volume  $v_t$  can be roughly computed as  $d_{\text{pp}} \approx 6(v_t / \pi n_0)^{1/3}$ , assuming the whole residual volume to be virtually occupied by the nanoparticles,  $v_t \sim n_0 v_p = (\pi d_{\text{pp}}^3 / 6) n_0$ . As the evaporation proceeds and  $v_t$  decreases, the long range vdW and electrostatic forces, to which one should add diffusion and electrostatic forces, vary respectively, as  $(1/n_0)^{2/3}$  and  $\exp(-1/n_0^{1/3})$ , and control particle sticking and bulk cluster formation in the drying suspension. A simplified phenomenological picture of these structural changes within the drying suspension, as expressed by the time dependence and spatial variation of the volume fraction  $\phi_t$  with the drop radius, is sketched out in Fig. 6D. Actually, these concentration-dependent morphological transitions and the existence of critical volume fractions are well known from phase diagrams studies of colloidal suspensions.<sup>[25]</sup> Finally, whenever the bulk conditions (threshold  $\phi^*$  and related seeds formation) are satisfied in a drying drop, both the emergence and morphological features of the complex patterns exclusively depend on the late-stage dewetting and hydrodynamics, which are controlled by the underlying substrates properties, as further evidenced by the drying patterns shown in Fig. 7. These results are obtained for the same general drying conditions of “30 nm susp” drop of volume fraction  $\phi = \phi_{\text{ref}}$ , on *precoated*  $\text{NH}_2$ ,  $\text{CH}_3\text{-NH}_2$ , and  $\text{NH}_2\text{-CH}_3$  substrates (substrates bearing the adsorption layer formed by deep-coating). Once again, the change in the complex aggregate morphology is strongly determined by the wetting properties and specific topology of these precoated substrates. While the patterns (not shown here) obtained on the precoated  $\phi\text{-NO}_2$  substrate are all comparable to the ones already observed on the virgin one, more complex aggregates now appear at the *precoated*  $\text{CH}_3\text{-NH}_2$  (Fig. 7A) and the initial coarse dendrites, which were formed on the virgin substrate, are now much finer. On the other hand, more qualitative differences emerge on *precoated*  $\text{NH}_2$  (Fig. 7B) and  $\text{NH}_2\text{-CH}_3$  (Fig. 7C) substrates. Contrary to its virgin homologous, large-scale multibranching aggregates, quite similar to those observed on virgin  $\text{NH}_2$  and  $\text{NO}_2$ , now appear on *precoated*  $\text{CH}_3\text{-NH}_2$  substrates. The most significant change arising from precoating is observed at  $\text{NH}_2$  substrate (Fig. 3B) where much finer and highly ordered fractal aggregates are formed (Fig. 7B), whose symmetry depends on the location in which they are formed along the drop radius. Whereas symmetric aggregates appear in the late stage of the drying at the center of the drop, during the dewetting (rupture) of the residual suspension film, the asymmetrical ones are formed at the periphery of the receding drop. The determining fingerprint of the underlying surface properties (wetting, topology), which shows up in the aggregates morphology, thus

**Fig. 7** Drying patterns of the reference volume fraction “30 nm susp” drops at the precoated substrates, showing the two structural types of aggregates formed on (A)  $\text{CH}_3\text{-NH}_2$  and (B)  $\text{NH}_2$ , and (C) the representative aggregation pattern observed on  $\text{NH}_2\text{-CH}_3$ .

seems to arise through the late-stage hydrodynamic shear that develops during the dewetting, and structures both the confined seeds (bulk clusters) and free particles in the residual film. The parameters that control this shear structuring are 1) the receding contact angle  $\theta_r$  and 2) the surface topography (roughness, porosity) of the substrate, which determines the magnitude of the shear stress experienced by the seeds. Assuming interface tension gradients,  $\partial\gamma/\partial x$ , at the suspension–air interface to be negligible,<sup>[26]</sup> the structuring of the seeds is mainly provided by the viscous shear  $\tau$  at the solid–liquid interface, which is related to the velocity  $u$  in a unidirectional flow (along  $x$  axis  $\sim$  drop radius) through the phenomenological relation,<sup>[24]</sup>

$$\begin{aligned}\tau &= h(\partial p/\partial x) = -c^{te}\eta(u/h^*) \\ &\sim -\eta u(l\text{tg}\theta_r + b)^{-1}\end{aligned}\quad (1)$$

where  $(\partial p/\partial x)$  is the pressure gradient in the confined film (wedge),  $h^* = (h + b)$ , and  $h \sim l\text{tg}\theta_r$ .

Although both terms in Eq. (1) determine, to some extent, the magnitude of  $\tau$  (suspension viscosity  $\eta$ ,  $u$ ,  $\theta_r$ , and  $l$ , the lateral size of the wedge), the one that explicitly accounts for the particle attachment is  $h^* = (h + b)$ , the fluid thickness  $h$  in the receding wedge, augmented by the eventual slippage of the particles at the substrate, characterized by the length  $b$ .<sup>[27]</sup> Instead of the slippage length that is of general use

for liquid phases flowing past a wall, one may prefer for these nanoparticles the sticking coefficient  $\chi \sim (1 + b)^{-1}$  that rigorously accounts for the same boundary condition. Because of the complexity of the system, the direct determination of  $l$  and  $b$  that are necessary to a quantitative evaluation is rather difficult. On the other hand, the above relation provides a phenomenological basis for the qualitative discussion of the critical interplay between the surface properties, the late-stage dewetting and hydrodynamic shear, and the emergence and morphological feature of the complex nano-colloidal surface patterns. For instance, at nonwetted and nonparticle attaching  $\text{CH}_3$  substrates ( $\theta_r \gg 1$  rad, high  $b$  or equivalently low  $\chi$ ), one expects the magnitude of the shear  $\tau$  to be very low. Both free particles and seeds (if they exist) are simply collected within the rather large moving wedge, leading to the observed residual dense deposit in this case. On wetting and particle sticking substrates ( $\text{tg}\theta_r \sim \theta_r \ll 1$  rad, high  $\chi$ , or  $b \sim 0$ ), a higher magnitude shear stress  $\tau$  develops within the receding wedge. The confined seeds and free particles are further connected and stretched along the substrate, leading upon the retraction of the fluid to well-organized multibranching patterns.

As illustrated on *precoated*  $\text{NH}_2$  and heterogeneous substrates, these late-stage hydrodynamic effects can strongly couple with the topography of the underlying substrate to critically determine the specific topology and structural order of the aggregates. The most

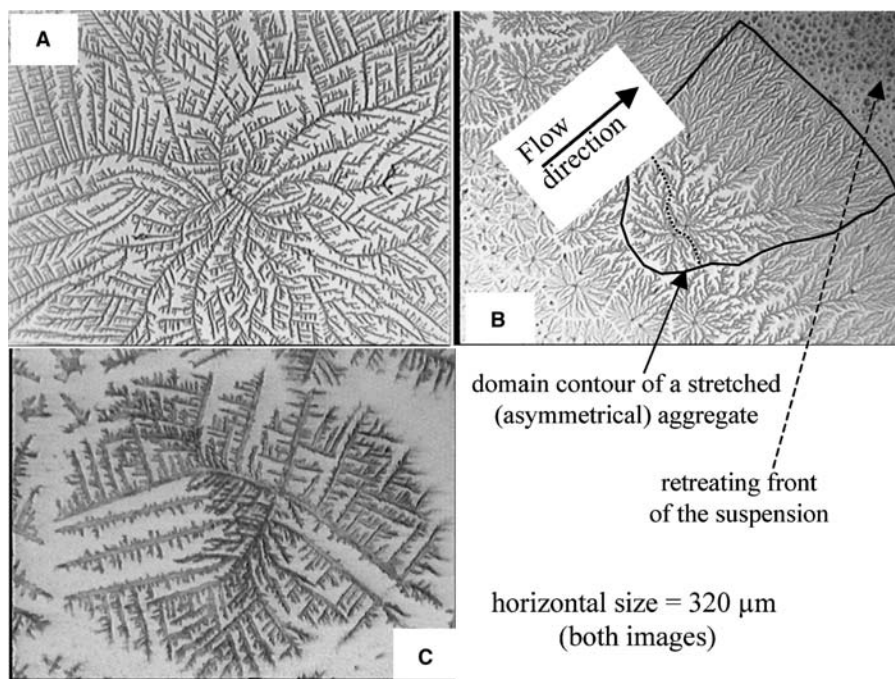

illustrative demonstration of this is given by the *precoated* NH<sub>2</sub> substrate, which actually constitutes a 2-D nanoporous lattice that can drive both the flow and the alignment of the aggregates along preferential “streamlines” of the porous bed during the shear-ordering. Contrary to micronscale particles that can individually (as opposed to clusters) protrude out of the residual solvent, allowing both meniscus and capillary forces to develop, one does not expect such attractive capillary force to play a determining role for nanocolloids, as long as their size remains comparable or less than the thickness at which the residual film dewets. This may, of course, no longer be true when clusters having thickness large enough to form such “interclusters” meniscus are present in the drop. Yet, the net force resulting from the balance between the late-stage hydrodynamic shear and anchoring forces would have largely dominated these attractive capillary forces which are essentially significant on non-attaching surfaces, on the pattern-forming NH<sub>2</sub> substrate, for instance. The high structural order of the patterns at these *precoated* NH<sub>2</sub> substrates, characterized by the repetition of hexagonal units cells along the aggregate branches, thus seems to be strongly correlated to the topography of the underlying preadsorbed particles lattice. However, the explicit length scale and structural correlations between the morphological features of the patterns, on one hand, and the underlying surface topography (preadsorbed particles lattice) and hydrodynamic flow, on the other, remain essentially obscure, and would certainly deserve more systematic model investigations. On the other hand, these investigations clearly show that the symmetry of the aggregate, which depends on its location in the drying spot (periphery or center), is exclusively determined by the local dewetting–retiring mode of the residual fluid, as illustrated in Fig. 8. The aggregates forming at the drop periphery as the contact line recedes have the characteristic asymmetry of the flow

**Fig. 8** Late-stage dewetting events and mechanisms that determine the topological feature of the emerging aggregates, (A) symmetrical and (B) asymmetrical dewetting-flow and aggregate stretching modes.

and viscous shear (Fig. 8A–B) associated with the inward motion of the fluid that highly structures these aggregates along the flow (peripheral nucleation, inward stretching, and propagation of the branches). The aggregates appearing in the center of the drying spot, on the other hand, are formed during the rupture-dewetting of the residual suspension film. These aggregates have the axisymmetry of the flow (fluid rims) and viscous shear around the nucleation point of the growing dewetting holes (Fig. 8A–B), which coincides with the aggregate center. One noteworthy factor here is the strong similitude between these nanocolloids drying patterns and their formation process, and those usually produced via Saffman–Taylor instabilities in Hele–Shaw cells.<sup>[28]</sup> Also, for these Hele–Shaw structures, the configuration of the flow, axial or radial, determines the symmetry of the resulting complex patterns.<sup>[28]</sup> In most of these flow-induced structures, both the symmetric and asymmetrical aggregates formed on the *precoated* NH<sub>2</sub> substrates (Fig. 8) are fractal, with dimensions  $D$  of 2.03 and 1.61, respectively, as determined from the log–log plot of the number of particles  $N$  contained in concentric boxes of radius  $R$ , using the standard relation  $N \sim R^D$ . Interestingly, the asymmetrical peripheral aggregates are almost completely absent, or are of very low stretching magnitude on lower wettability substrates (NO<sub>2</sub>, heterogeneous and, of course, CH<sub>3</sub>) compared to NH<sub>2</sub>. Furthermore, it was shown that these asymmetrical aggregates may not necessarily form, even on substrates that are wetted by the suspension solvent (Ref.<sup>[20]</sup>, see also Fig. 9C). This seems to suggest that the condition of wetting required for the formation of a large residual thin film can be achieved, principally with respect to the solvent of the dispersion, for a negligible attachment (adhesion, anchoring) of the dispersed particles to the substrate. On these substrates, the peripheral retraction of the drop mainly involves the simple entrainment and accumulation of the loosely attached particles and clusters, which therefore experience a negligible shear-induced stretching. Therefore it seems that not only the condition of wetting, which may be achieved by the solvent independently of the particles, is required for the two aggregation symmetries to appear, but also that of particle anchoring, which is necessary for the shear-induced stretching to develop within the clusters (bulk seeds, especially) at the receding drop edge.

If the two critical parameters that determine both the emergence topology of the drying patterns are the actual volume fraction of the suspension in the late stage of the drying and the surface properties of the underlying substrates, the size of the nanoparticles also provides an additional parameter for the control of the aggregates morphology. Once the required bulk criterion is satisfied, one disposes of two key parameters that can

**Fig. 9** (A) and (B) Influence of particle size on the morphology of emerging patterns, as shown on the precoated  $\text{NH}_2$  substrate using “10 nm susp” drops ( $d_p = 10$  nm,  $\phi_{\text{ref}} = 5 \times 10^{-6}$ ); (B) further illustration of the predominating influence of the surface properties, provided here by the drying of the reference “30 nm susp” on the hydroxylated inorganic  $\text{SiO}_x\text{H}$  substrate, as opposed to the organic ones used throughout the entry.

be used to tune the late-stage drying events and produce nanocolloids aggregates of desired complexity and topological features (fractality, size, structural ordering). These are 1) *the critical surface parameters* (wetting, topography) and 2) *the size and distribution of the nanocolloids particles*. The potential effect of this particle size is demonstrated in Fig. 9A–B, which represents the drying pattern of “10 nm susp” drops on the *precoated*  $\text{NH}_2$  substrates. As for “30 nm susp” drops on the same substrates, both the symmetric aggregates appearing at the center of the drying spot and highly stretched peripheral (asymmetrical) ones are formed in these drying “10 nm susp” drops. However, at the difference of the “30 nm susp” that forms thicker and highly structured branches composed of hexagonal units cells on *precoated*  $\text{NH}_2$  substrates, the aggregates resulting from the “10 nm susp” drops are composed of much finer and higher number density branches that are essentially  $\pi/2$ -oriented with each other (dendrites). On the other hand, the presence in these drying “10 nm susp” drops of both symmetric and highly stretched (asymmetrical) aggregates (which are therefore independent on the particle size) well supports the existing conjuncture on the predominance of the substrate properties and related dewetting mode in the emergence of these two aggregation symmetries. The already demonstrated effect of the critical surface parameter is further highlighted in Fig. 9C, which shows one of the most representative aggregation topologies resulting from the drying of the reference “30 nm susp” drop ( $8 \mu\text{L}$ , nominal volume fraction  $\phi_{\text{ref}} = 1.5 \times 10^{-5}$ ), on a clean hydroxylated bare silicon wafer. On this

inorganic substrate, which is almost completely wetted by the suspension, one could reasonably expect from all the above results and discussion, the formation of large-scale complex aggregates, which are here composed of  $\pi/2$ -oriented secondary branches that emerge from the main fourfold dendrites.

## CONCLUSION

Based on the extended experimental results, we discussed the formation of both nanometer-scale and micronscale aggregation patterns that form during deep-coating adsorption and drying of nano-colloidal suspension drops (and films), respectively, at a representative ensemble of model substrates. Our results show that large-scale and well-organized dendrites and multibranch patterns can form during these processes, the emergence and topological feature of which were shown to be essentially controlled by two critical parameters. These are 1) the actual volume fraction of the drop in the late stage of the drying and, 2) the hydrodynamic shear involved in the dewetting and receding motion of either the macroscopic drop or the thin residual suspension film. The former determines a *threshold volume fraction* required for wormlike bulk clusters to form in the drying drop, and which lately serve as seeds for the formation of the complex surface patterns. The second parameter explicitly depends on the *surface properties* (wetting, particle adhesion, nanoscale topography), and determines the magnitude of the shear-induced structuring

(stretching) experienced by the confined particles and seeds within the receding wedge and residual suspension film. It was demonstrated that once the required bulk criterion was satisfied, both the particle size and their distribution provide additional parameters, which can be used with their critical surface counterpart (shown to be adjustable) to tune the morphological features of the networks. Simple phenomenological models were proposed, which account for some of the observed experimental results. However, some fundamental questions remain. In particular, the relationship between the *underlying surface structure and properties*, on one hand, and the *characteristic length scales* (short and long-range ones) and *structural order in the emerging patterns*, on the other, remain essentially obscure. Understanding of these correlations is not only of fundamental importance regarding self-organization phenomena at interfaces, but also provides the practical key parameter toward the controlled elaboration of well-ordered, large-scale patterns from drying nanocolloidal dispersions. This issue certainly constitutes a central task that would deserve both theoretical and model experimental investigations in the near future.

## INTRODUCTION

A charged colloidal particle suspended in an electrolyte solution is surrounded by a cloud of counterions. The set of the surface charges and countercharges is called the electrical double layer. The electrical double layer plays an essential role in various interfacial electrical phenomena on the particle surface and in the particle–particle interaction of colloid suspension.

Generally, it is almost impossible to measure the surface potential on colloid particles. However, we can measure the potential near the particle surface. It is called the zeta ( $\zeta$ ) potential. The zeta potential is the potential at the hydrodynamic slipping plane in the electrical double layer, hence its value is not precisely the same as that of making a stable suspension because the total interaction potential between two particles a bit distant from their surface is essential for a stable dispersion. The  $\zeta$ -potential has been considered to provide useful information necessary for preparing stable colloidal suspensions in many application fields including food preparation, agriculture, pharmaceuticals, paper industry, ceramics, paints, coatings, photographic emulsions, etc. The concept of the zeta potential is also very important in such diverse processes as environmental transport of nutrients, sol–gel synthesis, mineral recovery, waste water treatment, corrosion, and many more.

## OVERVIEW

These are several origins from which solid surfaces are charged: dissociation of chemical groups on the surface, preferential adsorption of cation or anion onto the surface, etc. The distribution of each ionic compound between the surface and the solution bulk is determined by the differences in the electrochemical potential of each compound between two phases: the

solid (surface) phase and the solution phase. Therefore the composition of the solution is an important factor that determines surface potentials. When  $H^+$  is the potential-determining ion, we can change the amount of surface charge by changing the pH of the solution. It is important to know the position of the isoelectrical point (IEP) (i.e., the pH value at which the particles have zero  $\zeta$ -potential). At the IEP, there are no repulsive forces and the particles are strongly aggregated because of the attractive van der Waals forces. In many cases, the stable colloidal particle dispersion is desired, so the colloidal suspensions are designed such that the pH of the suspension is well away from the IEP. The IEP data for a number of colloids of various compositions have been reported.<sup>[1]</sup> [Table 1](#) lists the IEP for some typical dispersions.

If colloid particles are brought to a concentrated situation through some engineering processes, it is not certain if the surface charges, and hence surface potential, hold the same values as those in diluted dispersions. It must be measured experimentally, and several methods have been explored in recent years.

Here, we briefly describe experimental methods of the measurements of  $\zeta$ -potential for the diluted and the concentrated particle systems, and how the control of zeta potential is useful for preparing composite particle systems in the last part of this report. The fundamentals of electrokinetics in colloidal systems have been described in numerous books in recent years.<sup>[1–3]</sup>

## MEASUREMENTS OF $\zeta$ OF PARTICLES IN DILUTED SUSPENSION

### Regular Method by Electrophoresis

The historical prominence of  $\zeta$ -potential has been because of its experimental accessibility via measurement of the electrophoretic mobility  $\mu$ . Electrophoretic

**Table 1** Isoelectric points

Compound	IEP (pH)
$\alpha$ -AlOOH	9.4
$\gamma$ -AlOOH	5.5–7.5
$\alpha$ -Al(OH) <sub>3</sub>	5.0–5.2
$\gamma$ -Al(OH) <sub>3</sub>	9.3
CdO	10.4
Co <sub>3</sub> O <sub>4</sub>	5.5
Co(OH) <sub>2</sub>	10.5
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	8.3
$\beta$ -Fe <sub>2</sub> O <sub>3</sub>	6.7–8.0
Mg(OH) <sub>2</sub>	12
MnO, MnO <sub>2</sub>	6
NiO	9.5
SiO <sub>2</sub>	1.8–2.5
SnO <sub>2</sub>	4.5
TiO <sub>2</sub>	6
ZrO <sub>2</sub>	4

mobility is the velocity of the colloid particle  $v$  per unit field strength  $E$ :

$$v = \mu E \quad (1)$$

where  $\zeta$  is related with mobility by the equation from von Smoluchowski:<sup>[4]</sup>

$$\mu = \varepsilon \zeta / \eta \quad (2)$$

where  $\varepsilon$  or  $\eta$  are the permittivity or viscosity of the medium, respectively. In regular electrophoretic apparatus, we utilize a narrow capillary cell of cylindrical or rectangular shape. The migration velocity of the particles is measured by optical microscopy for larger-sized particles, or by observation of Doppler shift of laser light scattering signal for smaller particles. However, the capillary cells walls also bear electrical charges and hence have electrical double layers. Therefore the application of electrical fields causes the movement of charged liquid medium in the double layer, which is called electroosmosis. The electrophoretic migration of colloid particles is always superimposed on the electroosmotic liquid flow from the cell wall. The closed sample cell causes a back liquid flow through the generation of hydrostatic pressure gradient. At equilibrium, there are two positions where the liquid flow has zero velocity. These are called the stationary levels. Thus we can observe the true electromigration velocity of colloid particles at the stationary levels. Von Smoluchowski<sup>[4]</sup> showed the profile of electroosmotic

flow velocity ( $U_{\text{osm}}$ ) for a cylindrical cell:

$$U_{\text{osm}} = U_0(h^2/b^2 - 1) \quad (3)$$

and for a flat cell, which has an infinitely long width:

$$U_{\text{osm}} = U_0/2(3h^2/b^2 - 1) \quad (4)$$

where  $h$  is the distance from the cell center in the direction of cell thickness,  $b$  is the half-thickness of the cell, and  $U_0$  is the electroosmotic flow at the cell wall ( $h = b$ ). The stationary levels are located at a distance from the cell center to each side by the quantity  $h = b/\sqrt{2}$  for the cylindrical cell, or  $h = b/\sqrt{3}$  for the flat cell. Komagata<sup>[5]</sup> showed a more practically useful equation for a rectangular cell, which has a thickness of  $2b$  and a width of  $2w$  ( $b < w$ ); the stationary level is located at a distance from the cell center to each side by the quantity  $h = b\sqrt{(1/3)(1 + 384b/\pi^5w)}$ . The traditional measurements of zeta potentials of particles are conducted at these stationary levels.

