single-layer sample shows the effects of inhomogeneous broadening discussed in “Theory of Quantum Dot Vertical Alignment,” the 10-layer sample does not and is predominately thermally broadened.

## LEDs Using Coupled Quantum Dots

It is naturally desirable to extend device performance successes gained using QWs in electronic and optoelectronic devices to structures with more reduced density of states (DOS), such as quantum wires and quantum dots. For optoelectronics, the implementation of such structures should result in increasingly efficient LEDs, lower threshold lasers, and novel non-linear optical devices if: 1) the QD size is reduced to allow for room temperature applications; 2) the QD size uniformity is improved to take advantage of the sharp resonances in the QD DOS; and 3) reliable and simple fabrication techniques are developed. The QD structures described earlier have large-enough confinement energies for room temperature applications; however, the variation in the dot size leads to large inhomogeneous broadening and a loss of the sharp luminescence from the 0-D energy states. We believe that a major advantage of the self-assembled QDs is the high dot densities that can be produced in these self-organized random arrays. As shown in “Electronic Coupling in Quantum Dot Columns,” these densities can approach 80% of the ideal close-packed array density, and will be important for optoelectronic device applications.<sup>[41]</sup> In addition, we believe that the multilayer dot column structure will have an additional impact on optoelectronics. Other groups have made impressive contributions in QD lasers<sup>[46]</sup> (see the entry in this book by D. Bimberg),

**Fig. 16** Variable temperature PL of (A) a single-layer InAs dot sample and (B) 10-layer InAs quantum dots layers.

and it is not our desire to describe such results. However, we would like to show in this section how some of the properties of these dot columns can be used in optoelectronic device structures.

The vertical columns of quantum dots described in “Electronic Coupling in Quantum Dot Columns” can be used to increase the optically active volume of LEDs. LEDs are demonstrated in which the active regions are composed of columns of InAs QDs containing either 1, 5, or 10 QDs. Measurements indicate that the single dot layer diode is more efficient than the coupled multidot column diodes. However, at high injection levels, spectra show that much of the luminescence intensity in the single-layer sample is because of the QW formed by the preislanding (wetting) layer and recombination in the doped cladding regions. Luminescence from these regions is nearly eliminated in the multidot column samples. Thus these columnar QD structures may be important to understand high injection conditions, such as lasing. Because of variations in the island size, these diodes are spectrally broad and the sharp spectral features associated with 0-D DOS of these structures are lost. However, of considerable practical importance for optical communications is that spectral peak emission at  $1.3\ \mu\text{m}$  has been achieved.<sup>[47]</sup>

The LED structures consist of an n-type GaAs bottom cladding layer of  $0.75\ \mu\text{m}$  and a p-type GaAs top cladding layer of  $0.29\ \mu\text{m}$ . The diode intrinsic region is  $0.11\ \mu\text{m}$  thick and contains an active region of either 1, 5, or 10 InAs island layers in a GaAs matrix. The devices were wet etched to form  $20 \times 20\ \mu\text{m}$  mesas. The devices are bottom-emitting and only a portion of the light that is generated in the intrinsic region reaches the bottom interface. The numerical aperture (NA) of the collecting objective is 0.25. Therefore neglecting scattered light from different interfaces

passing into the objective, only about 1% of the light generated in the intrinsic region is collected by the objective and measured.

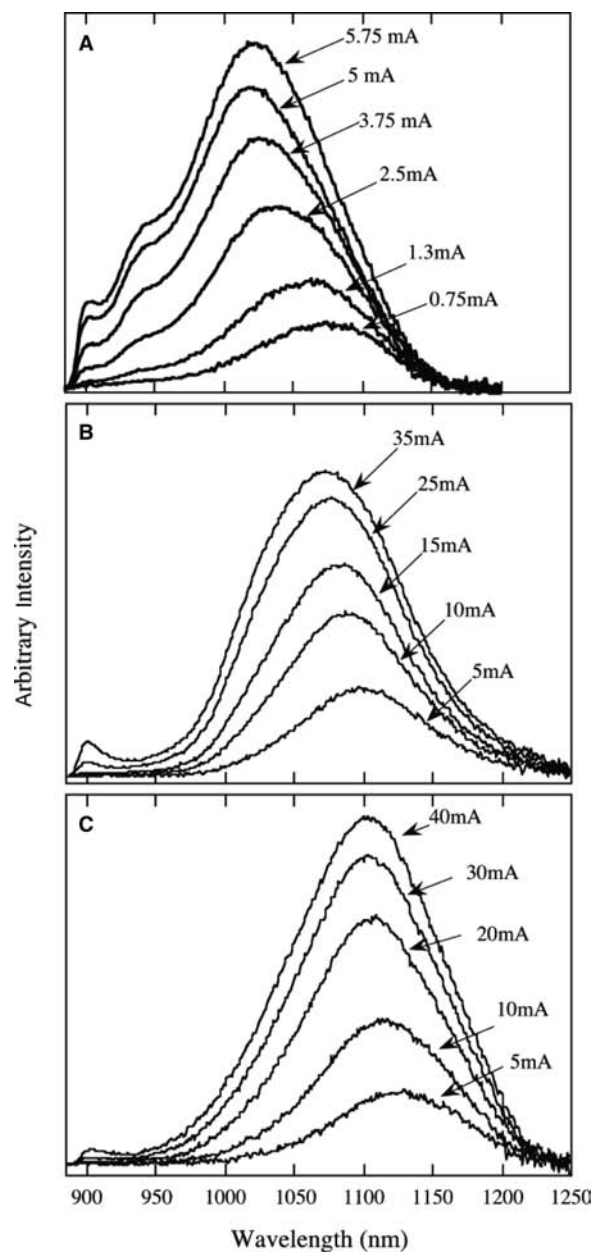

Light output collected through the substrate for the three LEDs is shown in the power output vs. current ( $L-I$ ) curves of Fig. 17. Two features are apparent. First, in the linear region of each curve, the slope of the diode with only a single quantum dot layer is higher than the slope of the diodes containing multidot columns. As the number of dots in a column increases, the steady-state carrier concentration throughout the active regions becomes more non-uniform, diminishing the radiative recombination rate. Carrier transport, particularly hole transport, is slowed because the carriers must tunnel through several dots in a column to recombine. Additional evidence of decreased radiative recombination rate is the small flattened onset region in the diodes containing multi-QD columns. If the non-radiative recombination rate is increased, then more current is required to overcome the non-radiative recombination and the slope of the  $I-V$  curve is initially decreased. The second feature seen is an increase in saturation current and peak intensity. Because there are more dots available, there is now an increased number of states for which recombination can occur. Thus as the number of dots in a column increases, the optically active QD volume increases; this shows the effectiveness of the vertically aligned, columnar QD system. The luminescence in these diodes comes from two distinct regions: the QW wetting layer, and the QDs nucleated on top of the QW. As will be seen, at high currents, a significant portion of the luminescence from the single QD layer diode observed in the  $L-I$  curve originates outside the QD region, whereas the luminescence is well confined to the QD regions in the diodes containing columns of multiple QDs.

**Fig. 17** The light output vs. bias current for three LEDs that use either single, 5, or 10 dot layers at the device active region.

The spectra of diodes containing columns of 1, 5, or 10 InAs QDs are shown in Fig. 18. As the number of QD layers increases, the spectral peak position of the diode shifts to longer wavelengths and the spectral line-width decreases (Fig. 12). As the current increases in each of the diodes, luminescence from the doped GaAs cladding region increases at 900 nm. This luminescence feature is the luminescence shoulder from recombination in the doped region of the diodes where band-gap narrowing is present. From top-emitting LED samples, it is estimated that one-half of the feature (the region below 900 nm) is absorbed by the GaAs substrate. Carriers travel through the active region and recombine with majority carriers in the doped region. The prominence of this feature is significantly reduced as the number of QDs in the dot columns is increased because carriers are more effectively captured in the InAs dot region. The spectra of the diodes with a single QD layer (Fig. 18A) exhibit an additional feature between the main QD peak and the luminescence from recombination in the barriers, which is absent in the diodes containing columns of multiple QDs. This extra peak is because of radiative recombination in the QW wetting layer region. The peak position is well modeled, assuming a strained, coherent InAs wetting layer (QW) with a wetting layer thickness of 1.8 ML, a thickness observed in Fig. 1 and by other researchers.<sup>[43,44]</sup> The coupling of dots in the QD columns is larger than the coupling between QWs, so that the dominant carrier transport is through the QD columns.

As the current increases in the diodes, the spectral peaks in all samples shift to shorter wavelengths. The LEDs are biased under d.c. conditions. Sample heating is not responsible for this effect because it will reduce

**Fig. 18** Luminescence spectra for three diodes with different numbers of quantum dot layers in the active region with various current bias. (A) Single quantum dot layer, (B) columns of five quantum dots, and (C) columns of 10 quantum dots.

both the InAs and GaAs bandgaps similarly and produce a red shift in each. The spectral shifts with bias are larger in the single-layer QD diode, whereas they are equal in the two multi-QD column samples. In all cases, the spectral peak shift stabilizes at higher currents. The spectral peak shifts result when the lower-energy states from larger QDs become saturated. The extra shift in the single QD layer sample results from the proportionally larger luminescence from the QW wetting layer.

A comparison of the three different diodes at the same current of 15 mA is shown in Fig. 19. In the

**Fig. 19** Comparison of the three diodes with columns of 1, 5, and 10 quantum dots using the same current of 15 mA.

single-layer QD diode, the intensity increase between 6 mA (Fig. 18A) and 15 mA results almost entirely from recombination in the QW InAs wetting layer and the GaAs barrier region; the energy states contributing to the main 0-D spectral peak luminescence are saturating. Thus this luminescence is a mixture of light from the 2-D QWs and light from the 0-D QDs. The luminescence intensity of the diodes containing the multi-QD columns results entirely from the 0-D energy states. At 15 mA, the peak intensity of the diode with five dot columns is larger than the peak intensity with 10 dot columns. Even without scaling, it is apparent that the internal quantum efficiency of the device is reduced between the 5- and 10-dot column samples.

An approximate comparison of internal quantum efficiency can be made by comparing the diodes when the current per QD layer is equal, and the luminescence intensity is scaled by the number of QDs in a column. This is shown in Fig. 20, where the current per dot

**Fig. 20** Comparison of the three diodes with columns of 1, 5, and 10 quantum dots where the current per quantum dot layer is constant at 3 mA for each of the three diodes. The luminescence from each diode is divided by the number of QD layers in each diode.

layer is 3 mA. The normalized peak intensity of the diode with the single dot layer is the highest of all the diodes, so that even with respect to only the 0-D luminescence, the single-layer diode has the highest efficiency. As observed in multiple quantum well (MQW) LEDs, holes are not being evenly distributed throughout the multi-QD column active region because their large effective mass reduces their tunneling probability between QDs in a column. However, the effects of non-radiative recombination processes, such as recombination at crystalline imperfections, must also be considered. This does not appear to be the case because the slope of the  $I$ - $V$  curves of diodes with either 5 or 10 dot columns is similar, implying that there is no significant increase in nonradiative recombination between the two diodes.

In summary, the increased active volume of the columnar structure containing multiple QDs leads to increased peak luminescence intensity and reduced carrier recombination in the doped GaAs region. However, this comes with a penalty, which is a decrease in luminescence efficiency as the QD column size increases. It is believed that the reduced luminescence is because of a partitioning of holes in the QD columns, but other effects such as non-radiative recombination at structural defects cannot be ignored. Finally, in the diodes containing QD columns, the luminescence from the QW wetting layers regions is eliminated because the coupling within the dot columns facilitates carrier transport through the QD columns. This is a significant advantage to using the quantum dot columns because early laser structures appear to lase through the wetting layer states or excited states of the dots. Because of the hole partitioning in columns with many dot layers, an optimum quantum dot active region should contain columns with a limited number quantum dots. The number will vary depending on the structure, but the results shown here indicate that columns containing about five QDs adequately balance the reduction in QW luminescence without significant hole transport penalties.

## IN-PLANE InAs ISLAND ORDERING USING A SUBSURFACE ISLAND SUPERLATTICE

### Columns Composed of Many Quantum Dot Layers

The focus of “LEDs Using Coupled Quantum Dots” was the electrical coupling that can occur in vertical columns of a small number of quantum dot layers. A different effect can be observed when a large number of layers are stacked. In this regime, the column structure can increase the structural and spatial uniformity of the uppermost in-plane QD ensemble. Although we

**Fig. 21** Cross-sectional STM empty states image of two columns of InAs quantum dots (bright) in a GaAs matrix (dark). The field of view is  $600 \text{ \AA}$  in (110) (horizontal) and in (001) (vertical). *Source:* W. Wu and J. R. Tucker.

have explored some of the structural properties of these columns in “LEDs Using Coupled Quantum Dots” using TEM, we will more closely examine these properties using AFM, XRD, and cross-sectional scanning tunneling microscopy (STM).

A cross-sectional STM image of columns of five InAs QDs is shown in Fig. 21. Here the image size is  $600 \times 600 \text{ \AA}$ . This and other STM images were made by W. Wu and J. R. Tucker at the University of Illinois, Urbana-Champaign. These samples are prepared by in situ cleaving in a  $5.5 \times 10^{-11}$  Torr chamber to expose the (110) surface. The measurements are made at room temperature. The STM image is an empty states image derived from current variations across the surface when electrons tunnel from the STM tip to available states in the valence band. Because of the charge transfer on the (110) III–V unreconstructed surface, empty valence band states are localized on the group III sublattice. Thus this imaging highlights Ga or In atoms. Because of the narrower bandgap of InAs and the larger size of the In atom (which pushes the exposed In further out into the vacuum), the tunneling current is higher in the In-rich regions than in the Ga-rich regions. Hence, the contrast is directly related to the mole fraction of In. In these images, discrete bright areas are the result of In surface atoms. Fainter bright spots are assumed to be from In atoms in the next group III layer below the surface.<sup>[48,49]</sup>

This image, as well as other STM images, are consistent with the TEM micrographs. The in-plane dot diameters in Fig. 21 are approximately  $130 \text{ \AA}$  and the heights are  $30 \text{ \AA}$ . The spacing between the two columns is  $200 \text{ \AA}$ . As in cross-sectional TEM, the exact diameter cannot be measured directly from these images because

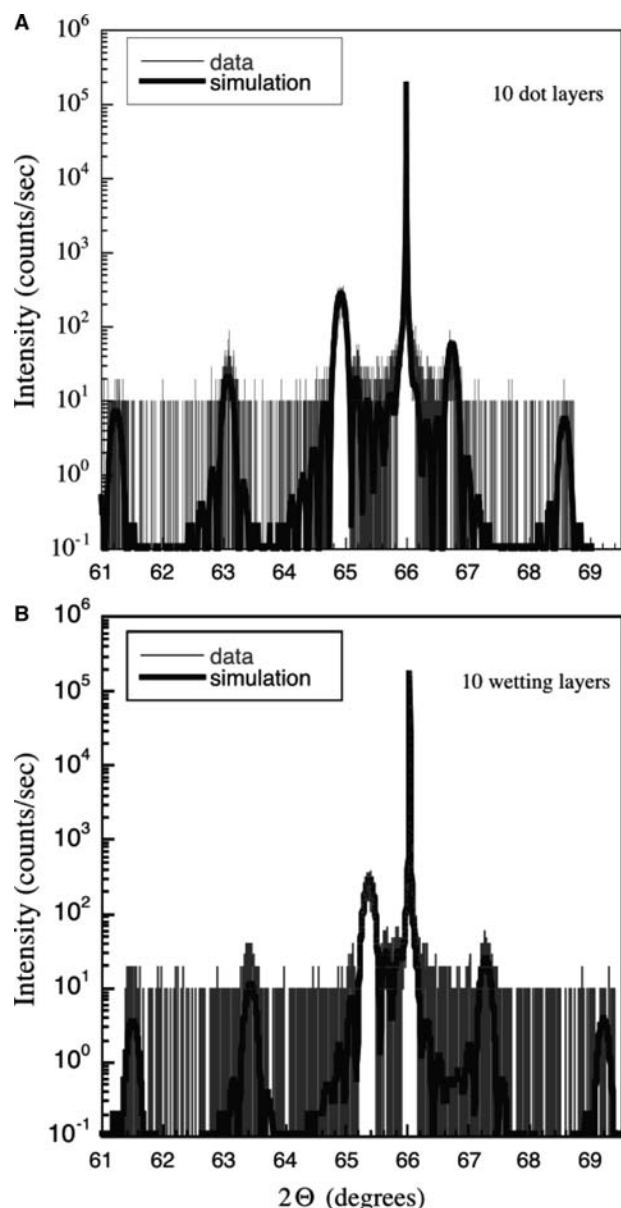

the cleave does not necessarily bisect the center of the QDs. TEM and STM are complimentary measurements. The advantage of this STM technique will be seen later in this section: Although TEM images are formed by columns of atoms in the plane of the image, the STM images are formed from states close to the surface. Thus individual In atoms that have diffused into GaAs regions can be imaged with STM. In addition, the DOS can also be examined using STM by sweeping the tip voltage.

We now focus on uniformity improvements that can be made using large columns containing up to 75 layers of dots. In these structures, there is an interaction between neighboring columns, which imposes a strain field on the growing surface and can lead to dot ensembles of both increased size uniformity and increased spatial uniformity. We begin by showing that, despite the layering of dots to form columns, the InAs diffusion from these dots is limited, especially with respect to the large InAs diffusion observed in the wetting layer regions.

In Fig. 22, a cross-sectional STM image of two adjacent 20-layer columns of InAs islands is shown. As in Fig. 21, the STM image is an empty states image highlighting tunneling current differences associated with Ga or In. In Fig. 22A, a speckled band, which is the planar wetting layer region, is present between the dot columns. This region has been shown by various groups to consist of between 1.6 and 1.8 ML of InAs, determined through reflection high-energy electron diffraction (RHEED). Although it has been shown in earlier InAs planar epitaxy studies that the surface segregation in this layer results in a broadly alloyed region,<sup>[48–50]</sup> in strain-induced quantum dot research, it is often assumed that this region remains relatively intact. In Fig. 22A, the In diffusion can be easily seen to extend to the height of the InAs dots, which is approximately six unit cells.

**Fig. 22** Cross-sectional STM image of (A) the region between two 20-layer quantum dot columns showing In diffusion between dot columns, and (B) the region around a column indicates no significant In diffusion from the dot regions. *Source:* W. Wu and J. R. Tucker.

**Fig. 23** X-ray diffraction from (A) a 10-dot layer sample formed in the columnar structure, and (B) a QW 10-wetting-layer sample (nominally planar InAs layers). Simulations are shown in black. In both cases, the superlattice diffraction is caused by the wetting layer regions.

We have observed the global structure of this wetting layer region using XRD. In Fig. 23A, XRD results are shown for a sample consisting of 10 InAs dot layers. The XRD was conducted using a Philips 4 crystal X-ray diffractometer. In the figure, we observe superlattice diffraction from a supercell consisting of the GaAs spacer and the InAs. Peaks for the  $n = 0$ ,  $\pm 1$ , and  $\pm 2$  reflections are present, with the (004) GaAs substrate peak residing between the  $n = 0$  and  $n = 1$  reflections. A fit using a dynamic diffraction model gives (Fig. 23A) a strained InAs thickness of 1.9 ML

( $\pm 0.2$  ML) and a GaAs thickness of 52 Å. Our interpretation of these results is that the wetting layers (in the dots wetting layer system) are the only contribution to the superlattice diffraction. Because Fig. 23A represents symmetrical diffraction about the (004) GaAs reflection, the dot regions, with their varying InAs and GaAs vertical sections, should not contribute to superlattice diffraction. The only extensive regions with periodic structure in the growth direction are the regions of the sample without InAs dots where only the wetting layers are present. To verify this result, XRD was conducted on a similar sample with only InAs wetting layers. This sample is composed of 10 periods of 1.5 ML of InAs; the GaAs spacer layer is 50 Å. The results are shown in Fig. 23B. When fitted using the same diffraction model, the best fit occurs for 1.5 ML (approximately 9 Å) of strained InAs.

This measured value of 1.9 ML for the 10-layer dot sample is close to the 1.8-ML wetting layer thickness observed by other researchers using RHEED. The RHEED measurements determined the equivalent amount of materials deposited leading to the dot transition, whereas this XRD measurement determines the wetting layer thickness after the dot transition. Because the transition to island growth results in an overall change in the surface topology, it is interesting to note that the wetting layer thickness is unchanged by the transition to islanding.

The width and decay of the superlattice diffraction in Fig. 23 indicate the uniformity of the wetting layers over the superlattice and the intermixing of the InAs wetting layers and GaAs spacer layers. The model indicates that the wetting has an alloyed profile, which decreases exponentially from  $\text{In}_{.99}\text{Ga}_{.01}\text{As}$  to  $\text{In}_{.10}\text{Ga}_{.90}\text{As}$  in 18 Å, or nearly two-thirds of the dot height. In addition, a small amount of In is present throughout the GaAs region. This diffusion of InAs in GaAs has been observed by other researchers in thin InAs QWs in GaAs.<sup>[48–50]</sup> The diffusion is the result of surface segregation of In. Like the InAs island formation, the surface segregation is a mechanism by which the lattice-mismatched strain can be reduced. After InAs has been deposited on the GaAs surface and GaAs deposition again begins, the In atoms switch sites with surface Ga adatoms. This strain-driven diffusion of In to the surface reduces the total system energy because the surface In is not completely constrained by the GaAs lattice. The complete sequence of In diffusion occurs as follows. Through the initial deposition of less than 2 ML of equivalently planar InAs, the InAs surface remains generally planar, except for some surface roughness that may be present to reduce strain. With the addition of a small amount of In to the surface, the surface transforms from planar to 3-D islands. However, through XRD, we have shown that the wetting layer region remains. If the

InAs deposition is terminated before plastic relaxation and the surface is covered with GaAs, In from the planar region surface segregates, leading to an alloyed region between the dots. A consequence of this segregation is that the InAs quantum dots are now less laterally confined because the vertically diffused In decreases the lateral confining potential.

In contrast to the In diffusion present in spaces between the dots, the In in the dot regions is remarkably stable. This can be seen in Fig. 22B, where an STM empty state tunneling image of three vertically aligned dots is shown. The shape of these dots is pancake-like and is the typical shape we observe in all samples. Although the bottom interface of each dot is abrupt, the top interface of the dot is also quite sharp; no isolated In atoms are observed in the vertical regions between the dots, as are seen in the spacer regions away from the dots. In addition, no In concentration gradient is observed to go away from the dots into the wetting layer regions (in the in-plane direction), further indicating the stability of the In in the dots.

We believe that the InAs in the dot regions is resistant to lateral and vertical diffusion because this InAs exists in regions where the lattice constant remains slightly dilated toward the InAs lattice constant. In the wetting layer regions, the InAs is strained to the GaAs lattice constant, and the full effect of strain-enhanced diffusion is present. In fact, if the GaAs regions surrounding the InAs dots have the GaAs lattice constant, then the small difference in lattice constant between the two regions inhibits InAs diffusion away from the dots [Eq. (10)].

### Increased Structural Uniformity

It has been theoretically and experimentally shown<sup>[18,41]</sup> that the vertical column structure increases the upper layer dot size uniformity and nearest-neighbor spatial

uniformity. The increased uniformity is the result of stress fields from the subsurface dot layers affecting the adatom diffusion on the new surface layer. Suppose that the initial dot density is large compared with the adatom surface diffusion length, and the strain fields from adjacent columns overlap. Because the nucleation of an InAs island occurs at a strain maximum, overlapping columns produce maxima that are closer together. With increased layering of islands, the strain maxima become closer together and columns will eventually be eliminated. If the initial dot density is sparse compared with the adatom surface diffusion length and the island strain distribution, new dots will nucleate between existing columns. Overall, some equilibrium density of islands will result. In this state, the strain field should be periodic over the growth surface; the spacing between strain maxima will be determined by strain, overlayer thickness, and surface diffusion. The nearest-neighbor distance between nucleating dots will become constant, resulting in uniform nutrient fields around each dot and thus a more uniform dot size distribution. In our work, we assume that the ideal equilibrium surface of a single dot layer is a dense array of dots in which the dots form from strain-induced surface roughness. Therefore the formation of columns should decrease the dot density in the uppermost dot layer.

A decrease in island density and an increased island uniformity are immediately apparent when comparing the bare InAs dot surfaces after a single layer of dots and after 20 layers of dots have been deposited. This is shown in the AFM images of Fig. 24. A statistical evaluation of the AFM images in Fig. 24 is found in Figs. 25 and 26. In Fig. 25, a comparison of the variation in height in the single-layer and 20-layer samples is shown. The average height increases from 43 Å in the single sample to 65 Å in the 20-layer sample. The full width at half maximum (FWHM) of the dot height is reduced from 17 to 10 Å between the single-layer and

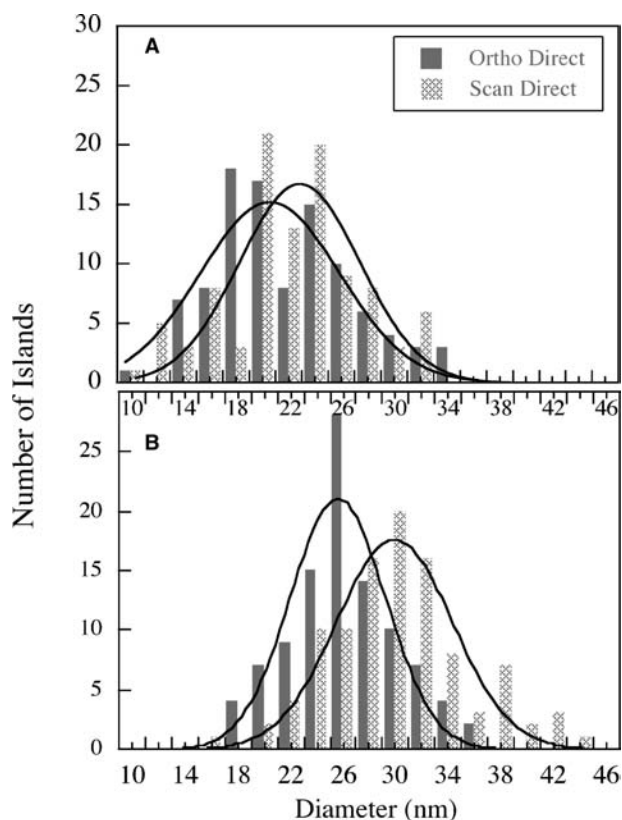

Fig. 24 AFM image of (A) the top surface of a single layer of InAs dots, and (B) of the top surface after 20 layers of dots.

**Fig. 25** In-plane dot diameter variations determined from AFM, where (A) is for a single layer of InAs dots and (B) is after 20 layers of InAs dots.

20-layer samples, even though the average dot height has increased in the 20-layer sample. In Fig. 26, a comparison of the variation in the in-plane dot diameter between the two samples is shown. The in-plane area is not circular but elliptical, and the two differently shaded regions in Fig. 26 represent the orthogonal directions with maximum and minimum values. (We cannot observe the facet planes in our AFM imaging, and it is assumed that the island base is rectangular or parallelogram.) As for the average dot height, the in-plane diameter has increased after 20 dot layers. The average in-plane diameter of the single dot layer is 218 Å, whereas the average in-plane diameter after 20 dot layers is 273 Å. The distribution of the in-plane diameter has also narrowed: The FWHM of the diameter distribution is reduced from 50 Å (single layer) to 41 Å (20 dot layers). There is a small but observable difference between the height increase and the diameter increase in the 20-layer dot distribution. The average height increases more than the average diameter, so that the ratio of height to in-plane radius changes from 0.4 to 0.48 after 20 layers (i.e., these dots are more hemispherical). The increase in dot height and diameter is in agreement with the reduced island density observed in Fig. 24. Because the dot density is reduced and the

**Fig. 26** Height variations determined from AFM (A) for a single layer of dots and (B) after 20 layers of dots.

wetting layer thickness is unchanged (Fig. 23A), the dot size must increase. The reduction in the size variation in height and diameter is because of the more uniform local dot environment resulting from stacking the dot layers. Because the strain field in the dot layers becomes more periodic with each dot layer, dots are nucleated with more uniform nearest-neighbor distances, and hence more uniform nutrient fields. These more uniform surroundings lead to more uniform dot sizes.

Cross-sectional STM reveals the way in which the dot columns are eliminated. Empty states images of 20 dot layers are shown in Fig. 27. In Fig. 27A, three columns that are not terminated are shown, and indicate the well-aligned dot column structure. In Fig. 27B, several columns are eliminated through the dot layering process. Two types of column elimination are present, yet it is not clear whether these two types of elimination are indeed distinct. The first process is by simple extinction: The column abruptly ends. Such a column is observed in Fig. 27B on the left. The second type of column elimination is observed on the right: Two columns merge after only two dot layers, whereas still another column dramatically bends

**Fig. 27** Cross-sectional STM images in two regions of a 20-layer dot column structure. On the left (A), column uniformity is maintained except for a small truncated column. On the right (B), two columns merge, and then the resulting column merges with a third column. *Source:* W. Wu and J. R. Tucker.

toward this stable column until it eventually merges and is eliminated. Because we only probe in one cross-sectional plane, we cannot be sure that the column that abruptly ends does not bend inward away from the surface; however, the abruptness in which the column ends suggests that this is not the case.

If one column exerts more of an effect on the resulting strain field, then the position of the new dot will be closer to this column. Such a description will account for the abrupt type of column elimination we observe. However, the slow bending of columns is a more dynamic process. In this case, we believe that overlapping strain fields from columns produce a situation in which distinct minima in misfit exist near each column, but that an overall lattice change between the columns shifts one or more of these minima toward the region between columns. It is unlikely that the observed bending is caused by competing nutrient fields because this situation would drive columns away from each other, and this is not observed.

### Increased Spatial Uniformity

When a large number of island layers are deposited, the strain created by adjacent columns interacts to

create a surface strain distribution. We have just shown how this imposed strain distribution leads to structural ordering of the quantum dot ensemble on the surface. Similarly, the strain distribution becomes a template that can lead to spatial ordering of the new island layer. In investigating the limits of this ordering, we have determined that, under various crystal growth conditions, a surface unit cell of islands is formed on the upper layer of the superlattice. Although some translational properties of the unit cell are observed, providing initial evidence of a 2-D surface lattice of quantum dots, a well-ordered lattice is not found. We demonstrate that this occurs because in this material system, with a (100) growth surface, surface diffusion effects and bulk strain effects compete in a manner that breaks complete translational symmetry. Adjusting growth parameters can diminish this effect.

An example of the variation in quantum dot ensembles with variations in spacer layer thickness and number of layers can be seen in Fig. 28. The first two images in Fig. 28 have different subsurface InAs dot layer parameters. In Fig. 28A, the subsurface multidot structure has 30 InAs dot layers, each containing the equivalent of 2.5 ML of planar InAs. The thickness between each wetting layer region is 55 Å, and the growth temperature was 500°C. In Fig. 28B, the subsurface multilayer contains 50 dot layers, the wetting layer spacer is 75 Å, and the growth temperature is 525°C. In “Single-Layer InAs Quantum Dot Ensembles” and our previous work,<sup>[36]</sup> we showed that the higher the growth temperature is, the larger is the average InAs dot size. Thus the GaAs spacer layer must be increased in the sample grown at a higher temperature so that the growth surface can planarize between dot layers. In Fig. 28A and B, a qualitative alignment along  $\langle 100 \rangle$  can be seen. Ordering in single-layer samples, if present at all, is along [110] and is because of step bunching.<sup>[6]</sup> An example of this is shown in Fig. 28C, where the growth parameters were adjusted to maximize step bunching. In contrast to the  $\langle 100 \rangle$  alignment seen in Fig. 28A and B, the alignment in Fig. 28C is in the vertical [110] direction. The alignment is caused by anisotropic surface diffusion because of

**Fig. 28** AFM images of after (A) 30 layers of InAs dots ( $T_g = 500^\circ\text{C}$ ), (B) 75 layers of InAs dots ( $T_g = 525^\circ\text{C}$ ), and (C) a single layer of dots grown to enhance surface step bunching.

ledge and surface reconstruction.<sup>[51]</sup> In contrast, the surface alignment of InAs dots in  $\langle 100 \rangle$  in samples containing subsurface dot multilayers is because of the interaction of the strain fields from the buried dots.

We can begin to see the extent of the spatial ordering present in these structures by making reciprocal space surface maps of AFM images. The Fourier transforms of the AFM images for the single-layer and the 30-layer samples shown in Fig. 28 are shown in Fig. 29. In the Fourier space image of the single island layer sample, only a centered peak is present, indicating there is no regular nearest-neighbor distance between islands. In the 30-layer sample, there is both regular nearest-neighbor distance and orientation. The nearest-neighbor directions are only approximately the  $\langle 100 \rangle$  directions, as shown by the thin lines added in the vertical and diagonal directions. Our explanation for this is that, although the strain distribution on the surface drives the unit cell of dots to have a nearest-neighbor direction in  $\langle 100 \rangle$ , the surface diffusion has a different preferential orientation. The anisotropic surface diffusivity in a sense competes with subsurface strain and pushes the nearest-neighbor direction slightly away from  $\langle 100 \rangle$ . We will show later in this entry that the situation is even more interesting because the second nearest-neighbor directions from the strain distribution will be shown to be  $\langle 110 \rangle$ , but because of the anisotropic surface diffusion, these unit cell directions are no longer degenerate.

In the case of an isotropic material, the region above a subsurface island is strained and becomes an advantageous site for island formation because the dilated lattice constant is closer to the InAs lattice than the surrounding surface. The strain interaction of two subsurface islands has been calculated for the isotropic case.<sup>[52]</sup> We use one island as an infinitesimal “test island” in analogy to the test charge in electrostatics, with the convention that it induces a negative strain in the crystal. The strain distribution on the surface from an island submerged a distance  $L$  from the

surface is:<sup>[18]</sup>

$$\epsilon(x) = C \frac{1}{(x^2 + L^2)^{\frac{3}{2}}} \left( 1 - \frac{3L^2}{(x^2 + L^2)} \right) \quad (13)$$

where  $C$  is constant. If two islands are in close proximity, the resulting surface strain distribution is the superposition of the strain distributions of the individual islands. On the 2-D surface, the possible first nearest-neighbor island positions fall on a circle. If the surface diffusion rate is adequate, the highest density of islands (a hexagonal cell) will result. If enough layers are deposited, different surface regions will coalesce into a close-packed 2-D hexagonal arrangement.

What is interesting to us is the effect of the crystal symmetry on this result. Thus for the moment, we ignore the surface diffusion effect and determine the nearest-neighbor arrangement from crystal symmetry. The nearest-neighbor ordering observed in Fig. 29 can be explained by the anisotropic properties of the GaAs zinc-blend crystal structure. The  $\langle 100 \rangle$  directions are elastically soft<sup>[53]</sup> (i.e., they have relatively small elastic moduli). Thus it is expected that nearest-neighbors should be in these directions. We investigate the effect of the anisotropic elasticity tensor on the orientation of the surface ordering by calculating the surface strain from a single buried island as a function of crystallographical orientation, and then assuming that the total strain from a buried layer of many islands is the linear superposition of the strain from individual islands. We do this by using a known isotropic solution<sup>[54]</sup> for an isolated subsurface island and adopting it to the anisotropic case. A more accurate but still approximate solution can be developed using the elastic stress tensor of a cubic crystal. However, approximations must still be made and, for our purposes, this simple solution is adequate. We use a Green’s function approach for a buried elliptical island where the island dimensions have been determined from the cross-sectional STM discussed in “Increased Structural Uniformity.” Following Hooke’s law, the stress  $\sigma$  and strain  $\epsilon$  are related by the elastic tensor  $c_{ijkl}$  by  $\sigma = c_{ijkl}\epsilon$ . For rotation about the surface normal, we assume that the inverse of the elastic tensor (denoted by  $s_{ijkl}$ ) is a slowly varying function of the orientation in GaAs, so that the already known isotropic Green’s functions can be applied. The displacement is related to stress  $\sigma^*$  induced by the buried InAs island by  $c_{ijkl}\mathbf{u}_{i,j,k,l} = \sigma_{ij}^*$ , where  $ij,kl$  indicates partial differentiation by the cyclical indices  $k$  and  $l$ . Then:

$$u_i(x) = -c_{jlmn}\epsilon * \int_{\Omega} G_{ij,l}(\mathbf{x} - \mathbf{x}')d\mathbf{x}' \quad (14)$$

**Fig. 29** Fourier transform of the AFM images of the surface of two InAs QD samples: (A) single-QD layer and (B) 30-QD layer.

is a solution for the displacement. An image island above the surface is used to force the surface tractions to zero. The strain is related to the displacement by  $\epsilon_{ij} = 1/2(u_{i,j} + u_{j,i})$  and leads to surface strain as a function of position  $x$  and crystallographical orientation  $\theta$ :

$$\epsilon_{ij}(x, \theta) = -\frac{\epsilon^* s_{11}(\theta) + s_{12}(\theta)}{4\pi s_{11}(\theta) - s_{12}(\theta)} \left( \int_{\Omega_1} \left( \frac{1}{R_1} \right)_{ij} dx' \right) + \left( 3 + \frac{4s_{12}(\theta)}{s_{11}(\theta)} \right) \int_{\Omega_2} \left( \frac{1}{R_2} \right)_{ij} dx' \quad (15)$$

The subsurface island is region  $\Omega_1$ , whereas the image island is region  $\Omega_2$ .  $R_1$  is  $|x - x'|$ , where  $x'$  is on  $\Omega_1$ , and  $R_2$  is the distance between a point in  $\Omega_2$  and  $x$ . The  $\theta$  dependence of the above equation can be evaluated by transformation of the stiffness constants  $s_{ijkl}(\theta)$  into a rotating coordinate system on the surface and centered above an island. This transformation is  $s_{ij} = \sum_{m,n} s_{mn} q_{mi} q_{nj}$  where  $q_{ij}$  is the transformation coefficient and is of second order in the directional cosines.

Fig. 30 shows the variation of the surface strain as a function of crystallographical orientation. The maximum strain is in the  $\langle 100 \rangle$  directions. Because InAs island nucleation will occur preferentially where the GaAs crystal is biaxially expanded, this direction becomes the nearest-neighbor direction.

In the Fourier-transformed AFM images, we would like to investigate higher-order modes related to the second nearest-neighbors. Therefore we have examined the autocovariance of the images. In Fig. 31, the autocovariance of the AFM image from Fig. 28A is shown.

**Fig. 30** The normalized angular variation in strain on the GaAs surface caused by an island below the surface. Zero degrees is taken in the  $[100]$  direction.

**Fig. 31** 2-D autocovariance of the AFM image in Fig. 28A.

This sample contains 30 InAs dot layers. The autocovariance of a function  $f$  is defined as:

$$\mathbf{R}_{ff}(\mu, \nu) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f(x, y) f(x + \mu, y + \nu) dx dy \quad (16)$$

Here  $f$  is a functional representation of the real space image in the  $x$ - $y$  plane,  $\mu$  and  $\nu$  are the  $x$  and  $y$  translations, and  $T$  is a spatial limit. We now investigate primary unit cell directions by taking slices through this transformation. Figure 32 shows autocovariance data from two samples in the  $\langle 110 \rangle$  and  $\langle 100 \rangle$  directions. Peaks in the figure indicate a translational correlation. In the single-layer case, shown in Fig. 32A, there is only a central peak, indicating no correlation between islands. In Fig. 32B, we show autocovariance sections of a sample grown at 500°C with 30 InAs dot layers, separated by 55 Å GaAs spacer layers. Here the single satellite peaks in the  $\langle 110 \rangle$  and  $\langle 100 \rangle$  directions near the central peak indicate the InAs quantum dot unit cell; once again,  $\langle 100 \rangle$  is only approximate. From the figure, the first nearest-neighbor directions are in the predominantly  $\langle 100 \rangle$  directions, whereas the second nearest-neighbor direction is  $[\bar{1}10]$  and the third nearest-neighbor direction is  $[110]$ . Because the subsurface strain should create four nearest-neighbors in  $\langle 100 \rangle$ , we believe that both the deviation from this direction and the nondegeneracy of the orthogonal second and third nearest-neighbors result from the anisotropic surface diffusion. The longer-wavelength, lower-intensity oscillations in Fig. 32B are the result of large-scale surface roughness, possibly because of steps on the

**Fig. 32** Autocovariance of AFM images in the  $\langle 110 \rangle$  and  $[100]$  directions: (A) a single dot layer sample, and (B) a 30-layer dot sample. The 30-layer sample has 55 Å spacer layers and was fabricated at 500°C.

surface. On top of this low-frequency roughness, some periodic intensity fluctuations can be seen, especially in one of the  $\langle 110 \rangle$  directions. This periodicity matches the fundamental unit cell distance and shows the translational symmetry in these directions.

To optimize the unit cell periodicity, we can adjust the crystal growth parameters. Figure 33 shows the autocovariance of images from two samples grown at 525°C. In Fig. 33A, 50 layers of InAs dots have been used, whereas in Fig. 33B, the number of InAs dot layers has been increased to 75. In both cases, the spacer layer thickness is 100 Å. Compared with the earlier samples grown at 500°C, this spacer layer thickness has been increased because of the increased dot size at

increased growth temperatures. In Fig. 33A, nearest-neighbor periodicity can be seen in both the  $\langle 110 \rangle$  and  $[100]$  directions. The nearest-neighbor distance has grown from 225 to 525 Å because of the increasing dot size with increasing growth temperature.<sup>[36]</sup> In Fig. 33B, the autocovariance shows a much more pronounced periodicity in the first, second, and third nearest-neighbor directions. We now see clear evidence of the emergence of a surface lattice of QDs. The condition that improves the surface lattice structure is primarily increased growth temperature.

We can combine the information from Figs. 32 and 33 to begin to understand why the quantum dots form only a weakly organized lattice. The lattice is weak

**Fig. 33** Autocovariance of AFM images in the  $\langle 110 \rangle$  and  $[100]$  directions for two structures fabricated at 525°C: (A) 50 layers of InAs dots were used in the subsurface structure, whereas in (B), 75 layers were used.

**Fig. 34** The unit cell is shown on a ledged surface. The unit cell is shown as a broken line whose center is translated to the small black dots. Experimentally determined first, second, and third nearest-neighbor sites are indicated by larger dots. The translated unit cell does not align with the second and third nearest-neighbors.

because the ratio of the first, second, and third nearest-neighbor distances does not allow for the complete filling of the surface. The anisotropic surface strain distribution creates a template for a cubic lattice of InAs dots. This process would create first nearest-neighbor sites in the  $\langle 100 \rangle$  directions. However, the surface diffusion of In or Ga adatoms is also anisotropic because of surface reconstruction and ledge dynamics. Because the surface diffusion is larger in  $[110]$ ,<sup>[51]</sup> the linear dot density in this direction should be largest. When these

two processes are combined, the degeneracy in the  $\langle 110 \rangle$  directions is lifted and the second nearest-neighbor sites in  $[1\bar{1}0]$  become closer than in  $[110]$ . In addition, the first nearest-neighbor site is rotated toward  $[110]$  because of the anisotropic surface diffusion.

The angular difference from the ideal first nearest-neighbor position ( $\langle 100 \rangle$ ) and the experimentally determined position is approximately  $3.5^\circ$ . This small difference from the ideal subsurface strain-driven case, where the first nearest-neighbor orientation should be  $\langle 100 \rangle$ , shows that the surface diffusion does not dominate the island ordering. However, it is enough to inhibit the formation of a well-ordered surface lattice. A cartoon of the quantum dot unit cell is shown in Fig. 34. The large dark circles represent the first nearest-neighbors, and the slight misalignment from  $\langle 100 \rangle$  can be seen. The second and third nearest-neighbors are represented by the large, lighter-colored circles. The anisotropy in the surface diffusion length,<sup>[51]</sup> attachment kinetics, and nucleation in orthogonal  $\langle 110 \rangle$  directions makes the nearest-neighbor distance in  $[1\bar{1}0]$  shorter than the nearest-neighbor distance in  $[110]$ . Finally, because of the anisotropy on the surface, the surface QD unit cell cannot be translated to fill the surface—no lattice is formed. This is seen in Fig. 34, where the small black dots represent the center of the translated unit cell. These smaller black dots do not fall on the second and third nearest-neighbor sites.

As the growth temperature increases, the anisotropy is reduced; this is shown in Fig. 35. As the growth temperature is increased, the difference in length between the second and third neighbors is reduced and the deviation from the ideal ratios between the first, second, and third nearest-neighbors is reduced. From Fig. 32 (510°C) and Fig. 33B (525°C), the ratio between the second and third nearest-neighbors is reduced from

**Fig. 35** The variation from an ideal rectangular unit cell is shown for samples grown at 510°C and 525°C. In (A), the  $[110]$  to  $[1\bar{1}0]$  nearest-neighbor distances are compared. The solid line indicates an ideal rectangular cell. In (B), the first nearest-neighbor distance is calculated based on the second and third nearest-neighbor distances, and compared to the measured values.

1.70 to 1.15. The reduction in anisotropy shows that the effect of surface diffusion is reduced. If the second and third nearest-neighbors are used to calculate the first nearest-neighbor position based on a simple rectangular lattice, the deviation from the ideal position drops from 0.22 to only 0.035 as the temperature is increased from 510°C to 525°C. Thus as the growth temperature increases, a more ideal simple rectangular unit cell can be formed. This more ideal unit cell is more easily translated on the surface to form a lattice. We believe that the increased growth temperature reduces the anisotropy in the surface diffusion. Although an increased growth temperature would create larger terrace lengths in an unstrained GaAs surface, this may not be the case in the strained surface. Further work is necessary to confirm these results and develop a better understanding of the interplay between the subsurface strain and the surface diffusion. However, from this work, the spatial ordering from a subsurface superlattice structure of dot layers is improved with increased growth temperature.

Finally, it is important to note that the competition between surface diffusion and subsurface strain shown here is a manifestation of our particular crystal system and substrate orientation. Other systems with different surface reconstructions and ledge dynamics, or other vicinal or crystallographical surfaces will certainly act differently.

## CONCLUSION

We began this chapter by highlighting certain aspects of strain-induced quantum dot formation. These dots are formed in dense arrays. Although the density and uniformity of these ensembles can be controlled by adjusting the growth parameters, inhomogeneous broadening continues to mask the atomlike nature of the quantum dot states. Two features of this system were discussed. First, the luminescence linewidth was compared with the dot structure. It was shown that, although the linewidth is reduced in samples made at lower growth temperatures, the dots are less distinct. The decreasing linewidth is the result of reduced localization as the wavefunctions of individual dots in the ensemble begin to extend into adjacent dots. Second, the density of the dot ensemble was shown to be a function of the V/III flux ratio. In some applications, a high density is important, and we show how to maximize the density and implications of the process on dot formation.

The main purpose of this chapter is to develop the idea of using stacks of InAs quantum dot layers. These structures can be used in two ways. First, when only a small number of dot layers are stacked, columns of dots form electronically coupled structures. In analogy

to coupled QWs, changing the number of dot layers and the spacer layer thickness between them can tune the coupling. As a simple test of the structures, LEDs were fabricated, and it was shown that luminescence from the wetting layer and higher dot states could be suppressed using these column structures. Second, when a large number of dot layers are used, the surface size and spatial distributions can be improved. However, the experimental improvements are limited in our system because of competition between subsurface strain and surface diffusion. The way in which these two processes interact is clearly evident in the AFM images. Higher growth temperatures reduce the anisotropic surface diffusion effect, leading to an extended lattice. This lattice is present, but is not perfect, and perhaps other substrate orientations or material systems may offer improvements.

This work is just the beginning of efforts to create ensembles of atomlike quantum dots using epitaxial crystal growth. Although GaAs and InAs are used in these experiments, this work is not limited to III-V materials or even semiconductors. If well-ordered arrays of quantum dots can be created, promising device and fundamental physics opportunities await. In the device world, regular arrays of quantum dots allow for lithographical alignment and possibilities of logic and memory devices. As well, many of the experiments in atomic physics can be repeated using quantum dots. An interesting extension of this work would be the combination of the two aspects of the vertical column structures: the fabrication of structures in which a subsurface island superlattice of one material is used to make a surface strain distribution that increases the ordering in the surface layers, whereas a small number of quantum dots of a different material are grouped together in short columns as a coupled active region.

## ACKNOWLEDGMENTS

This work was only made possible through collaborations with and support from many people. The STM images were performed by W. Wu in J. R. Tucker's laboratory at the University of Illinois at Urbana-Champaign. TEM images were made with A. F. Marshall (Center for Materials Research at Stanford University). AFM and autocovariance data were obtained and analyzed with the help of S. Komarov (Photonics and Electronics Laboratory at Stanford University). G. S. would like to thank Y. Yamamoto for continued support. We would like to thank M. Pelton for critical discussions and helpful comments. This work was supported by the DARPA and ONR through contract nos. N00014-93-1 and N00014-97-1, and by the JST through the ERATO Quantum Fluctuation Project.

Universität Hamburg, Hamburg, Germany*

## INTRODUCTION

Electrons confined in semiconductor quantum systems are a field of enormous and still growing research interest because they allow, in specially tailored systems, the investigation of fundamental properties, such as many-particle interactions of electrons in reduced dimensions. In this entry, we give an overview of experimental and theoretical investigations of electronic excitations in semiconductor quantum dots. Optical spectroscopy techniques, such as far-infrared (FIR) transmission<sup>[1–7]</sup> and resonant Raman scattering, i.e., inelastic light scattering (ILS),<sup>[8–12]</sup> are ideal tools to study the spectrum of elementary excitations of these systems. Since the work of Pinczuk et al.<sup>[13]</sup> on 2-D intersubband excitations in GaAs–AlGaAs quantum wells, it has been known that besides collective spin-density (SDEs) and charge-density excitations (CDEs), one can observe nearly unrenormalized excitations—the so-called single-particle excitations (SPEs)—in ILS experiments. Both SDEs and CDEs are collective excitations; SDEs are affected by exchange interaction while CDEs are affected by the full Coulomb interaction of the electrons. However, the origin of the SPEs, which seem to be unaffected by the particle–particle interaction, has posed a puzzle. Electronic excitations, and also SPEs in particular, could subsequently be observed in lower-dimensional systems, based on modulation-doped GaAs–AlGaAs quantum wells, and also particularly in quantum dots.<sup>[8–10]</sup> In an experimental work, it was shown that SPEs can be observed in low-dimensional electron systems under conditions of extreme resonance, when the laser energy is close to the fundamental band gap of the structures.<sup>[10]</sup> Thus SPEs are created in a resonant density-fluctuation scattering process,<sup>[14,15]</sup> whereas collective SDEs and CDEs ensue from an excitonic third-order scattering process.<sup>[10,16,17]</sup> Many theories of non-resonant Raman scattering accurately describe the energetic positions of the collective excitations, as well as the wave-vector and magnetic-field dependence of the CDE and SDE.<sup>[18–21]</sup> However, they fail in predicting the experimentally observed relative strengths of the different modes. Furthermore, the occurrence

of SPE cannot be explained within the confines of these theories. It has been known for a long time that valence-band states play a crucial role<sup>[22,23]</sup> in carrying out a correct treatment of the resonant scattering cross section. Recent theoretical papers on quantum wires<sup>[15,24,25]</sup> and quantum dots<sup>[26]</sup> showed that inclusion of the valence-band states indeed significantly changes the intensities of the excitations. During the past decade, self-assembled InAs quantum dots (SAQDs) have also proven to be highly interesting quantum structures, both from a technological as well as from a fundamental physics point of view. They exhibit relatively large quantization energies in the range of about 50 meV. In most experiments reported so far, SAQDs have been investigated by optical spectroscopy, in particular photoluminescence (PL). Nowadays, PL experiments on single dots are well established, which overcome the inhomogeneously broadened linewidths in typical ensemble measurements.<sup>a</sup> It has also been demonstrated that it is possible to charge SAQD with single electrons<sup>[28]</sup> via the application of external gate structures. So far, there are only two reports in literature about ILS experiments on electronic excitations in InGaAs SAQD.<sup>[29,30]</sup> In this contribution, ILS experiments on collective CDEs in InAs SAQD with tunable electron numbers  $N$  are described. In these experiments,  $N$  can be controlled at  $N = 1–6$ .