### Electrophoretic Measurements Using a Standard Sample

The profile of electroosmotic flow is parabolical. Thus the velocity gradient of the liquid at the stationary levels is usually large and the observed velocity of the particles changes rapidly with cell depth. It causes substantial errors in electrophoretic mobility measurements from the wrong setting of observing points. However, if the electrophoretic measurements can be carried out by using a reference sample as a standard, the electrophoretic mobility of the unknown sample can be determined at any cell depth by subtracting the mobility of the reference particles at the same level, because the velocity of electroosmotic liquid flow induced by the cell wall has the same value under the same experimental conditions. Therefore one can obtain real electrophoretic mobility rather accurately by measuring the velocity at the cell center, where the velocity gradient is zero.

The apparent electrophoretic mobility ( $U_{\text{app}}$ ) of an unknown colloid sample is always the sum of two contributions, one of which is the real electrophoretic mobility ( $U_{\text{el}}$ ) and the other is the liquid flow velocity induced by the electroosmotic effect ( $U_{\text{osm}}$ ) of the cell wall, which changes as a parabolical function of the cell depth:

$$U_{\text{app}} = U_{\text{el}} + U_{\text{osm}} \quad (5)$$

Similarly, the apparent velocity of the reference sample ( $U'_{\text{app}}$ ) was also indicated by the sum of the real

electrophoretic mobility ( $U'_{el}$ ) and the electroosmotic flow velocity ( $U'_{osm}$ ), that is,

$$U'_{app} = U'_{el} + U'_{osm} \quad (6)$$

Under the same experimental conditions, using a finite electrophoretic cell ( $U_{osm} = U'_{osm}$ ), the following relationship holds from Eqs. (5) and (6):

$$U_{el} - U'_{el} = U_{app} - U'_{app} \quad (7)$$

If  $U'_{el}$  is known exactly, the  $U_{el}$  value of the unknown sample can be determined from the difference between the two apparent mobilities at any cell depth. Thus if the particle mobilities of unknown samples and the reference sample are measured at the cell center where the migration velocity has a maximum, the real electrophoretic mobility of the unknown sample is given by:

$$U_{el} - U'_{el} = U_{app}(\text{maximum}) - U'_{app}(\text{maximum}) \quad (8)$$

Fig. 1 shows an example indicating the electrophoretic mobility profiles obtained experimentally for the reference sample (PSSNa lattices) and an unknown sample (SM lattices) along the cell depth in a  $1 \times 10^{-3}$  M KCl solution at 25°C. The SM lattices employed as an unknown sample were prepared by the copolymerization of styrene with 5% methacrylic acid (MA) at 70°C. It is apparent that both profiles indicate reasonable parabolical curves, and the curve for the reference

**Fig. 1** Examples of electrophoretic mobility profiles of PSSNa lattices ( $U'$ ) and SM lattices ( $U$ ). ( $h^*$ ) stationary level; (■) PSSNa lattices; (●) SM lattices ( $1 \times 10^{-3}$  M KCl, 25°C).

lattices shows a constant mobility at the two stationary levels. Furthermore, the difference between the two apparent mobilities at the cell center agrees well with the velocity of the SM lattices at the stationary level.

Fig. 2 shows the  $\zeta$ -potential vs. pH curves for the SM lattices, which have been determined from the maximum mobilities using the PSSNa lattices as a standard.<sup>[6]</sup> The same relation obtained from the velocity of the SM lattices at the stationary level is also indicated. As can be seen, both curves agree fairly well over the whole pH range. All of these results indicate that if we have a reliable colloid sample whose  $\zeta$ -potential is exactly determined, the  $\zeta$ -potential of the unknown sample can be determined precisely from the measurements of apparent electrophoretic mobility at the cell center. In that case, slight errors in focusing (i.e., errors because of the view field) are less important because the velocity gradient near the level of observation is very small.

According to Eqs. (3) and (4),  $U_0$  and hence the  $\zeta$ -potential of the cell wall are determined using a reference sample. The electroosmotic velocity ( $U_0$ ) obtained by the extrapolation of the velocity profile to the cell wall permits the determination of the  $\zeta$ -potential of the cell wall–solution interface, and the  $\zeta$ -potential measurement of various solid–solution interfaces,<sup>[7]</sup> including the dissimilar cell system,<sup>[8]</sup> has been determined. Here, we would like to emphasize again that the determination of the  $\zeta$ -potential of the cell wall is also possible from the maximum velocity of the reference sample, instead of the tedious plane interface procedure. According to Eq. (4), the apparent velocity of the reference sample at the cell center (at  $h = 0$ ) is  $U'_{app} = U'_{el} - U'_0/2$ . Therefore  $U'_0$  and hence the

**Fig. 2**  $\zeta$ -Potential vs. pH curves of unknown sample (SM lattices) determined by the maximum velocity of reference sample (●) and the usual method (○).

**Fig. 3** Apparent flow velocity profile of standard latex samples at various pH values ( $1 \times 10^{-3}$  M KCl,  $25^\circ\text{C}$ ).

$\zeta$ -potential of the cell wall can be quickly determined if the  $U_{cl}^0$  has been previously known.

Fig. 3 shows some examples of apparent flow velocity profiles of standard latex samples (PSSNa lattices) at various pH values in which both boundaries refer to the glass–solution interface. A symmetrical parabola was given at all pH conditions where the surface charge of glass is consistent with both sides.

## ELECTROKINETIC CHARACTERIZATIONS IN CONCENTRATED DISPERSIONS

In recent years, electroacoustics offered studies on surface characterization and the stability of suspended colloid particles. The term electroacoustics refer to two kinds of related phenomena: 1) colloid vibration potential (CVP), in which an electrical field arises in colloidal suspension when a sound wave passes through the dispersion (i.e., ultrasonic vibration causes the difference in movement between charged core particles and countercharges around them, which induces oscillating dipole moments and hence the potential drop in the sample cell),<sup>[9]</sup> and 2) electrokinetic sonic amplitude (ESA), the reciprocal effect of the above phenomena, in which an alternating electrical field is applied to a suspension and a sound wave arises as a result of the inertia of the particles, caused by their time-alternating electrophoresis (i.e., high-frequency electrical waves cause a difference in movement

between the core particles and the countercharges, which generates an ultrasonic waves in the sample cell).<sup>[10,11]</sup>

A very important advantage of these electroacoustical techniques is their ability to provide accurate measurements of the  $\zeta$ -potential in concentrated colloid systems. In this section, two of the typical data obtained by these methods are shown.

## Surface Characterization of Concentrated Latex Suspensions

In this section, the CVP technique is demonstrated for zeta potential measurements of concentrated suspensions of latex particles with different surface groups.<sup>[12]</sup> Three types of polystyrene lattices with different surface groups were synthesized in emulsifier-free systems. The usual polystyrene (PSt) lattices were prepared by the method of Kotera et al.,<sup>[13]</sup> and the two others (PStn and PStm) were synthesized by incorporating small amounts of ionic comonomer, methacrylic acid, and sodium polyvinylphenylsulfonate (NaSS) into a polystyrene chain, respectively, as in Juang and Krieger.<sup>[14]</sup> To increase the particle size, PStn was prepared in a system with  $1 \times 10^{-4}$  mol/dm<sup>3</sup> MgSO<sub>4</sub>. These latex samples were sufficiently dialyzed with distilled water and were then brought into contact with an ion exchange resin to remove ionic impurities. The samples were all composed of highly monodispersed spherical particles with  $D_w/D_n = 1.02$ , and the surface charge densities of the latex particles were measured by potentiometric and conductometric titration, as in Van den Hul and Vanderhoff.<sup>[15]</sup> The characterization data of all the samples are summarized in Table 2.

To compare the CVP with the conventional electrokinetic technique, first, the zeta potential of each sample in a dilute state was determined in a  $1 \times 10^{-3}$  mol/dm<sup>3</sup> KCl solution at different pH values using the microelectrophoretic technique. The resulting data for four samples are shown in Fig. 4. The  $\zeta$ -potential of the latex samples, especially the PStn sample, appears to be essentially independent of the medium pH. The zeta potential of PSt increases gradually from acidic to neutral pH. This behavior is probably dependent

**Table 2** Characterization of colloid particles

Sample	Diameter (nm)	Surface charge density ( $\mu\text{C}/\text{cm}^2$ )		
		Strong acid	Weak acid	Total
PSt	480	5.3	2.5	7.8
PStn	610	18	0	18
PStm	530	5	33	38

**Fig. 4** pH dependence of zeta potential in dilute state measured by the microelectrophoretic technique in  $1 \times 10^{-3}$  mol/dm<sup>3</sup> KCl at 25°C.

on the existence of carboxyl groups on the surface (with  $pK_a$  values between about 4 and 5), which are produced by the hydrolysis and subsequent oxidation of the  $OSO_3^-$  groups that come from the radical fragments used as an initiator ( $K_2S_2O_8$ ).<sup>[16–18]</sup>

The CVP measurements of polystyrene lattices give reliable data only in high-volume fraction ( $\phi$ ) systems above  $\phi = 0.1$  because the density of the latex particles is small ( $\rho_2 = 1.05$  g/cm<sup>3</sup>) and significant differences of CVP against the background signal can be detected only at high concentration ranges. Figs. 5 and 6 are graphs of the zeta potentials determined by CVP measurements for three kinds of polystyrene lattices at pH 5 and 9, as a function of the  $\phi$  value of each latex. It is apparent that the zeta potentials for

**Fig. 5** Concentration dependence of zeta potential for polystyrene latex suspensions in  $1 \times 10^{-3}$  mol/dm<sup>3</sup> KCl at 25°C and pH 5.

**Fig. 6** Concentration dependence of zeta potential for polystyrene latex suspensions in  $1 \times 10^{-3}$  mol/dm<sup>3</sup> KCl at 25°C and pH 9.

PSt and PStm at pH 5 and for PSt at pH 9 have nearly constant values over the entire concentration range of particles, and that the cell model theory is nearly valid for those systems. However, the zeta potentials for PStn at pH 5 and for PStn and PStm at both pH values decrease strongly as the particle concentrations increase. Furthermore, it was found that those of PStm at pH 9 are lower than those at pH 5, which is opposite in tendency to those in Fig. 4, determined directly in dilute states by the microelectrophoretic technique. It is thought, from a comparison with Table 2, that this abnormal behavior of the  $\zeta$ -potential is related to the high surface charge densities of the latex samples (i.e., PStn has many sulfonate groups on the surface brought about by the NaSS component), which dissociate completely under both pH conditions, and PStm becomes covered with thick carboxyl layers coming from the MA molecules, which gradually dissociate as the pH increases. These high surface charge densities bring about an expansion of the surface layer and may cause a double-layer overlapping at moderate particle concentrations, which results in restrictions for the prerequisite of the cell model of Levine, Neale, and Epstein<sup>[19]</sup>

To understand the abnormal behavior of the CVP and  $\zeta$ -potential that appeared in the latex suspensions, including the particles with high surface charge densities, the concentration dependence of conductivity was measured in the respective systems. The concentration dependence of the conductivity depends largely on the surface nature of the particles.<sup>[12]</sup> The conductivity of polystyrene latex systems increases as the particle concentration increases. This tendency is especially remarkable in the PStn systems at pH 5

and 9 and in the PStm system at pH 9. From a comparison with the results of the CVP, it was realized that this increasing tendency of the conductivity is closely related to the abnormal behavior of the CVP. This is explained as follows. On the highly charged surfaces of PStn or PStm at pH 9, a polyelectrolyte-like (“hairy”) layer is present. These layers overlap each other in this concentrated state, allowing electrical conduction through the hairy layer; thus the hairy layer results in interparticle surface conductance. The degree of interparticle surface conduction is affected by the particle concentration and the thickness of the hairy layer, which in turn depend on the surface charge density of the particle and the pH of the medium.

### Application of Electrokinetic Sonic Amplitude Technique in the Ceramic Industry

The concept of colloidal suspension processing has been successfully applied to the field of structural ceramic where inherent properties of dense suspension are used to transform a fluid suspension to a stiff gel. During colloidal processing, the state of dispersion has a significant influence on the casting behavior and the resulting green body properties. The good dispersion of particles gives optimum packing state (high green density), which influences the sinterability of the ceramic body and hence the physical and chemical properties of the final product. At present, fine-grained and uniform microstructures are desirable for most ceramic applications in producing strong and reliable structural parts.

Traditionally in the ceramic industry, polyelectrolytes have been utilized to prevent the flocculation of particles. Because of the charged nature of the polyelectrolyte, they impart stability to the particles via an electrosteric mechanism. Hence the adsorption of these charged molecules onto a particle surface will alter the surface charge and hence the zeta potential. Thus using electroacoustics, it is possible to follow the changes in the zeta potential with increasing amounts of polyelectrolyte. This is extremely useful in determining the optimum amount of polyelectrolyte required to stabilize the particles under different conditions.

Fig. 7 shows how the zeta potential of an alumina suspension (background electrolyte, 10 mM KCl) can be altered by the addition of three commercially available polyelectrolytes.<sup>[20]</sup> Initially, the zeta potential of the suspension is such that the suspension becomes more stable. The trend for all dispersants is very similar in that, initially, the zeta potential changes strongly with small amounts of dispersants and then after a certain concentration, the zeta potential begins to plateau out as no more dispersant is adsorbed on the

Fig. 7 Effect of three commercial dispersants on alumina suspension in  $1 \times 10^{-4}$  mol/dm<sup>3</sup> KCl: (●) Poly-CA; (◇) Poly-PC33; (◆) Poly-CE64.

surface. However, each dispersant imparts a different final zeta potential and requires a different amount of dispersants to cover the particles. Of these, Poly-CA imparts the greatest final zeta potential, so this would be an excellent dispersant for the alumina. However, it must be noted that the likely stabilization mechanism for polyelectrolyte dispersants is electrosteric stabilization. Therefore there may well be a steric contribution to the stabilization mechanism depending on how the dispersant adsorbs. Poly-CE64 imparts a final zeta potential of  $-45$  mV and requires approximately twice as much dispersant to do so, making it a poor candidate in comparison. The zeta potential from the suspension stabilized with Poly-PC 33 does not appear to level out, and further data points would be required to determine the optimum amount.

### ELECTROKINETIC MEASUREMENTS IN SYNTHESIS OF COMPOSITE PARTICLES

There is a variety of methods currently used to fabricate a wide range of stable, composite, and coating particles of various compositions. These include heterocoagulation,<sup>[21]</sup> seed polymerization,<sup>[22]</sup> emulsion/phase separation,<sup>[23]</sup> sacrificial core techniques,<sup>[24]</sup> and so on. The notion of adsorbing particles onto solid substrates in a layer-by-layer manner was introduced by Iier<sup>[25]</sup> in the mid-1960s. Decher and Hong<sup>[26]</sup> extended Iier's work to a combination of linear polycations and polyanions in the early 1990s. Decher<sup>[27]</sup> later adapted the layer-by-layer technique to include inorganic nanoparticles, biomolecules, clays, and dyes in polyelectrolyte multilayer assemblies. Very recently, Caruso and Mohwald<sup>[28]</sup> and Caruso, Caruso, and

Mohwald<sup>[29]</sup> reported very interesting results, which included a detailed investigation of the stepwise formation of the silica–nanoparticle/polymer multilayer templating of some latex particles. In this chapter, we demonstrate how we can utilize electrophoretic measurements in synthesis and coating processes of composite particles.

### Heterocoagulation Behavior of Polymer Lattices with Spherical Silica

Gherardi and Matijevic<sup>[30]</sup> have investigated various behaviors of mixed colloid particles obtained by mixing differently preformed particles. They showed that the nature of a mixing system depends on the conditions of preparations, and concluded that the most important parameter in controlling the morphology of composite particles is the surface charge of the component particles, especially the contrast between surface charges of the two component particles. A stable system consisting of a regular composite particle could be prepared only in a medium controlled at a definite pH, where the two components are charged with opposite signs. Typical results of the electrophoretic mobility for the single silica and the latex suspension are shown in Fig. 8.

The next important parameter to control morphology is the particle size ratio of the component particles when they are mixed in the vessel. Fig. 9 shows schematic pictures of the morphology of heterocoagulates of different silica particles and amphoteric

**Fig. 8**  $\zeta$ -Potentials of silica (□) and latex particles (○) as a function of pH at  $5 \times 10^{-3}$  mol/dm<sup>3</sup> KCl.

**Fig. 9** Schematic pictures showing the morphology of heterocoagulate particles formed from different silica samples.

lattices. Fig. 10 shows an optical micrograph of the real heterocoagulate generated from different silica samples and amphoteric latex systems, where the other conditions (e.g., the particle number ratio,  $N_{\text{silica}}/N_{\text{latex}} = 1/300$ ; medium pH 5.6) have been kept constant. The microscope used for observations was a lateral-type metallurgical microscope (Axio Mart, Carl Zeiss, Germany). It may be seen that at a particle size ratio ( $r = D_{\text{silica}}/D_{\text{latex}}$ ) higher than 3, the suspension is composed of uniform heterocoagulate particles and each heterocoagulate undergoes Brownian motion as

**Fig. 10** Optical micrograph showing the heterocoagulates prepared from different silica samples: (A) Silica-L; (B) Silica-M; (C) Silica-S; (D) Silica-SS.

an isolated unit. The insert of Fig. 10A shows a scanning electron micrograph of the heterocoagulate. It is apparent that the heterocoagulate takes a raspberry shape with one silica particle in the core. In contrast to this, the heterocoagulates generated at a particle size ratio lower than  $r = 3$  (Fig. 10C and D) are composed of large, irregular aggregates, and regular coagulates were hardly formed at any medium pH and particle number ratio investigated.<sup>[31,32]</sup>

It is interesting to analyze the different heterocoagulation behaviors from the concept of the adhesion isotherm for the amphoteric lattices on the silica particles. Fig. 11 shows some typical isotherms for the lattices on Silica-L at various  $K_2SO_4$  concentrations, where all the systems were controlled at pH 5.2. It is evident that the isotherms are all well defined and of very high affinity type, and the plateau value increases with increasing  $K_2SO_4$  concentration within the range from  $10^{-5}$  to  $10^{-2}$  mol/dm<sup>3</sup>. This means that in this concentration range, adhesion proceeds in a way characteristic of monolayer adhesion. This may be because of the strong blocking effect of adhering particles. However, in  $K_2SO_4$  aqueous solutions more concentrated than  $2 \times 10^{-2}$  mol/dm<sup>3</sup>, no reproducible isotherm could be obtained under any conditions tested, and only some irregular aggregates were generated in the course of the experiment.<sup>[31]</sup> In Fig. 12, the  $\zeta$ -potentials of the heterocoagulates prepared at different electrolyte concentrations, as well as the data on the amphoteric lattices, are presented as a function of the medium pH. As may be seen, a reversal of charge is observed in all samples, and the IEP in the heterocoagulated systems occurs at about pH 8, which is not so different from the IEP of the single lattices. Moreover, the fact that the limiting net positive  $\zeta$ -potential attained at  $3 < \text{pH} < 6$  increases with

**Fig. 11** Adhesion isotherms of amphoteric lattices onto Silica-L at various  $K_2SO_4$  concentrations: ( $\nabla$ )  $1.46 \times 10^{-2}$  M; ( $\square$ )  $1.46 \times 10^{-3}$  M; ( $\triangle$ )  $1.46 \times 10^{-4}$  M; ( $\circ$ ) 0 M.

**Fig. 12**  $\zeta$ -Potentials vs. pH curves for heterocoagulate particles prepared at different electrolytes: ( $\nabla$ ) heterocoagulates prepared at  $2.48 \times 10^{-1}$  M  $MgCl_2$ ; ( $\circ$ ) heterocoagulates prepared at  $1 \times 10^{-5}$  M  $KCl$ ; ( $\square$ ) amphoteric lattices.

increasing electrolyte concentration is also in line with the increase in latex adhesion with increasing electrolyte concentration.

### Multilayer Composite Particles Comprising Silica/Vesicle/Silica Particles

Composite particles, including vesicle particles, are an important topic in application fields. Composite particles can be used frequently in the biomedical field for diagnostic purposes and for treatment medicine. Here, we describe one example of such systems,<sup>[33]</sup> that is, PC vesicles, which are typical biocolloid systems and are introduced into composites as a one-component particle.

The silica/PC vesicle/silica multilayer composite particles were prepared by the alternate adsorption of PC vesicles and small silica particles on the large silica particles with negative charges (Fig. 13). In this study, electrostatic attraction is taken into account as the driving force. It is important that the silica and the vesicle surfaces bear opposite charges to be effective. We can control the surface charges of the vesicle and silica particles by adjusting the concentration of  $LaCl_3$ . In Fig. 14, the  $\zeta$ -potentials of PC vesicles and silica particles are shown as a function of  $LaCl_3$  concentration. The  $\zeta$ -potential of PC vesicles decreases with increasing  $LaCl_3$  concentration, and becomes positive over a

**Fig. 13** Schematic showing the process of synthesizing multilayer composite particles: (A) core silica; (B) PC vesicle/silica composite particle; (C) silica/PC vesicle/silica composite particle.

certain concentration of  $\text{LaCl}_3$ . This is because of the binding effect of  $\text{La}^{3+}$  ions to the phospholipids head group.<sup>[34]</sup> However, for silica dispersions, the  $\zeta$ -potential remained negative over the  $10^{-6}$ – $10^{-2}$  M concentration range of  $\text{LaCl}_3$ . Thus at  $10^{-4}$  M  $\text{LaCl}_3$ , the  $\zeta$ -potentials of the silica and PC vesicles were  $-30$  and  $+32$  mV, respectively. It is assumed that a strong electrostatic attraction will occur between the vesicles and the silica particles. Therefore we selected  $10^{-4}$  M  $\text{LaCl}_3$  as the heterocoagulation condition.

After mixing the PC vesicles with the core silica dispersion, the free vesicles were removed from the dispersion and the  $\zeta$ -potentials of the composite particles generated were measured. The value was determined to be  $+28$  mV. The positive  $\zeta$ -potential indicates that the PC vesicles are adsorbed on the silica surface because the surface of the PC vesicles binds with  $\text{La}^{3+}$  ions.

For the PC vesicle adsorption state on the silica surface, there are two possible states: 1) as a vesicle particle layer, or 2) as a lipid molecular bilayer. To

**Fig. 14**  $\zeta$ -Potentials vs. the concentration of  $\text{LaCl}_3$ : (◆) PC vesicles; (●) silica particles.

clarify the adsorption state of the vesicles, as the next stage, the adsorption amounts of PC on the silica surface have been measured. In Fig. 15, the results are shown as a function of the PC concentration. Adsorption amounts are expressed by the number of phospholipids molecules adsorbed per square meter of silica surface. The solid line represents a theoretical curve for the adsorption amount of the single bilayer model, assuming the area per PC molecule equals  $0.7 \text{ nm}^2$ . The dotted line shows a theoretical curve for the adsorption of a single vesicle layer model, assuming that the vesicles are of uniform size and have a unilamellar spherical shape. The saturated adsorption amounts in the experiments are located near the value for the latter, but over it. This is because of the existence of some multilamellar PC vesicles in the sample (i.e., the existence of multilamellar PC vesicles will induce a large number of PC molecules than the value of unilamellar vesicles). Thus we can expect that the PC vesicles will be adsorbed on the silica surface as a unilamellar vesicle layer (i.e., the composite particles have been generated as shown in Fig. 13B). Furthermore, we then separated the PC vesicle/silica composites from the free PC vesicles by the ultra-filtration method (with a polycarbonate membrane filter, pore size  $1.0 \mu\text{m}$ ), and determined the mean size of the composite particles by the dynamic light scattering (DLS) method. The diameter of the composite particles is  $1.93 \mu\text{m}$ , and this value is close to  $1.9 \mu\text{m}$ , which was calculated by the single particle layer model. This result means that the PV vesicles will be adsorbed on silica particles as the same spherical particle size.

In the second stage of composite formation, we mixed the PC vesicle/silica composite particles with a small silica ( $2a = 0.5 \mu\text{m}$ ) dispersion under the same  $10^{-4}$  M  $\text{LaCl}_3$  solution. The  $\zeta$ -potentials of the products reversed from positive ( $+28.4$  mV) to negative ( $-30$  mV) again, which indicates that the small silica particles (with negative charges) were adsorbed on the surface of the positively charged composite particles (Fig. 13C).

**Fig. 15** Adsorption amount for PC on core silica surface in  $10^{-4}$  M  $\text{LaCl}_3$  at  $25^\circ\text{C}$ .

The direct observation of the multilayer formation of composite particles is provided by a special optical microscopy technique. In Fig. 16, the composite particles of the silica/PC vesicle/core silica in the  $10^{-4}$  M  $\text{LaCl}_3$  solution are shown. We cannot clearly see the image of the PC vesicles on the silica because the PC vesicle has a large water core and a thin lipid bilayer (about 5 nm). Therefore the total refractive indices of the PC vesicle are close to those of water. However, the formation of the silica/PC vesicle/silica composite particles is indicated clearly in Fig. 16; the small silica particles are adsorbed on the spherical surface of the PC vesicle/core silica composite and are located on the outer layer of the composite particles.

### The Buildup of Polyelectrolyte and/or Colloid Particle Multilayer on Solid Surfaces

The multilayer formation of polyelectrolytes on colloid particles is usually characterized by a stepwise increase of the adsorbed amount and layer thickness, and by alternating highly positive and negative  $\zeta$ -potentials of the covered particles. Here, we describe two kinds of multicomponent layer systems using polyelectrolyte and colloid particles. One is the formation of polyelectrolyte multilayers on polymer colloids. Another is the formation of composite particles including organic and inorganic colloid particles using a layer-by-layer technique of polyelectrolytes.<sup>[35]</sup>

To emphasize the influence of the polarity of the substrate, three kinds of polystyrene lattices are employed. PS-740 lattices with large size ( $2a = 740$  nm) were prepared by the usual surfactant-free emulsion polymerization technique;<sup>[12]</sup> NaSS-190 lattices were made by incorporating a small amount of an ionic comonomer, sodium-*p*-vinylbenzyl-sulfate, into the polystyrene chain according to Kotera et al.<sup>[13]</sup> The charge density

**Fig. 16** Optical micrograph of silica/PC vesicles/silica composite particles.

of NaSS-190 lattices is much higher than that of PS-740 latex. DEAM-250 lattices consist of amphoteric particles prepared by the method described by Homola and James.<sup>[36]</sup> Characteristic data for these samples are shown in Table 3. Silica samples with different particle sizes ( $2a = 500, 300,$  and  $20$  nm), which were obtained from Nippon Catalisitic Co. Ltd. and Nissan Chemical Co. Ltd., were used. All these single dispersions consisted of monodisperse spherical particles with  $D_w/D_n < 1.04$  always, and were used after extensive dialysis.

As the cationic polymer, poly-L-lysine (PLL-19) with a fixed molecular weight ( $M = 190,000$ ) was used, and as the anionic polymer, polystyrene sulfonate (PSSNa-50) with  $M = 500,000$  was used. PSSNa-50 carries a constant charge for pH 3–10. However, PLL-19 is pH-dependently charged and it is known that a fixed positive charge is carried only in the region of pH 3–7.

The adsorption of polyelectrolytes was allowed to take place for 1.5–2 hr at a 0.1–0.3 mg/mL PLL or PSSNa solution using a very dilute latex or silica suspension ( $\phi = 0.0001$ ) and a saturated concentration without any free polymer of each polyelectrolyte that was determined by mobility measurements of the core particles. During the adsorption process, suspensions of the core particles were mixed slowly by means of rotating end-over-end.

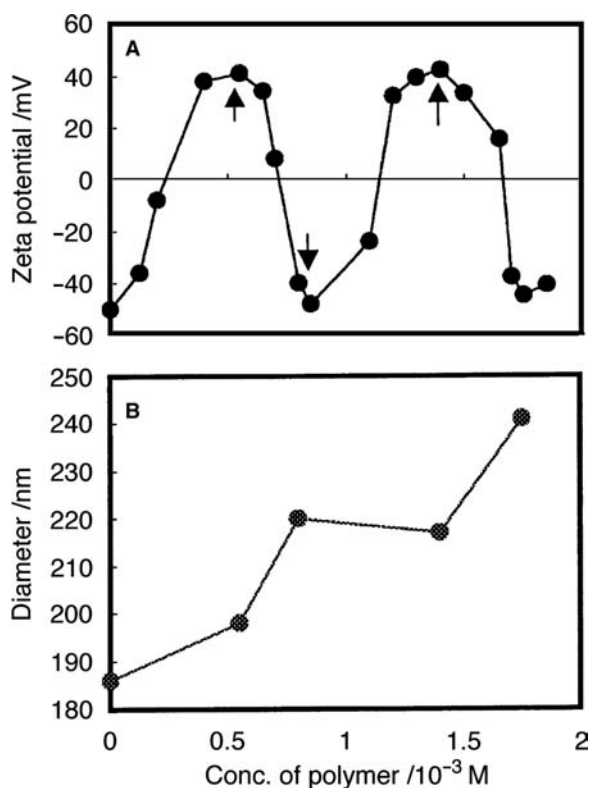

The DLS measurements were carried out to assess the development of hydrodynamic layer thickness on the addition of PLL or PSSNa molecules. The heterocoagulated state of composite particles was observed directly by the optical microscope and scanning electron microscope.

### Multilayer formation of polyelectrolytes on colloid particles

In Fig. 17, a typical cyclical curve of  $\zeta$ -potential on alternating additions of PLL-19 and PSSNa-50 on negatively charged NaSS-190 latex surfaces is shown. The switch to either of the new polyelectrolytes is

**Table 3** Particle diameters,  $\zeta$ -potentials, and functional groups of the colloids

Particle	Diameter (nm)	$\zeta$ -Potential (mV) in $10^{-3}$ M NaCl	Functional group
NaSS-190 latex	190	−50 (pH 4)	$\text{SO}_3^-$
DEAM-250 latex	252	+60 (pH 4)	$\text{NH}_3^+$
PS-740 latex	740	−30 (pH 4)	$\text{OSO}_3^-$
Silica-500	500	−30 (pH 6)	$\text{SiO}_2^-$
Silica-300	300	−30 (pH 6)	$\text{SiO}_2^-$
Silica-20	20	−30 (pH 6)	$\text{SiO}_2^-$

**Fig. 17**  $\zeta$ -Potential (A) and total particle size (B) of the composite system by multilayer deposition of PLL-19 and PSSNa-50 on NaSS-10 lattices against the concentrations of each polyelectrolyte solution ( $\phi = 7.5 \times 10^{-3}$  wt.%, pH 4,  $[\text{NaCl}] = 1 \times 10^{-3}$  M). The switch to a new polymer solution is indicated by the arrows.

indicated by the arrows. In the figure, the abscissa axis indicates the total number of repeating units of both polyelectrolyte molecules. The change of the  $\zeta$ -potential is substantial (i.e., the  $\zeta$ -potential is highly positive after the addition of PLL-19 and highly negative after the addition of PSSNa-50). This result indicates clearly that, on the adsorption of polyelectrolyte, the oppositely charged surface is not just compensated but strongly overcompensated. An overcompensation of polyelectrolyte adsorption is the main reason for progressing the multilayer formation. The buildup process was also confirmed from the stepwise increase of the layer thickness of the core latex particles. The stepwise increase of the layer thickness, especially after the adsorption of PSSNa-50 molecules on the core particle surfaces, is also shown in Fig. 17.

In the next stage, we tried to produce polyelectrolyte multilayers under different medium compositions. In Fig. 18, the results of multilayer formations of PSSNa-50 and PLL-19 in pure water at pH 4,  $10^{-2}$  M NaCl solution, and  $10^{-2}$  M BaCl<sub>2</sub> solution are indicated. In these experiments, the positively charged

**Fig. 18**  $\zeta$ -Potential of multilayers of PSSNa-50 and PLL-19 on DEAM-250 lattices against the concentrations of each polyelectrolyte solution under different salt conditions ( $\phi = 7.5 \times 10^{-3}$  wt.%, pH 4).

DEAM-250 lattices were used as the core particles. In this figure, the locus of  $\zeta$ -potentials obtained under different salt conditions is plotted for the total amounts of repeating units of PLL-19 and PSSNa-50 molecules. As can be seen, the step in the  $\zeta$ -potential obtained in the BaCl<sub>2</sub> solution is delayed, indicating that the electrostatic attraction between PSSNa-50 and the charged surface of DEAM-250 lattices is weakened. This is caused by the strong affinity of Ba<sup>2+</sup> to SO<sub>3</sub><sup>-</sup> in PSSNa-50 molecules. The existence of such a specific effect has been reported in the literature.<sup>[37,38]</sup>

Fig. 19 indicates the stepwise increase of layer thickness on DEAM-250 latex particles under different salt

**Fig. 19** The total particle sizes in each step to stable multilayers of PSSNa-50 and PLL-19 on DEAM-250 lattices under different salt conditions ( $\phi = 7.5 \times 10^{-3}$  wt.%, pH 4).

conditions. Surprisingly, in the  $10^{-2}$  M  $\text{BaCl}_2$  solutions, the layer thickness of adsorbed polyelectrolytes increased steadily and the weak attraction effect coming from  $\text{Ba}^{2+}$  was not observed on the layer-by-layer formation. However, in distilled water, the layer thickness increased quickly at an early stage of deposition. However, in the final stage, the layer shrunk. The reason for this phenomenon cannot be explained, but this result indicates surely that strong electrostatic attraction is not always the sole factor necessary to form a stable multilayer.

#### Multilayer formation of colloid particles with polyelectrolytes

The layer-by-layer deposition technique of polyelectrolytes can be applied to the formation of composite particles comprising organic and inorganic colloid particles. Fig. 20 shows the buildup processes of colloid particles using PS-740 latex sample as the core. Here, PLL-19 was used as a binder polyelectrolyte. The abscissa axis in this figure indicates the total amounts of the binder polyelectrolyte + adhering particles. As can be seen from the figure, the  $\zeta$ -potential of the core particle has changed from a negative value to a positive value by adsorption of PLL-19 molecules, and changed again to negative values with an increasing number of adhering silica particles (Silica-300). These results suggest that the composite formation of colloid particles has progressed reasonably by the binder layer of

**Fig. 20**  $\zeta$ -Potential of composite particles by multilayer deposition of PLL-19 (concentration,  $2 \times 10^{-4}$  wt.%) and Silica-300 (concentration,  $1.0 \times 10^{-3}$  wt.%) on PS-740 lattices ( $\phi = 7.5 \times 10^{-4}$  wt.%, pH 6,  $[\text{NaCl}] = 1 \times 10^{-3}$  M). The switch to Silica-300 from PLL-19 is indicated by the arrow.

**Fig. 21** Electron micrograph showing hybrid particles of outer Silica-300 particles on core PS-740 lattices.

PLL-19 molecules. Fig. 21 is a photograph showing a typical example of hybrid particles consisting of outer Silica-300 particles on core PS-740 latex as prepared in this experiment. It is known that the composite consists of regular hybrid particles comprising organic and inorganic particles. However, the structure form is not so stable and sometimes the system includes free silica particles.

In the next stage, the synthetic process of hybrid particles with multilayers of silica particles on PS-740 was examined. As the binder polyelectrolyte, the PLL-19 molecule was also used under the same medium conditions. Fig. 22 shows the cyclical behavior of the  $\zeta$ -potential in the formation process of multilayers of Silica-20 and PLL-19 layers. As can be seen, the cycle of  $\zeta$ -potential after adhesion is systematical, indicating that the deposition of PLL and Silica-20 has progressed regularly. Fig. 23 is a photograph of

**Fig. 22**  $\zeta$ -Potential of composite particles by multilayer deposition of pair (PLL-19 + Silica-20) layers. The switch is indicated by the arrow.

**Fig. 23** Electron micrograph showing hybrid particles of small Silica-20 particles on core PS-740 latex particles: (A) PS-740 lattices; (B) hybrid particles deposited by a single (PLL-19 + Silica-20) layer; (C) hybrid particles deposited by pair (PLL-19 + Silica-20) layers.

an original PS-740 latex and two kinds of composite particles covered with a single silica + polymer layer and two silica + polymer layers. Two kinds of composite particles can be distinguished based on the thickness of the adhering silica particle layer.

From these results, it is concluded that, by combining a multilayer formation of polyelectrolytes and charged colloid particles, we can prepare many new synthetic materials comprising different chemical species, different structures, and different shapes.

## CONCLUSION

Here, several preparation processes of composite particles relating to the electrical properties of particles are described: 1) the heterocoagulation process of amphoteric polymer lattices on spherical silica; 2) composite formation comprising silica/vesicle or silica/vesicle/silica particles; and 3) the buildup process of polyelectrolyte or colloid particle multilayers on latex or silica surfaces. All these results indicate that the electrokinetic measurement is an essential and powerful technique for monitoring the formation process of composite particles with different compositions. Finally, the present authors would like to stress that the formation processes described here were concerned with the semimicron-sized particles, but these techniques can be applied to systems, including nanosized particles with slight reversions.

## INTRODUCTION

Colloidal particles are liquid or solid objects with dimensions ranging from a few to several hundred nanometers (and, in a broader sense, up to many micrometers), that are suspended in a solid, liquid, or gas matrix.<sup>[1–3]</sup> These particles can show very distinct properties compared to small molecules and macroscopic systems, because of their mesoscopic size with the resulting large surface-to-volume ratio and intermediate dynamics. One of the most common forms of colloids are solid particles suspended in a liquid medium, such as paint and adhesives, and this format will be discussed here. Solid colloid particles are available from many different materials, such as organic compounds (drugs and pigments), polymers, and inorganic materials (ceramics and semiconductors). Depending on the interactions between the particles and of the particles with the suspending medium, the colloids can form aggregates and ordered structures in three dimensions, e.g., colloidal crystals (Fig. 1A). Such 3-D aggregates may serve as mesoporous materials for filter applications, or if the particle diameter is in the wavelength range of visible light, colloid crystals can diffract and filter light of specific wavelength (photonic bandgap structures).<sup>[4]</sup>

If the particles additionally interact with a surface, colloid adsorption can take place that leads to planar structures (Fig. 1B). For such structured surfaces, many current and potential applications exist, such as self-cleaning, superhydrophobic or antireflecting surfaces, adhesion control (like protein adsorption and antifouling), chemo- and biosensors, optical filters and switches, electromechanical devices, microfluidics, and surfaces for separation technology.<sup>[5]</sup> For such applications, lateral patterning of the colloid layer is

often required (Fig. 1C, which can be achieved via various methods, such as site-selective surface modification or templating with a 3-D mold).

This entry provides an overview on the methods and effects that lead to structured colloid assemblies at substrate surfaces. Besides the fundamental interactions in colloidal systems that lead to 3-D and 2-D assembly structures, several techniques are discussed which can be used to build highly ordered particle assemblies with complex lateral structure in a controlled way. The patterning is realized by the application of templates and directing methods during particle deposition, which will be presented in further detail.

## FUNDAMENTAL INTERACTIONS IN COLLOID SYSTEMS AND SURFACES

Interactions between colloidal particles and between surfaces and colloidal particles are primarily governed by three main force types: van der Waals, electrostatic, and capillary forces (listed by increasing strength).<sup>[1,2,6]</sup> We present an overview of these colloidal forces, which play a crucial role in determining the particle deposition efficiency and stability. Other types of interactions are briefly discussed, as they can be important in particular cases.

### van der Waals Interactions

The universal attractive forces between atoms and molecules, known as van der Waals forces, operate between all particles in any suspension medium and are responsible for particle flocculation.<sup>[7]</sup> When these forces occur between two atoms or molecules, their

**Fig. 1** Progression of interactions in colloidal particle systems that lead to: (A) 3-D aggregates by particle-particle interactions; (B) particle layers on planar substrates by additional interaction with the substrate surface; (C) and structured colloid assemblies by lateral patterning of the substrate surface.

range is in the order of a nanometer or less (potential  $V$ -separation  $r$  dependence:  $V \sim 1/r^6$ ), but when colloidal particles are considered, these forces can act at a much longer distance. This is because the atoms of a particle mutually interact, to some extent, with all the atoms of other particles, and these effects are partially additive. The potential associated to such interactions is usually expressed as  $V = -A/12\pi r^2$ , where  $A$  is the Hamaker constant of the particular system and  $r$  is the distance between the particles.

### Electrostatic Interactions

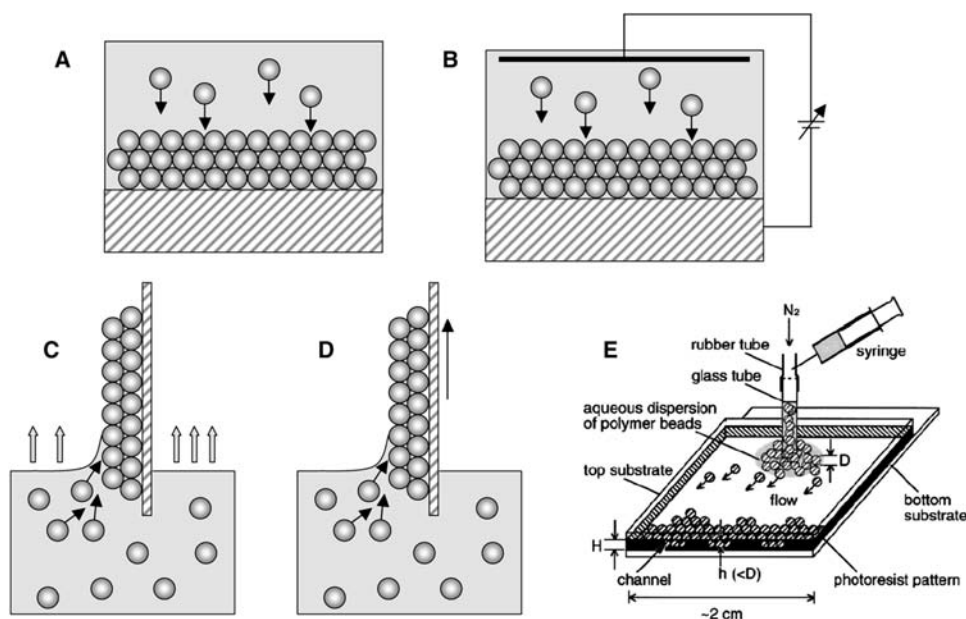

These long-range forces are usually responsible for the stabilization of colloidal suspensions through repulsion between identically charged particles. The associated potential is expressed as  $V = C \exp(-\kappa r)$ , where  $1/\kappa$  is the Debye-Hückel length,  $r$  is the distance between the particles, and  $C$  is a term depending on  $\kappa$ , on temperature, on the surface potential of the particles, and on the electrolyte concentration. In an electrolyte solution, the distribution of ions in the vicinity of the solid surface (the diffusion layer) is determined by electrostatic interactions with the surface and the thermal motion of the diffusing ions. Solid surfaces of similar charge that approach each other repel when their diffusion layers overlap. On the other hand, solid surfaces with opposite charge experience an attraction when they come close to each other. This attraction is utilized in colloid self-assembly on charged surfaces and leads to irreversible adhesion.<sup>[8]</sup>

### Capillary Forces

Similar particles floating on a fluid attract each other by lateral capillary forces and can form clusters. These flotation capillary forces are caused by the

deformation of the interface due to the effect of gravity pulling the particles into the liquid and the surface tension that tends to minimize the liquid surface.<sup>[6]</sup> The energy of capillary interactions between floating particles becomes negligible, i.e., smaller than the thermal energy  $kT$ , for particles smaller than 5–10  $\mu\text{m}$ . Particles on a solid surface partially immersed in a liquid are also subject to similar attractive forces, called immersion capillary forces, which occur at the liquid–solid interface (e.g., during drying). Because of the confinement at a solid surface, the energy of immersion interactions is much larger, for the same particle size, than the energy of flotation interactions, and it can be substantially greater than  $kT$  even for particles of nanometer size. These very strong (about 3 orders of magnitude higher than the electrostatic forces) and long-range forces (up to macroscopic dimensions) pull the particles together and are responsible for their ordering, yielding 2-D or 3-D crystalline layers in certain cases.<sup>[6,9]</sup> The potential of immersion forces can be expressed as  $V \sim CR/(r-2R)$ , where  $R$  is the radius of the particle,  $r$  is the distance between the particles, and  $C$  is a factor depending on the surface tension, on the contact line at the surface of the particle, and on the mean slope angle of the meniscus at the contact line. These forces are attractive between objects of the same polarity (both wetting or non-wetting, same curvature of liquid meniscus at particle–liquid–air contact line), and repulsive between objects of different polarity (wetting in contact with nonwetting objects, opposite liquid meniscus at object–liquid–air contact line).

There are several other types of interactions which can be important in certain cases and may play a large role in determining whether or not particles will adhere to each other or to other surfaces. In aqueous systems, the effect of hydration can be important. This is often associated with hydration of ions at particle surfaces, and usually gives an extra repulsion. Hydrophobic effects, which are associated with the high internal structure in water, can also be relevant and may provide an extra interaction between particles or between particle and surfaces. Other significant effects arise from external forces, such as gravity and hydrodynamic drag. These external forces have a strong dependence on particle size. For instance, the gravity force is proportional to the mass of particle and hence, to the cube of the particle size. The hydrodynamic forces (particularly relevant in electrophoretic particle deposition), as a result of fluid flow, depend roughly on the square of particle size. This means that, for large particles, gravitational and drag forces will predominate over colloidal forces, while the latter may be much more significant for small colloidal particles.