The entry is organized as follows. In the section “Characteristics of Quantum Dots and Experimental Details,” we describe the quantum-dot structures under investigation: modulation-doped GaAs–AlGaAs quantum dots and InAs SAQD, and give a brief discussion of the electronic structure and the excitations of these systems. Furthermore, the experimental realization of ILS is outlined in this section. In the section “Scattering Mechanisms,” a summarized description of the scattering mechanisms, which lead to the creation of electronic excitations in quantum dots, is provided. In the section “Experiments on GaAs–AlGaAs Deep-Etched Quantum Dots,” we start to

<sup>a</sup>For a recent review, see Ref.<sup>[27]</sup>.

discuss experiments on modulation-doped GaAs–AlGaAs quantum dots. There, basics such as parity selection rules are elaborated. The section “Experiments on InAs Self-Assembled Quantum Dots” summarizes recent experiments on InAs SAQD, which contain only a small number of electrons and which can be regarded as artificial atoms.

## CHARACTERISTICS OF QUANTUM DOTS AND EXPERIMENTAL DETAILS

### Preparation of Quantum Dots

The vast majority of ILS experiments on electronic excitations in quantum dots have been performed on modulation-doped GaAs–AlGaAs structures. Fig. 1A shows a scanning electron micrograph of deep-etched quantum dots. Typical sizes of these structures are on the order of several hundred nanometers. In many cases, 2-D electron systems, realized in modulation-doped single quantum wells, are used as a starting material. In Fig. 1A, the location of such a 25-nm-wide quantum well is indicated by thick dashed lines. By a reactive-ion etching process, the pillar-shaped quantum dots were defined. Typically, such deep-etched structures contain electron numbers on the order of several hundreds. An alternative and very effective way to produce quasi zero-dimensional semiconductor structures is the so-called self-assembled growth of InAs quantum dots. Here the lattice mismatch between GaAs, which is used as the starting material, and InAs is exploited. The minimization of strain energy leads to the formation of small InAs islands, if InAs is grown on a GaAs surface. In contrast to the etched structures,

the typical lateral sizes of these islands are on the order of only a few tens of nanometers. Therefore they exhibit much larger quantization energies. Fig. 1B displays a transmission electron micrograph of an InAs quantum dot, embedded in GaAs. The boundaries of the InAs dot are indicated by a white dashed line. It has been shown that electrons can be filled into these quantum boxes either by modulation doping<sup>[29]</sup> or by application of external gates.<sup>[28]</sup> With the application of gates, it is even possible to fill in single electrons in a very controlled way. Fig. 1C shows a schematic picture of the band structure of an InAs SAQD sample, as used in Ref.<sup>[30]</sup> There, an inverted modulation-doped AlGaAs–GaAs structure serves as a back contact. By application of a voltage between the back contact and a metallic front gate, the dots can be charged with single electrons, which then tunnel from the two-dimensional electron system (2DES) to the dots.

### Electronic Ground State and Excitations

As will be explained below, in the etched GaAs dots, as well as in the InAs SAQD,<sup>[31]</sup> the lateral external confining potential is to a good approximation parabolic. In the deep-etched samples, the potential is determined by the homogeneously distributed ionized remote donors in the AlGaAs barrier and negatively charged surface states. By analytical calculations, one can show that this lateral potential, which acts on a test electron within the structure (*external* potential), is in  $x$  and  $y$  directions (lateral directions) in good approximation parabolic.<sup>[32]</sup> Therefore we will start our investigations by assuming that the corresponding single-particle energies are given by the eigenvalues of a

**Fig. 1** (A) Scanning electron micrograph of deep-etched GaAs–AlGaAs quantum dots. The white dashed lines mark one of the dots. The long dashes indicate the active electron layer. (B) Transmission electron micrograph of an InAs quantum dot. The white dashed lines mark the borders of the InAs island. (With permission of S. Mendach.) (C) Schematic band structure of an InAs SAQD sample with a two-dimensional electron system (2DES) as a back contact.

Fig. 2 (A) Schematic picture of the lateral potential of a quantum dot. (B) Energy levels of a quantum dot with parabolic potential. The curved dashed arrows indicate possible excitations of single electrons.

two-dimensional harmonic oscillator

$$E_{nm} = \hbar\Omega_0(2n + |m| + 1) = N\hbar\Omega_0 \quad (1)$$

Here the two relevant quantum numbers are the radial quantum number  $n = 0, 1, 2, \dots$  and the azimuthal or angular-momentum quantum number  $m = 0, \pm 1, \pm 2, \dots$ . We define a lateral quantum number  $N = (2n + |m| + 1)$ , which characterizes the  $2N$ -fold degenerate discrete levels, as sketched in Fig. 2A. Naturally, the presence of many other electrons in the sample leads to a screening of the potential, which acts on the test electron. Theoretically, this is described, e.g., in a self-consistent Hartree calculation of the ground state. Thus the effective lateral potential is flattened in the center of the dot, i.e., it becomes more and more square-well-like. This results, in a mean field approach, in a decrease of the single-particle level spacings and to a lifting of degeneracies. For simplicity, we stay for the moment in the simple picture, where we assume that also the effective, or Hartree, potential is parabolic which is a good approximation for the ground state of dots with small electron numbers.

In such a single-particle picture, the electronic excitations, which can be created in the inelastic light scattering process, are transitions of electrons from occupied to unoccupied levels, as, e.g., sketched in Fig. 2B. In Fig. 2B, the energy levels for a parabolic quantum dot, which contains six electrons, is shown in more detail. The corresponding radial- and angular-momentum quantum numbers are indicated. Of course, in a real interacting system, the electronic excitations will be collective excitations, CDEs and SDEs, which are affected by Coulomb interaction.

For large electron numbers, on the order of 100 or more, it is instructive to leave the quasiparticle picture described above for a while, and discuss the electronic excitations in terms of plasma oscillations of the electrons. For CDEs, in that case, some of the excitations are also called confined plasmons. For all following considerations, we assume that the external potential is parabolic. Consequently, the simplest CDE is a plasma oscillation where all electrons oscillate in phase in the quantum dot back and forth. This situation is, for a fixed time, schematically shown in Fig. 3A, where a dark color should indicate a large

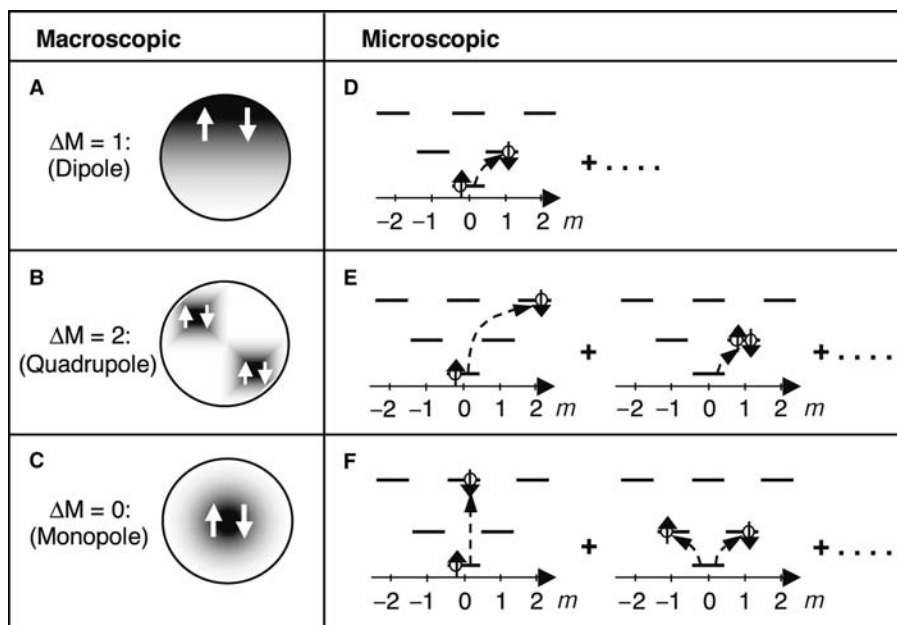

Fig. 3 Schematic drawings of the electron-density distributions for different confined plasmon modes [(A)–(C)]. Microscopic picture for the excitations of a parabolic quantum dot with two electrons [(D)–(F)].

induced electron density. White indicates an induced positive charge distribution. Hence the induced electron density has, in this case, one node. Obviously, this excitation has a large dipole moment. It is also called the first confined plasmon or Kohn's mode, because, for the case of a parabolic external potential, its energy exactly equals the quantization energy of the external potential, and the energy of the lowest energy dipole excitation is independent of the number of electrons  $N$  in the dot. This fact is known as the so-called generalized Kohn's theorem.<sup>[33]</sup> The dipole excitation is characterized by a change of  $\Delta M = 1$  of the total angular-momentum quantum number  $M$ , i.e., the angular momentum of the  $N$ -electron system. This will become clearer when we discuss the microscopic picture below. The CDEs with the next higher energies are the quadrupole excitation corresponding to  $\Delta M = 2$  [Fig. 3B], and the monopole excitation with a change in total angular momentum of  $\Delta M = 0$  [Fig. 3C]. The next higher excitation would again be a dipole excitation (not shown here), which is additionally accompanied by a change in the radial quantum number  $n$ . In all CDEs, the electrons with spin up and spin down oscillate in phase against the positively charged background. This is schematically indicated by the white arrows in Fig. 3. This means that the CDEs are strongly affected by the direct part of the Coulomb interaction, which in most cases results in a blueshift of the excitations. In contrast, in the corresponding SDEs, the electrons with spin up and spin down oscillate with a phase shift of  $\pi$ . For the *spin dipole* excitation (not shown here), corresponding to the CDE in Fig. 3A, e.g., this means that the center of mass of the charge does not oscillate. Thus the energies of the SDEs are only renormalized by exchange-correlation interaction and are therefore redshifted. We note here already that, in experiments on zinc-blende semiconductors, SDEs and CDEs can be distinguished by polarization selection rules.<sup>[34]</sup> CDEs are observed if the polarizations of the incoming and scattered light are parallel to each other (*polarized* geometry), and, for SDEs, the polarizations have to be perpendicular (*depolarized* geometry).

In the following, we will discuss how this macroscopic picture translates into the quasiparticle picture, which we introduced at the beginning. This makes sense for small electron numbers only, otherwise it would be too complicated. The simplest interacting system that comes to mind is a quantum dot with two electrons. In Fig. 3D–F, the dipole, quadrupole, and monopole CDEs are schematically shown for a two-electron quantum dot, respectively. More precisely, Fig. 3D–F pictorially displays the occupation of the Slater determinants, which predominantly contribute to the two-particle wavefunctions of the respective excited states. The exact many-particle

wavefunction can always be written as an infinite series of single-particle Slater determinants. Fig. 3D–F exhibits the occupation of the most important Slater determinants of the respective excited states. The ground state of a two-electron dot has a total angular momentum of  $M = 0$ , because both electrons occupy the  $s$  level with  $m = 0$ . In Fig. 3, one can see that for the dipole excitation, the angular momentum of the excited state is  $M = 1$ , for the quadrupole excitation,  $M = 2$ , and, for the monopole excitation,  $M = 0$ . For CDEs, as displayed in Fig. 3, the spin is preserved during the excitation ( $\Delta S = \Delta S_z = 0$ ). For the excitation of SDEs, which are triplet excitations,  $\Delta S = 1$ , and  $\Delta S_z$  can take on values of 1,  $-1$ , and 0. This means that spinflip transitions of electrons are involved in SDEs. For zero magnetic field,  $B = 0$ , the three triplet excitations with  $\Delta S_z = 0, \pm 1$ , corresponding to the same excitation type (e.g., spin dipole, spin monopole, etc.), are degenerate. As already noted, we expect the SDEs to have lower energies than the corresponding CDEs because they experience no direct Coulomb interaction.

## Experimental Details

For resonant ILS experiments, tunable lasers such as dye lasers or Ti:sapphire lasers are used. Usually, the samples are kept in a cryostat at low temperatures, typically below 10 K. A special feature of ILS spectroscopy is that a finite wave vector  $\mathbf{q}$  can be transferred to the excitations. This is achieved by tilting the sample with respect to the incident and scattered beams. Fig. 4 schematically displays the most often used backscattering geometry, which allows the largest wave-vector transfer  $\mathbf{q}$  into the system. Here  $\mathbf{k}_i$  and  $\mathbf{k}_s$  represent the wave vector of the incident and inelastically scattered photons, respectively. Under the assumption that the wavelengths of the incident,  $\lambda_i$ , and scattered light,  $\lambda_s$ , are almost equal ( $\lambda_i \sim \lambda_s$ , which is a good approximation because light in the visible or near-infrared range is used to excite excitations with energies in the FIR), the equation  $\mathbf{q} \sim 4\pi\lambda_i \sin\Theta$  holds for the relation of  $\mathbf{q}$  vs. the tilt angle  $\Theta$ . The experiments discussed in this entry were performed using backscattering geometry. A Ti:sapphire laser

Fig. 4 Sketch of the backscattering configuration.

was applied for excitation, and the ILS signals were detected with a triple Raman spectrometer, equipped with a cooled, charge-coupled device detector. The samples were mounted in cryostats at temperatures between  $T = 2\text{ K}$  and  $T = 12\text{ K}$ .

### SCATTERING MECHANISMS

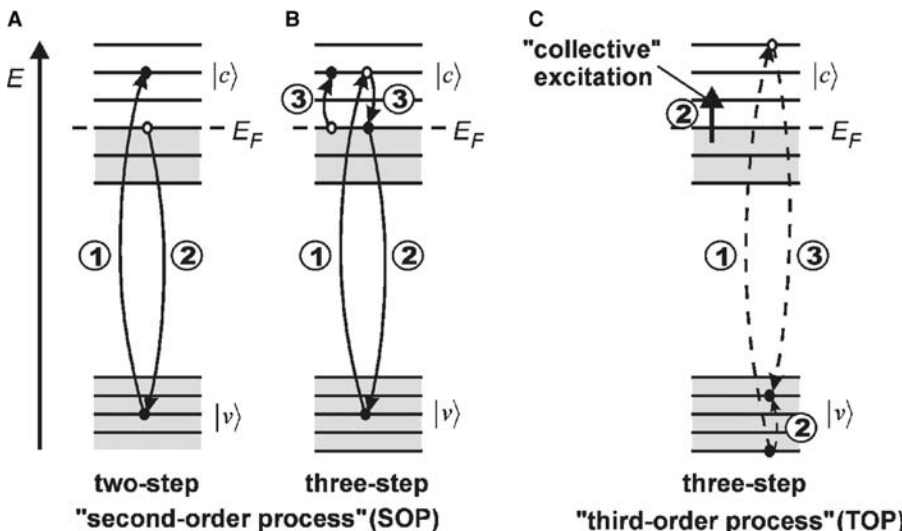

In this section, the dominant scattering mechanisms, which lead to the light scattering in low-dimensional electron systems, are qualitatively discussed. In general, the inelastic light scattering by electronic excitations in semiconductor microstructures with relatively small numbers of electrons can be observed only under specific interband resonance conditions. That means that in the scattering process, valence-band states are involved as intermediate states. Nevertheless, most of the theoretical work concerning the dynamic Raman response in microstructures is performed for non-resonant conditions, neglecting the valence-band structure. We summarize here the dominant *resonant* scattering processes, which are fragmentarily present in the literature, and which we found in our experiments on quantum wells, wires, and dots to be the dominant ones.<sup>[14]</sup>

The coupling of the radiation with the electron system is taken into account by replacing the momentum  $\mathbf{p}$  of the electron by  $\mathbf{p} + e\mathbf{A}$  in the Hamiltonian  $H_0$  of the unperturbed system.  $\mathbf{A}$  is the vector potential of the electromagnetic field.

$$H = \frac{1}{2m} \sum_i [(\mathbf{p}_i + e\mathbf{A}(\mathbf{r}_i))^2 + U(\mathbf{r}_i)] + V_{e-e} + V_{e-ph}$$

$$= H_0 + \frac{1}{2m} \sum_i [(A(\mathbf{r}_i))^2 + \mathbf{p}_i A(\mathbf{r}_i) + A(\mathbf{r}_i) \mathbf{p}_i] \quad (2)$$

$V_{e-e}$  is the Coulomb interaction,  $V_{e-ph}$  the electron-phonon interaction, and  $U$  includes the lattice-periodic potential as well as all types of external potentials. For simplicity, the spin-orbit coupling is neglected in Eq. (2). In a perturbation theory approach, the last three terms of Eq. (2) can be treated as the perturbation. Here the  $A^2$  terms give contributions to the light scattering cross section in *first* order, the  $\mathbf{pA}$  terms in *second*-order perturbation theory. The  $\mathbf{pA}$  terms, together with either the Coulomb interaction  $U_{e-e}$  of a photoexcited exciton with the electron system, or the electron-phonon interaction  $V_{e-ph}$  of a photoexcited exciton with the phonon bath, give contributions in *third*-order perturbation theory.  $V_{e-ph}$  leads to the scattering by phonons, which shall not be discussed here. The second-order (SOP) and third-order light scattering processes (TOP) appear to be the dominant ones in electronic Raman scattering on microstructures because they exhibit a resonant behavior.<sup>[35]</sup> In Fig. 5, transitions which contribute to the second- [Fig. 5A,B] and third-order [Fig. 5C] processes in quantum dots are sketched. Valence band levels are marked by  $|v\rangle$ , and conduction band levels by  $|c\rangle$ . In the first step of the two-step SOP, an electron is excited from a valence band level to a conduction band state. In the second step, an electron, either with the same or with opposite spin as the photoexcited electron, recombines with the hole in the valence band. Thus as a net effect, either a non-spinflip or spinflip single-particle excitation has been created in the conduction band. In the third step of the three-step SOP, another SPE is created by Coulomb interaction. This represents the screening of the SPE by other SPEs in the system. This screening also leads to the formation of collective CDEs and SDEs by direct and exchange Coulomb coupling. For non-resonant conditions, the SPEs are screened by the interaction. This is formally implemented by the

**Fig. 5** Schematic pictures of the (A) two-step, (B) three-step second-order scattering processes, and (C) a three-step third-order process, which contribute to the resonant ILS in quantum dots. *Source:* From Ref.<sup>[14]</sup>.

cancellation of the two-step SOP contribution by the three-step SOP in the scattering cross section for off-resonance conditions. In experiments on deep-etched GaAs samples with relatively large electron numbers, it was observed that under conditions of extreme resonance, which means that the laser frequency is in the vicinity of the fundamental bandgap of the underlying 2-D structure, quasi unscreened SPEs occur. They show stronger resonance enhancements than the collective excitations.<sup>[10]</sup> This means that the above-mentioned cancellation of terms does not hold in the case of extreme resonance and thus single-particle-like excitations can be observed. A quite similar behavior was reported for intraband excitations in n-type GaAs bulk samples.<sup>[36]</sup>

It was found that for laser energies well above the bandgap, an excitonic third-order scattering process, as for the case of quantum dots displayed in Fig. 5C, is the dominant one (for 2-D excitations, see Refs.<sup>[16,17]</sup>). For this scattering mechanism, which is assisted by the Coulomb interaction, in the first step the incident photon creates an exciton with a hole in the valence band and an electron in a higher conduction band level. This exciton is scattered by direct and exchange Coulomb interaction with the electron system into another state, where, e.g., as drawn in Fig. 5C, the hole is scattered into another state. By this scattering process, a collective excitation (SDE or CDE) is created in the conduction band system. In the third step, the scattered exciton recombines. This scattering process exhibits very sharp and intense resonance profiles in a plot of the scattered intensity vs. laser energy.<sup>[16]</sup> It was found that this TOP is the dominant scattering mechanism for excitation of collective SDEs and CDEs in low-dimensional GaAs samples.<sup>[10]</sup>

In the following, we elucidate these scattering processes in more detail. The scattering cross section is given by<sup>[34]</sup>

$$\frac{d^2\sigma}{d\Omega d\omega} = \frac{\omega_S}{\omega_I} \frac{e^4}{c^4 m^4} S(\omega) \quad (3)$$

where the structure factor  $S(\omega)$  is defined as

$$S(\omega) = \sum_F |\langle F | V_{\text{eff}} | I \rangle|^2 \delta(E_F - E_I - \hbar\omega) \quad (4)$$

$\omega_I$  ( $\omega_S$ ) is the frequency of the incident (scattered) photon, and  $\hbar\omega = \hbar\omega_I - \hbar\omega_S$  is the energy transfer.  $V_{\text{eff}}$  is the effective operator, which describes the transition of the system from the many-particle initial state  $|I\rangle$  with energy  $E_I$  to the final state  $|F\rangle$  with energy  $E_F$ . Using the second-quantization technique, this effective operator of the light scattering  $V_{\text{eff}}$  can, in a many-particle system, be expanded in terms of creation ( $\hat{c}^+$ ) and

annihilation ( $\hat{c}$ ) operators of single-electron states<sup>[17]</sup>

$$V_{\text{eff}} = \sum_{\alpha,\beta} \gamma_{\alpha\beta} \hat{c}_\beta^+ \hat{c}_\alpha \quad (5)$$

Here each  $\alpha$  and  $\beta$  represents a set of quantum numbers  $(n,m,\sigma)$ , for the radial, azimuthal, and spin quantum numbers of the corresponding state, respectively. If we treat, for a moment, the excitons as simple electron-hole pairs without interaction, which for a quantitative analysis is certainly not correct, the scattering amplitudes  $\gamma_{\alpha\beta}$  can approximately be written as

$$\gamma_{\alpha\beta} \propto \langle \alpha | e^{iqr} | \beta \rangle e_I e_S + \frac{1}{m} \sum_{\beta'} \frac{\langle \alpha | \mathbf{p} \mathbf{A}_S | \beta' \rangle \langle \beta' | \mathbf{p} \mathbf{A}_I | \beta \rangle}{E_\beta - E_{\beta'} + \hbar\omega_I} + \sum_{\nu,\nu'} \frac{\langle \beta | \mathbf{p} \mathbf{A}_S | \nu' \rangle \langle \nu' | U_{e-e} | \nu \rangle \langle \nu | \mathbf{p} \mathbf{A}_I | \alpha \rangle}{(E_\beta - E_{\nu'} + \hbar\omega_S)(E_\alpha - E_\nu - \hbar\omega_I)} \quad (6)$$

where, in the last two terms, we have written only the strongest resonant term. The first term in Eq. (6) represents the non-resonant contributions from the  $A^2$  terms in first-order perturbation theory. Here the scalar product of the polarization vectors of the incident ( $e_I$ ) and scattered ( $e_S$ ) photon shows that this non-resonant term yields only scattering by plasmons (CDEs). Spin-flip processes, which are necessary for the excitation of SDEs, are only possible in the resonant second and third terms. The second term describes second-order processes, as schematically shown in Fig. 5A, and the third term represents third-order resonant scattering, as displayed in Fig. 5C.

To illustrate this, Fig. 6 shows experimental ILS spectra of electronic excitations in deep-etched GaAs quantum dots with 240 nm geometrical diameter and about 200 electrons per quantum dot. The spectra in the lower part were recorded at laser energies well above the effective bandgap. In the lowest spectrum at a laser energy of  $E_L = 1587$  meV, three peaks can be observed, which can be identified as SDEs because of polarization selection rules. (We will come to the detailed interpretation of the excitations in the section ‘‘Experiments on GaAs–AlGaAs Deep-Etched Quantum Dots.’’) Correspondingly, the peaks in the polarized spectrum can be identified as CDEs. We have found that CDEs, in particular, exhibit a very sharp [full width at half-maximum (FWHM)  $\sim 3.5$  meV] resonance profile in this range of laser energies—which leads us to the interpretation that this scattering by *collective* excitations is caused by the third-order TOP, as discussed before. If the laser frequency is slightly lowered (spectra at  $E_L = 1585$  meV in Fig. 6), additional broad features appear, especially in the polarized spectrum, which then slowly evolve into intense peaks, by further lowering  $E_L$  toward the bandgap. These features are marked in Fig. 6 by dotted arrows. Under conditions of extreme resonance

**Fig. 6** Polarized and depolarized ILS spectra of deep-etched GaAs–AlGaAs quantum dots for different laser energies  $E_L$ . Source: From Ref.<sup>[37]</sup>.