**Fig. 2** Schematic outlines of five common procedures to assemble colloids into 3-D crystalline structures: (A) sedimentation in a gravitational field; (B) electrophoretic method; (C) vertical deposition by evaporation; (D) deposition by vertically lifting of the substrate; (E) flow cell technique. *Source:* From Ref.<sup>[18]</sup>. © 1999 American Chemical Society.

## COLLOID ASSEMBLY IN 3-D

Three-dimensional closed pack structures of monodisperse microspheres, also called synthetic opals, present a spatial periodic variation of the dielectric constant. Thus they can influence the propagation of electromagnetic waves in a similar way as semiconductors do for electrons, i.e., there exists a bandgap that excludes the propagation of photons in a given range of frequencies. These so-called photonic crystals attract major interest because they represent promising candidates for the manipulation of the flow of light. Several methods to assemble colloidal crystals have been reported; the five most common procedures will be presented here, as schematically outlined in Fig. 2. Whatever method is applied, the utilization of monodisperse colloids, i.e., polydispersity below 5%, is a prerequisite to obtain ordered crystals with a low defect density. Usually, fcc structures with the (111) direction oriented perpendicular to the surface of the film are obtained.

### Sedimentation in a Gravitational Field

This is a simple technique requiring no special equipment (Fig. 2A), in which a particle suspension is standing undisturbed over a long period of time.<sup>[10,11]</sup> The colloids settle at the bottom of the container due to gravity and form dense 3-D crystalline structures. However, several parameters such as the size and density of colloids and the sedimentation rate, which has

to be slow enough to allow a disorder-to-order transition to occur, have to be carefully controlled to obtain a 3-D ordered lattice. Silica colloids are usually employed in sedimentation because of their high density ( $\sim 2.2 \text{ g cm}^{-3}$ ). The major drawbacks of this method are the long time needed to obtain colloidal crystals (days to months), the restricted control over the morphology of the top surface and over the number of layers, and the limited size range of colloidal spheres that can be used (300–550 nm).

### Electrophoretic Deposition

Several of the above-mentioned problems can be circumvented by the electrophoretic deposition method, which uses an electric field to control the sedimentation rate (Fig. 2B).<sup>[12,13]</sup> The particle suspension is held between two parallel electrodes and an applied voltage generates an electric field that drives the particles to the bottom electrode. With this technique, a broader range of particle sizes, with diameters up to 900 nm, can be used and the time needed to settle small spheres is substantially decreased.

### Vertical Deposition by Evaporation

A convenient and versatile way to obtain colloidal crystals is the vertical deposition technique, in which a hydrophilic substrate is vertically immersed into a colloidal suspension while the liquid medium is allowed to evaporate (Fig. 2C).<sup>[14,15]</sup> In this case, capillary forces are

responsible for the organization of the colloids (see the section “Colloid Assembly at Planar Surfaces” below). The thickness of the crystal can be precisely controlled by adjusting the concentration of the suspension and the sphere size. Ethanol is usually used as suspending medium because of its relatively fast evaporation rate at room temperature; however, water can also be used if the temperature is raised to about 50–60°C.<sup>[16]</sup>

### Vertical Lifting

A variant of the vertical evaporation method has been developed, where the substrate is withdrawn from an aqueous suspension at a controlled speed instead of letting the solvent evaporate (Fig. 2D).<sup>[17]</sup> The withdrawing speed provides an additional parameter to control the thickness of the deposited film and can substantially decrease the preparation time.

### Flow Cell

Colloids have also been assembled into ordered 3-D structures by using a flow cell (Fig. 2E).<sup>[18]</sup> An aqueous dispersion of particles is injected into a cell formed by two glass substrates and a square frame of photoresist that is patterned on the surface of one of the substrates. One side of the frame has channels on the upper rim that can retain the particles while letting the solvent flow through. External gas pressure generating a flow and agitation by sonication are the driving forces to assemble the particles into a close-packed structure. This method can be applied to a relatively broad range of particle sizes and the number of layers in the crystalline assemblies is controlled by the distance between the two opposing glass slides.

## COLLOID ASSEMBLY AT PLANAR SURFACES

Planar colloid layer systems consisting of particle monolayers and multilayers can be classified by their preparation method or by the interactions that control their formation. There are various techniques to deposit colloid particles at planar surfaces that allow the formation from disordered to highly crystalline particle mono- and multilayers, depending on the particular method and the intrinsic properties of the particles. Such methods are partially related to the techniques described above for 3-D colloid assemblies. Examples include spin coating of particle suspensions, centrifugation, evaporation of suspensions on surfaces, adsorption from solution/self-assembly, electrophoretic deposition from suspension, Langmuir–Blodgett (LB) deposition of colloidal monolayers from the air–water interface, or laminar flow methods.<sup>[19]</sup>

The various interactions that drive particle deposition and possibly ordering in the layer are van der Waals attraction between particles and the substrate surface, polar interactions and hydrogen bonding if polar groups and hydrogen donor–acceptor pairs are present, and strong Coulomb forces (electrostatic interactions) if charged surface functions are available. If the colloid particles are suspended in an aqueous medium and the thickness of the liquid film reaches the particle diameter, strong long-range capillary forces, in combination with convective flow, can cause high order in the colloid layers.

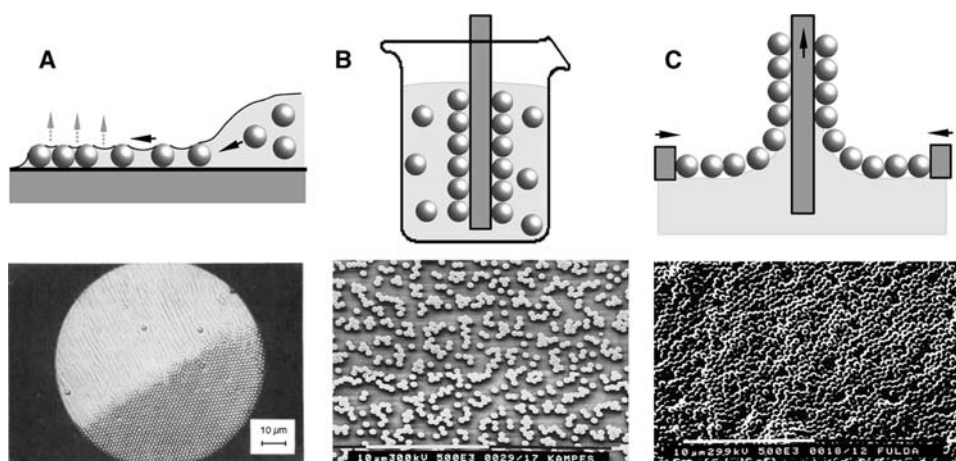

Three characteristic deposition methods and the involved interactions are described in more details below.

### Evaporation from Suspension on Planar Surfaces

The controlled evaporation of a latex suspension (concentration usually around 1 wt.%) in a very thin liquid film leads to the formation of densely packed colloid layers (Fig. 3A).<sup>[20]</sup> If the particles are monodisperse, highly ordered two-dimensional colloid crystals are formed. The ordering process occurs where the thickness of the liquid film reaches the particle diameter and a meniscus is formed between the colloids, pulling them tightly together by capillary forces. The driving force is the high surface tension of water that tends to minimize the free liquid surface between the particles. In addition, water evaporation in the dense particle layer generates a convective flow of the surrounding liquid with its suspended particles toward the colloid layer. It was found that high evaporation rates (controlled by ambient humidity) favor higher order in the colloid films and that smaller particles crystallize faster. The shape or slope of the drying meniscus controls the formation of multilayers, with a steeper meniscus producing thicker layers.

### Adsorption from Solution/Self-Assembly

By immersing a substrate into a colloid suspension, particles can adsorb onto the surface if sufficiently strong attractions between the substrate surface and the particles exist (Fig. 3B).<sup>[19]</sup> Very often, oppositely charged substrates and particles are used in which strong electrostatic attraction causes irreversible adsorption. In such cases, the substrate surface either carries an intrinsic charge (such as mica, a layered mineral), or the charge is introduced by surface modification with charged molecules. For this purpose, charged thiols can be adsorbed on gold, while oxidic surfaces such as glass are modified with charged silanes or polyelectrolytes. The complementary latex particles can be synthesized with charged surface groups by adding the corresponding monomer during

**Fig. 3** (A) Formation of ordered particle mono- and multilayers by capillary forces upon drying. (B) Self-assembly of colloid monolayers by adsorption from suspension. (C) Formation of a Langmuir–Blodgett particle film by transfer of a colloid monolayer from the air–water interface. *Source:* From Ref.<sup>[20]</sup>. © 1992 American Chemical Society. From Ref.<sup>[56]</sup>. © 1999 Elsevier. From Ref.<sup>[19]</sup>.

polymerization. Here often carboxylic acid functions (e.g., from acrylic acid) are used that are negatively charged at  $\text{pH} > 5$ . Because of the irreversible adsorption via electrostatic interactions in disordered particle layers, the maximum absolute surface coverage that can be practically achieved is about 56%, compared to a theoretical coverage of 91% in a dense hexagonal lattice. The process can be described by the theoretical model of “random sequential adsorption” (RSA), in which irreversibly and randomly adsorbed particles do not move laterally and prevent rearrangement into densely packed layers.<sup>[21]</sup> By alternately immersing the substrate in suspensions of oppositely charged colloids, highly disordered particle multilayers are obtained. If functional groups of the particles can react with groups on the substrate surface to form chemical bonds, very stable particle layers are obtained by chemisorption.<sup>[22]</sup>

### Langmuir–Blodgett (LB) Deposition of Colloid Monolayers from the Air–Water Interface

Polar colloid particles (e.g., sulfonated or carboxylated polystyrene latex) can be spread from an organic solvent (like ethanol) at the air–water interface, similar to low molar mass amphiphiles (Fig. 3C).<sup>[19]</sup> After solvent evaporation, the colloids float at the air–water interface, and by reduction of the free surface area with a moving barrier, the initially disperse particle layer is compressed up to the point where the colloids are tightly packed. The colloid monolayer formation is favored by low pH and high salt concentration, which drives the particles from the aqueous subphase to the surface as a result of the reduced polarity of the

screened charges. When a submerged substrate is vertically pulled up through the compressed colloid film, the particle monolayer can be transferred to the solid support. By annealing the transferred film close to the glass transition temperature of the latex material, the particles slightly deform and then adhere sufficiently to the substrate to allow an additional colloid layer transfer. Repeated transfer and annealing cycles allow the formation of particle multilayers. The colloid monolayers are usually disordered with many defects, and in particular, the multilayers possess a high surface roughness.

### STRUCTURED COLLOID ASSEMBLIES AT SURFACES

As discussed above, monodisperse colloidal particles can assemble into long-range ordered lattices under appropriate conditions, but self-assembly alone is restricted to the formation of 2-D or 3-D particle arrays and usually does not lead to more complex patterns. However, additional degrees of control over the colloidal structures can be achieved through the application of external electric, magnetic, or optical fields, by selective deposition onto previously patterned substrates, or by the use of templating structures (Fig. 4). These laterally structured surfaces can be fabricated by different techniques such as lithography with photons, particles, and scanning probes, replication against masters via physical contact (printing, molding, embossing), molecular self-assembly, or templated deposition.<sup>[23]</sup> Colloidal assembly onto such patterned surfaces, as outlined in Fig. 4, and the mechanisms governing the deposition will be discussed in the following sections.

**Fig. 4** Various concepts for the generation of structured colloid assemblies in 2-D and 3-D on solid substrates: (A) external field templating (here, electrical field example); (B) chemically patterned surface; (C) topographic surface structure (with feature sizes in the colloid dimension lead to directed crystallization/epitaxy, left, while large feature sizes induce structuring of whole crystals, right); (D) 3-D template; (E) direct lithographic patterning of colloid layers.

## External Fields

### Electrical fields

As outlined before, colloidal particles can be manipulated with electric fields to form 2-D and 3-D ordered crystals. Two conceptual geometries can be distinguished by the orientation of the electric field with respect to the substrate surface: first, a parallel plate geometry, as presented in Fig. 2B, with the field vector perpendicular to the surface, and second, an in-plane electrode arrangement, as shown in Fig. 4A, with the principal field vector parallel to the substrate surface.

The *parallel plate geometry* has been used for the electrophoretic deposition of colloidal particle layers,<sup>[12,24,25]</sup> but this technique does not necessarily generate complex lateral structures by itself. Some basic in-plane structuring was observed during the different stages in the deposition process, such as initial random adsorption of isolated particles after short adsorption times, followed by the formation of 2-D clusters and islands of particles at longer times, and the coalescence of these individual domains up to complete coverage. The islands showed high order, but the crystallographic axes of neighboring islands were not correlated. Changes in the magnitude of the current did modulate the strength of the lateral attraction and allowed the formation of different 2-D “gas,” “liquid,” and crystalline colloidal arrays on the electrode. The ordering phenomena in electrophoretic deposition were explained with electrokinetics (charged particle acceleration in the electric field), electrohydrodynamics (flow of the liquid medium due to particle and ion migration), and Brownian diffusion (driven by thermal energy).<sup>[26,27]</sup>

More complex in-plane structures could be obtained by a combination of vertical confinement (which is controlled by the electrode separation) with variations

of the applied electric field.<sup>[28]</sup> A close electrode separation in the range of the colloid diameter strongly influences the electroosmotic (and hydrodynamic) fluid flow and switches it from an attractive into a repulsive character. By variation of the nature of the applied electric field and the degree of particle confinement, the relative strength of attraction and repulsion can be independently varied, providing a way to tune both the strength and range of the effective interaction potential. The technique allowed ordering and structure formation in the colloid layers from extended crystalline lattices with periodicities larger than the particle diameter over dense crystal patches to honeycomb and worm-like structures (Fig. 5).

A larger control over the lateral patterning of colloid layers with electric fields can be achieved by *in-plane structured electrodes*. It was shown that, on a planar patterned electrode in the parallel plate geometry (Fig. 2B), the colloid particles migrate laterally at the surface from the non-conducting to the conducting regions by electrohydrodynamic flow.<sup>[29]</sup> In the in-plane geometry of Fig. 4A, the electrode and counter electrode are on the same substrate surface and produce an in-plane field when a voltage is applied. Protein-covered latex microspheres were collected and coagulated onto the micrometer-sized gaps between two addressable electrodes under the action of a nonuniform electric field, an effect known as dielectrophoresis.<sup>[30]</sup> After particle fixation by induced coagulation, such colloid structures can be used in biosensor arrays with direct electric conductivity readout (after target molecule binding, tagging with colloidal gold and enhancement by silver nucleation).

Defined 2-D structuring in electrophoretic colloid deposition can also be obtained by a combination with lithographic illumination.<sup>[31]</sup> In this experiment, colloid particles were deposited in the parallel plate geometry onto an indium tin oxide (ITO) electrode that was

**Fig. 5** Colloid monolayer structures prepared by electrophoretic deposition in confined geometry (particle diameter, 4.2  $\mu\text{m}$ ). Source: From Ref.<sup>[28]</sup>. © 2002 American Chemical Society.

irradiated from the other side with ultraviolet (UV) light through a mask. The irradiated electrode regions showed a photochemically induced higher current density that, in turn, led to particle aggregation on these regions, while the non-irradiated areas were depleted of particles. By this method, crystalline particle monolayers with the shape of the mask geometry can be generated (Fig. 6).

### Optical fields

Individual colloid particles made of dielectric material can be optically trapped and manipulated in a strong electromagnetic field gradient of focused laser beams, a technique which is nowadays referred to as “optical tweezers.”<sup>[32]</sup> The dielectric particles are drawn into the region of highest light intensity and accelerated in the direction of the light propagation by the radiation pressure. If a laser beam hits a substrate surface in a perpendicular manner, the colloid particles become trapped at the intersection of the beam with the surface. An extension of this technique, called scanning laser optical trapping, was used to simultaneously trap multiple colloids in a designed pattern which was locked-in by photopolymerization of a monomer-containing solvent (Fig. 7).<sup>[33]</sup>

If three laser beams are brought to interference at a substrate surface, a standing wave 2-D pattern is generated, which allows entrapping of particles in the virtual lattice geometry of the interference pattern.<sup>[34]</sup> Such systems were used to create arrays of extended crystalline and noncrystalline colloid structures and to study the crystallization and melting of the 2-D colloid lattice by modulation of the light potential.<sup>[35]</sup> The use of optical fields to pattern surfaces with colloidal particles features the following advantages: 1) it does

not require contact with a probe, 2) it is not limited in particle number or morphology, and 3) it offers a very precise control over particle position.<sup>[36]</sup>

### Chemical Patterning

The combination of the modern patterning techniques with the ability of functionalized thiols or silanes to form self-assembled monolayers (SAM) onto specific surfaces (gold, silica) provides convenient methods to generate regions of modulated surface potentials on a substrate by differences in their chemical nature. The contrast between the opposite regions in the pattern is achieved by differences in wetting (hydrophobic against hydrophilic regions), charge (charged against opposite charged or neutral regions), or chemical affinity (covalent bonding) of the head groups located at the top of the SAM. Colloids with specific surface functions can

**Fig. 6** Photopatterned colloid assembly by electrophoretic deposition combined with illumination through a mask. Source: From Ref.<sup>[31]</sup>. © 2000 Nature.

**Fig. 7** Ordered colloid cluster generated by scanning laser optical trapping. *Source:* From Ref.<sup>[33]</sup>. © 1999 American Chemical Society.

be assembled onto the substrates by a combination of attractive or repulsive interactions between the surface groups of the particles and the substrate, and the effect of the capillary forces upon drying.

Utilizing wetting, selective particle deposition could be obtained for magnetite colloids on thiol and silane pattern or for polystyrene particles on gold patterns on mica.<sup>[37]</sup> Upon drying of the latex suspension on the patterned surfaces, the liquid retracts onto the hydrophilic regions and selectively deposits the particles there.

A higher selectivity could be achieved with the assembly of charged spheres onto micropatterned substrates bearing cationic and anionic regions that were prepared by  $\mu$ CP of thiols on gold (Fig. 8).<sup>[9]</sup> Observation of the colloidal assembly in the wet state and during drying suggests two steps in the assembly mechanism. First, a selective attachment of colloids onto the substrate in a loose packing is driven by long-range attractive electrostatic forces between oppositely charged particles and the pattern. Second, rearrangement of the structure occurs upon drying through capillary forces that displace the particles toward the center of the pattern and induce the formation of dense clusters.

Patterned SAMs of charged thiols could be further modified by alternating polyelectrolyte adsorption from solution, which reverses the surface charge.<sup>[38]</sup> Colloid adsorption onto the polyelectrolyte multilayer patterns was controlled by three independent parameters: pH of the colloidal suspension (determines ionization of the surface), ionic strength of the suspension (charge screening by salt addition), and concentration of added surfactant (leads to charge screening

**Fig. 8** Localized adsorption of charged colloids onto oppositely charged thiol monolayers on gold. *Source:* From Ref.<sup>[9]</sup>. © 2000 American Physical Society.

and hydrophobic interactions). By reducing the size of the polyelectrolyte regions to less than three times the particle diameter, clusters of controlled size and packing geometry were obtained (Fig. 9).<sup>[57]</sup>

Colloid assembly experiments with negatively charged polymer spheres on photolithographically patterned alkylsilane SAMs on silica surfaces showed the competition of selective wetting and pH-dependent charge effects during the wet and dry states of the assembly process. By changing the pH from 1 to 9, the particle selectivity could be switched between adsorption onto the hydrophilic silica surface and deposition onto the hydrophobic alkylsilane patterns.<sup>[5]</sup>

The high selectivity of biological recognition can also be introduced into the colloid assembly process on chemically patterned surfaces by the utilization of short DNA strands. The complementary single strands of oligodeoxynucleotides are attached onto the colloids and specific regions on the substrate surface, respectively, and site-selective particle deposition is directed by hybridization of the complementary strands. Polystyrene beads as well as gold nanoparticles could be selectively deposited by this method.<sup>[39,40]</sup> The advantage of DNA to guide the assembly is the large number of recognition elements that can be encoded by the nucleotide sequence. Moreover, as the length of the sequence increases, the number of recognition elements increases dramatically, providing an almost limitless number of interaction pairs that can be designed to guide multicomponent assembly.

Photochemistry at the surface has been proven as an elegant way to directly obtain chemically patterned surfaces without the use of extra structuring tools.<sup>[41]</sup> Surface modification of a silicon substrate with a

**Fig. 9** Selective clustering of charged colloid particles onto small polyelectrolyte regions with opposite charge (particle diameter,  $4.34\ \mu\text{m}$ ). *Source:* From Ref.<sup>[57]</sup>. © 2002 Wiley-VCH.

photosensitive silane and subsequent irradiation through a mask generates active surface groups at selected positions.<sup>[42]</sup> The chemical contrast between exposed and unexposed areas guides the posterior colloidal assembly, as was shown on a photoprotected aminosilane surface with carboxylated latex particles, which assembled specifically onto the free amino regions of the irradiated areas by Coulomb attraction (Fig. 10).

Radiation damage processes can be also used to selectively remove SAMs from a surface and generate alternating modified and unmodified regions on the substrate to guide the site-selective assembly of particles. By high-energy UV irradiation of a thiol monolayer through a mask and subsequent SAM formation with a charged thiol, a charge pattern was prepared and used for electrostatic colloid deposition.<sup>[43]</sup> Irradiation of a fluoroalkylsilane monolayer on a titanium dioxide surface resulted in the photochemical degradation of the silane and generation of very hydrophilic surface regions, which allowed selective colloid deposition by the vertical transfer method (as outlined in Fig. 2D).<sup>[44]</sup>

### Topographic Patterning

Several examples of colloids deposited onto topographically patterned surfaces are reported in the literature, which can be divided into three classes:

**Fig. 10** Photopatterning of a light-sensitive silane monolayer by irradiation through a mask led to selective particle adsorption onto the irradiated regions. *Source:* From Ref.<sup>[42]</sup>. © 2002 National Academy of Sciences USA.

1) the crystallization of colloids in 2-D confining media (Fig. 4C), 2) the crystallization of colloids in 3-D confining media (Fig. 4D), 3) the growth of colloidal crystals with an induced orientation, i.e., colloidal epitaxy (Fig. 4C, left).

### Colloid crystallization in lateral confinement (2-D)

Ribbons of colloid monolayers were obtained by electrophoretic deposition (Fig. 2B) of charged colloidal spheres onto stripe-patterned ITO electrodes with a groove depth exceeding half the particle diameter.<sup>[45]</sup> Variation of the conducting groove width had a substantial influence on the order in the particles bands, depending on the width being commensurate or incommensurate with the dimensions of a discrete number of colloidal spheres. For commensurate grooves smaller than eight times the particle diameter, ordered particle monolayers were obtained (Fig. 11).

Rectangular-shaped microchannels, prepared by etching (plasma, reactive ion etching (RIE)) of a silicon wafer or by micromolding, were used as template to generate stripes of colloidal crystals.<sup>[4,46]</sup> Colloids were deposited on such patterned surfaces, either by vertical evaporation (Fig. 2C) or vertical lifting (Fig. 2D). Colloids are deposited selectively in the microchannels because of the strong capillary-driven directional mass flow of colloids from the dispersion exclusively into the microchannels and not on the top of the unetched area (Fig. 12A–C).

If the feature size of the templating surface allows the accommodation of only a small number of particles, colloid clusters of well-defined size and

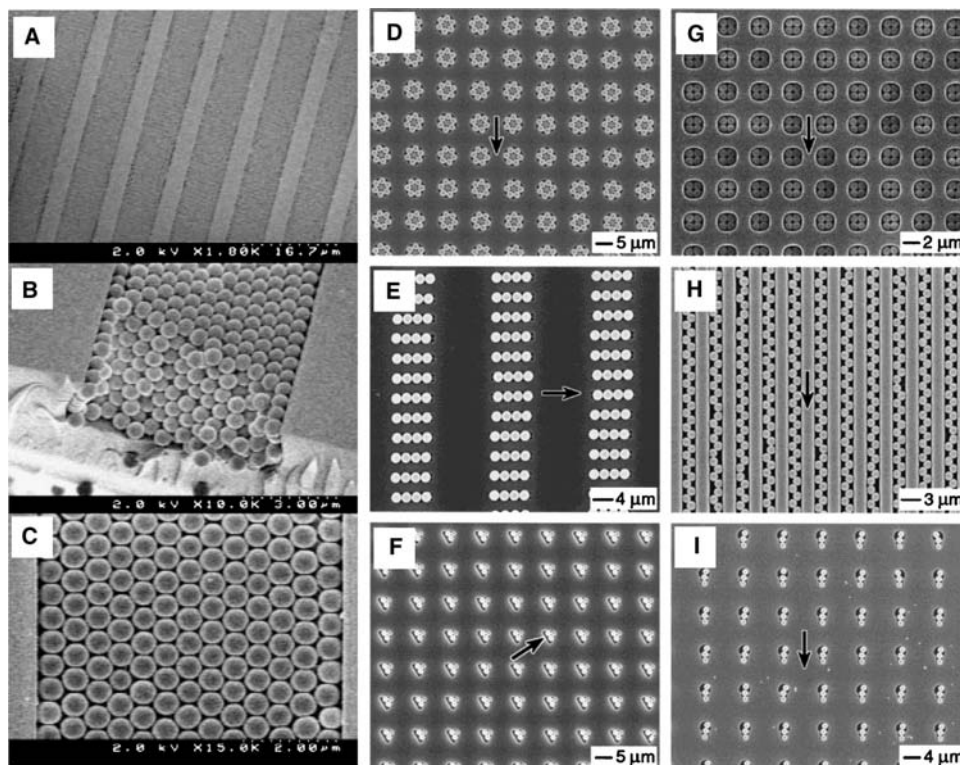

**Fig. 11** Electrophoretic deposition of colloids in grooves of a structured electrode (particle diameter,  $0.58\ \mu\text{m}$ ). For grooves which are commensurable with the particle packing, ordered layers are obtained (A,C), while incommensurable widths yield disordered layers (B). *Source:* From Ref.<sup>[45]</sup>. © 2002 Wiley-VCH.

geometry can be fabricated—triangular, squared, pentagonal, and hexagonal aggregates (Fig. 12D–I).<sup>[47]</sup>

### Colloid crystallization in spatial confinement (3-D)

Two related methods have been reported to grow colloidal crystals in 3-D confining templates. The first one,

called microfluidic colloidal self-assembly, utilizes a pattern of V-shaped grooves (made by anisotropic etching of a Si(100) wafer), which are covered with a polydimethylsiloxane (PDMS) block in conformal contact.<sup>[48]</sup> A drop of an aqueous colloid dispersion is then added at the interface between the patterned silicon wafer and the block. The spheres are driven into the V-shaped grooves by capillary forces and form a close-pack structure, with the (100) orientation perpendicular to the wafer surface, upon evaporation of the water. The shape (opening angle) of the grooves induces the (100) orientation and is therefore an example of colloidal epitaxy (see below and Fig. 14A,B). The second method, called micromolding in capillaries (MIMIC), consists of placing a microstructured PDMS mold onto a flat surface, then adding a drop of a colloidal suspension at the interface, which is drawn into the microchannels as described above.<sup>[49]</sup> When the water has evaporated, the PDMS mold is removed and close-packed colloidal structures with the (111) orientation perpendicular to the surface is obtained on the planar substrate (Fig. 13). In both of these techniques, the channels have to be open at both ends to allow the flow and evaporation of the aqueous colloid suspension.

**Fig. 13** Micromolding in capillaries technique (MIMIC) and crystalline colloid structures obtained by MIMIC. Source: From Ref.<sup>[49]</sup>. © 1998 Wiley-VCH.

### Templated colloidal epitaxy

Colloidal epitaxy is the controlled crystallization of colloid particles on a structured surface with topographic periodicities commensurate to the colloid

crystal lattice dimensions, where the crystal orientation is induced by the surface structure. In early examples of colloidal epitaxy, silica spheres were sedimented onto a polymer film bearing holes (drilled by electron beam lithography).<sup>[50]</sup> When the pattern of holes is commensurate with the (100) or (110) plane of a fcc lattice, colloid crystal growth proceeds with the (100) or (110) plane parallel to the substrate surface. The major drawback of this technique is the small feature sizes of the template in dimensions of individual colloids, which requires advanced nanolithographic techniques for colloids smaller than 500 nm. To circumvent this problem, square or rectangular pyramidal pits much larger than the particles were anisotropically etched in a Si(100) wafer and used to grow small colloidal crystals within these pits by spin coating.<sup>[48]</sup> The apex angle of the pits determines the packing geometry, and if a square lattice is favored inside the pits, eventually the whole crystal on top of the substrate will grow with the (100) plane parallel to the surface (Fig. 14C,D).<sup>[51,52]</sup> With other apex angles, non-fcc packing geometries are obtained. Additional parameters that control bulk crystal growth are the lateral dimensions and the separation between the square pyramidal pits.

**Fig. 14** (A,B) Epitaxial growth of the (100) orientation of close-packed colloid crystals in pyramidal pits by spin coating self-assembly. (C,D) Bulk colloid crystallization of the (100) orientation by epitaxial growth on pyramidal pit template by flow cell deposition (see Fig. 2e). Source: From Ref.<sup>[48]</sup>. © 2001 Wiley-VCH. From Ref.<sup>[51]</sup>. © 2002 Wiley-VCH.

The stabilization of crystalline structures on patterned substrates can be considerably enhanced by entropic depletion or excluded-volume effects when smaller particles or nonadsorbing polymers are added to the colloidal suspension.<sup>[53]</sup> In suspensions of large and small particles or macromolecules, such forces push the large spheres together, toward flat walls, and toward inner corners on surfaces. This attraction is due to the extra volume that becomes available when the larger particles approach one another as a result of the overlap of the exclusion zones, with the consequent increase in the entropy of the system. These effects were exploited to confine large spheres from a binary mixture in the corners of a patterned surface and to sort particles according to size and shape without sensitivity to surface charge or surface chemistry. On patterned template surfaces with periodic 1-D and 2-D height profiles, the formation of 1-D, 2-D, and 3-D commensurate structures of polymethylmethacrylate (PMMA) spheres in the presence of dissolved, non-adsorbing polymers was investigated as a function of sphere size and grating periodicity.<sup>[54]</sup>

### Direct Lithographic Patterning of Colloidal Layers

The direct patterning of colloid layers can be achieved by selective irradiation of the particles with high energy radiation or particle bombardment (electrons, ions), which changes the material properties of the irradiated particles (Fig. 4e). Multilayers of polymethylmethacrylate particles could be patterned by e-beam lithography and selective dissolution of the irradiated colloids.<sup>[55]</sup>

### CONCLUSION

As reviewed by this entry, complex colloid particle structures can be prepared by applying the intrinsic interactions and self-organizing properties of colloids to deposition and lateral patterning methods on substrate surfaces. These colloid structures of particle mono- or multilayers can be obtained in disordered to highly ordered and crystalline states, depending primarily on the particle size distribution and the structure preparation method. Of particular interest for future applications are highly crystalline colloid assemblies with particle diameters in the wavelength of visible light, which can be fabricated by the described methods. Such particle structures show photonic properties (filtering and manipulation of specific wavelengths) and thus might be implemented in optical chips for information and data processing via light.<sup>[48]</sup>

### ACKNOWLEDGMENTS

Anne-Sophie Duwez is Chargé de Recherches of the Belgian National Fund for Scientific Research and would like to credit her permanent position at the Unité de Chimie et de Physique des Hauts Polymères and Research Center in Micro and Nanoscopic Materials and Electronic Devices (CERMIN), Université Catholique de Louvain, Louvain-la-Neuve, Belgium. The authors would like to thank Prof. Hans Wolfgang Spiess and Prof. Rudolf Zentel for their helpful discussion and continued support of this research. Financial support by the Max Planck Society, the Fonds der Chemischen Industrie, the European Commission, and the Gesellschaft Deutscher Chemiker/Dr. Hermann Schnell Stiftung is highly appreciated.

## INTRODUCTION

The complexity of real materials with their intriguing interplay between chemical composition, atomic arrangements, microstructures, and macroscopic behavior makes computational modeling and materials design extremely difficult. Even with the fundamental laws of quantum mechanics and statistical physics, the availability of high-performance computers, and with the growing range of sophisticated software systems accessible to an increasing number of scientists and engineers, the goal of designing novel materials from first principles continues to elude most attempts. On the other hand, computational experiments have led to increased understanding of atomistic origins of molecular structure and dynamics. In particular, the molecular dynamics and mechanics methods have yielded a wealth of knowledge on the structural and dynamical behavior of various polymeric materials as a function of temperature and pressure.

For a number of years, computational scientists have been able to perform first principles quantum mechanical calculations on small systems, typically tens to hundreds of atoms and molecular dynamics simulations on larger systems composed of thousands of atoms. Calculations on larger systems, however, remain at the edge of tractability, due to memory, storage, and computation limits. These systems include a wide range of important applications, from biological applications such as protein modeling, to materials applications such as bulk properties of ceramics, metals, and polymers. Recently, there has been much effort to make theoretical predictions of nanoscale structures, both for use in mesoscale simulations and

microscopic engineering design problems, and also for the pure intellectual challenge of working with these large molecular structures.<sup>[1–4]</sup>

## OVERVIEW

Many systems are envisioned of being made up of repeating subunits that can be assembled into the desired structure. In the case of proteins, the subunits can be considered as the set of amino acids, or perhaps even larger morphological structures such as alpha helices.<sup>[1]</sup> In molecular machines, these subunits can be structures such as buckyballs, carbon nanotubes, or polymer particles, which have recently been employed in designed structures.<sup>[5–8]</sup> It has been suggested that instead of treating the full atomistic problem, inherent with many degrees of freedom, it may be possible to replace the system with a simplified framework, where it suffices to describe only the interactions between the various subunits in the structure.

Such an approximation could have great utility, for instance, in the case of polymer particles composed of thousands of monomer units, one could replace each of the pairwise distances for thousands of monomer units with a single pairwise difference between two particles, and perhaps 5 more degrees of freedom for the positional orientation between the particles. In addition, internal bending, stretching, and torsional coordinates within the individual polymer strands could be neglected, reducing the total number of degrees of freedom treated in the calculation from tens of thousands, to perhaps tens. In essence, the individual structural subunits are replaced by subunits with some

average property. Such a technique is frequently employed in so-called “multibody dynamics” analysis of structures.<sup>[9]</sup>

In the present entry, we seek to address whether the mechanics of the approximate system resembles that of the full system by studying the vibrational normal modes of complicated polymer particle structures. The most direct approximation to these motions is to examine the vibrational motion of structures composed of individual subunits. In the case of the aforementioned polymer particle structures, the “multibody” analysis would be to consider a system of interacting polymer sphere subunits, whereas the full system would include all the motions of the individual monomer units within the polymer spheres.

The natural question in this case can be rephrased in terms of the vibrational motions of a coupled system. In the present case, we ask whether the eigenmodes of the full system represent the vibrations of the multimode system. In particular, the very large systems have motion that rapidly becomes chaotic<sup>[10,11]</sup> and we suspect the behavior of the simplified system may be significantly less so.

## NORMAL MODE ANALYSIS

When transforming the more complicated system to a simplified one, we must naturally neglect many specific interactions. A number of fundamental questions arise. First among them is the question of whether the mechanics of the approximate system resembles that of the full system. This is a particularly difficult question to approach, because the full system tests the limits of computability, while the approximate system remains quite simple. In addition, one must try to account for the size-dependent properties of nanoscale building blocks.

The two sets of normal modes are quite different, and we require a simple method by which they can be compared. The fundamental idea of normal mode analysis is to express the total vibrational motion  $Q_j$  as a linear combination over a set of linearly independent motions,  $q_i$ ,<sup>[12,13]</sup>

$$Q_j(t) = \sum_i c_{i,j} q_i(t) \quad (1)$$

## SIMPLIFIED NORMAL MODE ANALYSIS

In the simplified model, there are naturally fewer degrees of freedom, so the set of vibrational modes is similarly smaller. We require a mapping from the smaller set of vibrational modes onto the larger set, and ask whether one of the “multimodes” may, in fact,

be a sum of linearly independent eigenmodes for the whole system. As it turns out, this can only be the case when the eigenmodes for the whole system are degenerate in frequency, otherwise there will be rapid dephasing, and after a few cycles of the periodic behavior the motion will no longer be coherent. For mismatched modes of this type, the recurrence time is lengthy, and chaotic behavior ensues. As a result, any correspondence between the two sets of eigenmodes should be dominated by a single mode in each case, and the correspondence should be apparent from a simple and direct inspection. Using this correspondence, one can immediately evaluate the efficacy and any possible limitations of the multibody approximation.

From an engineering perspective, the concept of multibody dynamics is well founded.<sup>[9]</sup> Machines are made of interconnected rigid parts, and the machine operates by the interactions of these parts. Recently, however, there has been much interest in building well-defined structures on the nanoscale out of blocks that are only a few micrometers in dimension. For instance, it is now possible to design and construct polymer structures from individual polymer nanoparticles isolated in an electromagnetic trap and manipulated with the influence of a linear quadrupole placement device.<sup>[14]</sup> These systems can be designed specifically for their optical and mechanical properties.<sup>[15]</sup> As opposed to devices built on macroscopic scales where one expects components to be structurally rigid, at the molecular scale one expects that the particles may be subject to significant deformation, or “softness.” As a result, we have undertaken the study of these structures on the nanoscale.

## METHODS AND COMPUTATION

The theory of the computation of normal modes of molecules is well known and has been reviewed extensively elsewhere,<sup>[12,16–19]</sup> so we provide only a brief summary here of the results that are important to the present study. The essence of normal mode analysis is the solution of the secular equation,

$$|\mathbf{F} - \lambda\mathbf{I}| = 0 \quad (2)$$

where  $\lambda$  are the eigenvalues and  $\mathbf{F}$  is the force constant matrix in mass-weighted Cartesian coordinates. The squares of the frequencies of vibration are given by the eigenvalues,  $\lambda$ . As the eigenvalues are the squares of real numbers, they should all be positive or zero in an accurate calculation. (The eigenvalues that have a frequency of zero are termed “indifferent modes” and correspond to the physical translations and rotations of the entire system in space.)<sup>[13]</sup> The force constant matrix is obtained from the second derivatives

of the potential function,  $V$ ,

$$\mathbf{F} = \mathbf{M}^{-1/2}(\nabla^2 V)\mathbf{M}^{-1/2} \quad (3)$$

where  $\mathbf{M}$  is a diagonal matrix composed of the masses. In a traditional normal coordinate analysis (NCA) calculation for a large molecule, there are numerous negative eigenvalues that correspond to imaginary frequencies, which are in contrast to the assumption that the system is at a local minimum.

To examine the types of vibrational modes within a multibody system, computations consisting of several steps must be performed. The first step is the construction of the particle structures by molecular dynamics simulation, followed by annealing of the structures to a local minimum on the potential surface via a molecular mechanics procedure. The minimized configuration is used to generate a trajectory averaged Hessian matrix, which is diagonalized using sparse matrix techniques to yield the eigenvalues (frequencies) and eigenvectors (displacements) of the molecular normal modes. Finally, the eigenvectors are searched to evaluate their character as consisting largely of inter- or intraparticle motions. Each of these procedures is discussed in some detail in the following sections. In this study we have examined the vibrational structures of polymer particle dimers, which we have discussed extensively elsewhere,<sup>[20,21]</sup> and also polymer particle trimers in bent and approximately linear configurations, as well as a hexagonal arrangement composed of six polymer particles in a near plane geometry, similar to one that has been constructed experimentally (M. D. Barnes, private communication).

## Molecular Dynamics

For the purposes of the present entry, we discuss the motions and interaction forces between individual polymer particles both before and after interactions take place. The details of the geometric statement function approach developed by several of the authors are described more fully elsewhere.<sup>[22]</sup>

Polymer particles have been treated with a molecular dynamics approach,<sup>[23,24]</sup> integrating Hamilton's equations of motion in time,

$$\dot{q}_i = \frac{\partial H}{\partial p_i} \quad (4)$$

$$-\dot{p}_i = \frac{\partial H}{\partial q_i} \quad (5)$$

where  $H$  is the Hamiltonian of the system and the  $q_i$  and  $p_i$  represent the coordinates and their conjugate

momenta. In the present case, we have treated coordinates and momenta in the Cartesian frame, where the total kinetic energy is diagonal. Integration of the equations of motion was accomplished by use of novel symplectic integrators developed in our laboratory.<sup>[25]</sup>

As a simplification we have collapsed the  $\text{CH}_2$  and  $\text{CH}_3$  units of the polyethylene chain into a single monomer of mass 14.5 amu. By neglecting the internal structure of these groups, the number of coordinates and thus the number of equation of motion for the system are greatly reduced. The model has been shown to be useful to study the low-temperature behavior of the system where the effects of the hydrogens have little effect on the heat capacity and entropy of the system.<sup>[26]</sup>

The Hamiltonian for the system is specified as.<sup>[26,27]</sup>

$$H = T + \sum V_{2b} + \sum V_{3b} + \sum V_{4b} + \sum V_{nb} \quad (6)$$

where  $T$  is the kinetic energy component, expressed in terms of Cartesian coordinates, and the terms  $V_{2b}$ ,  $V_{3b}$ , and  $V_{4b}$  represent the 2-, 3-, and 4-body terms for monomer units in an individual polymer strand, respectively, and  $V_{nb}$  is the non-bonded interaction between individual monomer units separated by 4 or more monomer units along the chain, and within a spherical cutoff of 10 Å. The functional forms of the potentials are given by<sup>[26,28–31]</sup>

$$V_{2b} = D\{1 - \exp[-\alpha(r_{ij} - r_e)]\}^2 \quad (7)$$

$$V_{3b} = \frac{1}{2}\gamma(\cos \theta - \cos \theta_e)^2 \quad (8)$$

$$V_{4b} = 8.77 + a \cos \tau + b \cos^3 \tau \quad (9)$$

$$V_{nb} = 4\epsilon \left[ \left( \frac{\sigma}{r_{ij}} \right)^{12} - \left( \frac{\sigma}{r_{ij}} \right)^6 \right] \quad (10)$$

with the values of the constant terms given in Table 1. The distances between the various monomer units,  $r_{ij}$ , are given by the standard Cartesian relation,

$$r_{ij} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} \quad (11)$$

In the present case, initial conditions for the trajectories composed the coordinates of individual amorphous polymer particles composed of 60 chains of 100 monomer units, which had previously been obtained by annealing.<sup>[32]</sup> Momenta were chosen randomly in the radial coordinate so as not to excite internal

angular momentum. The randomly chosen momenta were rescaled to produce the appropriate temperature for the simulation,

$$\sum_i \frac{1}{2m_i} p_i^2 = \frac{3}{2} k_B T \quad (12)$$

These thermalized particles are then placed in proximity and given an initial impulse to drive them together. Several types of collisions are observed. At high kinetic energies (high relative velocities of the particles) particles are observed to fracture and break apart. At high kinetic energies and orbital angular momenta one observes glancing collisions resulting in either particle fracture or chain transfer between the particles.<sup>[33–35]</sup> In the present case, however, we are interested in building structures of particles, so the range of relative collision velocities has been selected to produce collisions where the particles stick together.

## Soft Matter, Multiparticle Structures

### Dimer structure

The thermalized particles (with an initial temperature of 5 K) offset in the  $z$  coordinate so that their minimum edge to edge distance was 5.75 Å. The particles were then given an initial impulse toward each other of 0.25 Å/ps to induce a collision of the particles. The molecular dynamics simulation was allowed to run for a minimum of 100 ps to allow the particles to equilibrate and relax to their final configuration. The particle dimers formed were then subjected to potential minimization, described below (Fig. 1).

**Fig. 1** Particle dimer composed of two particles each with 60 chains of 100 monomer units.

### Trimer structure

Particle trimers were formed by using three preformed thermalized particles and aligning them along the  $z$  axis in the coordinate system. The centers of mass of the three particles were located at such that the minimum distance between  $z$  coordinates in the two particles was 5.75 Å. The initial  $z$ -velocities of the particles were established at 0.25, 0, and  $-0.25$  Å/ps to induce a collision and coalescence of the particles. Two simulations were run, one in a linear configuration and the other with an offset of 35 Å in the  $x$  coordinate of the middle particle, to produce linear and bent configurations (Fig. 2). The two structures were then subjected to potential minimization, described below.

### Hexmer structure

We have also simulated a hexagon of polymer particles, similar to that which has been designed and constructed experimentally. The structure was created by arranging six preformed and thermalized polymer particles with centers of mass locations given by

$$x = R \cos \frac{n\pi}{3} \quad (13)$$

$$y = R \sin \frac{n\pi}{3} \quad (14)$$

where  $n = 0, \dots, 5$  and  $R = 2R_{\max}$ , where  $R_{\max}$  is the maximum particle radius for an individual particle. An impulse of 0.25 Å/ps was given toward the origin of the system for each of the particles, and the simulation was

**Fig. 2** Particle trimers in (A) linear and (B) bent configurations. Each of the individual particles is composed of 60 chains of 100 monomer units.

run for 300 ps, where partial coalescence of the particles into a ringlike structure was observed. Structures were then subjected to potential minimization, described below, to find a local minimum (Fig. 3).