(e.g.,  $E_L = 1558$  meV in Fig. 6), these peaks dominate the spectra and are present in both polarization configurations. Therefore we interpret them, within the framework described above, as SPEs, which are caused by an SOP under conditions of extreme resonance. We note that the observation of similar SPEs in multi-layered quantum dots were reported by Lockwood et al.<sup>[9]</sup> From the experimental spectra in Fig. 6, we can directly deduce for the corresponding collective SDEs and CDEs the energy renormalizations due to many-particle interactions.<sup>[10]</sup>

### EXPERIMENTS ON GaAs–AlGaAs DEEP-ETCHED QUANTUM DOTS

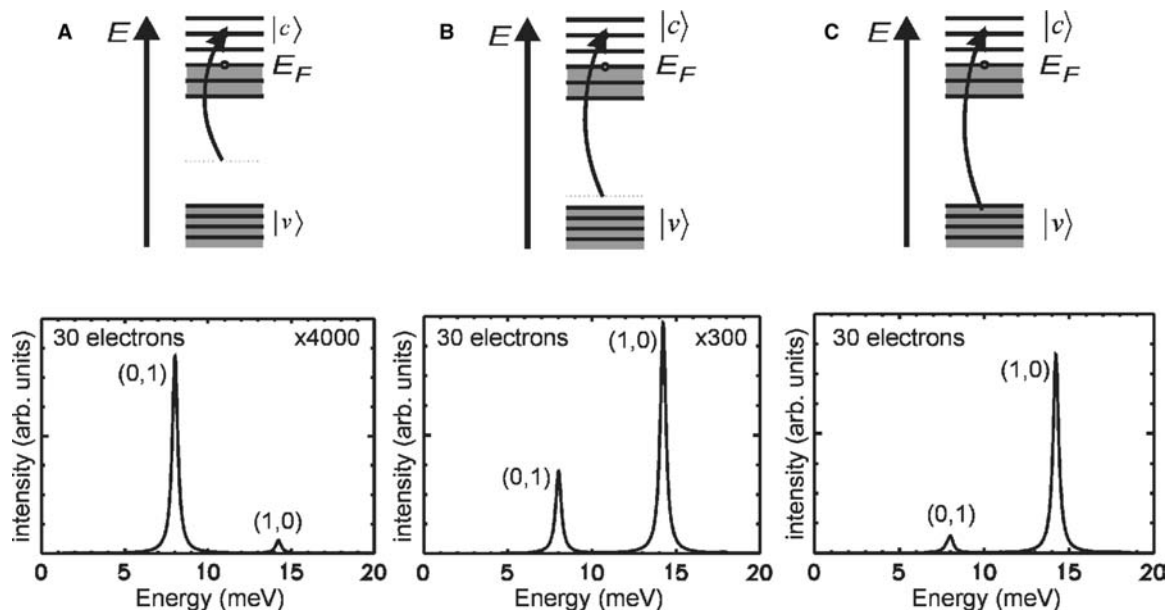

In this section, we focus on ILS experiments on modulation-doped GaAs dots in more detail. In particular, we will discuss parity selection rules for the collective excitations and the importance of resonant excitation.

Fig. 7 shows experimental ILS spectra of quantum dots with approximately 200 electrons per dot.<sup>[37]</sup>

**Fig. 7** Polarized and depolarized ILS spectra of 240 nm GaAs–AlGaAs quantum dots with approximately 200 electrons per dot. Source: From Ref.<sup>[37]</sup>.

In these experiments in backscattering geometry, the wave-vector transfer  $q$  parallel to the plane of the dot was close to zero. In each scattering configuration, depolarized and polarized, there is one mode visible. On general grounds, one can say that in a symmetric system, the allowed modes have even parity because the ILS process is a two-photon process. This is in contrast to direct absorption, which is a one-photon process. Consequently, the observed SDE and CDE are even-parity modes. Referring to the section “Characteristics of Quantum Dots and Experimental Details,” we find that the lowest energy modes with even parity are the monopole modes with  $\Delta M = 0$ . The modes are labeled  $(\Delta n, \Delta m)$  corresponding to the changes in radial ( $\Delta n$ ) and angular-momentum ( $\Delta m$ ) quantum numbers, respectively, of the involved transitions. The assignment of the SDE was deduced from its magnetic field behavior<sup>[11]</sup> (not shown here) and the CDE is considered in more detail below. We want to note here that the polarized spectrum demonstrates the exclusion principle between FIR and Raman spectroscopy: the FIR-allowed mode  $CDE_{(0,1)}$ , the Kohn’s mode, has odd parity and hence a large dipole moment (in the section “Characteristics of Quantum Dots and Experimental Details”). It has, for the sample displayed in Fig. 7, an energy of about 6 meV and is not visible at all in the Raman spectrum (Fig. 7). On the other hand, the Raman-allowed monopole mode [ $CDE_{(1,0)}$ ] has no dipole moment at all. Considering that the induced density of this mode has only nodes in radial direction [see Fig. 3C], it can also be regarded as a so-called breathing mode. Thus the experiments demonstrate that, for resonant ILS on circularly

**Fig. 8** Calculated ILS spectra for a quantum dot with 30 electrons for (A) off-resonance, (B) close-to-resonance, and (C) resonant conditions. The schematic pictures show the different resonance conditions. The curved arrows indicate the laser energies. *Source:* From Ref.<sup>[37]</sup>.

symmetric dots at approximately zero wave-vector transfer, the general parity selection rules hold.

In the following, we will elucidate these parity selection rules from the theoretical point of view in more detail. Most of the calculations of ILS spectra for low-dimensional electron systems have been carried out for non-resonant conditions, because in such cases, one does not have to deal with the complex valence-band states. Fig. 8 shows a series of calculated resonant ILS spectra for off-resonance and for different resonance conditions.<sup>[37]</sup> The calculations have been performed for a 30-electron quantum dot with  $\hbar\Omega_0 = 8$  meV for the external potential. In Fig. 8A, the laser energy was chosen to be far away from resonance, i.e., off-resonance conditions. Under experimental conditions, in this regime the scattered intensities are much too low to be observable. Note that the calculated spectrum in Fig. 8A is multiplied by a factor of 4000 to be of comparable strength with the resonant spectrum in Fig. 8C. One can observe in Fig. 8A that, in the off-resonance case, the parity selection rules have completely changed: for the sake of curiosity, the FIR-allowed Kohn's mode [CDE<sub>(0,1)</sub>] is the dominant mode. As the laser energy approaches resonance, the situation changes, and, under resonance conditions [Fig. 8C], the experimentally observed parity selection rules are confirmed, i.e., the monopole mode CDE<sub>(1,0)</sub> is the dominant mode in the polarized spectrum. This clearly demonstrates that, for a correct description of the relative intensities of the excitations, the resonant scattering process is crucial.

An at least partial breakdown of the parity selection rules can be achieved by the transfer of a finite wave vector  $\mathbf{q}$  parallel to the plane of the dot. Fig. 9 shows a series of depolarized and polarized spectra for the same dots in Fig. 7 for different wave-vector transfer  $\mathbf{q}$ . As  $\mathbf{q}$  increases, symmetry-forbidden modes (the spin dipole mode SDE<sub>(0,1)</sub>, and a higher dipole mode CDE<sub>(1,1)</sub>) gain relative intensity. Furthermore, the spin quadrupole mode SDE<sub>(0,2)</sub>—which, for a parabolic effective potential, would be energetically degenerate with the spin monopole mode SDE<sub>(1,0)</sub> if interaction effects are neglected—becomes visible.<sup>[11]</sup> A so-far unsolved puzzle focuses on why the violation of parity selection rules with wave-vector transfer  $\mathbf{q}$  is much stronger for SDEs than for CDEs.

## EXPERIMENTS ON InAs SELF-ASSEMBLED QUANTUM DOTS

### Few-Electron Quantum-Dot Atoms

It has been demonstrated that, by application of metallic gates, InAs SAQD can be charged with single electrons. For experiments that will be described below, a special sample design, where a 2-D electron system was used as a back contact, was applied (for details, see Ref.<sup>[30]</sup>). The charging of dots can be monitored in situ by capacitance measurements (Fig. 10, inset). For the ILS experiments, resonant excitation was achieved by tuning the laser to the  $E_0 + \Delta$  gap of the InAs SAQD

Fig. 9 (A) Depolarized and (B) polarized ILS spectra of GaAs quantum dots for different wave-vector transfer  $q$ . Source: From Ref.<sup>[11]</sup>.

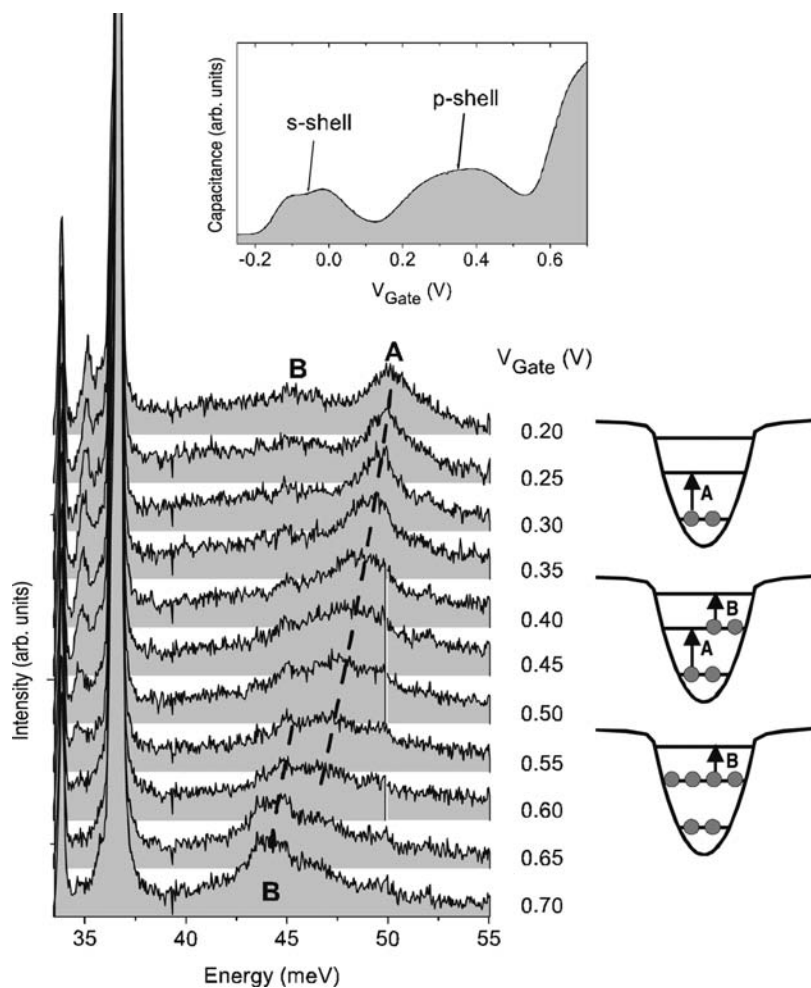

Fig. 10 Series of polarized ILS spectra of InAs SAQD for different gate voltages  $V_{Gate}$ . The upper inset shows a capacitance measurement of the sample. On the right-hand side, different electron configurations in the dots are schematically shown. Source: From Ref.<sup>[30]</sup>.

( $\sim 1.65$  eV), which is far above the fundamental PL transition energies of the structure ( $\sim 1.1$ – $1.2$  eV). Fig. 10 displays a series of polarized ILS spectra. At  $E = 33.4$  meV and  $E = 36.6$  meV, two sharp lines can be observed that result from the TO- and LO-phonon excitations of the GaAs bulk material in the structure. At higher energies, broader bands are visible in the range 45–55 meV (labeled as A and B), which we attribute to CDEs of the electrons in the quantum dots. Both the positions and the linewidths of these bands change with applied gate voltage  $V_{\text{Gate}}$ . The capacitance trace, displayed in the inset of Fig. 10, shows that, by varying  $V_{\text{Gate}}$ , the s- and the p-shell of the quantum dots can be charged with electrons. The doublet structure around  $V_{\text{Gate}} = -0.05$  V stems from the charging of the s shell with two electrons, and, at the broad plateau at positive  $V_{\text{Gate}}$ , the p-shell is loaded with four electrons. The bands A in Fig. 10 were interpreted to be a result of transition of electrons from the s to the p shell (s–p transitions) of the quasiatoms, and the B bands from p–d transitions:<sup>[30]</sup> it was assumed that 2–3 confined single-particle energy levels exist in the quantum dots, which is schematically shown in the drawings on the right-hand side of Fig. 10. Here three selected situations with  $N = 2$ ,  $N = 4$ , and  $N = 6$  electrons per quantum dot are sketched in a single-particle picture. The vertical arrows indicate possible transitions of single electrons. The SAQD stick out of the InAs wetting layer. Therefore the dot potentials are flattened at the edges because of the wetting-layer continuum. This leads to the situation that the single-particle transition, sketched as B in the inset of Fig. 10, has a smaller energy than the transition A. So far, in the interpretation, only transitions between single-particle states have been considered. Within this simplified picture, one is not able to explain the observed shift of excitation A (s–p transitions) with increasing electron number  $N$  in the quantum dots, as observed in Fig. 10. In the voltage range where the p-shell is filled with electrons ( $V_{\text{Gate}} \sim 0.2$ – $0.6$  V), we find, in Fig. 10, a shift of A to lower energies and a broadening of the transition.

More accurately, the experimentally observed excitations are of course collective CDEs of the few-electron quantum dots, and are therefore affected by Coulomb interaction. To take account of this, model calculations where the excitation energies were calculated by using exact numerical diagonalization of the Hamilton operator

$$H = \sum_{i=1}^N \left[ \frac{\mathbf{p}_i^2}{2m^*} + \frac{m^*}{2} \Omega_0^2 \mathbf{r}_i^2 \right] + \frac{e^2}{4\pi\epsilon\epsilon_0} \times \sum_{i \neq j}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \quad (7)$$

of the  $N$ -electron quantum dot were performed.<sup>[30]</sup> There, a two-dimensional quantum dot with a parabolic confining potential in lateral direction [ $\mathbf{r} = (r_x, r_y)$ ] with quantization energy  $\hbar\Omega_0 = 50$  meV was assumed. By exact numerical diagonalization, the low-energy excitations of the  $N$ -electron quantum dot were determined, where, during the excitation, the total spin is preserved. This selects the excitations, which one expects in polarized ILS spectra (CDEs). Fig. 11 exhibits the calculated excitation energies for electron numbers  $N = 2$ – $6$  in the quantum dot. The vertical bars mark the energetic positions of the few-particle excitations. First, one can see that, independent of  $N$ , there is always an excitation at the energy  $\hbar\Omega_0 = 50$  meV of the external confining potential. This represents the Kohn's mode. However, for  $N > 2$ , in the calculations additional mode energies appear below the energy of the Kohn's mode. These are a consequence of the different possible final states of the electrons after excitation. For very small electron numbers, these different final states make a significant difference in the energy of the state. For  $N = 3$ , e.g., the configuration where two electrons in the  $p$  shell have antiparallel spin has the lowest energy. With increasing electron numbers, more complex electron configurations occur that can have different energies. The most important result of Fig. 11, concerning the experiments, is that with

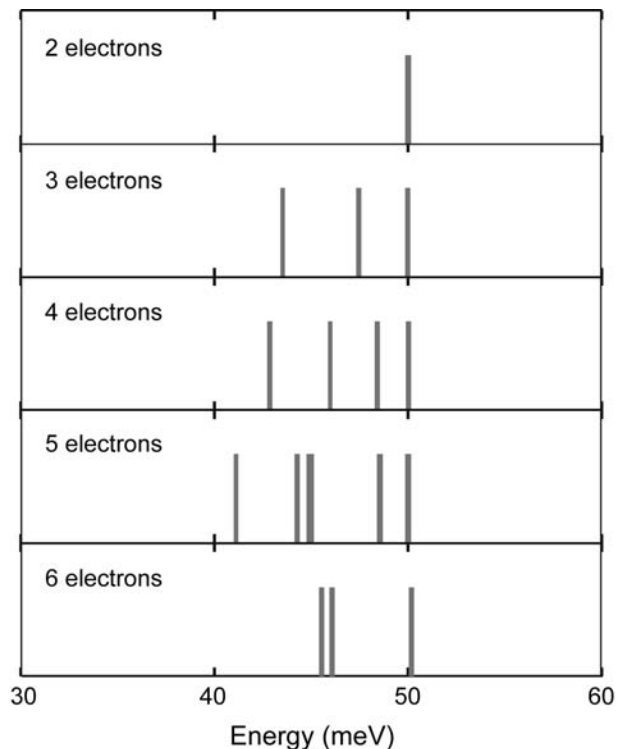

Fig. 11 Calculated few-electron excitation energies for a parabolic InAs quantum dot. Source: From Ref.<sup>[30]</sup>.

increasing  $N$ , the spectral weight of the low-energy excitations shifts to lower energies. This might ascribe the shift and broadening of the s-p transitions, as observed in the experiments (band A in Fig. 10), to be due to additional excitations at lower energies, which cannot be individually resolved in the ensemble experiment. Clearly, the model can only qualitatively explain the experiments. The most important limitation is the assumption of a parabolic potential, which deviates from the more realistic form (sketched in Fig. 10) and which cannot account for the lower energy of band B. However, one should note that the important qualitative result, i.e., the appearance of additional collective modes at lower energies for increasing electron number, is independent of the choice of parameters and the form of the confining potential. This leads to the conclusion that these results might generally apply for quantum-dot atoms.

## CONCLUSION

There is a variety of theoretical and experimental literature on ILS spectroscopy of electronic excitations in quantum dots. Most of the experiments have been performed on modulation-doped GaAs-AlGaAs quantum dots. In these mesoscopic systems with electron numbers on the order of 100 per quantum dot, CDEs, SDEs, and SPEs could be observed. More sophisticated theoretical models demonstrated, in comparison with experiments, the importance of the resonant scattering process, including valence-band states as intermediate states, for a correct description of, e.g., parity selection rules. Recently, resonant ILS experiments on InAs SAQD with tunable electron numbers have been reported. This opens the road for the investigation of excitations in few-electron quantum dot atoms. With the prospect of single-dot Raman spectroscopy, in the future one might be able to observe and resolve electronic excitations as individual sharp lines, caused by interaction effects of few electrons in artificial atoms.

## ACKNOWLEDGMENTS

I would like to thank many colleagues who contributed to our work, as listed in the references, and B. Wunsch for providing the theoretical results, which were used to prepare Fig. 3D–F. In particular, I am grateful to D. Heitmann for his support and critical reading of the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft via SFB 508 and a Heisenberg Grant (SCHU 1171/2).

## INTRODUCTION

Self-assembled Ge quantum dots by the Stranski–Krastanov growth mode have attracted much attention for many years. Similar to the purpose of the research on short-period Si/Ge superlattices and Er-doped Si, self-assembled Ge/Si quantum dots may be exploited to fabricate Si-based on-chip light emitting sources for 1.55- $\mu\text{m}$  fiberoptic communication applications. Takagahara and Takeda<sup>[1]</sup> and Ren<sup>[2]</sup> have theoretically predicted that an indirect-to-direct conversion of the optical transition of SiGe quantum dots would occur whenever the sizes of the quantum dots were small enough. In order to increase the component of quasi-direct transition of the Ge/Si quantum dot system and thus to enhance light emission intensity of the quantum dots for practical applications, the understanding of non-radiative recombination mechanisms (such as phonon-assisted process) is essential.

To probe phonons from self-assembled semiconductor quantum dots, Raman spectroscopy is an efficient and indispensable experimental tool. Up to date, several groups have already reported Raman scattering studies of self-assembled quantum dots of group III–V systems, such as (In, Ga, Al)Sb/GaAs,<sup>[3]</sup> InSb/InP,<sup>[4]</sup> In(Ga)As/GaAs,<sup>[5–9]</sup> InAs/InP,<sup>[10–13]</sup> (Al, Ga)As/InAs,<sup>[14]</sup> InAs/AlAs,<sup>[15,16]</sup> and GaN/(Si)AlGaIn,<sup>[17,18]</sup> group II–VI system, such as CdSe/ZnSe,<sup>[19]</sup> and group IV system, i.e., Ge/Si.<sup>[20–38]</sup> Optical phonon spectra of any of these systems were basically used to extract the chemical composition of the quantum dots as a result of interdiffusion between the dots and the surrounding media or the substrates. It should be pointed out that a few other techniques for the determination of composition of self-assembled quantum dots have been reported. These include scanning tunneling microscopy,<sup>[39]</sup> transmission electron microscopy (TEM) with high-resolution imaging,<sup>[40]</sup> electron energy loss spectrometry,<sup>[41]</sup> X-ray energy disperse spectrometry,<sup>[42]</sup> high-resolution X-ray

diffraction,<sup>[43,44]</sup> and scanning TEM.<sup>[45]</sup> Most of these techniques are capable to show non-uniform dot material distribution in the dots. Optical phonon Raman scattering method is simple and direct to give an average concentration of the dots. In contrast to the tremendous research on optical phonons, the effort on the research of phonon process in the low-frequency acoustic spectral region, however, is much smaller. In self-assembled Ge quantum dot system, for example, one early work reported the observation of equal-distance acoustic peaks in 25-period Ge quantum dot superlattices.<sup>[21]</sup> Afterwards, Milekhin et al. investigated folded longitudinal acoustic phonons in their Ge dot superlattices and explained the acoustic vibrations by the elastic continuum model.<sup>[26–29]</sup> Recently, resonant Raman scattering by acoustic phonons in double- and multilayered Ge dot structures was reported and the observed equal-distance oscillation peaks were explained by interference and ordering effects.<sup>[32,33]</sup> The origins of these observed low-frequency acoustic phonon spectra in Ge dot superlattices therefore remain unclear and debatable because there is a lack of systematic studies, such as the dependence of acoustic phonons on island sizes and other island-related parameters.<sup>[23]</sup>

In this entry, we systematically study Raman scattering by optical and acoustic phonons in multiple Ge quantum dots. The analysis of GeGe and SiGe optical phonon features takes the phonon confinement effect, strain effect, and atomic intermixing into account. Acoustic phonons are found to originate from folded acoustic phonons associated with a superlattice and can be explained by elastic continuum model.

## RESULTS ON SELF-ASSEMBLED MULTIPLE GE QUANTUM DOTS

All samples were grown on Si (100) wafers using a solid source molecular beam epitaxy (MBE) system.

Samples A, B, and C were grown at 540°C with 10 periods of Ge and Si bilayers and contained a Ge coverage of 12, 15, and 18 Å, respectively. Samples D and E were grown with the same Ge layer thickness of 15 Å but at different growth temperatures of 500°C and 600°C, respectively. In addition, sample D has 10-period Ge and Si bilayers while sample E contains 22 periods. The Si spacer layer thickness of 20 nm was used for all superlattices. No cap Si layers were grown intentionally on these samples for convenience of atomic force microscopy (AFM) characterizations. Transmission electron microscopy measurements were exploited as well to obtain the size, density, and uniformity of the self-assembled dots. Raman scattering measurements were performed on a Renishaw Raman Imaging 2000 system with a 514 Ar<sup>+</sup> laser as the excitation light source in the backscattering configuration.

Fig. 1A shows a typical cross-sectional TEM image of sample A. Ten-period vertically correlated layers of Ge dots are evident. The dots in the different layers (beyond the third Ge layer) are identical in size and shape. This observation is also seen for other dot samples. Fig. 1B and C shows an AFM image, and height and base statistic analysis of sample A, respectively. Gaussian distributions were used to fit the data. Most of the dots appear as pyramid and the average dot base and height are 11.9 and 110.4 nm, respectively. Similar measurements have been performed on other samples as well. The growth parameters and structural data were summarized in Table 1. It should be noted that the structural data were from AFM measurements only and not calibrated by TEM characterizations.

## Optical Phonons

Fig. 2 shows the Raman spectra of the dot samples in the spectral region of SiGe and GeGe optical phonons. Similar SiGe (from 400 to 420 cm<sup>-1</sup>) and GeGe lines (near 300 cm<sup>-1</sup>) are observed for dot samples. The frequency position of SiGe optical phonons more or less represents the degree of the interdiffusion between Si spacers and Ge dots. Samples A, B, and C have almost the same Si-Ge optical phonon line shape. The peak frequency changes slightly from 418 cm<sup>-1</sup> for sample A with a nominal Ge thickness of 1.2 nm to 416 cm<sup>-1</sup> for sample C with a nominal Ge thickness of 1.8 nm. To understand this, we shall notice that the interdiffusion arises from both thermal diffusion and strain-induced diffusion. As the same growth temperature of 540°C was used for the three samples, the degree of interdiffusion due to thermal management is the same. The slight difference in frequency therefore comes from the difference in strain-induced diffusion. The thicker Ge was deposited the more relaxation was presented in the dots (as will be discussed in detail

**Fig. 1** (A) TEM image of sample A. Vertically correlated islands are evident. (B) AFM image of sample A. Most of the islands appear as square-based pyramids and the island density is determined to be  $3.6 \times 10^9 \text{ cm}^{-2}$ . (C) Statistical base diameter and height distributions of the Ge islands of sample A. A typical Gaussian peak is used to fit the distribution data. The most probable height and base diameter are 11.9 and 110.4 nm, respectively.

in the following). Strain-induced interdiffusion in the samples with thicker nominal Ge thickness is smaller. The resulting lower frequency can be understood with the following picture: The eigen-frequency of these optical phonons is determined by the effective stretching force constant for each bond and the mass of atoms at the end of each bond. For example, SiSi optical phonon band is centered at 520 cm<sup>-1</sup> for all of the samples and the substrate (not shown in the figure), considering the force constant of SiSi to be 39.5 N/m, and atomic weight of 28.1 for Si.<sup>[46]</sup> Likewise, optical phonons of crystal Ge can be found at 300 cm<sup>-1</sup> with the GeGe bond force constant of 35 N/m and atomic weight of 72.6. Any mixture of Si and Ge leads to SiGe optical

**Table 1** Growth parameters and structural data of the samples

Sample	Ge layer thickness (Å)	Si layer thickness (nm)	Growth $T$ (°C)	Dot base (nm)	Dot height (nm)	Density (cm <sup>-2</sup> )
A	12	20	540	110.4	11.9	$3.6 \times 10^9$
B	15	20	540	122.0	14.0	$4.1 \times 10^9$
C	18	20	540	122.2	16.0	$3.5 \times 10^9$
D	15	20	500	114.7	15.1	$5.9 \times 10^8$
E	15	20	600	175.5	10.2	$2.6 \times 10^8$

phonons with the frequency in between 300 and 520 cm<sup>-1</sup>. For simplicity, we assume that Ge quantum dots are fixed and only Si atoms move. At a situation of stronger interdiffusion, more Si atoms are introduced into Ge dots. Thus SiGe optical phonon band has a frequency closer to SiSi optical phonon band, which is exactly the case for samples A through C. Likewise, much lower frequency position of 406 cm<sup>-1</sup> for sample D and slightly larger frequency of about 420 cm<sup>-1</sup> for sample E compared with that of sample B (due to the same nominal Ge) can also be explained by the above picture.