### Potential Energy Minimization

The premise behind normal mode calculations is that the structure resides at a local minimum that can be treated in the harmonic approximation. The collisions between particles do not necessarily correspond to a local minimum, as there is a considerable amount of

**Fig. 3** Ringlike structure composed of six particles. Each particle is comprised of 60 chains of 100 monomer units.

excess kinetic energy in the initial conditions that may be converted to potential energy in the collision, resulting in a large displacement from a local minimum. Thus, subsequent to creation of the particle structure, it is necessary to establish suitable equilibrium positions for each of the monomer units in the structure, finding the local potential minimum. The method employed in the present approach is a hybrid molecular dynamics–molecular mechanics simulation using the Broyden, Fletcher, Goldfarb, and Shannon (BFGS) quasi-newton minimization algorithm and simulated annealing via classical trajectories (a short trajectory in which the momenta are periodically quenched to zero).<sup>[36]</sup> The resulting structures are shown in Figs. [1–3].

### Hessian Matrix Evaluation

The usual method for normal coordinate analysis is to choose a single configuration and to evaluate and diagonalize the Hessian matrix for this configuration. Since finding the exact minimum of the potential is difficult, such an approach invariably leads to obtaining the Hessian away from the minimum, leading to numerous negative eigenvalues. These negative eigenvalues correspond to imaginary vibrational frequencies and are clearly not physically realistic. This problem is particularly pervasive in the low-frequency modes, as a small computational error can shift an eigenvalue from positive to negative.

In the past, methods to alleviate this problem have included averaging and performing a shift in the

eigenvalues,<sup>[16,17]</sup> which yields positive eigenvalues, but suffers from being an ad hoc solution with little physical justification. In a recent development, it has been shown that the matrix elements of the Hessian for coordinates obtained by sampling over a classical trajectory in the vicinity of the local minimum randomly fluctuate about the true value. As a result, it is possible to employ the average value of the Hessian over a short trajectory, rather than the value of the Hessian at a fixed configuration.<sup>[37]</sup> The accurate integration of the trajectories for polymer systems and calculation of the Hessian matrix is rendered particularly rapidly due to expressions for analytic derivatives that have evolved in our laboratory.<sup>[38,39]</sup>

### Sparse Matrix Diagonalization

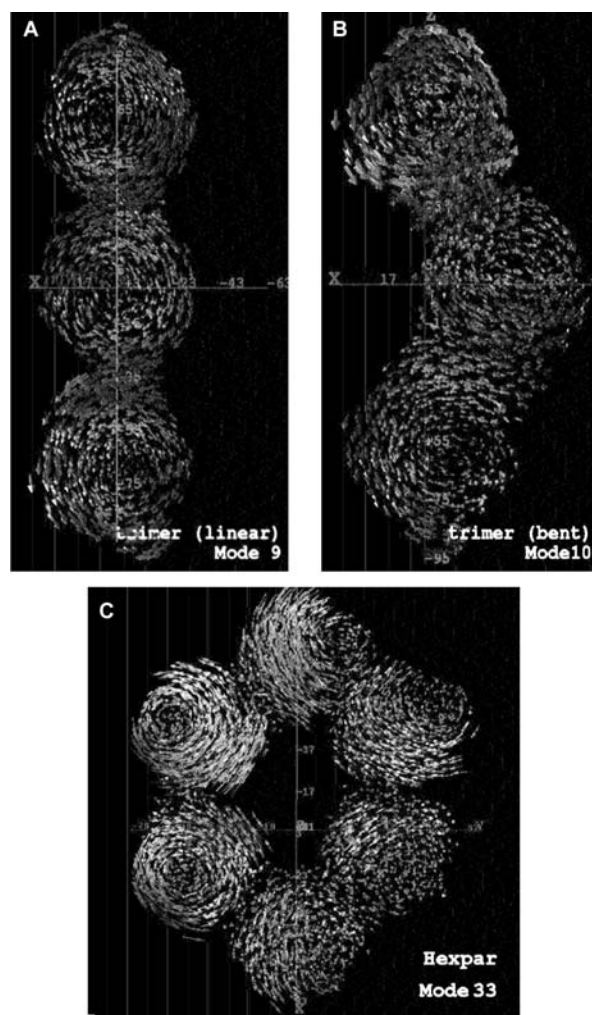

We have used a modified version of ARPACK to compute the lowest vibrational modes of the sparse matrix representing the time averaged Hessian matrix. The ARPACK software is based on a variant of the Arnoldi process<sup>[40]</sup> and for symmetric matrices is equivalent to the Lanczos algorithm. Essentially, the method relies on constructing and refining an orthonormal basis for a small dimensional subspace of the full, sparse matrix. The method employed in the present study involves implicitly restarting the algorithm using a method for modifying the initial starting guess in the iterative Lanczos method to accelerate convergence to the desired solution.<sup>[41]</sup> The exact details of the computations employed in our computations have been described and reviewed extensively elsewhere.<sup>[37,42–44]</sup>

### NORMAL MODES OF MULTIPARTICLE SOFT MATTER SYSTEMS

The eigenvectors corresponding to the lowest 100 frequencies were explicitly visualized in order to observe characteristic behaviors. Modes corresponding to higher vibrational frequencies did not have any readily discernible characteristic behavior, with the exception of modes in which the majority of the motion was restricted to a single particle (local or “spectator” vibrations).

#### Indifferent Modes

Each of the systems was observed to have six true “indifferent” modes, corresponding to overall translations and rotations of the system.<sup>[12,13]</sup> As expected, these normal modes are the first six modes, and have eigenvalues quite close to zero, with the exception of a small amount of numerical round-off error. These

**Fig. 4** Normal modes composed of coupled particle rotations. Examples are chosen for each of the structures represented in Figs. [1–3].

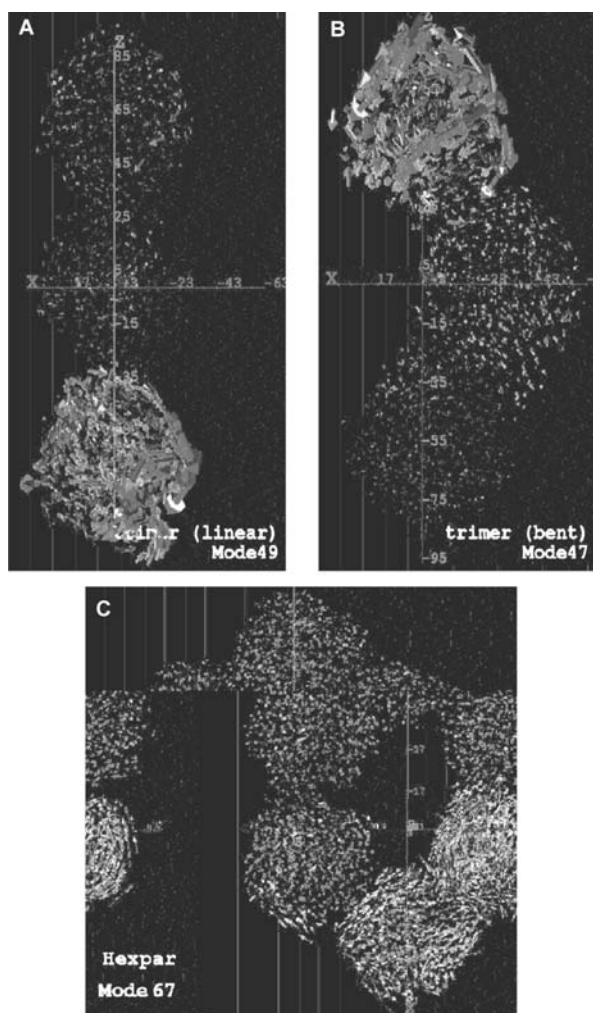

modes are as one would expect and are not illustrated to save space.

#### Coupled Rotational Modes

For each of the systems there are several modes that could be described as “coupled rotations.” Essentially, these modes correspond to gearlike motions of individual polymer particles with respect to each other. These modes are likely to be well described in the multimode approximation as torsional vibrations because the modes appear to preserve the volume of the individual particles (Fig. 4).

#### Spectator Modes

Another class of modes that we observe are those we deem to be “spectator modes.” These are modes where

**Fig. 5** Normal modes composed of “spectator vibrations,” where the majority of motion is restricted to a small subset of particles. Examples are chosen for each of the structures represented in Figs. [1–3].

all of the dynamical motion is constrained largely to one part of the structure, with the remaining parts of the structure largely immobile (with the exception of small shifts to leave the center of mass invariant.) These modes are likely to be poorly described by multibody vibrations because they are largely dependent on the internal elasticity of the subunits where the motion is confined (Fig. 5).

### Particle Vibrational Modes

In the context of multibody dynamics, one expects to see modes that are vibrations of the individual particles connected by a single force constant. In the case of the dimer particles, we would expect to see a vibration that essentially amounts to a displacement of the center of mass separation of the two particles. In the case of

**Fig. 6** Normal mode approximating a dimer “stretch” in the particle dimer system. The center of mass separation motion is coupled to the internal elasticity of the particle.

the linear and bent trimers, we would expect to find bending and stretching normal modes reminiscent of the vibrations of carbon dioxide or water. In the case of the six-member ring, we might expect normal modes similar to benzene.

We do not observe such pure stretching modes. In the case of the dimer system, there are some modes that are similar to the displacement of the center of mass, but it is by no means a pure dimer stretch, and this mode is strongly coupled to the internal elasticity of the particles (Fig. 6). These modes are not well described in a multibody context, as multibody vibrations insist on the preservation of the volume of the individual subunits in the structure and neglect the internal compressibility of the particles.

### CONCLUSION

The goal in the present study was to identify and characterize interparticle vibrational modes and to relate them to characteristic multibody vibrational modes. In a multibody treatment, for “free” joints, there should be six degrees of freedom for each connection between particles<sup>[9]</sup> (if we fix the position of the first subunit to remove overall translations and rotations).

This reduced number of degrees of freedom, if applicable, represents a huge savings in computational effort and provides a direct avenue for interpretation of the vibrational motion of the structure.

What we find in the present investigation is a lack of “pure” multibody stretching modes. These modes are apparently strongly coupled to the internal elasticity of the particles.

At the same time, however, we do observe a number of modes that can be interpreted in the multibody context. These modes are “particle torsional modes,” or modes that involve coupled rotations of the particles and are absent of any internal vibrational structure within the particles. We also observe a number of so-called “spectator modes,” where the dynamical behavior is largely localized within a single particle, or a small collection of particles. In the multibody dynamics context, these modes consist of intrabody vibrations, largely decoupled from the interbody vibrations.

Whereas it appears that there is some promise to the multibody technique for vibrational analysis, the present study indicates that in the present case where the subunits in the structure are composed of “soft matter,” it is necessary to modify the treatment to allow for the internal elasticity of the particles, because the particles deform significantly and couple the vibrational motion between subunits with internal compression of the particles. This class of substances includes both polymers and biopolymers (e.g., proteins). Although the internal elasticity of these types of substances must undoubtedly be accounted for, particles that are substantially more rigid and with definitive chemical structures, such as metal oxide particles or structures with a rigid chemically bonded network, such as structures based on derivatives of buckminsterfullerenes, may not undergo gross defects in particle structure that couple the vibrational modes. These types of particles require additional study to determine the extent to which the internal and overall motions of the structures are coupled.

## ACKNOWLEDGMENTS

This work was sponsored by the Division of Computer Science and Mathematics and the Division of Materials Sciences, Office of Basic Energy Sciences, U.S. Department of Energy under Contract DE-AC05-00OR22725 with UT-Battelle at Oak Ridge National Laboratory (ORNL), using resources of the Center for Computational Sciences at Oak Ridge National Laboratory. We would like to thank Ross Toedte of the ORNL Visualization Group for assistance in producing figures for the manuscript.

# Computational Analysis of Switchable Catenanes

Xiange Zheng  
Karl Sohlberg

Department of Chemistry, Drexel University, Philadelphia, Pennsylvania, U.S.A.

## INTRODUCTION

The first synthesis of a catenane was reported in the 1960s.<sup>[1,2]</sup> Since then, the chemistry of topologically non-trivial macromolecular systems such as knots, catenanes, and rotaxanes<sup>[3–23]</sup> has attracted considerable attention. With the surge of interest in nanoscience since 1990, this attention has focused on their promise for the fabrication of molecular devices. The design, synthesis, and characterization of nanodevices and molecular devices are now grand challenges to the scientific and engineering communities.<sup>[24–28]</sup> Consequently, reports of novel catenanes are appearing with increased frequency.

Catenanes form a subset of a special class of topologically complex host/guest complexes where the host and guest components are chemically independent but mechanically interlocked with each other. Catenanes are an entirely different class of mechanically interlocked molecules from their close relatives—the rotaxanes. In particular, a catenane is a complex comprising two (or more) macrocyclic rings interlocked like adjacent links of a chain. The two (or more) macrocycles are not linked covalently to each other; rather, their dissociation is prevented only mechanically. The associated co-conformations are stabilized by intercomponent non-covalent interactions, and interconversion among these co-conformations requires the circumrotation of the macrocycle rings. In a switchable catenane, the relative populations of these co-conformations are controllable reversibly by an external stimulus such as complexation/decomplexation by metal ions, protonation/deprotonation, or oxidation/reduction process. Like the rotaxane systems discussed in the accompanying entry entitled “Computational Analysis of Switchable Rotaxanes,” switchable catenanes have recently become the subject of intense interest because of their potential to form components of nanodevices and molecular devices.

## BACKGROUND

The dissociation of catenanes requires the breaking of covalent bond(s). The synthesis of such systems often

relies on the presence of molecular recognition sites in the components, and on the use of transition metal templates or complementary  $\pi$ -electron-rich and  $\pi$ -electron-deficient recognition segments to enable the construction process. For the construction of catenanes, it has been suggested that the most rational construction strategy is through the clipping of one macrocycle onto another preformed one.<sup>[29]</sup>

A characteristic example, [2]catenane ([2] indicates the number of chemically independent subcomponents), may be found in Ref.<sup>[30]</sup>, which reports complexes constructed from a  $\pi$ -electron-deficient bipyridinium-based cyclophane, cyclobis(paraquat-*p*-phenylene), and a  $\pi$ -electron-rich dioxoarene-based and/or dithioarene-based macrocyclic polyether. In this way, the system is designed with intercomponent non-covalent bonding interactions. Ref.<sup>[30]</sup> gives several examples of such interactions including:  $\pi$ - $\pi$  stacking (Ref. 4 in Ref.<sup>[30]</sup>), [CH $\cdots$ O] (Ref. 5 in Ref.<sup>[30]</sup>), and [CH $\cdots$  $\pi$ ] interactions (Ref. 6 in Ref.<sup>[30]</sup>). It was suggested that self-assembly processes might be facilitated by non-covalent interactions between complementary recognition sites on the constituent components.<sup>[30]</sup> For mechanically interlocked molecules, an understanding of the self-assembly processes is an issue of considerable interest. Here, we review theoretical and computational studies of switchable catenanes.

## OVERVIEW OF COMPUTATIONAL METHODS AND TECHNIQUES

In general, there are three classes of theoretical modeling methods for investigating molecular properties. In approximate order of increasing computational expense, they are: molecular mechanics (MM) methods, classical molecular dynamics (MD) methods, and quantum mechanical (QM) methods. The last can be divided into two categories: semiempirical and ab initio techniques. The selection of a method to model supermolecular systems is dominated by consideration of the computational expense. For catenanes (and rotaxanes, as discussed in the accompanying entry entitled “Computational Analysis of Switchable Rotaxanes”), it is also important to choose

a model that reliably represents the non-covalent interactions involved in these systems that hold their constituent components together, often hydrogen bonding and/or  $\pi$ - $\pi$  interactions.

The MM methods, also known as force field methods, attempt to describe molecular structure with an empirical potential energy function that, while often containing physically motivated terms, is not based on fundamental theories of physics or chemistry. The potential is expressed as a function of the internal coordinates of the system. Finding molecular conformations and co-conformations is thereby reduced to finding the minima of the potential function. Because function evaluation is simply an algebraic procedure, computational implementations of MM are very fast and used in the qualitative description of large molecular systems comprising hundreds or even thousands of atoms. MD methods are concerned with molecular motion. They employ similar empirical potential energy functions to the MM methods, but solve the classical differential equations of motion based on this potential function (typically in the Hamiltonian or Newtonian formulation) given an assumed set of initial atomic positions and momenta. In addition to providing dynamical information about molecular motion, MD can also facilitate searching of the potential energy surface for minima. Obviously, carrying out classical trajectories based on a potential function is computationally more demanding than simple optimization to the nearest local minimum, but classical trajectories can aid in finding unknown and unsuspected minima. The general idea is that, based on the ergodic hypothesis, in the absence of resonant frequencies, a classical trajectory will eventually sample all of the energetically allowed configuration spaces. A solvent can also be explicitly included in an MD simulation by including adjacent solvent molecules. This is termed the “discrete solvent model.” This brings further complications and increases the computational expense. An alternative method of modeling a solvent is to replace the dielectric value of vacuum with that appropriate for the selected solvent. This is known as a “continuum solvent model.” Both general classes of solvent models exist in varying degrees of sophistication.

When one concentrates on electronic and/or spectroscopic properties, QM methods need to be employed because they explicitly treat the electronic degrees of freedom. These methods attempt a solution of the time-independent Schrödinger equation (TISE) for the system of interest. In ab initio quantum chemical methods, the molecular Hamiltonian is generally written in matrix form, and all integrals over basis functions are exactly evaluated in the calculation. Such methods are, in principle, applicable to any molecular system, but in practice are limited in that ab initio

calculations are extremely computationally demanding, especially for large molecular systems. In this respect, semiempirical quantum chemical methods are often a more appropriate choice for the modeling of large molecule systems. Like MM, they use empirical parameters (often derived by fitting the results to experimental data), but like ab initio methods, they solve the TISE. They are computationally faster than ab initio methods because many of the difficult integrals are neglected or empirically approximated.

Because of the large size of catenane complexes, consideration of the compromise between modeling accuracy and computational expense is paramount. Therefore MM methods and semiempirical procedures are finding wide applications in the modeling of catenanes. Some theoretical studies of catenanes have investigated the fundamental basis that underlies the co-conformational isomerism and switching mechanisms of such systems, such as metal-ligand interactions,<sup>[31,32]</sup> [C-H...O] hydrogen bonds, and [C-H... $\pi$ ] and [ $\pi$ - $\pi$ ] stacking interactions.<sup>[33,34]</sup> The modeling of catenane systems is generally even more challenging than that of rotaxanes due, in part, to the more frequent involvement of  $\pi$ - $\pi$  interactions.

## COMPUTATIONAL STUDIES OF SWITCHABLE CATENANES

### Structural Fundamentals

Hydrogen bonding is typically the dominant intercomponent interaction in mechanically interlocked molecules. Raymo et al.<sup>[35]</sup> carried out a study to determine the magnitude of [C-H...O] hydrogen bonding. Ab initio MP2/6-311++G\*\* calculations were used for an accurate description of these intercomponent interactions. Because the treatment of catenane and rotaxane systems with ab initio methods is computationally prohibitive owing to their large molecular size, representative structures were modeled. The structures considered were charged and uncharged complexes containing the following components: *N*-methylpyridinium cation, dimethyl ether, and dimethyl phosphate anion. It was found that the main non-bonded contacts involve [C-H...O] bonds on electron-deficient species and oxygen atoms on electron-rich species. The results provided quantitative measures of the large stabilization energies resulting from [C-H...O] interactions in charged systems, which were identified as responsible for the self-assembly of bipyridinium-based catenanes and rotaxanes.

To investigate host/guest chemistry, Kaminski and Jorgensen<sup>[36]</sup> modelled several highly charged catenanes and rotaxanes in the gas phase and in liquid CH<sub>3</sub>CN solution. Methods of MM and Monte Carlo

(MC) statistical mechanics were used. The gas-phase optimizations and MC simulations were carried out using the BOSS program, version 3.6, which was modified to account for the polarization interactions. The torsional energy was expressed as a Fourier cosine expansion, including all terms through  $\cos(4\phi)$ , where  $\phi$  is the torsional angle.<sup>[37]</sup> Explicit polarization was considered for these charged complexes through the use of a polarizable all-atom force field with and without non-additive electrostatic polarization terms. The modeling reproduced the observation from experiments that polarization generally strengthens the interactions in gas phase, but has a modest effect on the complex structures and their binding energies in solution.

Because of the extensive computational resources required for ab initio calculations on catenanes, few studies have been undertaken in which ab initio techniques were adopted. Exceptions include cases where the property of interest is a manifestation of the system's electronic structure, such as circular dichroism (CD) spectra and nuclear magnetic resonance (NMR) chemical shifts. Modeling in these cases requires an explicit electronic calculation. Dobrowolski and Mazurek<sup>[38]</sup> reported ab initio calculations of the qualitative theoretical <sup>13</sup>C NMR chemical shifts ( $\delta$ ) of model carbyne catenanes and knots including C<sub>10</sub>C<sub>30</sub> and C<sub>20</sub>C<sub>30</sub> (Hopf links). They found that the chemical shift ( $\delta$ ) tends to alternate from one carbon atom to the next along the catenane ring backbone or a knot branch. The  $\delta$  fluctuation relies on the redistribution of C≡C triple bond  $\pi$ -electrons, which arises from the repulsion between catenane components or knot branches. The polarization of the  $\pi$ -electron resulting from the repulsion occurs so that a carbon atom located closer to the perturbation is deshielded and, one placed further away, is more shielded.

For properties that require a true electronic structure description, semiempirical methods have been used more frequently than ab initio methods in the study of catenane systems because of the lower computational cost. For example, Fanti et al.<sup>[39]</sup> have reported semiempirical MNDO calculations of the infrared (IR) and Raman spectra of a benzylic amide, [2]catenane, to investigate its vibrational properties. A high sensitivity of the vibrational spectra of the catenane to the environment was revealed, and it was concluded that “the ability to tune this remarkable property of the catenane to modify its vibrational response under rather small perturbations may lead to a vibrationally based sensors [sic].”

## Dynamics of Catenane Systems

A detailed understanding of the factors that govern the relative motion of the components in a switchable

catenane is prerequisite to developing schemes for external control of the kinetics and thermodynamics of macrocyclic ring rotation—a critical issue for practical molecular devices.

Pioneering investigations of the mechanisms of macrocycle circumrotation in enzylic amide catenanes were reported by Leigh et al.<sup>[40]</sup> Based on the <sup>1</sup>H NMR energy barrier measurements in different types of solvent, circumrotation was thought to occur as a cooperative process of assembly and disassembly of hydrogen bonds,  $\pi$ - $\pi$  stacking interactions, and phenyl-phenyl “T-shaped herringbone interactions” (see below; Fig. 1). Given the large number of variables, they devised a reduced complexity computational approach to unravel the complex features. The potential energy surface was explored in terms of stationary points, local energy minima, and transition states. The calculations were performed for isolated molecules with the Tinker suite of programs<sup>[41–44]</sup> using the MM3 force field.<sup>[45–47]</sup> No attempt was made to include polarization and viscosity effects. Therefore the results were compared with the NMR data obtained in apolar solvents. It was reported that the interlocked macrocycle dynamics is governed by a balance of steric effects, intermacrocyclic arrays of hydrogen bonds,  $\pi$ - $\pi$  stacking, and “T herringbone-type interactions.” T herringbone-type  $\pi$ - $\pi$  interactions are phenyl-phenyl interactions in the geometry of a distorted “T.” Fig. 1 presents the schematic drawing of the T herringbone interaction geometry. It was found that a cascade of hydrogen bond ruptures and formations occurs during circumrotation, and that these are accompanied by a series of cooperative conformational and co-conformational rearrangements that help to stabilize the energy of the molecule. The

**Fig. 1** Schematic drawing of the T herringbone interaction geometry. *R* and *R'* are functional groups attached to the aromatic rings. All other atoms not labeled are carbon atoms (solid gray circles) and hydrogen atoms (open circles). Source: From Ref.<sup>[74]</sup>.

polarity of the environment was also reported to play a role in determining the inter-ring dynamics.

As noted in the accompanying entry about rotaxane systems, entitled “Computational Analysis of Switchable Rotaxanes,” the accurate simulation of inelastic neutron scattering (INS) spectra provides a description of the atomic motions in a system. Leigh et al.<sup>[48]</sup> demonstrated the application of INS spectroscopy, in combination with MD simulations, to investigate the dynamics of catenane systems. They noted<sup>[48]</sup> that owing to its large incoherent scattering length, hydrogen atoms dominate the INS response of organic molecules. Therefore INS spectra are a monitor of the amount of motion of the hydrogen atoms. This is particularly valuable in benzylic amide catenanes because they form a number of inter-ring hydrogen bonds. All calculations were performed with the Tinker program<sup>[41–44]</sup> and the MM3 force field.<sup>[45–47]</sup> MD calculations were run on isolated systems and after applying boundary conditions to reproduce the crystal structure. The INS spectroscopy for the catenane systems was compared with simulated spectra obtained from the MD simulations, and a good agreement with experiments was achieved for the spectra of the two catenanes for the location of the most prominent bands. This report and other successes<sup>[48–50]</sup> establish that the combination of INS and MD is becoming a powerful tool for the study of catenane and rotaxane systems.

Leigh, Troisi, and Zerbetto<sup>[13,51]</sup> reported a low-dimensional QM modeling of circumrotation in benzylic amide [2]catenanes, with a model similar to that used in their studies of ring shuttling in catenanes. The goal was to demonstrate that low-dimensional QM modeling is able to produce rate constants and barriers similar to those obtained by temperature-dependent NMR experiments, by appropriately fitting the parameters in the analytic potential form to match the symmetry and energy properties of the system. Both non-hydrogen bond-disrupting (e.g., CDCl<sub>3</sub>) and hydrogen bond-disrupting (e.g., [D6]DMSO) solvents are considered. The successful simulation of the rates of circumrotation was achieved by employing transition state theory (TST) in the harmonic approximation, therefore validating this QM model.

Ceroni et al.<sup>[52]</sup> reported an investigation of the electrochemistry of a benzylic amide [2]catenane and its topological subcomponents. They proposed that the redox behavior of the catenane could be understood in terms of the electrochemistry of smaller molecular fragments and simple molecular orbital considerations. Semiempirical quantum chemical (MNDO) calculations were performed on both neutral and doubly charged catenane species. The authors noted some uncertainty specifying the atomic connectivity in the doublet state. (Such connectivity information is

required for an empirical potential calculation, but “connectivity” is essentially a chemist’s book-keeping scheme. Given a chemically reasonable starting geometry, specified only by atomic coordinates, geometry optimization with a true electronic structure method will yield a minimum energy co-conformation. Identification of the *global* minimum energy co-conformation remains a challenging problem indeed.) The results from the calculations were compared with the analysis from experimental electrochemical data. Their electrochemical study and theoretical considerations suggested that the amide carbonyl groups predominantly control the reductive behavior of the catenane. It was suggested that the formation of a C–C bond between two reduced carbonyl groups, because of the close proximity caused by macrocyclic ring rotation, prohibits further macrocyclic ring circumrotation. They termed this as “soldered structure.” In fact, if a chemical bond forms between the different macrocycles of the catenane on electrochemical reduction, the reduction transforms the catenane into a polycyclic molecule. This may provide a useful means of switching “on” and “off” the dynamics of such interlocked macrocycles.

An INS spectroscopy study and complementary MD simulations (simulated annealing) were performed by Caciuffo et al.<sup>[50]</sup> The simulations were based on calculations of the normal modes of the isolated catenane. Anharmonic and crystal effects were neglected. This study suggested that the combination of INS spectroscopy and MD can distinguish between different proposed structures in large interlocked molecular systems, and that this combination of techniques is particularly suitable for accessing the strength of intramolecular and intermolecular hydrogen bonds, which dominate the dynamics of such systems.

Deleuze, Leigh, and Zerbetto<sup>[53]</sup> reported a computational study on the structure and dynamics of the three benzylic amide catenanes shown in Fig. 2. The objective of the study was to describe the relative rotation of the benzylic amide [2]catenane rings. MM and unimolecular reaction rate theory were employed. The study provided a theoretical description of the

**Fig. 2** Chemical structure of the benzylic amide thiophenyl catenane investigated by Deleuze et al. *Source:* From Ref.<sup>[53]</sup>. ©American Chemical Society, 1999.

lowest energy pathway for the circumrotation of macrocycles in a catenane system. It showed that the circumrotation process involves several cooperative large-amplitude motions. These motions include rearrangements to minimize steric and electrostatic interactions through hydrogen bonding, form  $\pi$ - $\pi$  stacking structures, facilitate phenyl-phenyl T-shaped interactions, and accomplish amide rotamer interconversions. The calculations of rate constants provided insights into the dynamics of these catenanes. Important results include the observation that the rate-determining step is not necessarily the passage of the bulkiest groups, and that the rotations of the rings are cooperative (i.e., rotation of one macrocyclic ring facilitates rotation of the other ring).

### Origin of Binding Site Selectivity

For the purpose of understanding the factors that govern the equilibrium populations of translational isomers and the nature of  $\pi$ - $\pi$  stacking interactions in catenane systems, Raymo, Houk and Stoddart<sup>[30]</sup> carried out a computational investigation on several unsymmetrical [2]catenanes by using empirical force field and ab initio QM methods. MC conformational searching<sup>[54]</sup> was performed individually on each of those catenane complexes and its individual components, which were then energy-minimized with the AMBER force field<sup>[55]</sup> and the GB/SA solvation model for H<sub>2</sub>O and CHCl<sub>3</sub> as implemented in Macromodel 5.0.<sup>[56]</sup> Single-point (SP) calculations were performed in vacuum at the HF/6-31G\*\* level

by using the program Spartan 4.1<sup>[57]</sup> to determine the electrostatic potential (calculated on the surface of the aromatic units) and the energies of the highest occupied molecular orbitals. It was proposed that the more stable translational isomers of the [2]catenane complex do not necessarily correlate to the more stable structures of its components. Both the calculated and experimental population ratios for the translational isomers could be correlated with the dielectric constant of the solvent. Binding was observed to be electrostatic. Therefore translational isomerism was interpreted to arise from the balance between two factors: "1) by the electrostatic effects which govern the  $\pi$ - $\pi$  stacking interactions between the 'inside'  $\pi$ -electron-rich unit and the sandwiching bipyridinium recognition sites; and 2) by the solvation energies of the two translational isomers."<sup>[30]</sup>

### Co-conformational Isomerism in Catenanes

Hydrogen bonding, especially [C-H...O] interactions, plays an important role in biological systems and the self-assembly of many mechanical interlocked molecules. Houk et al.<sup>[58]</sup> presented computational studies of two [3]catenanes presented in Fig. 3, which incorporate  $\pi$ - $\pi$  stacking and [C-H...O] hydrogen bonding. Conformational analyses were performed using the AMBER\* force field and ab initio QM calculations to evaluate the binding affinity of bipyridinium-based guest to catenane hosts. The calculations showed that the combined strength of numerous [C-H...O] hydrogen bonds is quite large and quantitatively much more

**Fig. 3** The schematic showing the [3]catenane structure investigated by Houk et al. *Source:* From Ref.<sup>[58]</sup>. ©American Chemical Society, 1999.

important than that of  $\pi$ - $\pi$  stacking interactions in these particular systems. This finding is consistent with experimental observations, showing again that hydrogen bonding plays a controlling role.

Rauwolf and Strabner<sup>[59]</sup> carried out computational investigations on several host/guest systems, including catenanes, to examine the concept of self-organization. Conformational searching was performed by the MLTOR option in PCMODEL 3.0,<sup>[60]</sup> and resulting conformers were minimized with the MM2 force field.<sup>[61,62]</sup> The force field minimization was followed by a full optimization without constraints using the semiempirical PM3 Hamiltonian,<sup>[63,64]</sup> together with the EF optimizer.<sup>[65]</sup> They reported that for inclusion complexes with experimentally identified structures, their computed structures agreed with those determined experimentally. The driving forces responsible for the formation of those molecular complexes were determined to be  $\pi$ - $\pi$  stacking and electrostatic interactions.

Hu et al.<sup>[66]</sup> conducted force field (MM2) calculations for a novel [2]catenane to obtain information about the behavior of catenane in solution. A continuum dielectric constant of  $\epsilon = 30$  was used to mimic acetonitrile as the solvent. The model revealed that the catenane exhibits  $C_2(2)$  crystal point symmetry, whereas the ([2]catenane)ruthenium(ii) complex adopts conformers with different sensitizer-acceptor distances and an extended macrocyclic polyether unit because of weakened  $\pi$ - $\pi$  interactions and electrostatic repulsion. This observation was confirmed by X-ray analysis.

Cyclobis(paraquat-1,5-naphthalene) has been prepared by a template-directed synthesis. It can exist in three different stereoisomers—an achiral (*RS*) form and two chiral forms, (*RR*) and (*SS*)—because of the presence of the two chiral planes formed by its 1,5-disubstituted naphthalene residues. Ashton et al.<sup>[67]</sup> assessed the relative stabilities of the two diastereoisomeric forms. MC conformational searching was performed. The calculations showed that the chiral *RR* and *SS* forms are preferred over the achiral *RS* one. In addition, the energy of the tetracationic cyclophane was calculated as a function of the dihedral angle of the bond linking one of the methylene groups and its adjacent naphthalene spacer. The interconversion barrier of the achiral form into the chiral form was predicted to be 21.7 kcal/mol (for back interconversion, it was found to be 23.0 kcal/mol). These observations were consistent with results of <sup>1</sup>H NMR studies.

Brouwer et al.<sup>[68]</sup> proposed that for material science applications, the properties of interest for catenanes might be electronic and vibroelectronic. Such properties require a theoretical model that explicitly addresses electronic degrees of freedom. They conducted the calculations on a benzylic amide [2]catenane to study its

electronic states through a combination of experimental and theoretical techniques. Semiempirical quantum chemical calculations were performed with the CNDO/S method.<sup>[69,70]</sup> The results showed partial delocalization of electronic states over the many chromophores of the catenane. This study is notable because it is (to the authors' knowledge) the only QM study of a catenane or rotaxane to date that includes configuration interaction.

Recently, Zheng and Sohlberg<sup>[71]</sup> carried out a computational investigation of an electrochemically switchable [2]catenane consisting of a tetracationic cyclophane and a cyclic polyether, which was experimentally realized by Collier et al.<sup>[72]</sup> The purpose of this study was to validate the applicability of a modeling procedure,<sup>[73]</sup> previously developed for a rotaxane system (the procedure is reviewed in the accompanying entry), to modeling the multistability structural- vs.-energy profile and switching mechanism of a catenane. An ensemble of >5000 structures of the catenane was generated by conformational searching on the polyether followed by translation and rotation of the cyclophane with respect to the ring backbone of the polyether. SP semiempirical calculations were then carried out for all of the structures that were found to be chemically reasonable to correlate the interlocking position of the two rings with energy. The resulting structure-energy relationship identified by the SP calculations was further refined by geometrical optimizations for a select subset (~3%) of the structures. The calculations not only confirmed the structural preferences previously inferred experimentally, but also gave insights into the fundamental basis of the switching mechanism and resolved earlier ambiguities concerning the connectivity of the TTF unit in the polyether ring. It was reported that the conformation of the TTF unit differs in the catenane from that in isolated TTF. Such changes in the conformation of subunits on incorporation into a catenane or rotaxane have been reported previously.<sup>[30]</sup>

## CONCLUSION

Stimuli-responsive molecular “shuttles” based on mechanically interlocked molecules are attracting considerable attention because of their potential for application in nanoscience and nanotechnology. Computational investigations of switchable catenane (and rotaxane) systems are a major challenge because of their large size, but studies employing a wide range of theoretical methods have been reported and useful capabilities are starting to emerge. For example, identifying the dominant co-conformations at thermal equilibrium, the corresponding factors that determine binding site selectivity, and the dynamics of the

switching process is an issue that has been successfully treated with theoretical calculations. The systems described above provide strong evidence that for structural information, force field methods are of considerable value, particularly after one acquires experience in their application to mechanically interlocked molecules. For systems that involve multiple charge and/or electronic states, and for the investigation of properties that are inherently QM, semiempirical calculations are capable of predicting molecular device characteristics that are consistent with measured properties. Although computationally expensive, for fundamental studies of intercomponent interactions, the accuracy and flexibility of ab initio methods are proving valuable. Computational studies provide details complementary to experimental results. Therefore the development of computational approaches to studying catenane and rotaxane systems will undoubtedly open up new areas of interest and new directions for research.

## ACKNOWLEDGMENT

Our molecular devices research is funded, in part, by the NSF–NER program, startup funds from the Drexel University, and Dupont Corp. in the form of a Dupont Young Professor award to K. S.

# Computational Analysis of Switchable Rotaxanes

Xiange Zheng  
Karl Sohlberg

*Department of Chemistry, Drexel University, Philadelphia, Pennsylvania, U.S.A.*

## INTRODUCTION

A rotaxane is an assembly of interlocked molecules in which a dumbbell-shaped component is encycled by one (or more) chemically independent ring component(s). For example, a [2]rotaxane is created when a cyclodextrin or another ring molecule such as a crown ether (called the “shuttle” or “ring”) is threaded with a linear molecule (called the “shaft” or “chain”). The shaft terminates with a bulky substituent on each end to prevent its unthreading, and is therefore sometimes referred to as a “dumbbell” because of its appearance. A rotaxane with multiple rings upon a single shaft is a polyrotaxane. In some rotaxanes, the macrocyclic component can shuttle back and forth between binding sites on the dumbbell component. Such a system constitutes a molecular shuttle. With appropriate molecular design, the shuttling process can be controlled reversibly by external stimuli, including light, electrons, pH, and the chemistry of the environment,<sup>[1–5]</sup> thereby endowing the system with the essential characteristics of a mechanical machine or device, but on the molecular scale.

A pseudorotaxane is closely related to a rotaxane. This type of complex also consists of a chain component threaded through a macrocyclic ring, but unlike a rotaxane, a pseudorotaxane can undergo dissociation into its components without breaking any covalent bonds. A pseudorotaxane in which this threading and unthreading can be controlled with an external stimulus has the essential characteristics of a piston and cylinder, and external inputs are converted into cyclical translational motion.

Early reports of switchable rotaxanes include the thermally switched system reported in 1991 by Anelli, Spencer, and Stoddart<sup>[6]</sup> and the electrochemically switched system prepared by Bissell et al. in 1994,<sup>[7]</sup> which is shown in Fig. 1. Since then, the construction of rotaxane-based molecular shuttles has produced numerous schemes for shifting the ring between two or more “stations” on the linear chain in response to external stimuli.<sup>[6–24]</sup>

Particularly attractive for the construction of molecular machines are rotaxanes with a redox- and/or photo-active unit present in one or more of their constituent components.<sup>[1–5]</sup> The synthesis of such

systems often relies on the presence of molecular recognition sites in the components, and on the use of transition metal templates or complementary  $\pi$ -electron-rich and  $\pi$ -electron-deficient recognition segments to enable the construction process. Three approaches have been proposed for the construction of rotaxanes:<sup>[25]</sup> 1) threading of a long molecule through a ring, followed by capping the end(s) of the thread with stoppers; 2) slipping of a preformed ring over the stoppers of a preformed dumbbell-shaped component; 3) clipping of a preformed dumbbell with a suitable U-type component, which is subsequently cyclized. Technically, the complex formed through the second approach is a pseudorotaxane, because the ring can slip onto and off the thread without breaking any chemical bonds. However, if the barrier to the slipping process is sufficiently high, the rate of decomposition will be exceedingly slow and the system is effectively a rotaxane.

Theoretical studies of rotaxanes are warranted to elucidate the fundamental basis underlying the stability and switching mechanisms of these interlocked molecules, such as metal–ligand interactions,<sup>[26,27]</sup> [C–H...O] hydrogen bonds, and [C–H... $\pi$ ] and [ $\pi$ – $\pi$ ] stacking interactions.<sup>[28,29]</sup> The accompanying entry, entitled “Computational Analysis of Switchable Catenanes,” contains an in-depth discussion of the various theoretical and computational techniques that have been employed for modeling switchable catenanes, and rotaxanes as well, including the relative strengths of these techniques. While a wide range of theoretical techniques has been brought to bear on the modeling of rotaxanes, because of the consideration of computational expense (the simplest prototype rotaxane-based molecular devices involve nearly 200 atoms), structural studies have overwhelmingly employed molecular mechanics (MM) methods, and semiempirical procedures are finding considerable use in the modeling of electronic and/or spectroscopic properties.

For theory-accelerated design of molecular device systems, computational models are needed that accurately capture the multiple stabilities and switching mechanisms of switchable rotaxanes and similar systems. The modeling of such molecular-based devices is a great challenge to computational chemistry because

**Fig. 1** The switchable rotaxane designed by Bissell et al. *Source:* Adapted from Ref.<sup>[7]</sup>. © 1994, with permission from Nature ([www.nature.com](http://www.nature.com)) and the author.

of their large molecular size; nevertheless, modeling efforts are reaping success. In this work, some of the most recent achievements in the field of computational modeling of rotaxane systems will be reviewed.

## COMPUTATIONAL STUDIES OF SWITCHABLE ROTAXANES

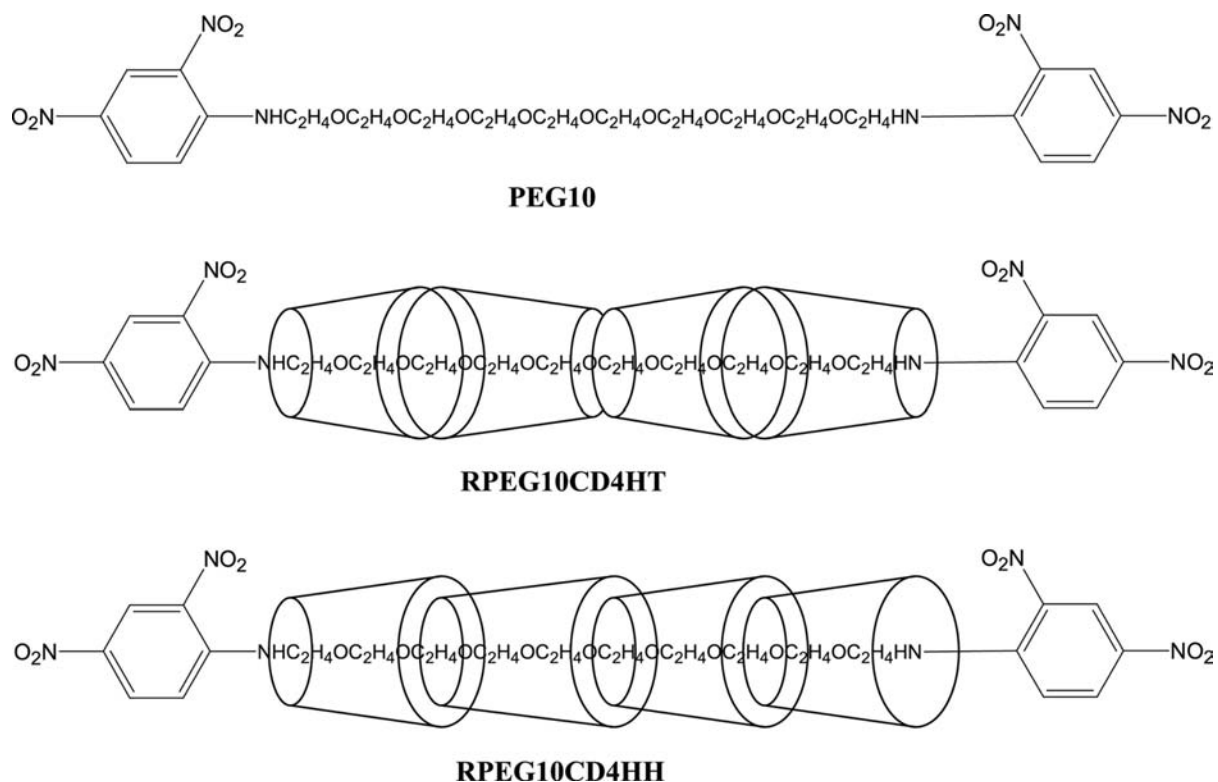

### Structural Fundamentals

In 1994, Ricketts, Stoddart, and Hann<sup>[30]</sup> presented one of the first attempts at modeling interlocked molecules. They noted that, over time, chemical systems of interest tend to increase in structural complexity and molecular size. They argued that as a consequence, existing experimental analysis techniques such as <sup>1</sup>H nuclear magnetic resonance (NMR) and X-ray crystallography would eventually become less effective. They proposed a technique that combines molecular mechanics and semiempirical methods to determine structures and binding energies. Test applications of the method predicted structures of inclusion complexes and mechanically interlocked molecules in agreement with those obtained by using X-ray crystallographic methods.<sup>[30]</sup> Trends in binding energies were detected and non-covalent binding interactions consistently agreed with those found by experiments.