Now let us analyze the GeGe optical phonons in the samples. It is important to note that the GeGe modes from the dot samples are different from the second-order transverse acoustic (2TA) phonon mode<sup>[47]</sup> for Si at 303 cm<sup>-1</sup>. For comparison, the vertical dotted line is plotted at 300 cm<sup>-1</sup> to represent the optical phonon position for bulk crystalline Ge. The frequency positions of the GeGe optical phonons in dot samples are shifted slightly to higher frequencies with respect to their bulk value. There are several mechanisms to

cause a Raman shift of GeGe optical phonons. The first one is phonon confinement. It is known that the optical phonon branches of bulk Ge are quadratic and, moreover, nearly flat at the Brillouin zone center ( $k \cong 0$ ). Confined optical phonons in a nanocrystal are equivalent to those vibrations in an infinite crystal whose wave vector is given by  $m\pi/d$ , where  $m$  is an integer and  $d$  is the size of the nanocrystal, in our case, the height of the dots. In the dots with a very small height of 1.5–2 nm,<sup>[21]</sup> the phonon confinement effect was observed to result in a shift less than 2 cm<sup>-1</sup>. As the dot size for the present samples is much larger than the lattice constant of Ge, the wave vector is extremely small, leading to insignificant phonon confinement effect.

The size confinement effect of optical phonons in quantum dots with small size should give rise to a shift of phonon band to lower frequency side due to the negative dispersion of the optical phonon branch. A compressive strain on the dots in the lateral directions as a result of the lattice mismatch of Si and Ge, however, leads to a GeGe mode shift to the higher frequency side. This concept can be written as:<sup>[48]</sup>

$$\omega = \omega_0 + \frac{1}{2\omega_0} [p\varepsilon_{zz} + q(\varepsilon_{xx} + \varepsilon_{yy})] \quad (1)$$

where  $\omega$  is the Ge-Ge mode frequency induced by a biaxial strain,  $\omega_0$  is the frequency of the Ge zone-center LO phonon;  $p$  and  $q$  are the Ge deformation potentials;  $\varepsilon_{xx}$  and  $\varepsilon_{yy}$  are the biaxial strain  $(a - a_0)/a$  with  $a$  and  $a_0$  being unstrained and strained lattice constants, respectively. The physical parameters used in Eq. (1) can be obtained from Ref.<sup>[34]</sup>. For fully strained pure Ge on Si, we obtain  $\omega = 317.4$  cm<sup>-1</sup>. The large difference between this calculated number and the experimental GeGe mode values (close to 300 cm<sup>-1</sup> as shown in Fig. 2) suggests that the dots are not fully strained as assumed in the calculation. By using Eq. (1) and the experimental GeGe optical phonon frequencies  $\omega$ , the residual biaxial strain ( $\varepsilon_{xx}$ ) on the quantum dots can be estimated and listed in Table 2. Very small residual strain values obtained suggest the dots are almost fully relaxed.

An obvious reason of the strain relaxation is the atomic intermixing at the Si–Ge interface. The degree

**Fig. 2** Raman spectra of the dot samples. Similar SiGe and GeGe lines are observed for these samples. The frequency positions of the GeGe optical phonons in dot samples are shifted slightly to higher frequencies with respect to their bulk value (300 cm<sup>-1</sup>).

**Table 2** The experimental GeGe mode frequencies, integrated peak intensity ratios, and calculated Ge composition in dots and residual in-plane strain in the dot samples

Sample	$\omega(\text{GeGe}) (\text{cm}^{-1})$	$\omega(\text{SiGe}) (\text{cm}^{-1})$	$I_{\text{GeGe}}/I_{\text{SiGe}}$	Ge composition in dots	$\varepsilon_{XX} (10^{-3})$
A	302	418	1.45	0.48	-4.8
B	301.1	417.5	1.45	0.48	-2.65
C	300.5	416	1.45	0.48	-1.2
D	302.4	406	2.14	0.58	-5.8
E	300.4	419.5	1.29	0.45	-0.96

of the interface intermixing can be determined by the integrated peak intensity ratio  $I_{\text{GeGe}}/I_{\text{SiGe}}$  as the intensity depends on the relative number of corresponding bonds. This concept was used for SiGe alloy<sup>[49]</sup> and Ge quantum dots<sup>[37]</sup> and can be expressed as:

$$\frac{I_{\text{GeGe}}}{I_{\text{SiGe}}} \cong B \frac{x}{2(1-x)} \quad (2)$$

where  $x$  is the average Ge concentration and the coefficient  $B$  is related to the Bose factor and the frequencies of GeGe and SiGe optical modes of the alloy. It is found that the coefficient  $B$  varies weakly with alloy composition and is determined to be 3.2.<sup>[50]</sup>  $I_{\text{GeGe}}/I_{\text{SiGe}}$  can be obtained from the spectra in Fig. 2. The Ge concentrations in quantum dots estimated by this method are listed in Table 2. It should be noted that the estimation by such interpolation is rough because the Si 2TA phonons and optical phonons from wetting layers have not been subtracted in the calculation. Moreover, the composition obtained is an average value, which does not show any information about composition distribution in the dots.

Fig. 3 plots the GeGe peak position as a function of the Ge concentration in the dots. Symbols are experimental data. Solid straight lines 1 and 2 are used to guide the eyes and indicate that the different GeGe mode frequency is obtained for dots not only with different Ge concentrations but also with a similar Ge concentration. Solid line 3 is a calculation result using Eq. (1). In this calculation, we assume the same  $\omega_0$  and other deformation potentials for pure Ge. This approximation is reasonable because the interdiffusion occurs in the interface and the “core” of the dots remains pure Ge. For example, the non-uniform Ge content in the dots has been proved by elemental distribution analysis using an electron filtering imaging method in TEM<sup>[51]</sup> and scanning TEM.<sup>[45]</sup> The in-plane strain  $\varepsilon_{xx}$  used can be written as  $(a_{\text{Si}_{1-x}\text{Ge}_x} - a_0)/a_{\text{Si}_{1-x}\text{Ge}_x}$  with the lattice parameter of an alloy with Ge concentration of  $x$  determined by Vegard's law  $a_{\text{Si}_{1-x}\text{Ge}_x} = xa_{\text{Ge}} + (1-x)a_{\text{Si}}$ , where  $a_{\text{Ge}}$  and  $a_{\text{Si}}$  are lattice parameters of pure Ge and Si, respectively. Simple calculations show, for example, in-plane strain to be  $-0.02$  for an alloy with Ge

concentration of 0.48 (samples A, B, and C), leading to a GeGe mode frequency of  $308.3 \text{ cm}^{-1}$ . The calculated values show a considerable shift from the value obtained for fully strained Ge on Si ( $317.4 \text{ cm}^{-1}$ ); however, these are still larger than the peak frequencies of the GeGe modes of the samples A through E. As a matter of fact, the absolute value of the residual strain on the dots shown in Table 2 is much smaller than the absolute value estimated here by interdiffusion only. Moreover, the picture of interdiffusion does not completely account for the peak position difference for the different samples with the same Ge composition as of line 3 in Fig. 3. The above analysis suggests that additional strain relaxation mechanisms exist apart from Ge/Si interdiffusion. We believe that this additional strain relaxation comes from the process of the formation of Ge dots.

The relaxation of the dots in addition to atomic interdiffusion consists of the relaxation of the surface-layered dots and the relaxation of the embedded dots.

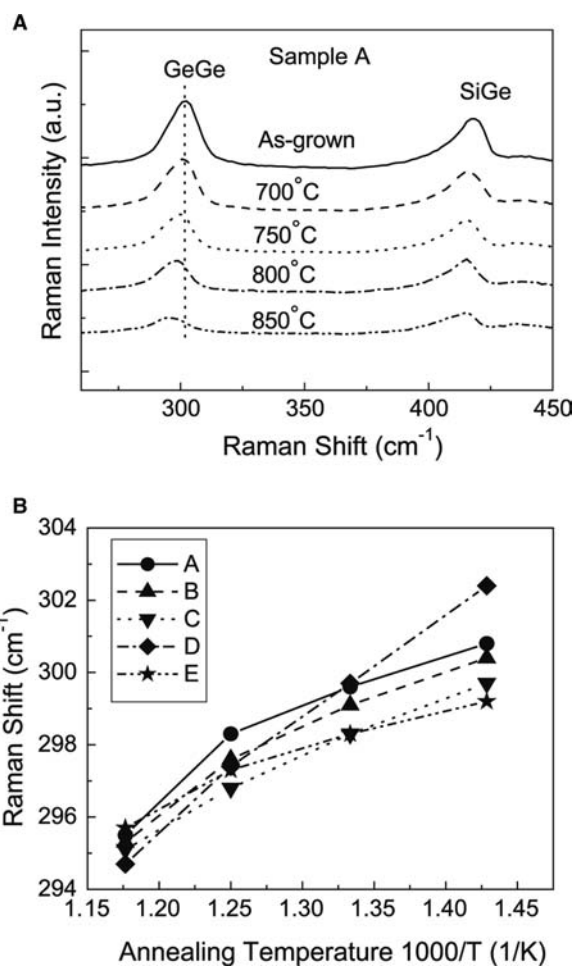

**Fig. 3** GeGe mode position as a function of Ge concentration in dots. Ge concentration is obtained by means of the integrated intensity ratio of optical phonons of GeGe and SiGe. Solid lines 1 and 2 are used to guide the eyes. The results show that the different GeGe mode frequency is obtained for dots not only with different Ge concentrations but also with a similar Ge concentration. Line 3 is the calculated data by assuming Si/Ge interdiffusion only.

The relaxation of the surface-layered dots is related to the nature of Stranski–Krastanov growth mode. When Ge is deposited on Si, it first takes a layer-by-layer growth format. As the Ge film exceeds its critical thickness, it becomes rough by forming pyramidal islands to relieve strain energy. As more Ge is deposited, the islands transform from the pyramid shape to the dome shape, leading to more strain relaxation. Atomic force microscopy measurements on our samples indeed showed, for example, the pyramid-over-dome ratio decreases as the increase of the Ge deposition for these samples grown at the same temperature of 540°C.<sup>[25]</sup> The relaxation is also induced by the dot embedding effect. Sutter and Lagally have used a strain-driven atom diffusion model to show that the dot shape transforms to truncated shape after the growth of Si layer on top.<sup>[52]</sup> Indeed, we have observed this transition from the cross-section TEM measurements. Because of the capping process, the in-plane strain is relaxed.<sup>[39]</sup>

After recognizing all the above relaxation mechanisms, we can fully explain the observed GeGe optical phonon frequencies. First, let us take a look at line 1 of Fig. 3. This line represents the GeGe mode trend of a set of samples (C, D, and E) grown at different temperatures. GeGe mode frequency changes from 302.4 to 300.4 cm<sup>-1</sup> when the Ge concentration decreases from 0.58 to 0.45 as a result of growth temperature from 500°C to 600°C, indicating that the sample grown at higher temperature induces stronger interface intermixing, or more strain relaxation. Quantitative calculations using Eq. (1) show that a shift of 2.2 cm<sup>-1</sup> is obtained for the present interdiffusion difference in the three samples (as can be seen from line 3 in Fig. 3). This number is almost the same as the experimental observed shift, suggesting that the strain relaxation from the different degrees of interdiffusion is the main factor responsible for the different frequencies of the GeGe mode in this set of samples. In other words, the overall effect of the dot shape transition on the GeGe mode frequency is about the same for the three samples. Line 2 in Fig. 3 represents another set of samples (A, B, and C). As shown previously, this set of samples has the same Ge concentration in the dots. Nevertheless, the GeGe optical phonon frequency is different and the largest difference is 1.5 cm<sup>-1</sup>. This suggests different strains are present on the dots in different samples, which arises from the different dot morphologies in the different samples, such as pyramid-over-dome ratios, dot height-over-base ratios, and embedding effect.

The above-analyzed, negligible phonon confinement effect but dominant atomic intermixing and/or strain effect in determining frequencies of optical phonons for quantum dot samples can also be proved by performing annealing experiments. Fig. 4A shows the Raman spectra of sample A under rapid thermal

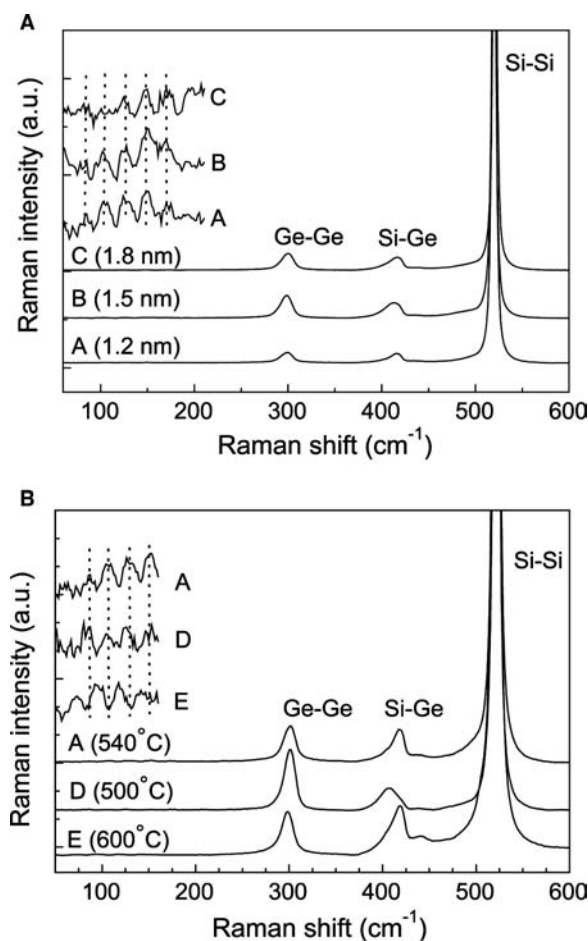

**Fig. 4** (A) Raman spectra of sample A under RTA for 5 min at different temperatures, and (B) Raman shift as a function of annealing temperature for different samples.

annealing (RTA) for 5 min at different temperatures. The vertical dotted line is plotted at the center of GeGe mode from as-grown sample for comparison. The GeGe Raman line broadens and shifts to lower frequencies as the annealing temperature increases. This phenomenon was also observed when annealing other samples. Fig. 4B shows the annealing temperature dependence of the Raman shift for the dot samples grown at different temperature. After 850°C annealing for 5 min, the GeGe optical mode shifts downward by as much as 8, 6–7, and 5 cm<sup>-1</sup> for the samples grown at 500°C, 540°C, and 600°C, respectively. The intermixing after annealing leads to fully relaxed SiGe alloy-like dots, causing the observed peak shift.

## Acoustic Phonons

Fig. 5A shows the Raman spectra of the samples A, B, and C, which were grown with the same temperature and different Ge layer thickness. The vertical dot lines

**Fig. 5** Raman spectra of the samples with (A) different nominal Ge thicknesses of 1.2, 1.5, and 1.8 nm for samples A, B, and C, respectively, and (B) with different growth temperatures of 540°C, 500°C, and 600°C for samples A, D, and E, respectively. Acoustic phonon modes with the same frequencies are observed for different Ge-thickness samples, while different frequencies and periods are observed for different samples with different growth temperatures.

are used to facilitate the comparison among the samples. Similar SiSi, SiGe, and GeGe optical vibration peaks are seen at around 520, 415, and 300  $\text{cm}^{-1}$ , respectively. Besides these peaks, low-frequency oscillation peaks are observed for all of the three samples around 84.3, 104.7, 126.6, 150, and 171.8  $\text{cm}^{-1}$ , respectively. These nearly equal-distance peaks with a period of about 20  $\text{cm}^{-1}$  are higher-order acoustic phonons. The lower orders were attenuated by the Rayleigh line rejection filter and thus were not observed. An interesting phenomenon is that the acoustic peak frequencies do not scale with the dot size. Lamb's theory predicts that confined phonon frequency should be inversely proportional to the nano-crystal size<sup>[53]</sup> and was shown to be true for a number of nano-crystal systems such as  $\text{CdS}_x\text{Se}_{1-x}$  in glasses<sup>[54]</sup> and Si in  $\text{SiO}_2$  matrix.<sup>[55]</sup> The present result suggests that the observed

low-frequency peaks are not confined phonon modes in quantum dots.

Fig. 5B shows the Raman spectra of the samples A, D, and E, which were grown at different temperatures. The vertical dot lines are again used here to facilitate the comparison among the samples. Acoustic phonons for different samples have different frequencies. Specifically, acoustic phonon peak frequencies for sample A have been assigned in Fig. 5A. Sample D has acoustic phonons around 71.4, 95.7, 118.8, and 141  $\text{cm}^{-1}$ , and sample E has acoustic phonons around 83.8, 105.8, 126.8, and 149.8  $\text{cm}^{-1}$ . The period of these nearly equal-distance peaks is about 24, 22, and 20 for samples D, E, and A, respectively.

There are two possibilities, which may be used to explain the observed periodic acoustic phonons.<sup>[56]</sup> The first one is that these are probably phonon modes confined in quantum wells where zone-edge phonon modes have been made, "allowed" by breakdown of wave vector conservation. The second one is that they are associated with a superlattice where low-frequency zone-edge phonon modes have been folded into zone center. The first concept has been used to explain the periodic acoustic phonon oscillations in the InAs/InP self-assembled quantum dots.<sup>[12]</sup> The period of the periodic acoustic phonons can be expressed by:

$$\Delta\omega = \frac{1}{2L} \cdot \frac{v}{c} \quad (3)$$

where  $L$  is the thickness of the quantum layer,  $v$  is the sound velocity of the phonons, and  $c$  is the speed of the light. If the observed phonons were the confined phonons in the Si spacer layers, then with the velocity  $v_{\text{Si}} = 8.44 \times 10^5 \text{ cm/sec}$ <sup>[57]</sup> and the peak periods of 20–24  $\text{cm}^{-1}$  for the present samples, we would obtain the Si layer thicknesses for our samples to be around 5.9–7 nm. The designed thickness of Si spacer thickness for all the samples was 19–20 nm. The actual effective thickness of Si spacer layers has shrunk to around 14 nm characterized by cross-sectional TEM. The reason is that Si spacers were deposited on curvature surfaces containing three-dimensional dots. A similar situation was often observed when growing short-period superlattices on relaxed substrate, which consisted of cross-hatch undulation patterns. The layer deposited on top was stretched as a result of undulation and the effective thickness along the growth direction was shrunk. The effective thickness of about 14 nm for the present samples, however, is still more than two times of the calculated 5.9–7 nm, suggesting that these phonons have nothing to do with the confinement in the Si spacers. Likewise, the phonons are not confined phonons in the wetting layers either. Samples grown at different temperatures lead to different wetting layer thickness because of Si/Ge

interdiffusion. Different from the dots grown at much lower temperature (300°C)<sup>[26]</sup> or by the use of anti-mony as surfactant,<sup>[34]</sup> where the wetting layers were more or less around 3–4 MLs, the wetting layers in this set of samples had the thickness in the region of 15–20 Å with cross-sectional TEM characterizations (not shown here). Therefore the wetting layers are not pure Ge but SiGe alloy. Phonon velocity for SiGe can be obtained by the linear interpolation of LA phonon velocity of Si and Ge. Simple calculations showed that one could never obtain an agreeable solution compared with the experimental results.

The above analysis leaves the only possible origin for these phonons, i.e., they are folded acoustic modes related to the periodicity of the superlattice. Rytov's elastic continuum model<sup>[58]</sup> has been well applied for folded acoustic phonons in quantum well superlattices and was also seen to explain the acoustic phonon features in Ge dot multilayers<sup>[26–29]</sup> and InAs/GaAs dot multilayers.<sup>[14]</sup> In this model, the acoustic phonon dispersion can be written as:

$$\cos(qd) = \cos\left(\frac{\omega d_1}{V_1}\right) \cos\left(\frac{\omega d_2}{V_2}\right) - \frac{1}{2} \left(R + \frac{1}{R}\right) \times \sin\left(\frac{\omega d_1}{V_1}\right) \sin\left(\frac{\omega d_2}{V_2}\right) \quad (4)$$

where  $q$  is the superlattice wave vector perpendicular to the layers and is roughly determined to be  $q \cong 4\pi n' / \lambda_L$ , where  $\lambda_L$  is the incident laser light wavelength and  $n'$  is the refractive index of the material at that wavelength. In addition,  $R = (V_1\rho_1)/V_2\rho_2$ ,  $d = d_1 + d_2$ ,  $d_1$  and  $d_2$ ,  $\rho_1$  and  $\rho_2$ , and  $V_1$  and  $V_2$  are the thickness, density, and sound velocity in Ge and Si layers, respectively. The physical parameters can be obtained from Ref.<sup>[57]</sup>. The model designed for quantum well superlattice can be considered as a zero-order approximation to the real quantum dot superlattice as it does not take into account quantum dot shape, size, and density. It was suggested in Ref.<sup>[27]</sup> to use nominal thickness of Ge layer as an effective thickness  $d_2$ . Nevertheless, with this rough approximation, good agreement with experimental data was achieved.<sup>[26–29]</sup> Following this approach, with the effective Si spacer layer thicknesses of about 14 nm and wetting layer thicknesses of about 1.5 nm in our samples, we calculated the phonon dispersion and showed acoustic phonon peak period of 19–21 cm<sup>-1</sup>, which was close to the experimentally observed 20–24 cm<sup>-1</sup>. Therefore we conclude that the observed low-frequency modes are folded acoustic phonons. More accurate description of the acoustic spectra of semiconductor quantum dot superlattices will require rigorous calculations of acoustic phonon scattering on quantum dot as well as multiple scattering effect produced by quantum dot ensemble in each layer.

## CONCLUSION

We have studied Raman scattering from optical phonons and acoustic phonons in the Ge quantum dot superlattices. The GeGe optical phonon frequencies of the dot samples were larger than 300 cm<sup>-1</sup> but within 3 cm<sup>-1</sup>, indicating that the dots were relaxed in the superlattices. Strain relaxation was found not only from the atomic interdiffusion but also from the dot morphology transition both for the surface dots and the embedded dots. The annealing experiments also proved that the strain relaxation and intermixing were the key parameters for the observed optical phonons. Optical phonon studies show that Raman spectroscopy is an efficient tool for the determination of the average compositions and strains for zero-dimensional quantum dots. Periodic oscillations in the lower frequency region were observed for quantum dot superlattice samples. These acoustic phonons were found to be related to superlattice period and could be well explained by the elastic continuum model.

Furthermore, the method for analysis of phonons in the above Ge quantum dot superlattice system can be generally used for other quantum dot systems, such as, InGaSb/GaAs, InSb/InP, InGaAs/GaAs, InAs/InP, AlGaAs/InAs, InAs/AlAs, and GaN/(Si)AlGaN, CdSe/ZnSe, and so on. Phonon spectra in these material systems depend on the physical parameters of superlattice, such as concentration in dots, dot size, and period thickness. In the case of very small dots with high density (e.g., greater than 10<sup>11</sup> cm<sup>-2</sup>), multiple scattering effects may play an important role in the modification of phonon spectra. The phonon densities of states in quantum dot superlattices change as seen from the strong modification of phonon spectra with the appearance of quantum dots and can be used to calculate the thermal conductivities of superlattices. Research has shown a great reduction of thermal conductivities in quantum dot superlattices, which have great applications in the fabrication of new-generation solid-state thermoelectric devices. Phonon spectra modification by quantum dots also suggests the potential applications of quantum dot superlattices as phonon lenses, filters, and reflectors for phonon-assisted lasers in indirect-band gap material systems.

## ACKNOWLEDGMENTS

The authors wished to thank Dr. S. G. Thomas of Motorola Semiconductor Products Sector for performing some of the TEM characterizations and Prof. Peter Y. Yu of UC Berkeley for valuable discussions. This work was funded by the DoD MURI-ONR program on Thermoelectrics (N00014-97-1-0516) and the AFOSR MURI program on phonon engineering (F49620-00-1-0328).

## INTRODUCTION

Natural carbon exhibits its distinct properties in two forms: diamond, an insulator, gives the strongest mechanical strength; graphite, a brittle material, conducts electricity at room temperature. A recently synthesized carbon form, the carbon nanotube (CNT), combines the mechanical strength of diamonds with the electric conductivity of graphite. However, the as-grown form of this almost perfect new material is actually a mixture of semiconducting and metallic tubes, in the approximate 2:1 ratio estimated by the tight binding model.<sup>[1]</sup> Furthermore, as-grown single-wall nanotubes (SWNTs) generally possess a very high aspect ratio of length to diameter (on the order of 1000:1). They tend to bundle together as ropelike hydrophobic aggregates—not an individual tube of either semiconductor or metallic tube. However, controlling growth and follow-up processing and treatment conditions can change the metallic and semiconducting ratio in the mixture (see “Carbon Nanotubes”).

To take advantage of their unique electronic properties, mixed SWNT bundles can be dispersed and separated to tailor to various device applications. One ideal matrix for separation and self-assembly is a scheme using polymers consisting of a carbon backbone because of their structural compatibility. The electric conductivity of the filler-based polymer composite is substantially increased with CNT loading. Raman frequency shifts have demonstrated their non-covalent interfacial interactions, through tensile and strain as well as compression transferred by the outer and inner layers of the multiwalled nanotube (MWNT), respectively.<sup>[2,3]</sup> These interfacial interactions, along with the high aspect ratio (D/L in the order of 1:1000), are believed to enhance conduction path through hopping and tunneling in the composite.

The study and design of the CNT/polymer composite emerged with increased knowledge of the interactions in the composites. Most recently, CNT-based composites appear promising for applications in telecommunication,<sup>[4]</sup> actuators,<sup>[5,6]</sup> photovoltaic cells,<sup>[7]</sup> light-emitting diodes (LEDs),<sup>[8]</sup> field emission<sup>[9]</sup>

and radiation shielding.<sup>[10]</sup> The performance and lifetime of devices are enhanced through CNT composites. This also opens a venue for many non-conducting polymer applications with good structural stability and flexible processability. Because mobility can be increased to avoid electrostatic effect, the composites can be used for passive electronic components as well as electromagnetic shielding.<sup>[11]</sup> By forming the CNT composites, we overcome the disadvantages pertinent to nonconducting polymers to improve their performance as a result of the superior electric, thermal, and mechanical properties of CNT.

## RAMAN SPECTROSCOPY BACKGROUND

The interfacial molecular structure studied by the high-throughput micro-Raman probes is correlated with macroscopic physical properties. In particular, resonant Raman spectroscopy probes the electronic density of states (DOS) singularity band gap by tuning the Raman excitation energies. The optical approach has the advantage of eliminating the contact between the electrode and the nanometer-scale material. It has become a very powerful technique to study the electronic properties of nanostructured materials.

Figure 1 shows the energy level diagram of the Raman effect. When the monochromatic light excites matter (solid, liquid, or gas), it scatters light as a result of relaxation from virtual states, which are short-lived and distorted by the oscillating electric field of the incident light. A photon is immediately emitted or absorbed during the scattering. Depending on higher or lower vibration states, it relaxes back, resulting in stoke and antistoke scatterings, respectively. A small percentage of light scatters the same frequency as the incident light when it relaxes back to the same vibration state as the initial state (called Rayleigh scattering). When the incident light matches the electronic transition states, resonance scattering occurs with an intensity of up to  $10^8$  over the nonresonance intensity. Thus the electronic band gap can be measured.

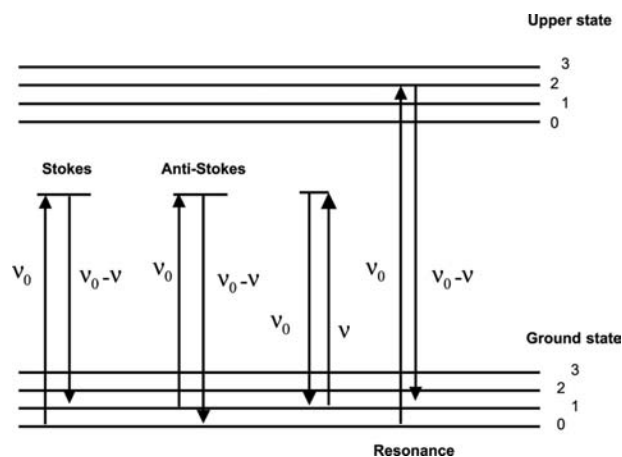

Fig. 1 Energy level diagram of Raman scattering effect.

Raman spectroscopy emerged as a powerful tool to study carbonaceous materials in recent years with the breakthrough in charge-coupled detectors and laser radiation sources. Both polymer and CNT have very high percentages of the chemical composition of carbon. The high polarizability intensity of the carbon bond (C–C or C=C) results in especially strong Raman scattering in these classes of materials. Although infrared (IR) spectroscopy is frequently used for probing the polymer side-chain vibration symmetry, Raman spectroscopy is an ideal technique to study the properties of polymer backbones, the CNT lattice structure, and their interactions in composites.

Raman spectroscopy has been used to study the polymer vibration structure of backbone composition, conformation, and crystallinity. Targeting the conjugation length, chain conformation, interchain interaction, and polaron–bipolaron ratio, the correlation of

the electronic and chemical structural changes of polymers can be established.<sup>[12]</sup> In the CNT composite, the polymer structure changes caused by the CNT loading can be monitored by the Raman frequency shift and lines shape analysis.

Fig. 2 shows the Raman spectra of crystalline diamonds, graphites, and SWNTs. Like its parent forms of diamond and graphite, SWNT also processes distinct spectroscopic signatures. The characteristic D-band and G-band correspond to  $sp^3$  and  $sp^2$  vibration modes displayed in diamonds and graphites, respectively. The quasi one-dimensional (1-D) CNT also displays nanometer-scale signatures in tangential modes (TMs) and radial breathing modes (RBMs) regions. The rich information about structure provided by Raman spectroscopy has been also demonstrated in probes of CNT chirality, size, and defects.

A detailed analysis of SWNT structures and SWNT Raman modes can be found in an excellent review<sup>[1]</sup> and the entry on “Single-Walled Carbon Nanotubes: Geometries, Electronic Properties, and Actuation.” Briefly, SWNT is a graphene sheet rolled into a cylindrical shape with very high aspect ratio. The axial symmetry exhibits the spiral conformation called chirality. The CNT belongs to  $D_{nh}$  ( $n$  is even number),  $D_{nd}$  ( $n$  is odd number), and  $C_n$  (achiral) groups. The G-band is formed through graphite Brillouin zone folding. According to group theory, the TM exhibits  $A_1$ ,  $E_1$ , and  $E_2$  symmetries that are Raman-active; the characteristic Raman signature consists of TMs including G-bands around  $1590\text{ cm}^{-1}$  and D-bands around  $1350\text{ cm}^{-1}$ ; another signature band is the second-order Raman mode at  $1730\text{ cm}^{-1}$  in the single-walled CNT. In the TM region, the line shape displays a symmetric profile around  $1590\text{ cm}^{-1}$  for semiconductor SWNTs; a

Fig. 2 Raman spectra of crystalline diamond, graphite, and SWNT in visible excitations.

broad asymmetric G-band around  $1560\text{ cm}^{-1}$ , as well as a sharp band around  $1580\text{ cm}^{-1}$  are characteristic features associated with metallic SWNT in the bundle.<sup>[13]</sup> Usually, Breit–Wigner–Fano (BWF) line shape is used to fit the lower-frequency component of the G-band. This phonon and electron continuum Raman line shapes can be obtained from:

$$I(\omega) = I_0 \left\{ 1 + \frac{(\omega - \omega_0)/q\Gamma}{2 \left\{ 1 + \left( \frac{\omega - \omega_0}{\Gamma} \right)^2 \right\}} \right\} \quad (1)$$

where  $I_0$ ,  $\omega_0$ ,  $1/q$ , and  $\Gamma$  are intensity, renormalized frequency, the interaction of the phonon with continuum states, and the broadening parameter, respectively.<sup>[14]</sup>

The energies of allowed optical transitions (ATOs) are determined by both the diameter and the chirality of the SWNT,<sup>[15]</sup> as schematically illustrated in Fig. 3.

Below  $500\text{ cm}^{-1}$ , the frequencies are contributed from the RBM  $\Omega$ . The SWNT diameter  $d$  is computed<sup>[16,17]</sup> from the low-frequency Raman spectra region using a phenomenological Eq. (2)

$$\Omega_{\text{RBM}}(\text{cm}^{-1}) = \alpha/d \text{ (nm)}, \quad \text{where } \alpha = 248\text{ cm}^{-1}\text{nm} \quad (2)$$

The MWNT consists of tens of SWNTs. The stacking and assembly of each tube rarely align perfectly.

**Fig. 3** Allowed optical transitions for SWNT with various diameters and chiralities calculated in the zone folding scheme. Black areas correspond to semiconducting tubes; dashed areas correspond to metallic tubes. The laser energies are labeled in write frames. The maximum of Raman intensity is expected for RBMs and TMs at the high and low limit of the frames, respectively. *Source:* ©APS, 2001.

illumination of a small region at the center of the field of view

Two forms are commonly observed in experiments: bamboo structure and cone shape stacking. Tube stacking generally lowers the symmetry of the CNT. The Raman mode resulting from these two stacking assemblies gives the secondary defect-induced mode at about  $1612\text{ cm}^{-1}$  as a shoulder peak in the D-band. The cap at the end of the tube is usually open with the larger-diameter CNTs and chemical treatments. This feature can be monitored for MWNTs undergoing purification and dispersion because of their interactions with chemical agents and the chemical environment. The G-band to D-band ratio is substantially lower than that of SWNTs.

The confocal microscopic Raman probe enables the study of unique properties exhibited in nanometer-scale composite materials in the volume order of  $1\text{ }\mu\text{m}$ . Various techniques such as polarized Raman and Raman imaging<sup>[18]</sup> became possible for the study of SWNT interactions in non-conjugated polymer matrices in high spatial resolution. The interfacial van der Waals interaction of SWNTs in the polymer composite demonstrates important contributions to many physical properties.

The Raman instrument is generally composed of three parts: the excitation light source, the spectrometer, and the detection apparatus. Fig. 4 is the schematic setup of a typical micro-Raman from Renishaw, Inc. The setup enables relative low laser power (2–3 mW) focused on the  $1\text{-}\mu\text{m}^2$  sample spot, providing the necessary high spatial resolution for nanomaterial studies.

## SYNTHESIS OF CNT/POLYMER COMPOSITES

### In Situ Growth

It is a challenge to control the growth process, but managing it effectively is nevertheless an effective

way to obtain homogeneous composite films and to achieve a uniform CNT dispersion.

UV and chemical-polymerized composites were processed by polymerization of monomers in the presence of SWNTs (an initiator sometimes is added as needed) in the sonication bath. The same polymerization can incorporate SWNTs into a polymer matrix through ionic surfactant solution, with a concentration slightly higher than the critical micelle concentration. This second polymerization approach is so-called “emulsion-processed.” Either oil or water-soluble initiators maybe added to accelerate the polymerization. The third method is electropolymerization. The CNTs will be used either as the electrode onto which the polymer is deposited, or as part of the electrolyte to be codeposited. When the CNT array is used as the electrode, the composite formed through the polymerization occurs on the surface of the CNT electrode. As the nanotube is dispersed with a monomer in the organic solution as a mixed electrolyte, the composite forms homogeneously onto a conventional electrode such as platinum. The redox potential, oxidation–reduction cycle time, and choice of dopant ions<sup>[19,20]</sup> in the electrolyte and the functional group in the CNT all act as control parameters to adjust composite film thickness and conductivity. Conducting polymers, such as polypyrrole (PPy), are commonly synthesized with either scheme.<sup>[21,22]</sup>

### Shear Field Processing

SWNTs are added to a solution of polymer in toluene or *N,N*-dimethylformamide solution. High sonic power is briefly (a few minutes) used to break up the CNT aggregates, and then low power is applied to the sonic bath for a few hours. Generally, a few percent of CNTs remain in the solution other than those precipitated as aggregates. After a few days of settlement, the polymer/CNT composite from the supernatant can either be piped out and cast as thin film, or further thermally blended. In the latter, the composite can be dried in the oven and then melt-pressed above its glass transition temperatures a few times to ensure uniform mixing. The anisotropic effect introduced in the melt-blended process may seem predominant than in situ-polymerized composites. Some researchers<sup>[23]</sup> believe that the different thermal expansions between SWNTs and PMMAs can significantly contribute to their interfacial adhesion. This causes stress and improves alignment between the two components in the melt-blended composite in anisotropic directions. For example, molecular dynamic simulations of polyethylenes and SWNT composites show that the polyethylene diffusion coefficient is 30% higher in the direction in which its backbone is parallel to the SWNT axial direction than perpendicular to it.

### INTERFACIAL INTERACTIONS IN THE COMPOSITE OF INCREASED ELECTRIC CONDUCTIVITY

Some of the processing conditions have subtle, yet profound, impacts on composite properties. Raman studies show that applied sonication shear field strength during CNT composite formation can introduce defects to the CNT sidewall, change its diameter,<sup>[24,25]</sup> or even open the end caps on the tubes. The defect sites are usually the most active sites where the charge transfer most likely occur. The chemical interaction usually occurs on the CNT tip because the fullerene-like cap is more reactive. The less invasive noncovalent interaction generally happens along the CNT sidewall in the form of van der Waals, hydrogen bond, or electrostatic interactions, all of which are more commonly observed in the polymer composites. Raman analysis is a very sensitive technique for investigating these interactions. The G-band and D-band ratio in the Raman shift can illustrate processing and growth-related mechanisms. However, the backbone conformation changes of the polymer in conjunction with the diameter changes of the CNT routinely probed by Raman spectroscopy are likely the causes of the constituent components electronic conductivity increases in the polymer composites.

In many cases, the measured conductivity change depends on interactions on the molecular level for nanometer-scale composites. Raman spectroscopy has demonstrated that the electronic DOS band gap of CNTs in the composite can be influenced by interactions formed during the composite formation.

### PMMA/SWNT Composites

The polymethyl methacrylate (PMMA/CNT) composites are among the most studied composites. The electronic conductivity of the MWNT composite is increased by several orders of magnitude.<sup>[26]</sup> Because there is no conjugated bond in PMMA to interact with the CNT, the interfacial interactions are likely to play important roles in composite formation. Therefore this is an ideal system to investigate the structure and conductivity changes simultaneously. These changes can be interplayed with direct conductivity measurements, as well as optical probes to electronic DOS through resonant Raman spectroscopy.

The PMMA/SWNT composite is fabricated into a spun fiber by the melt-processed film and analyzed by Raman spectroscopy.<sup>[27]</sup> The SWNT could either position itself to the fiber axis, or isotropically disperse in the composite. Fig. 5 shows the polarized Raman spectra of the composite. The intensity dependence of the RBMs with respect to the laser incident angles

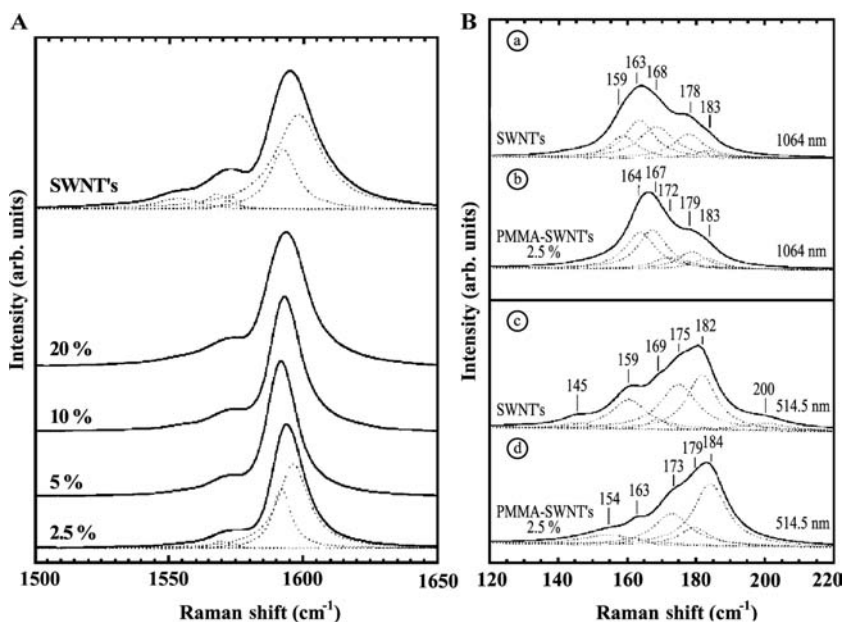

**Fig. 5** Raman spectra of SWNT/PMMA nanocomposite fiber at the indicated fiber angles with respect to the incident laser polarization axis. Spectra were recorded using the 647.1-nm excitation, with the analyzed polarization parallel to the incident polarization. The angle-dependent intensity of the breathing mode of the SWNTs ( $202\text{ cm}^{-1}$ ) was used to determine the extent of nanotube alignment relative to the fiber axis. *Source:* ©Elsevier Science B.V., 2000.

demonstrates that the SWNT is highly anisotropically aligned with the fiber axis. This corresponds to the much higher conductivity directly measured in the fiber axial direction, as opposed to the lower conductivity perpendicular to the processing flow direction.

Apparently, further investigations are needed of the PMMA and SWNT structural details that affect the change of conductivity. The changes of SWNT sizes

with loading have been studied with Raman spectroscopy by using multiple wavelength excitations.<sup>[28]</sup> At both 514- and 1064-nm excitations, Fig. 6A shows that SWNT RBM frequency upshifts toward larger-diameter distributions as calculated from Eq. (2). The PMMA composites with SWNT loadings of 2.5%, 5%, 10%, and 20% are also studied with resonant conditions at 1064 and 647 nm for semiconducting and metallic SWNTs, respectively. These two excitations correspond to the first semiconducting and metallic DOS singularity bandgaps, respectively. In the 1064-nm excitation that corresponds to the semiconducting SWNT, Fig. 6B shows that among the five components in the TM region ( $1553, 1568, 1573, 1592,$  and  $1597\text{ cm}^{-1}$ ), the intensities of the three peaks located at  $1553, 1568,$  and  $1573\text{ cm}^{-1}$  decrease in the composites. More drastically, in the 633-nm laser excitation that corresponds to the metallic SWNT, the relative ratio of  $1543/1558\text{ cm}^{-1}$  in the G-band is reversed from the pristine SWNT. This is an indication of the increased percentage of metallic SWNT because the G-band line shape featured by the BWF fit in Eq. (1) in the metallic SWNT resonant condition. The other possibility is that PMMA/SWNT interaction replaces the interface in the SWNT bundles. Furthermore, the interaction between SWNT and PMMA is investigated in full width at half maximum (FWHM). The FWHM increases with SWNT loadings, and decreases with excitation wavelengths go from 458, 514, 676, to 1064 nm. The observed G-band blue shifts and the SWNT diameter increases, clearly demonstrating the van der Waals interaction between SWNT/PMMA in the composites, in place of intertube interactions in the pristine SWNT.

**Fig. 6** (A) Raman spectra of PMMA/SWNT composites and SWNT films in the frequency range  $1500\text{--}1650\text{ cm}^{-1}$  with 1064 nm excitation. The spectra are resolved for PMMA/SWNT composites of 2.5% concentration and SWNTs. (B) Decomposition of low-frequency bands: (A) SWNT film with 1064 nm excitation; (B) PMMA/SWNT film for 2.5% concentration with 1064 nm excitation; (C) SWNT film with 514.5 nm excitation; and (D) PMMA/SWNT film for 2.5% concentration with 514.5 nm excitation. *Source:* ©Elsevier Science S.A., 2000.

The interfacial interaction in SWNT/PMMA composites can be further illustrated by Raman studies on two differently processed composites.<sup>[29]</sup> Figure 7A gives the Raman results of melt-processed and UV-polymerized composites in the metallic resonant excitation energy at 633 nm (1.96 eV). SWNT Raman spectra are used for reference. Comparing to both UV-polymerized composites and pristine SWNTs, the melt-blended composite exhibits a significant difference in the SWNT G-band line shape profiles around  $1590\text{ cm}^{-1}$ . The G-band in UV-polymerized composites retains the same Lorentzian line shape as that of the pristine SWNT. The broader G-band feature in the thermally treated composite can be fit with the BWF line shape for the SWNT diameter between 1.2 and 1.6 nm in the AOT,<sup>[30]</sup> as discussed in Fig. 3. The BWF line shape is the signature of metallic SWNTs resulting from the coupling between the phonon and the electronic continuum.<sup>[31]</sup> The predominant metallic feature shown in Fig. 7A demonstrates a significant increase of the metallic SWNT percentage in the melt-blended composites. The SWNT in the UV-polymerized composite, in which PMMA exhibits no anisotropic effect, retains the same chirality as in the pristine SWNT sample.

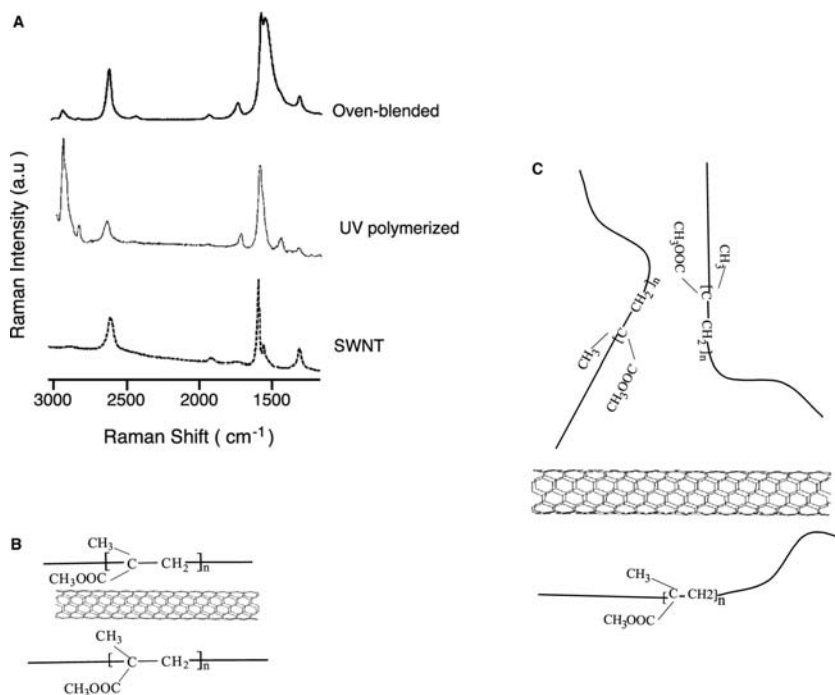

The anisotropic interfacial interaction between PMMA and SWNT in the melt-blended composite can be monitored by the PMMA backbone conformation change, especially when the C–H stretching in the backbone is amplified by Fermi resonance.<sup>[32,33]</sup> The stretching symmetry contributions from the backbone relative to the side chain are significantly different

in the two composites examined. The relative ratio of the C–H<sub>2</sub> stretch bands to the side-chain C–C and C–O stretching mode is 30% higher in the melt-blended composite than that in the UV-polymerized composite. Schematically, the C–H<sub>2</sub> stretching is little affected by the anisotropic SWNT/PMMA interactions in Fig. 7B; however, it is hindered by isotropic SWNT/PMMA interactions in Fig. 7C. Because the side-chain vibrations are not sensitive to the orientation of PMMA/SWNT interaction, the higher intensity of the C–H<sub>2</sub> stretching band suggests the likely stronger anisotropic interaction between PMMAs and SWNTs. This interaction is believed to cause metallic SWNT enrichment in the melt-blended composite.

The electric conductivity increase investigated by Raman spectroscopy was also confirmed by composite dielectric measurements.<sup>[34]</sup> The higher dielectric constant is obtained for the melt-blended composite than for the UV-polymerized composite. This is consistent with the possible dipole interaction enhanced by the anisotropic interaction between the PMMA and SWNT in the melt-blended composite. The strain-induced band gap change<sup>[35]</sup> possibly could also contribute to the increase of the metallic percentage of SWNTs in the melt-blended composites.

## Other Polymer Composites

The similar interfacial interaction effect on the conductivity in PMMA/SWNT composites has been observed in several other polymer composites.

**Fig. 7** (A) Raman spectra of the two PMMA/SWNT composites and pristine SWNT excited at 633 nm. The G-band of SWNTs in the melt-blended composite around  $1590\text{ cm}^{-1}$  is distinctly different. This line shape fits with the BWF line shape and is recognized as the signature for a metallic SWNT. The G-band in UV-polymerized composites retains the same Lorentzian line shape as in pristine SWNT. (b, c) Schematic illustrations of the PMMA and SWNT anisotropic and isotropic interactions in the melted-blended and UV-polymerized composites, respectively. The anisotropic interaction between SWNT side wall and PMMA backbone has little effect on side-chain vibrations, but will affect the backbone C–H<sub>2</sub> stretch because axial stretching can be blocked by SWNT/PMMA if not aligned.

The in situ-polymerized rigid polymer poly(*p*-phenylene)benzobisoxazole (PBO)/SWNT composite is similarly prepared as UV-polymerized PMMA/SWNT composites.<sup>[36]</sup> Its measured conductivity remained the same as that of the neat polymer, possibly because of a lack of strong interfacial interactions in the composite, which is not detectable from Raman studies.

The conductivity of polystyrene and SWNT composites formed from a miniemulsion process increases by ten order of magnitude at 8.5% SWNT loading.<sup>[37]</sup> The interactions between polystyrene and SWNT in the composites are both exhibited in the Raman spectra. The SWNT G-line at  $1580\text{ cm}^{-1}$  shifted to higher frequencies whereas the RBM upshifted. The loss of intensity of polymer C=C stretch modes at  $1670\text{ cm}^{-1}$  is also observed among the polystyrene Raman modes.

Polyimide (PI)-based composites appeared to increase electric conductivity with SWNT loading. Conductivity percolation is reached with SWNT loading between 0.02% and 0.1%.<sup>[38]</sup> The interactions in CNT/PI nanocomposites can be controlled to increase polaron mobility and quantum efficiency. The Raman results of this photovoltaic electrolyte material suggest the charge transfer mechanism correspondingly.<sup>[39]</sup>

### CHARGE TRANSFER AND STRONG $\pi$ INTERACTION IN COMPOSITE WITH INCREASED ELECTRIC CONDUCTIVITY

The SWNT G-band is very sensitive to the doping and charge process. The Raman frequency shifts depending on the types of donor or acceptor. The charge transfer between halogen or alkali metal and SWNT was first demonstrated by Raman studies<sup>[40]</sup> shown in Fig. 8. The TM frequency shifts in the SWNT sidewall around  $1550\text{ cm}^{-1}$  show the changes in accordance with the corresponding diameter changes in RBM. The charge transfer soften mode is identified as BWF interference in the alkali metal-doped SWNT bundle. The  $\pi$  electron transfer from the carbon to the acceptor ( $\text{Br}_2$ ,  $\text{I}_2$ ) or donor (K, Rb) is believed to introduce both TM and RBM changes.

The  $\pi$ -stacking of the planar pyrenylene  $\pi$ -moiety in the 1-pyrenebutanoic acid succinimidyl ester with the CNT graphite basal plane forms a very stable self-assembled composite,<sup>[41]</sup> which changes the SWNT from hydrophobic to hydrophilic nature. This structure interaction was schematically illustrated in Fig. 9. Although Raman studies are not reported for this composite, the strong interaction was investigated by another similar polymer composite in terms of charge transfer. The Raman studies of composites of the aromatic perylene-doped SWNTs are believed to have a charge transfer in the G-band modes.<sup>[42]</sup> Fig. 10 shows the similar Raman shifts as observed

**Fig. 8** Raman scattering spectra for pristine SWNT bundles reacted with various donor and acceptor reagents. From top to bottom:  $\text{I}_2$ ,  $\text{Br}_2$ , pristine SWNT, Rb, and K. The backscattering spectra were taken at  $T = 300\text{ K}$  using  $514.5\text{ nm}$  radiation. In the spectra for both halogen-doped SWNT bundles, a harmonic series of peaks (indicated with asterisk) is observed, which are identified with the fundamental stretching frequency  $\omega_s$ :  $\sim 220\text{ cm}^{-1}$  ( $\text{I}_2$ ) and  $\sim 324\text{ cm}^{-1}$  ( $\text{Br}_2$ ). The spectra have been scaled so that the strongest SWNT feature appears to have the same intensity. In the vicinity of the strongest high-frequency mode around  $1550\text{ cm}^{-1}$ , the Raman spectra for SWNTs doped with K or Rb are fitted with superposition of Lorentzian functions and an asymmetric BWF line shape on a linear continuum. Source: ©Macmillan Publishers, 1997.

in alkali and halogen doping in the SWNT. Although the strong perylene modes, such as  $1296\text{ cm}^{-1}$ , are not observed in the areas investigated by Raman spectra, the inactive SWNT vibrational modes around  $1542$ ,  $1549$ , and  $1610\text{ cm}^{-1}$  in the G-band emerge in

the composite and exhibit different degrees of enhancement because of perylene doping interaction.

The PmPV composite is well studied by various spectroscopy techniques. PmPV is an important photovoltaic and LED material in optoelectronic applications. The CNT composite is expected to improve device performance by optimizing the SWNT loading, tube length, and its chirality. The scanning tunneling microscopy (STM) results indicate that PmPV, as a coiling polymer, is interacting with SWNT with periodical surface wrapping,<sup>[43]</sup> as shown in Fig. 11. The wrappings are refractive and conform to the sidewall lattice structure of the SWNT. The electric conductivity increased up to eight orders of magnitude at 8.5% MWNT loading. At less than 7% SWNT loading, an increase of one order of magnitude to  $1.5 \times 10^{-9}$  S/m was observed; between 7% and 11% loading, an increase in conductivity of eight orders of magnitude has been observed; whereas the conductivity plateaus to 3 S/m after 36% loading.<sup>[44]</sup> The interactions in the composite possibly enhance polaron mobility through the change of the polymer backbone conformation and through a better hopping and tunneling path. It is believed that PmPV significantly reduces electron delocalization and vibrational freedom after the interaction with SWNT in the composite.

The dependence of increased conductivity on CNT loading in the composites is established by Raman studies under resonant conditions of the semiconducting

**Fig. 11** STM image of two PmPV-coated SWNTs lying on HOPG substrate. The ordered coating can be seen in the tube on the right. There are two individual tubes on the left, separating at the bottom. *Source:* ©ACS, 2002.

and metallic SWNTs, respectively.<sup>[45]</sup> At 676 nm wavelength excitation resonant with the metallic SWNT, the polymer vinylene stretch mode at  $1627\text{ cm}^{-1}$  evolves into two well-defined modes at  $1630$  and  $1625\text{ cm}^{-1}$ . The SWNT TM of  $1598\text{ cm}^{-1}$  is simultaneously downshifted to  $1593\text{ cm}^{-1}$ , whereas the  $1568\text{ cm}^{-1}$  mode disappears. The RBMs measured with laser excitation energies resonant at the semiconducting condition display the upshifts by about  $7\text{ cm}^{-1}$ ; the relative intensity ratio of the individual frequencies is also changed. The SWNT diameter distributions derived from Eq. (1) indicate that the diameters shift toward smaller size distribution in the composites. However, the D-band to G-band ratio is significantly changed, which suggests that  $\text{sp}^3$  carbon may act as the active site that interacts with PmPV. The spectroscopy evidence of these vibration symmetry changes from both PmPV and SWNT, combined with STM studies, show the helix wrapping of PmPV backbone around the MWNT sidewall with strong interactions. The luminescence study shows no quenching, which is usually associated with the charge transfer mechanism. Therefore it can be concluded that the composite conductivity increases are because of the PmPV backbone's strong  $\pi$ - $\pi$  interactions with the SWNT sidewall, rather than charge transfer mechanism.

The majority of the pristine LED polymer materials needed to be doped to achieve high-enough carrier mobility for device application. The polaron and bipolaron ratio not only reflects the conductivity of the composite, but also is the direct result of the symmetry change of the polymer because of the interaction of the CNT with the polymer.

The electropolymerized polypyrrole (PPy)/CNT thin film composite has attracted considerable attention. Being a conjugated polymer, PPy has strong electron and phonon interactions (called polaron) in the lattice. It resembles an ionic lattice, so bipolaron can form through interactions between neighboring polarons. Two significant changes in the MWNT symmetry mode are shown in the curve-fitting results of Raman spectra at 633 nm excitation.<sup>[46]</sup> First, the defect-induced MWNT shoulder peak D' at  $1612\text{ cm}^{-1}$  substantially decreased after the composite film formation. The normalized intensity ratio of D-band to G-band significantly decreases from 2.5 in the MWNT arrays to 0.4 in the composite film. This indicates that the MWNT sidewall  $\text{sp}^3$  graphitic carbon interacts with PPy. The observed decrease of the D-band intensity is similarly demonstrated in the PmPV/SWNT composite as well.<sup>[8]</sup> Therefore the symmetry of both MWNT and PPy is expected to change. Examine the bipolaron (labeled with\*) and polaron (labeled with †) pair<sup>[47]</sup> in Fig. 12. MWNT composites have much higher bipolaron contributions than in the CPE composite. Furthermore, bipolaron-only<sup>[48]</sup> mode

**Fig. 12** Raman spectra of PPy electropolymerized at (A) MWNT array electrode, and (B) at carbon paste electrode. In the MWNT/PPy composite, the dipolaron modes at  $986$  and  $1051\text{ cm}^{-1}$  (labeled with\*) corresponding to polaron modes (labeled with †)  $986$  and  $1051\text{ cm}^{-1}$  are much higher than that in the CPE/PPy composite. The bipolaron mode at  $1247\text{ cm}^{-1}$  is only observed in the MWNT/PPy composite. However, the polaron mode at  $1044\text{ cm}^{-1}$  is more predominant in the CPE/MWNT film. The skeletal band C–N stretching mode at  $1487\text{ cm}^{-1}$  shoulder is higher in the MWNT/PPy composite, indicating stronger backbone vibrations.

at  $1247\text{ cm}^{-1}$  is only observed in the MWNT/PPy composite film. However, the polaron mode at  $1044\text{ cm}^{-1}$  is more predominant in the CPE/MWNT film. In addition, the skeletal band<sup>[49]</sup> C–N stretching mode at  $1487\text{ cm}^{-1}$  shoulder is higher in the MWNT/PPy composite, indicating stronger backbone vibrations. All the Raman results suggest better PPy backbone conjugation in the MWNT composite than that in the CPE composite. When PPy electropolymerized onto the highly orientated electrode array, its backbone conforms to the MWNT sidewall. Therefore the polymer chain deformations, kinks, twists, and angle distortions between aromatic ring planes can be reduced. The high bipolaron density enhances conjugation in the MWNT/PPy composite film. Thus the resultant film is structurally very stable and highly conductive. This preferred configuration is confirmed by the SEM image of the MWNT after composite formation. The remarkable uniformity of this widely studied<sup>[50,51]</sup> composite film can be understood because of its unique nanostructural interactions.

Recently, Raman analyses have become a powerful technique to identify the separation of metallic and

semiconductor SWNTs in both the bulk quantity and the nanoscale approach.

Resonant Raman analysis is used to probe the conductivity of SWNTs treated in the polar organic solvent, with octadecylamine (ODA) possibly self-assembled onto SWNTs.<sup>[52]</sup> The Raman line shape analysis around frequency of TMs is used for gauging semiconducting and metallic features under the respective resonant conditions. The resonant Raman spectroscopy concludes the predominant semiconducting and metallic compositions in the supernatant and precipitant, respectively.

Raman study of CNT conductivity has also been successful in nanodevices.<sup>[53]</sup> Both RBM and TM frequencies are used to analyze compositions in the electrode and in the suspension after the a.c. electric field on a pair of microelectrodes laid out on the oxidized Si substrate. The induced dipole moment migrates the metallic SWNTs to the electrodes, leaving the semiconducting SWNT in the suspension. The polarized Raman also shows the highly aligned nanotube along the electric field. In this application, the in situ microscopic Raman probe demonstrates the ideal technique to study CNT conductivity beyond macroscopic chemical environments.

## CONCLUSION

Recent research progress in Raman spectroscopy demonstrates that it is an ideal technique to study the electronic conductivity of the CNT and polymer composites in two approaches. In the first approach, the vibration symmetry studies of the CNT and polymer are directly correlated with conductivity measurements, providing possible mechanisms of the composite electronic conductivity change caused by nanostructural interactions. In the second approach, Raman spectroscopy directly probes the composite electronic DOS band gap through resonant scattering. The implications of interfacial interaction, as well as charge transfer between the constituent components in the composite are studied by Raman spectroscopy. The Raman spectroscopy study will guide processing conditions, including thermal treatment and shear field strength, as well as polymerization specifications for better control in electronic and optical applications.

# Ring Structures from Nanoparticles and Other Nanoscale Building Blocks

Zhen Liu

Rastislav Levicky

*Department of Chemical Engineering, Columbia University,  
New York, New York, U.S.A.*

## INTRODUCTION

Over the last two decades nanomaterials have attracted growing interest because of their unique, potentially useful electronic, magnetic, and optical properties. For example, carbon nanotubes possess tunable electronic structure from metals to insulators. Nanoparticles can act as “artificial atoms” which, when assembled into meso- or macroscopic structures may lead to novel functional materials. Thus self-assembled particle arrays not only preserve the properties of individual particles but can also exhibit new behaviors due to interparticle correlations and coupling. The ability to organize nanoscale components into specific geometrical arrangements, with defined interconnections, underpins much of their promise for future applications as well as current fundamental studies. Here we focus on the organization of nanoparticles and, to a lesser extent, other nanoscopic building blocks into ringlike arrangements ranging over five decades of length scale, from macroscopic ( $\sim 1$  mm) to nanoscopic ( $\sim 10$  nm). In addition to the simple geometry of a ring, a variety of other arrangements have been realized. For example, following earlier reports of close-packed crystalline nanoparticle superstructures,<sup>[1–5]</sup> Korgel et al. analyzed nanoparticle self-assembly into superlattices in detail highlighting the effects of size-selection, ligand coverage, and interparticle attraction.<sup>[6]</sup> Detailed reviews on the fabrication and properties of nanoparticle superlattices are now available.<sup>[7,8]</sup> Other efforts have focused on organizing nanoparticles according to highly specific biological interactions<sup>[9–19]</sup> or using self-organized polymeric media such as block copolymers to spatially template nanoparticle synthesis and distribution.<sup>[20–28]</sup> Albeit the focus of this review restricts it from broadly considering the general theme of nanomaterial self-assembly, the above and related efforts continue to make critical advances toward functional materials and devices incorporating nanoscale components.

The formation of ringlike assemblies, whether over macroscopic or nanoscale dimensions, is intriguing for reasons other than simple curiosity about their physical or chemical origin. Thus continuous rings, for example, will develop circulating currents when magnetic flux is applied across the ring.<sup>[29]</sup> This “persistent” current has a periodicity as a function of the enclosed magnetic flux. Moreover, the electronic states of the ring are likewise functions of the applied field, leading to magnetically tunable optical and other properties that, in addition to being fundamentally interesting, may provide unique capabilities in applications. While a variety of routes to microscopic rings have been reported, including lithography,<sup>[30]</sup> direct chemical synthesis,<sup>[31]</sup> and diffusive coalescence on free liquid surfaces,<sup>[32]</sup> self-assembly of ring structures using wetting and capillary phenomena has perhaps been the most common. By its nature, self-assembly often provides a facile fabrication route, and generally similar methods can be effectively used to organize different particle types, making these methods fairly general. In what follows, various mechanisms that have led to the formation of ring structures will be described.

## SELF-ASSEMBLY OF MACROSCOPIC RINGS

Ringlike patterns formed by precipitated solute particles that are visible to the naked eye, such as coffee rings, are familiar phenomena. The formation of macroscopic ( $\sim 1$  mm to  $\sim 1$  cm) ring patterns from non-wetting droplets placed on a solid support was investigated by Deegan et al.<sup>[33]</sup> The mechanism presented by these authors invoked pinning of the contact line of the drying droplet as the carrier solvent evaporates. In order to maintain the contact line pinned at its initial position in the face of continued evaporation, a capillary flow of solvent is engendered from the interior of the droplet to its perimeter. Dispersed solute particles are carried by this resulting outflow to the edge where they accumulate (Fig. 1A). When the

droplet fully dries, a ringlike residue consisting of the accumulated particles remains. Notably, in this mechanism the ring formation is largely independent of the nature of the underlying surface, the deposited solute particles, and the carrier solvent. Maenosono and collaborators formed millimeter scale annular rings by precipitating 4–6-nm CdS and CdSe nanoparticles from a suspension droplet (Fig. 1B).<sup>[34]</sup> These authors postulated that, in addition to the pinning of the droplet's contact line as discussed by Deegan et al., convection from the suspension droplet to its perimeter where ring assembly occurs could be driven by the capillary pressure from the meniscus curvature within the porous, drying ring of nanoparticles. In this model, the capillary pressure produces an effective pressure-driven suction of solvent into the ring. Both mechanisms are potentially operative in the formation of macroscopic rings of nanoparticles and provide useful insights into how such arrays may be assembled.

## SELF-ASSEMBLY OF MICRON-SIZED RINGS

A number of investigators reported micron-scale annular ring assemblies of various nanometer subunits such as nanocrystals, nanotubes, and even small organic molecules. The origins of these microscopic structures are likely very different from those of macroscopic rings. Ohara and Gelbart observed micron-sized rings of nanoparticles,<sup>[35]</sup> possibly originating from the accumulation of particles along the rims of dewetting holes formed during the evaporation of nanoparticle suspensions on solid supports.<sup>[36]</sup> In these studies, the particle suspensions wetted the underlying support. Maillard and coworkers presented that thermocapillary flows engendered within an evaporating particle suspension could also lead to microrings and even hexagonal meshes of nanocrystals.<sup>[37,38]</sup> Stowell and Korgel observed the self-assembly of nanoparticles into rings and honeycomb networks.<sup>[39]</sup> The selection

**Fig. 1** (A) Motion of microspheres driven by the capillary flow of solvent from the interior to the periphery in an evaporating water droplet.<sup>[33]</sup> (B) Optical microscope photograph of a CdS ring with an outer diameter of 0.23 cm. *Source:* From Ref.<sup>[34]</sup>.

of a particular geometry was attributed to the variation of the thermal susceptibility of the suspension's surface tension because of the presence of nanoparticles, triggering a transition from hole nucleation in the evaporating film to Marangoni instability-induced convective flow. Microrings formed from other materials include a report by Schenning et al. of such structures generated from disk-like porphyrin molecules. These authors suspected that the rings formed as a result of hole nucleation possibly induced by foreign particles.<sup>[40]</sup> In the following discussion some of these mechanisms are examined in greater detail.

## Thermocapillary Mechanisms

As discussed by Maillard et al. and others,<sup>[37–39]</sup> convective flow driven by variations in surface tension at the free interface of a thin evaporating liquid film can engender film rupture and hence the formation of holes or dry patches around which nanoparticles deposit. The physical origins of thermocapillary flows in liquid films have been well documented (e.g., see Ref.<sup>[41]</sup> for a review). For sufficiently thin (less than about 1 mm) volatile liquid films, evaporation generates a temperature gradient between the film's lower and upper boundaries due to the removal of latent heat, leaving the free upper surface cooler. Local fluctuations in the extent of cooling cause variations in the interfacial tension of this interface, with surface tension  $\gamma$  typically decreasing with temperature  $T$  according to a thermal coefficient  $B = -d\gamma/dT$ . As a result, the liquid from warmer surface regions where the interfacial tension is lower is pulled along the surface to spread over the cooler regions, where it is forced to move downward into the film as it cannot accumulate without limit. Simultaneously, warm liquid is fed upward to the warmer surface regions. Viscous coupling propagates this convective flow throughout the film to establish three-dimensional convective cells as illustrated in Fig. 2.

As evaporation proceeds, the thinning film may eventually rupture at the accompanying depressions, exposing the nearly bare substrate to form holes.<sup>[42–44]</sup> Evaporation and/or interfacial dewetting then drive the growth of the holes. When film rupture and subsequent hole growth occur in a suspension layer of nanoparticles, the particles can collect at the expanding hole rims eventually leaving behind drying patterns in the shape of rings (Fig. 3A). Possibly, the hole rims become pinned before complete drying of the film due to a build-up of frictional interaction between particles accumulated at the hole rim and the underlying surface.

A dimensionless Marangoni number,  $M_a = (B\Delta T h)/(\rho\nu\kappa)$ , is customarily used to compare the time

**Fig. 2** Illustration of thermocapillary convective flows in volatile liquid films. The mean temperature drop across the film is  $\Delta T$ .  $\lambda$  is a characteristic wavelength of the induced convective cells.

scale for the propagation of temperature disturbances across the thickness of the film with that needed to establish convective flow.<sup>[45,46]</sup> Temperature perturbations leading to the establishment of convective flow must be sufficiently long lived, corresponding to a critical  $M_a$  value above which convective flow becomes possible, and below which Marangoni instabilities will not appear. The critical  $M_a$  depends on the boundary conditions at the film's interfaces.<sup>[45,46]</sup> At the most basic level, convective flow is favored by greater temperature variation across the film ( $\Delta T$ ), film thickness ( $h$ ), and susceptibility of interfacial tension to variation in temperature ( $B$ ), but is suppressed by increases in the liquid's kinematic viscosity ( $\nu$ ), density ( $\rho$ ), or thermal diffusivity ( $\kappa$ ).

## Wetting Mechanisms

For apolar liquids and surfaces interacting purely via long-range dispersive forces, a drop of solvent placed on a solid support is typically characterized as either "wetting," meaning it thins so as to fully cover the support, or "non-wetting," meaning it beads up and forms a finite contact angle with the solid support. More completely, a set of classification rules can be devised that incorporate not only long-range apolar interactions but also short-range "contact" forces due to polar interactions.<sup>[47]</sup> By appropriate balancing of short polar and long-range apolar interactions, additional wetting states become possible including coexistence of thin wetting films with macroscopic, non-wetting droplets, and of dewetting thin films even when thicker layers of the same liquid wet. In considering the formation of microring assemblies from evaporating films, the approximation of either strictly (i.e., irrespective of film thickness) wetting or non-wetting liquids is usually sufficient as the surfaces and organic solvents used have been largely apolar in nature.

Ohara and Gelbart theoretically analyzed microring formation from evaporating particle suspensions when the suspension wets the surface.<sup>[35]</sup> Their analysis was motivated by accompanying experiments in which dilute nanoparticle solutions in wetting organic solvents such as hexane or toluene were spread on carbon-coated TEM grids and allowed to dry.<sup>[36]</sup> Drying patterns consisting of  $\sim 1\text{-}\mu\text{m}$ -diameter rings were found (Fig. 3B). As a wetting liquid film evaporates,

**Fig. 3** (A) Microrings formed from ferrite nanocrystals precipitated out of hexane after deposition on a TEM grid under air.<sup>[37,38]</sup> (B) A microring of organically functionalized Ag nanocrystals precipitated out of hexane solution.<sup>[35]</sup> (C) Porphyrin rings generated from evaporating chloroform solutions.<sup>[40]</sup> (D) Microrings of gold nanocrystals prepared by spin coating from octane solutions on a polymer film (surface defects were indicated by red circles). (E) Nanotube rings formed after irradiation of bulk suspensions with ultrasound. *Source:* From Ref.<sup>[50]</sup>.

it will continue to thin until the film thickness decreases to nearly molecular dimensions, on the order of a few nanometers. At this stage, further thinning leads to increasing loss of attractive liquid–liquid dispersive interactions, which prefer to thicken the film. Ohara and Gelbart argue that, rather than dry uniformly to zero thickness, the film may seek to maintain a minimal thickness  $t_e$  to counteract the loss of favorable liquid–liquid interactions, following a previous theoretical analysis for non-volatile liquid films by de Gennes.<sup>[48]</sup> In their model, as evaporation proceeds, the drying film will develop holes which will expand so as to maintain remnant wetted regions at the thickness  $t_e$ . The holes would open once the film thickness decreases sufficiently for free energy barrier to hole nucleation to become comparable to the thermal background  $kT$ , where  $k$  is the Boltzmann constant. For typical solvents this occurs at thicknesses of  $\sim 1$  nm. Once holes open and grow, nanoparticles can collect at the receding rims in a manner analogous to that described above for thermocapillary flows, leaving behind drying patterns in the shape of rings. Alternately, for sufficiently thin wetting films, holes can nucleate simply by spontaneous local evaporation of liquid molecules to form a dry patch or because of the presence of surface heterogeneities (e.g., a small non-wettable region).

Schenning et al. observed micron-sized ring assemblies composed of porphyrin molecules.<sup>[40]</sup> Their experimental procedure was similar to those used to form rings of nanoparticles. A droplet of porphyrin molecules in a solvent such as chloroform was placed on a substrate and allowed to evaporate for 10 sec, followed by draining of the remaining solution with filter paper. These authors suggested that the ringlike patterns originate from the nucleation of holes engendered by possibly combined influences of 1) non-wetability of the surface by the liquid; 2) progressive thinning of the liquid due to evaporation; and 3) deposition of foreign particles (e.g., from the laboratory ambient) that lowers the free energy barrier for hole nucleation. As the holes nucleate and grow, porphyrin molecules would accumulate at the rim increasing their concentration. Eventually, the concentration will exceed solubility and a condensed porphyrin phase will precipitate out to form the ring structures (Fig. 3C).

Liu and Levicky observed that spin coating of nanoparticles from organic solvents on polymer films produced micron-sized rings very similar to those reported by Ohara et al. and others.<sup>[35–40]</sup> Spin coating instead of droplet drying was used to better control deposition conditions. Samples for transmission electron microscopy (TEM) were prepared as reported previously.<sup>[28]</sup> From TEM micrographs, these authors identified that microrings formed around defects in the polymer film (Fig. 3D). Based on this evidence, ring

formation was attributed to defect-induced nucleation of holes in the spin-coated particle solution followed by particle accumulation at the hole rims, leaving microring drying patterns as discussed above. The defects appear white in the images (Fig. 3D), suggesting that the polymer film is thinner (possibly punctured) at those locations. Others have similarly connected surface topography with nucleation of holes and subsequent formation of drying patterns. For example, step edge defects on highly oriented pyrolytic graphite surfaces led to the formation of ringlike patterns from drying collagen solutions.<sup>[49]</sup>

Microring assembly will, in general, also depend on other factors such as solute concentration and evaporation speed. Clearly, rings cannot form if the solute (e.g., nanoparticle) concentration is too low because of the insufficiency of available material. Moreover, microring formation, at least in wetting systems, appears favored by faster rates of evaporation. For instance, in experiments by the present authors in which nanoparticle suspensions were spin coated from relatively low volatility, wetting solvents such as octane, microrings did not form if the deposition speed was below 100 rpm or if static evaporation was used. Presumably, under such wetting conditions, a nucleated hole can quickly seal unless solvent evaporation from the hole rim is sufficient to ensure hole growth.

### Other Types of Microrings

Microrings of carbon nanotubes have also been reported.<sup>[50,51]</sup> Martel and coworkers observed microrings of single-walled carbon nanotubes (SWNTs) following ultrasound irradiation of nanotubes in a warm solution of sulfuric acid and hydrogen peroxide (Fig. 3E). This process shortens the SWNTs and evidently can cause them to coil into rings. The physical origin of coiling was suggested to stem from tube bending due to the nucleation of bubbles on the hydrophobic surfaces of the SWNTs during ultrasound irradiation, followed by subsequent bubble collapse. Once a tube becomes coiled into a ring, the strain energy of bending can be balanced by physical van der Waals attraction along the nanotubes. This renders the rings highly permanent, sufficiently so that they can be recovered by filtering. High yields of rings, up to 50%, were reported.

### SELF-ASSEMBLY OF NANOSCALE RINGS

Rings with diameters ranging from 10 to 100 nm have been made out of magnetic nanoparticles or metal nanocrystals by several groups. In contrast to

**Fig. 4** (A) Nanorings formed by 16-nm cobalt nanoparticles.<sup>[13]</sup> (B) Nanorings composed of 2.5-nm gold nanocrystals, formed by spin coating from octane solutions.

micron-sized rings, these structures are approximately one particle wide along their perimeter (Fig. 4). The self-assembly mechanisms, as may be expected, are distinct from those effective for forming macro- or microrings and involve magnetostatic particle interactions in the case of magnetic nanoparticles.<sup>[52,53]</sup> The present authors have also assembled nanoscopic rings from metal nanoparticles by spin coating nanoparticle solutions on thin polymer films.

### Magnetostatic Mechanisms

Tripp et al. synthesized weakly ferromagnetic cobalt nanoparticles (~30 nm in diameter), possessing a 3- to 0.4-nm oxide layer.<sup>[52]</sup> The nanoparticles were dispersed in toluene or  $\text{CH}_2\text{Cl}_2$  in the presence of a resorcinarene as a stabilizing surfactant. Droplets of nanoparticle solution containing surfactant were deposited on carbon-coated TEM grids and allowed to dry. If the concentration of surfactant was sufficiently high, this procedure produced a large population of nanorings with diameter in the range of 50 to 100 nm. A possible mechanism for ring formation is minimization of magnetostatic energy realized when a string of magnetic dipoles (i.e., a string of “head-to-tail” aligned ferromagnetic Co nanoparticles) closes, thus eliminating unpaired magnetic poles at its ends. Notably, without sufficient surfactant the Co nanoparticles aggregated into dense, continuous layers or “rafts.” The need for the non-volatile resorcinarene surfactant in the assembly of rings was believed to stem from kinetic stabilization attributed to the enhancement of the viscosity of the deposited particle layer. Otherwise, at low surfactant concentrations, the nanoparticles were sufficiently mobile to rearrange into more thermodynamically stable, dense aggregates. Other aggregate structures, such as oriented strings of particles, were also identified with preference for a particular geometry somewhat adjustable by application of external magnetic fields.

A previous report by Puntès et al. similarly described, among many other structures, the self-assembly of nanorings from ferromagnetic Co

nanoparticles (Fig. 4A).<sup>[53]</sup> Closed motifs, such as nanorings, did not form with smaller Co nanoparticles that were superparamagnetic rather than ferromagnetic. These results indicate that the permanency of the particles’ magnetic dipole plays a crucial role in facilitating the formation of closed loops or rings. In the work of Puntès et al., the Co nanoparticles had a thin organic coating and were deposited onto carbon-coated TEM grids from evaporating suspensions.

### Assembly of Nanorings on Polymer Films

Polymer media have been used to template spatial distributions of nanometer-sized particles in a variety of ways, including in situ synthesis of nanoparticles in ordered block copolymer matrices,<sup>[54–56]</sup> introduction of premade nanoparticles into the bulk or on the surface of such media,<sup>[25,57–61]</sup> or via additional routes exploiting polymeric micelles<sup>[62,63]</sup> or multilayered structures.<sup>[64–69]</sup> Liu and coworkers have been investigating the organization of nanoparticles in polymer “brushes,”<sup>[28]</sup> which are monolayers of polymer chains tethered by one end to a planar support. The polymer brushes consist of poly(ethylenepropylene) (PEP) chains and are typically between 5 and 20 nm in thickness. The PEP chains incorporated a shorter polystyrene (PS) endblock to provide anchoring to an underlying film of PS homopolymer. Dodecanethiol-stabilized gold nanoparticles about 2.5 nm in diameter were spin coated on top of the polymer brush from octane and their drying patterns imaged by TEM. On some specimens, rings of nanoparticles 10 to 50 nm in diameter were observed in high yields (Fig. 4B). The underlying physical cause of ring assembly has not yet been identified.

### CONCLUSION

Fabrication of structures at submicron length scales is a difficult yet crucial capability in advancing devices and technologies that may one day incorporate nanomaterials. Prospective examples of applications include novel analytical tools, ultrasmall chemical sensors, optoelectronics, and new reagents and catalysts for use in chemistry and biology. The last few years have seen rapid developments in the self-assembly of a variety of structures from nanoparticles and other components such as nanotubes or nanorods. This brief review has specifically emphasized the methods for organizing tiny building blocks into ring-shaped assemblies, with the predominance of the responsible physical phenomena traced to wetting and hydrodynamics of thin liquid films. Even as the theme of self-assembly in nanomaterial science continues to expand,

as illustrated by this report, at least for specific geometries general methods can begin to be formulated.

# Risk Assessment and Benefits

Douglas Mulhall

Marsh Harbour, Bahamas

## INTRODUCTION

Risk assessment is the foundation of our capacity to evaluate economic, health, and ecological impacts. Yet, a wave of scientific discovery is transforming our understanding of not only risk but also the environments that sustain us. This will force basic changes to how we evaluate risk and make decisions to restrict new technology.

Until we acknowledge such changes and incorporate them into our assessment of risk, it will not be possible for detractors or supporters of nanotechnologies to accurately evaluate their risks and benefits.

## OVERVIEW

Some critics perceive the risk of nanomaterials as too great to go ahead with until we study them further.<sup>[1]</sup> The most often-cited example is the risk that out-of-control nanomachines, which use carbon-based life forms for an energy source, will turn everything alive into “gray goo” as they multiply. Technology luminaries such as Eric Drexler and Robert Freitas,<sup>a</sup> Ray Kurzweil and Bill Joy,<sup>b</sup> along with science fiction writers such as Michael Crichton<sup>c</sup> have explored such potential threats. Related debates have often spilled over into the legislative arena as governments have limited development of biotechnologies such as stem cell research,<sup>[6]</sup> while initiating investigations into ways of restricting nanotechnology.<sup>[7]</sup>

These debates are similar to those presented in the early 1950s when it was postulated that nuclear proliferation would get out of control and lead to

contamination of the whole world. As with the nuclear argument, critics say that this new generation of technologies may be too volatile to control. Similar arguments were made about the machine gun at the turn of the century. As every new major technology comes along, fears are expressed that it may annihilate humanity.

Many scientists disagree with these arguments and say that the potential benefits outweigh the potential risks.<sup>d</sup> They point to near-term benefits such as nano-scale methods that can detect and target diseases far more precisely and less invasively than we do today. Vast improvements in energy efficiency created by a new generation of solar cells may also solve our energy supply problems, they argue. They say further that while the destructive power of technologies has been growing enormously, this has not hindered the expansion of civilization on Earth so far.

So we are faced with a familiar quandary: risk the benefits or eliminate the risks?

Principles for controlling powerful technologies, so that we can manage risks and get benefits, have been around for some time. For example, as early as 1950 the well-known science fiction writer Isaac Asimov put forward his “Laws of Robotics.”<sup>[9,10]</sup> Organizations that specialize in nanotechnology, such as the Foresight Institute have developed principles for managing nanotechnology risks.<sup>[11]</sup> Still other organizations such as the Center for Responsible Nanotechnology have drafted ethical guidelines to help cope with disruptive economic and social impacts.<sup>[12]</sup>

These works are each helpful. Together they may constitute the beginnings of a regulatory framework for administering technology risks. Yet by themselves and together they are still incomplete.

This article briefly describes three considerations that could transform the debate: *Technologies that merge with ecology, enhanced intelligence, and punctuated equilibrium*. Finally, the article shows how these discoveries may completely change the regulatory

<sup>a</sup>The term “gray goo” was put forward by Eric Drexler in 1986 in Ref.<sup>[2]</sup> and has been extensively quoted and misquoted. For a summary of the gray goo discussion, see Ref.<sup>[3]</sup>.

<sup>b</sup>Sun Microsystems co-founder Bill Joy<sup>[4a]</sup> revitalized the concept of voluntary relinquishment of dangerous technologies that was put forward by other scientists in relation to earlier technologies such as nuclear weapons. Inventor Ray Kurzweil disagrees with this approach. A summary of the discussion is found in Ref.<sup>[4b]</sup>.

<sup>c</sup>Eric Drexler’s 1980’s description of uncontrollable nanobots was given great popularity by the science fiction novel: Ref.<sup>[5]</sup>.

<sup>d</sup>Updates on the nanoethics debates, are found in the December and February newsletter of Ref.<sup>[8]</sup>.

paradigm. This entry is necessarily limited on space and I encourage the interested reader to look at my book-length work *Our Molecular Future*<sup>[13]</sup> and the reference list for more details and information.

## BACKGROUND

Some scientists have begun to describe a point known as the “Singularity,” where the rate of technology convergence makes it impossible for human beings to accurately forecast the near future. If this point is approaching, then it seems that all the present discussions by environmentalists, scientists, and government regulators over how to regulate nanotechnologies may soon become moot, because the process will be out of our hands regardless of what we do, unless we impose a draconian ban on all new technology development. Given our history, such a ban seems improbable; therefore we must consider the implications of exponentially accelerating technologies.

The ideas that *Homo sapiens*—as we are presently constituted—won’t be able to control our own destiny, and that some other form of development that we can’t comprehend right now may take over from present paradigms, seem so fatalistic that many people don’t dare to consider such thoughts. These confound the basic human tenet of belief in the future. Yet with technology rapidly progressing, and with the particularly accelerating advances in nanotechnologies—that are described throughout this encyclopedia—we must consider such a possibility as a starting point in the discussion over how to regulate the risks posed by new technologies. Nor do we need to be fatalistic about it, because there are avenues whereby we can participate in the accelerated evolution that has begun to occur.

Just in the same way that the atomic bomb transformed the concepts of security and war, so advanced technologies are already upending conventional notions of evolution. For example, it has now become clear that computers have started to solve problems in ways that their human designers do not comprehend. Chess Grand Master Gary Kasparov acknowledged this reality many years ago when, after having been defeated by a computer at his own game, he stated that he had lost to “an alien.”<sup>[14]</sup> This was rapidly followed by the development of genetic computing where software using genetic algorithms was used to design circuits in ways that human designers couldn’t fully comprehend.<sup>[15]</sup>

Why is this so relevant right now to the discussion over regulation of nanotechnology?

The extrapolation to be drawn from this is that because some computers already exceed human intelligence in limited areas, that nanotechnology-enabled artificial intelligence will increasingly supercede our

own. Given that it would be extremely difficult to regulate something that is smarter than a human, again we are confronted with this possibility that the regulatory discussion is moot.

However, such a viewpoint—and the fears expressed about “runaway” technology—overlook one central development. Human intelligence and machine intelligence are beginning to merge. As they do, the possibilities for anticipating and regulating development of further technologies take on a new light.

The perceptual problem that we face today is that most discussions over regulation of nanotechnologies are based on the assumption that while technology continues to evolve rapidly, *Homo sapiens* will somehow continue to evolve as we have for millennia: slowly and biologically. If this is true, then we can stop the discussion over regulation, because the rate of technological evolution is already exceeding the rate of biological evolution, and will render *Homo sapiens* intelligence obsolete or at least inferior.

However, this article looks at another possibility: that evolution of human intelligence is about to accelerate past our biological limitations into another realm. If so, this will transform the regulatory landscape.

Furthermore, our growing understanding of the natural environment is showing us that we may have no choice but to proceed, because history demonstrates that sooner or later nature will create conditions that make our existence on Earth difficult or untenable unless we take measures to protect ourselves.

## NEW FACTORS THAT MAY TRANSFORM RISK ASSESSMENT

Using Life Cycle Assessment methodologies,<sup>[16–18]</sup> combined with an examination of new technological developments and new discoveries about the natural environment, these emerging theories and technologies can be identified as having the potential to profoundly transform the present paradigm of technology regulation.

### Technologies That Merge with the Natural Environment

Ray Kurzweil, who pioneered technologies such as the flatbed scanner, argues that technology is a continuation of evolution by other means.<sup>[19]</sup> This implies that our technologies are becoming an integral part of the ecology. What are the physical manifestations of this?

Smart Dust<sup>[20]</sup> comprises a massive array of micro-machines made of nanoscale components that ride on air or water currents, undetectable to the human eye. Each expendable machine can have a camera,

communications device, and varying sensors for chemicals, temperature, and sound. It has its own rechargeable energy source. It can serve as the eyes, ears, nose, and guidance mechanism for everyone from soldiers to hurricane watchers. It may soon cost a fraction of a penny to manufacture, and its prototype exists today. It forms part of a massive array that delivers information to one or hundreds of computers in one or many locations. It may soon be in our environment in the trillions, delivering information about everything from troop to sewage movements.

This nanoscale level of incursion into—and integration with—the ecology suggests emergence of an *intelligent environment*. Just as the natural environment exercises its own type of intelligence by passing on information from generation to generation via DNA, so we are creating an intelligent human-built environment not just alongside that, but also as part of it. An intelligent environment has elements that are able to sense virtually every part of the ecology, from the epicenter of earthquakes to the heart of a hurricane and the heartbeat of every species, then interpret what this means and how to react. Right now, we are only at the very first primitive stages of this, but our sensing capacities are accelerating.

Such intelligent particles are also gaining the capacity to *self-assemble*. Several universities have pioneered self-assembling photovoltaic materials that generate and conduct an electric current (see entry on “Photovoltaics for the Next Generation: Organic-Based Solar Cells”).<sup>[21]</sup> These materials can be painted onto surfaces, thus eliminating the need for solar panels. Such chemical self-assembly is only a primitive precursor to molecular assembly that is described in other entries to this encyclopedia.

When we combine self-assembly with intelligent sensing at the nanometer scale, then multiply it a trillion-fold, we see that our technology is becoming an integral part of the ecology instead of just impacting it, and that human technologies may soon be indistinguishable from the natural environment. This is a profound transition.

Furthermore, such pervasive intelligence is developing outside the human brain, but also in deep contact with it.

### Enhanced Intelligence Changes the Groundrules

Hans Moravec, of Carnegie Mellon’s Robotics Institute, has shown convincingly—as have others—that the rate of acceleration in information processing is logarithmic.<sup>[22]</sup> Not only is the capacity to process ones and zeros multiplying, but the *rate* at which it is multiplying is also increasing.

For millennia, this exponential rate was barely perceptible, because it took thousands, then hundreds,

then tens of years for such capacity to multiply, from the abacus to the microprocessor, and now the nano-processor.

Today, this exponential acceleration enables superfast manufacturing by machines and software. An example of this is desktop manufacturing that is transforming desktop printing into three-dimensional desktop manufacturing of products.<sup>[23]</sup>

Such hyperchange is upending the ground rules for intelligence, and by extension for environmental risk management.

Most risk assessment today implicitly assumes that evolution of human intelligence will proceed in the same way that it has over the past few thousands of years—that is, gradually.

Here are examples of why this assumption may be wrong.

In 2001, a computer used “genetic computing”<sup>[24]</sup> to build a thermostat and actuator that were superior to the counterparts designed by a human. The computer’s programmers were unable to trace how the computer reached its conclusion. This is because genetic algorithms allow computers to solve problems in their own way without human intervention.

Machines with enhanced intelligence do certain things far faster and better than we do. Not everything, but many things. Stockbrokers now use algorithms that forecast commodity markets more accurately than humans do.<sup>[25]</sup> Satellites that repair themselves and make unilateral data transmission decisions are already in orbit.<sup>[26]</sup>

Moreover, massive networks are enhancing our own intelligence. It is now possible for the layperson to perform Internet searches in real time to get answers to complex questions. This acceleration in data retrieval *by the general population* constitutes a mass enhancement to our own memories.

At the more specialized level, remote robotic surgery is creating a networked medical “mind” that can perform operations in and from many locations at once.<sup>[27]</sup>

The extraordinary development is that human intelligence and primitive forms of machine “intelligence” are merging already. This is apparent from the use of artificial retinas for the blind, where computer microchips are implanted in the eye then connected to the optical nerve. They interpret and relay visual information to the brain. The merging of human intelligence with genetic algorithms and massive networks is being applied to modeling of, for example, climate change, but it has only just begun to be applied to evaluation of phenomena such as those described below.

### Understanding Punctuated Equilibrium

The theory of *punctuated equilibrium*<sup>[28]</sup> was first proposed in 1972 by Niles Eldredge and Harvard

evolutionary biologist Stephen Jay Gould.<sup>[41]</sup> This holds that evolutionary change occurs relatively rapidly in comparatively brief periods of environmental stress, separated by longer periods of evolutionary stability. After many years of skepticism, their theory is now gaining acceptance. This is because proof is emerging.

Intelligent tools, such as those described earlier, are helping us to discover that the natural ecology experiences periodic instability that threatens our society; not just in the extended time frames that we used to think.

In 1994, Comet Shoemaker–Levy 9 (SL9) hit Jupiter,<sup>[29]</sup> blasting holes the size of Earth in its atmosphere. Had this hit the Earth, human life would have been virtually extinguished. Only recently have we developed the tools to see such distant impacts, and until such technologies were invented we could only theorize about how often catastrophic collisions occur.

Before that, it was thought that such upheavals happened only every few million years and that we'd have lots of time to see them coming. SL9 demolished this idea. It demonstrated that we live in a galaxy where life can be snuffed out on a planetary scale without warning—in this era, not just the distant past.

Furthermore, scientists have found that smaller events have upset the ecology here on Earth. Ice core and tree ring records show that around the year A.D. 536 an unknown event triggered a catastrophic cooling of the Northern Hemisphere, resulting in years without summers that led to wholesale crop failures and starvation.<sup>[30]</sup>

Thousands of samples taken from ice cores and tree rings around the world show that naturally induced climate flips occur more frequently than we once thought they do, and that they don't only unfold over centuries but also erupt in a few years.<sup>[31,32]</sup>

At the regional scale, in 1700, a fracture at the Cascadia subduction zone produced a gigantic tsunami that scoured much of the Pacific coast for miles inland, where many of our cities now stand.<sup>[33]</sup> In 1958, a 1,500-foot wave swept away a forest after a mountain collapsed into Lituya Bay, Alaska.<sup>[34]</sup>

At the nanometer scale we are also getting a surprise. Researchers have discovered vast numbers of nanoscale organisms that are a hundred times smaller than most bacteria. In geology, they are named nanobacteria,<sup>[35]</sup> nanobes, and nanoarchaea.<sup>[36]</sup> In human ecology, a similar-sized entity has been labeled *Nanobacterium sanguineum* or blood nanobacteria.<sup>[37]</sup> Despite the name, it may not be a bacterium at all, but instead seems to be a newly discovered infection with the unusual ability to form a tough shell consisting of the same type of calcium found in many diseases. For decades, researchers have seen evidence that epidemic illnesses such as heart disease are triggered by infection.<sup>[38]</sup> This was proven for stomach ulcers

decades ago, but for other illnesses no one could find a culprit. Now it seems that one has been discovered,<sup>[39]</sup> as chronicled in the book *Has Heart Disease Been Cured?*<sup>[40]</sup>

If the existence of such organisms turns out to be valid after the hot discussion over them is resolved, then it may fundamentally alter our understanding of how ecology works, what constitutes an ecosystem, and how epidemics decimate populations.

The reality that has been overlooked by environmental agencies and theorists is that many of these nano- and macro-scale phenomena pose deep threats to our society. Agencies such as the United States Federal Emergency Management Agency (FEMA) and United States Environmental Protection Agency (EPA) have few defenses against them. Such agencies usually do not consider how to adapt to climate altering super-volcanoes or epidemics from strange nano-organisms, because these are perceived as indefensible, or they haven't entered the awareness of the organizations yet.

Thus, punctuated equilibrium is not part of the risk assessment framework. As such, a chunk of the equation is missing. This is especially true when considering the relative risks and benefits posed by nanotechnologies. Such technologies may be driving the next “punctuation” in evolution by upending longstanding paradigms. At the same time they may give us the tools to protect ourselves from newly discovered big natural threats. Such is the contradictory reality of the two-edged sword.

## MATCH NATURE'S COMPLEXITY

The convergence of these discoveries may let us achieve something that we have only dreamed of until now: how to match nature's complexity.

Right now, most of our technologies are unable to match the complexity of natural environments. For example, we use antibiotics to cure bacterial infections, but they lose their potency when the environment that they work in adapts to them. We build power lines to survive ice storms, but our miscalculation of the worst scenarios leads to collapses that paralyze our high-technology infrastructures.

Most of our agricultural, medical, energy, transportation, and housing systems are in a constant struggle to respond to the complexity of the natural environment.

Yet this imbalance may shift. Molecular technologies are empowering us to find solutions that replicate natural processes at the molecular level (for some examples, see entries on “Biomedical Applications: Tissue Engineering, Therapeutic Devices, and Diagnostic Systems” and “Nanomaterials: New Trends.”).

We may see energy grids based on solar “paint” that slash the political and economic risks associated with fossil fuel infrastructures. Our drugs may be so precise that they backfire only occasionally instead of generating widespread immune responses as they do now.

This nascent capacity to match nature’s complexity constitutes the next environmental revolution. Over the centuries, such efforts to replicate natural processes have been criticized as arrogant and unachievable approaches to nature, and today are sparking a political and religious furor. Nonetheless, they may soon force us to redefine the boundaries of risk assessment.

## WHAT TO DO

These new realities—enhanced intelligence, technologies that merge with the environment, and newly understood evolutionary paradigms—are the elephants in the room of risk assessment. To cope with them, we must initiate a new regulatory discussion. We must first acknowledge that the yardsticks for measuring risk are being moved dramatically by our own rapidly expanding knowledge.

Just a few small examples: Although nanoscale organisms have been identified in geological formations and the human body since the early 1990s, few projects have examined the implications for human or natural ecology or for environmental chemistry. NASA is studying it, as are the universities of Texas, McGill (Canada), Regensburg (Germany), Kuopio (Finland), Melbourne (Australia), and others. However, no major government initiative is considering the implications. At the opposite end of the scale, few if any governmental, environmental, or disaster preparedness agencies are examining newly discovered mega-scale anomalies such as the naturally induced climate flip of circa A.D. 536, or the giant west coast tsunami of 1700. These would certainly disrupt natural ecosystems and civilized society if they recurred today, and evidence suggests that they may.

No disaster preparedness or environmental agency yet examines how nanotechnologies might be used for adapting to such phenomena. Future initiatives may develop, but at this time they are not apparent. To rectify this, the author has suggested that a forum be held under the auspices of one or several of the nanotechnology Non-Governmental Organizations such as The Foresight Institute or Center for Responsible Nanotechnology, to examine such an issue.

Examples of technologies that might help us to adapt to “nature’s time bombs,” and to explosive risks that may be posed by nanotechnologies themselves, include:

- Artificially intelligent software that is transforming the way that we make products and carry out

business. The role that artificial and enhanced intelligence will play in risk assessment is so far understudied and overlooked. This takes us to the heart of the issue of evolution of human intelligence relative to thousands of years of biological evolution. Likewise, technologies that are merging with the human body and mind, such as artificial retinas and other implants, merit far greater attention, as these are the stepping stones to development of *Homo sapiens* who have enhanced evaluative capacities.

- Superstrong nanostructured materials such as aerogels that exist now and that may let human settlements withstand mega-hurricanes, earthquakes, and tornadoes without causing more environmental damage than they prevent. Furthermore, the self-assembling and disassembling properties of other newer materials may protect us from more serious near-earth object threats that are now considered impossible to defend against, and that have been badly misjudged as too infrequent to worry about.
- “Desktop manufacturing” that may replace thousands of polluting factories while producing materials such as self-assembling solar materials that may stabilize our energy supplies.
- Nanomedicine that is opening the doors to new solutions for many prevalent diseases, and that may stop epidemics that have retarded human progress for millennia.
- Many other technologies that are cited throughout this encyclopedia and constitute an excellent basis to start with.

Of equal importance is the process used to evaluate them. By expanding the interdisciplinary approach to technology, it is possible and necessary to bring together experts in fields that are infrequently combined. These include:

- Computer scientists who have applied artificially intelligent software to technologies that might be used for environmental adaptation and risk assessment.
- Biochemists, geologists, and physicians who discovered nanobacteria in the environment and human body, and also developed treatments that seem to reverse nanobacterial infections.
- Climatologists, geologists, and astronomers who uncovered evidence of recurring climate disruptions, giant tsunamis, and near-earth object collisions.
- Scientists who have developed adaptive technologies such as desktop manufacturing and self-assembling photovoltaic materials that may let us adapt rapidly to big ecological changes.
- Critics who have proposed moratoria on nanomanufacturing.

## CONCLUSION

By focusing such wide-ranging expertise on the challenges depicted in this article, risk assessment could be made into a more effective tool for proponents, detractors, and users of advanced technologies.