Pozuelo and coworkers<sup>[31]</sup> reported molecular dynamics (MD) simulations in vacuo for “channel-type” polyrotaxanes, one of which is presented in Fig. 2. In these polyrotaxanes, alpha-cyclodextrins ( $\alpha$ CDs) are threaded onto poly(ethylene glycol) (PEG) chains. Molecular dynamics trajectories were computed by using the Sybyl 6.0 software from Tripos Associates (St. Louis, MO)<sup>[32]</sup> and the Tripos Force Field 5.2,<sup>[33]</sup> at a fixed concentration and *T*. The strengths of the intra- and intermolecular hydrogen bonds and of the van der Waals interactions were evaluated by averaging each property over all classical trajectories. Based on the simulations, they concluded that van der Waals interactions are the main source of the stabilization of these polyrotaxanes. Hydrogen

bonds between successive  $\alpha$ CDs slightly favor head-to-head, tail-to-tail sequences over head-to-tail sequences. Here head-to-head and tail-to-tail sequences mean that the adjacent cyclodextrin rings are threaded onto the polymer chain in the opposite direction. More recently, they carried out molecular dynamic simulations<sup>[34]</sup> on the two polyrotaxane systems, shown in Fig. 3, to determine their preferred configurations. Both of the polyrotaxanes consist of two polymeric chains threaded into the channel formed by eight stacked  $\alpha$ CDs. The simulations were performed by using the Sybyl<sup>[32]</sup> molecular modeling package and the Tripos Force Field<sup>[33]</sup> at 500 K in vacuum, and the results were compared with those of the isolated polymer chain. It was shown that the rotaxane structure is stabilized with respect to the separated chain and alpha cyclodextrins, principally by van der Waals interactions. This stabilization upon threading is noted in several studies reviewed below, and appears to be quite general. As rotaxane assembly is almost certainly entropically unfavorable, generally speaking, the internal energy of a rotaxane must be lower than that of its isolated components to achieve thermodynamically spontaneous self-assembly. We will note below several other instances where theoretical calculations have revealed this result.

The change in the nature and strength of the inter-component hydrogen-bonding interactions in a rotaxane can induce the macrocycle(s) to move along the thread between two or more discrete stations. Altieri et al.<sup>[35]</sup> reported a molecular modeling study of three rotaxane-based molecular shuttles to address this effect. They used simulated annealing, followed by geometrical optimization, to identify the positional preference between the two binding states and the population distribution of the coconformers. The MM3 force field,<sup>[36–38]</sup> as implemented in the Tinker program,<sup>[39–42]</sup> was used in the simulation. The calculations consistently reproduced results in agreement with experimental ones, and evoked the following explanation for the positional discrimination in the rotaxane systems: When certain sites are not occupied, they may hydrogen bond to themselves and thus two possible

**Fig. 2** The system investigated by Pozuelo et al., with the cyclodextrin rings, which are represented by tori, oriented head-to-tail in the upper molecule and head-to-head or tail-to-tail in the lower one. *Source:* Reprinted with permission from Ref.<sup>[31]</sup>. © 1997, American Chemical Society.

hydrogen bonding sites (carbonyl and NH) are used to form just one hydrogen bond. The translational isomers with such stations unoccupied have at least one hydrogen bond fewer than isomers with those stations occupied. It was concluded that, in molecular machines powered by weak noncovalent interactions, the use of such “self-binding” in unoccupied stations is a common driving force for submolecular motion.

### Studies of Rotaxane Dynamics (MD)

An important aspect of the design of a multicomponent molecular device is the prediction of its dynamic

**Fig. 3** The two polyrotaxanes studied by Pozuelo et al. Shown are two minimum energy conformations obtained during MD simulations. *Source:* Reprinted from Ref.<sup>[34]</sup>. © 2002, with permission from Elsevier.

behavior. Molecular device dynamics are often studied using classical molecular dynamics (MD) methods. Most of the existing computational studies of the dynamical behavior of switchable rotaxanes have been devoted to systems with cyclodextrins as the macrocycle.<sup>[31,34,43–46]</sup> In these studies, one primary goal has been to rationalize the driving forces responsible for the preferred arrangement of the macrocyclic component on the threaded chain and its interconversion between binding stations.

Experimental investigations performed by Amabilino et al.<sup>[47]</sup> on [2]rotaxanes bearing dendritic stoppers (Fig. 4), reveal a strong dependence of the shuttling

**Fig. 4** The [3]rotaxane containing dendritic stoppers investigated by Amabilino et al. *Source:* Reprinted with permission from Ref.<sup>[47]</sup>. © 1996, American Chemistry Society.

process on the polarity of the solvent. To investigate the origin of this dependence, they carried out molecular dynamic simulations on the [2]rotaxanes, with  $\text{CHCl}_3$  and  $\text{Me}_2\text{CO}$  solvents, as included in the form of the GB/SA<sup>a</sup> solvation model.<sup>[48]</sup> The simulations were performed both with and without the inclusion of acetate counterions. The molecular modeling package Macro-model 5.0 was used.<sup>[49]</sup> Estimations of the approximate size of the rotaxanes based on these simulations suggested that extending the rotaxane shaft with an additional bipyridinium recognition site increases the end-to-end length by about 1.5 nm. Total lengths ranged from 3 to 6 nm, and the molecular volumes from about 4 to 6 nm<sup>3</sup>. Significant conformational changes were found to occur upon changing the polarity of the solvent. Folding of the structure occurred in  $\text{CHCl}_3$  even in the presence of counterions, which was assumed to minimize the exposure of the rotaxane to a low-polarity solvent. The resulting folded structure of the rotaxane complex in  $\text{CHCl}_3$  solvent presents a large steric and electronic hindrance to the shuttling process, revealing a significant solvent dependence of the rotaxane dynamics. The activation energy for the shuttling process was determined to be higher in  $\text{CHCl}_3$  than in  $\text{Me}_2\text{CO}$ . The results of the simulations were consistent with the experimentally observed dependence of the rate of the *shuttling* process on the polarity of the solvent. Therefore, the simulations suggested that the dramatic solvent dependence of the rate is a result of conformational changes induced by varying the solvent polarity.

Inelastic neutron scattering (INS) allows for the observation of motions present in a system and is therefore ideally coupled with MD simulations. Bottari et al.<sup>[50]</sup> reported that the INS spectra of a benzylic amide rotaxane, and of the isolated chain that results from the removal of the benzylic amide macrocycle, show significant differences in some regions. To understand qualitatively the origin of this spectral difference, they carried out molecular dynamics (MD) simulations based on an MM force field. The calculations were performed with the MM3 force field<sup>[36–38]</sup> as implemented in the Tinker program.<sup>[39–42]</sup> Molecular dynamics were run on isolated systems with boundary conditions applied to reproduce the crystal structure. The experimental spectra were compared with the calculated ones. While there were some shifts in the positions of the bands, their number and shape were well reproduced. The shaft features present, inferred from the experimental spectrum of the rotaxane complex

relative to those for the isolated thread, were confirmed by the simulation. This was presented as a “fingerprint” of the ring threading.

The hopping model, which was proposed by Herrmann, Keller, and Wenz,<sup>[51]</sup> was demonstrated to have the potential for investigating the threading process. In this model, the threading movement is assumed to take place by a consecutive hopping of the ring over a series of distinct binding sites on the chain. Compared to the diffusional model proposed by Meier et al.,<sup>[52]</sup> where the movement of rings along the polymer chains is treated as one-dimensional Fickian diffusion, they believed the hopping model to be more suitable for polymers. Horsky<sup>[43]</sup> applied this model with modifications to several pseudorotaxanes, in order to identify the central features of cyclodextrin threading, and to identify the cooperative interactions between adjacent rings. Pseudopolyrotaxane formation was treated. Stochastic simulation was used to address the problems of time evolution of threading and transport across connected sites. The simulation based on the hopping model showed that completely regular head-to-head/tail-to-tail arrangement could not be expected. This is consistent with the result reported by Pozuelo, Mendicuti, and Mattice<sup>[31]</sup> reviewed above. The orientational preference of adjacent rings is not sufficiently strong to guarantee a completely ordered assembly.

Grabuleda and Jaime<sup>[53]</sup> applied molecular mechanics and molecular dynamics methods to model the switching processes of [2] rotaxanes. The MM3 and MM3\* force fields were chosen, which they noted model non-bonded interactions reasonably well. The simulation of the rotaxanes was performed by using the MM3 force field, and the solvent effects were taken into account by changing the dielectric constant. Complementary computations were carried out by using the MM3\* force field, which showed less reliable and, reportedly, sometimes wrong behavior in the prediction of stability between different coconformers.<sup>[53]</sup> The molecular mechanics studies on the rotaxanes showed that electrostatic and van der Waals interactions are the major factors controlling the energy minima. This conclusion is probably generally true for large macrocycles containing highly electronegative atoms.<sup>[54]</sup> MD computations showed qualitative agreement with MM computations in estimates of the shuttling barrier, and the results supported those from experiments for the preferred translational isomers. Additionally, the MD computations provided information regarding [C–H...O] hydrogen-bonding interactions throughout the shuttling process. In comparison,  $\pi$ - $\pi$  stacking interactions were found to be considerably less important. More recently, similar calculations on pseudorotaxanes<sup>[55]</sup> studied their structures and energies, with the intent to establish a

<sup>a</sup>Represents a method which combines the generalized Born (GB) method of interpreting the electrostatic contribution to the solvation free energy with a solvent-accessible-Surface-Area (SA) determination of the hydrophobic contribution to the solvation free energy.

computational procedure for investigating the shuttling process in rotaxanes. The SANDER module of the AMBER v.5 program,<sup>[56]</sup> the parm94 force field<sup>[57]</sup> with RESP charges, and an explicit solvent model for acetonitrile were employed. Here RESP represents Restrained ElectroStatic Potential, which fits the quantum mechanically calculated electrostatic potential (esp) at molecular surfaces using an atom-centered point charge model. Reportedly, the experimental results were reproduced by the computational model. It was concluded that the AMBER force field with RESP charges and the explicit solvent model for acetonitrile<sup>[58]</sup> provide a useful computational scheme for studying pseudorotaxanes, and that they can further be applied for modeling [2]rotaxanes.

### Studies of Rotaxane Dynamics (Quantum)

Leigh, Troisi, and Zerbetto<sup>[59]</sup> reported quantum-mechanical modeling of the shuttling in a rotaxane. A one-dimensional quartic potential was used to describe the potential energy variation with shuttle movement along the shaft of the rotaxane. The parameters of the quartic function were set to yield a double well potential, each well corresponding to one of two ring binding stations on the shaft separated by a potential barrier. The coefficients on the quadratic and quartic terms in the potential were adjusted to reproduce the observed shuttling rate at 298 K. Such a model affords a reduced-dimensionality analysis of the contributions of quantum effects to the shuttling dynamics. It was found that energies slightly exceeding the barrier to binding site interconversion correspond to very high quantum number eigenstates. In such high-lying vibrational eigenstates, the probability distribution approaches the classical limit, i.e., at these energies the shuttle will be found with the greatest probability in the vicinity of the classical turning points on the barrier. High probability of finding the ring at one of the ring binding stations only occurs at energies far below that of the barrier.

There is considerable interest in the possible use of nested carbon nanotubes in molecular-bearing and molecular-motor applications.<sup>[60–62]</sup> In fact, nested carbon nanotubes form a pseudorotaxane. Sohlberg et al.<sup>[63]</sup> carried out rigid-body dynamics and semiclassical mechanics calculations of a nested carbon nanotube molecular bearing to demonstrate the utility of rigid-body dynamics for studying the dynamical properties of nanosystems. In this rigid-body approximation, the entire body (bearing shaft in this case) was allowed to translate and rotate, but all of its internal coordinates are frozen in their equilibrium positions. This avoids the zero-point energy problem of fully atomistic classical molecular dynamics simulations,

i.e., the unphysical pooling of large amounts of zero-point energy into a single mode. Simulations were carried out for a model consisting of a pair of nested carbon nanotubes, with the outer nanotube (sleeve) held in place, while the inner nanotube (shaft) is held in position only in its longitudinal direction. This represents a bearing in application where the shaft axis is fixed in position by the construction of the machine. The simulations demonstrated that, for certain operational conditions, particularly where the bulk of the system kinetic energy is contained in rotation of the shaft, the rotation of the shaft is smooth exhibiting quasiperiodic motion. For other conditions, especially with low shaft rotational kinetic energy, the motion is chaotic. Semiclassical analysis of these dynamical trajectories revealed a significant difference in the level spacing of rotational and processional quantum eigenstates.

### Coconformational Isomerism in Rotaxanes

MD techniques can also identify low-energy configurations of the system. The principle of this application of MD is that a dynamic trajectory will eventually sample all of the energetically accessible configuration space. In a practical calculation, any trajectory must be finite in time; nevertheless, this is often an efficient way to sample configuration space. MD methods have been employed with considerable success in this manner in the study of molecular and nanodevices.

Mayer et al.<sup>[45]</sup> conducted a computational study on the formation of a molecular necklace (a class of polyrotaxane), formed by threading cyclodextrins onto a block copolymer. Allinger's MM3-92 force field was employed in all calculations. A dynamic Monte Carlo (DMC) routine<sup>[64,65]</sup> was used within the program package MultiMize<sup>[66]</sup> to locate low-energy coconformations. It was shown that the formation of the intermolecular hydrogen bonds between adjacent cyclodextrin rings contributes significantly to the overall stability of the molecular necklace. The preferential intramolecular and intermolecular interactions result in the formation of the stable and highly ordered multicomponent complex. This somewhat contrasts to the results of Pozuelo, Mendicuti, and Mattice<sup>[31]</sup> and Horsky,<sup>[43]</sup> both of which reported the ordering preference to be insufficiently weak to guarantee highly ordered stacking of the macrocycles in a polyrotaxane. Indeed, the degree of ordering probably varies from system to system. It should, in principle, be possible to take an experimental measurement of the degree of ordering and convert it to a difference in stacking energy between head-to-head and head-to-tail ordering, but such an analysis has not, to the author's knowledge, been reported.

Fradera et al.<sup>[67]</sup> presented a molecular dynamics study of a [2]rotaxane using the molecular mechanics/Poisson Boltzmann-surface area (MM/PB-SA) strategy developed by Srinivasan et al.,<sup>[68]</sup> to determine its conformational preference and to evaluate the influences of cations and solvation on coconformation. Solvents considered include chloroform, dimethyl sulfoxide (DMSO), and water with the MST<sup>b</sup> continuum solvent model.<sup>[69–71]</sup> It was observed that in chloroform solution, the [2]rotaxane system exists as a mixture of coconformations with intercomponent hydrogen bonds. In DMSO solvent, no coconformation with such hydrogen bonding was found because of the formation of hydrogen bonds between the macrocycle NH group on the rotaxane with solvent molecules. It was found that the insertion of a Na<sup>+</sup> ion into the crown ether, where it coordinates to the ester C=O group, restricts coconformational exchange. Overall, it was demonstrated that the nature of the solvent, the addition of salts, and changing the flexibility of the rotaxane shaft all change the dynamic processes of the rotaxane.

Sohlberg and Tarbet<sup>[72]</sup> carried out a semiempirical investigation of a light-driven rotaxane-based molecular shuttle synthesized and characterized by Murakami et al.<sup>[73]</sup> Some preliminary structural optimizations on the cyclodextrin and shaft components were carried out with the MM<sup>+</sup> molecular mechanics method<sup>[74]</sup> to generate starting structures, followed by the full geometry optimizations assuming the semiempirical AM1<sup>[75]</sup> Hamiltonian. The results of the semiempirical calculations support the experimental results obtained by Murakami et al.<sup>[73]</sup> As an isolated molecule the rotaxane shaft shows twofold symmetry, but in both rotaxane conformers, the symmetry is broken. The loss of symmetry upon inclusion into the cyclodextrin was also observed experimentally.<sup>[73]</sup> Of the *cis* and *trans* coconformers of the rotaxane, the *cis* coconformer was energetically more stable, in agreement with the experimental findings of Murakami et al.,<sup>[73]</sup> where a 2:1 distribution of the *cis/trans* conformers at 278 K was reported. In the rotaxane *trans* conformer, the shaft is very nearly centered in the cyclodextrin cavity, as Murakami et al.<sup>[73]</sup> inferred from induced circular dichroism spectra. In the *cis* conformer, the shaft is off-center. This was suggested as the source of the shuttling action. Additionally, the *cis* conformer of the rotaxane structure displays a kink in the shaft and therefore the conformational isomerism from *trans* to *cis* (or vice versa) involves significant structural transformation. The barrier to conformational isomerization was estimated to be  $\geq 11$  kcal/mol. It

<sup>b</sup>A polarizable continuum model that was originally developed by Miertus, Scrocco, and Tomasi.

**Fig. 5** The “molecular 8” shaped [1]rotaxane investigated by Reuter et al. *Source:* Reprinted from Ref.<sup>[76]</sup>. © 2001, with permission from WILEY-VCH, STM-copyright & Licenses.

was noted that a significant structural transformation and a large energy barrier are consistent with the experimentally observed<sup>[73]</sup> very slow rate of isomerization at room temperature.

A new type of [1]rotaxane containing two aliphatic bridges between the “shaft” and “ring” was first obtained by Reuter et al.,<sup>[76]</sup> who noted that this system, shown in Fig. 5, is reminiscent of a self-intertwining chiral “molecular 8.” This system is topologically no different from a bridged macrocycle (bicyclic compound), but the “bridge” is very long and contains bulky substituents that lock the molecule into an interesting “intertwined” configuration. To locate the structure of the preferred isomer, they performed a molecular dynamic calculation at 360 K,<sup>[76]</sup> using the Amber\* force field implemented as in the Macro-model 6.5 software package.<sup>[49]</sup> The dominant conformation and the position of the two bridges of the [1]rotaxane, as predicted by the simulations were consistent with data from MS and NMR experiments.<sup>[76]</sup>

Biscarini et al.<sup>[77]</sup> carried out the molecular mechanics-based solid-state calculations on 25 rotaxanes and 1 catenane, to test which types of benzylic amide macrocycle-containing rotaxanes possess mobile components in the crystalline phase, and therefore have the potential to form the basis of solid-state molecular devices. The MM3 model<sup>[36–38]</sup> implemented in the TINKER package was used. Complete Ewald summation was used for the electrostatic interaction. The rotaxanes structures were optimized starting from structures determined by X-ray diffraction. Reoptimization of the X-ray structures was performed to set the positions of the hydrogen atoms, which are not revealed by X-ray analysis. For each minimized

structure, several physical properties were calculated: the packing energy, the molecular van der Waals surface, volume, and the ratio of the occupied volume to total volume of the cell (Kitaigorodski packing coefficient). For comparison with previous work, the same procedure was applied to other non-interlocked systems, similar to the rotaxanes and catenanes of consideration. These comparisons yielded calculated physical parameters in good agreement with literature results. The calculations showed that the experimentally determined rotational barriers and steric energies could be recovered by computations for these types of interlocked molecules.<sup>[77]</sup> The authors proposed their computational method for selecting rotaxanes that contain a macrocycle component that is highly mobile even in the solid phase.

Modeling studies of rotaxanes and catenanes often use an X-ray crystal structure as the starting geometry. However, in many cases, no crystal structure is available owing to experimental difficulties in the isolation of crystals of these complex species. Frankfort and Sohlberg addressed this issue in a semiempirical electronic structure study of a switchable rotaxane that was demonstrated experimentally by MartinezDiaz, Spencer, and Stoddert.<sup>[23]</sup> A starting structure of the rotaxane molecule was constructed from its principle subcomponents.<sup>[78]</sup> There are three subcomponent structures: the ring, shaft, and stopper. Low-energy conformations were identified for each subcomponent and optimized using the AM1 semiempirical method. The rotaxane was then assembled from the optimized subcomponents by computationally mimicking the S<sub>N</sub>2 mechanism by which it is synthesized. The computations showed that internal energy of the system decreases during construction. This result is consistent with the findings of Pozuelo, Mendicuti, and Mattice<sup>[31]</sup> for the assembly of alpha-cyclodextrin polyrotaxanes based on MM studies and also with MD studies of the process of nesting carbon nanotubes.<sup>[79]</sup> Again, we note that this result is confirmed for a wide range of systems and with multiple computational techniques, and undoubtedly has broad implication. In fact, as the association of the shaft and macrocycle is most probably entropically unfavorable, an accompanying decrease in internal energy is presumably necessary for a practical synthetic mechanism.

A second issue in modeling switchable rotaxanes is the involvement of multiple electronic and/or charge states of the system. In the switchable rotaxane reported by MartinezDiaz, Spencer, and Stoddert,<sup>[23]</sup> ring shuttling is initiated by a change in pH. Protonation or deprotonation of the amine functionality on the rotaxane shaft changes the preferred binding site of the ring. For techniques such as MM and classical MD, which are based on empirical molecular potential energy functions, the functions must be reparameterized for

each charge state. By contrast, electronic structure based techniques may be applied without reparameterization. For their study of the switchable rotaxane reported by MartinezDiaz, Spencer, and Stoddert,<sup>[23]</sup> Frankfort and Sohlberg selected the semiempirical AM1 Hamiltonian. After construction of a starting structure, they tracked the shuttling action of the [2]rotaxane by correlating the energy of the system to the position of the ring in both the protonated and deprotonated states.<sup>[78]</sup> For both the protonated and deprotonated species, 95 separate trial structures of the rotaxane were fully optimized at the AM1<sup>[75]</sup> level of theory. To generate these trial structures, the initial rotaxane structure (from the S<sub>N</sub>2-mimicking construction) was modified by translating and rotating the ring about the shaft. For the fully assembled rotaxane in the protonated state, the heavily dominant structure places the ring around the dialkylammonium station. This structure accounts for 64% of the total population at 300 K; the second and third lowest energy structures essentially constitute all of the remaining 36%. The most highly populated structure is representative of all three because they differ only by a slight translation of the macrocycle around the dialkylammonium center. Upon deprotonation, the ring is driven to the opposite side of the shaft where the bipyridinium station is located. The calculations identify three deprotonated structures that represent 86% of the population at 300 K. In all of these structures, the ring is oriented asymmetrically around the bipyridinium station. The bipyridinium station contains a nitrogen atom on either end. The macrocycle associates with either of these two nitrogen atoms, rather than being symmetrically positioned between the two. This asymmetric positioning around the bipyridinium station in the deprotonated state is in agreement with the experimental results based on proton NMR.<sup>[23]</sup> As shown by the energetic data for the structures, the addition of the proton to the dibenzylamine station is energetically favorable, which is also in accordance with experimental results. The calculations further show that relatively little structural change in the shaft accompanies the shuttling action.

In parallel experimental findings,<sup>[23]</sup> the semiempirical AM1 calculations predict that the DB24C8 ring initially resides on the NH<sub>2</sub><sup>+</sup>, and upon deprotonation with a base, the preference of the ring location changes to the bipyridinium station. Frankfort and Sohlberg proposed that such calculations may be useful for predicting the effect of proposed structural modifications on the shuttling action, and therefore, such calculations may be used in the presynthesis design of switchable rotaxanes.<sup>[78]</sup>

Zheng and Sohlberg<sup>[80]</sup> presented a procedure for modeling a photo-induced, redox-switchable, rotaxane-based molecular device that is designed to capture the

critical device-like features, and demonstrated it on an experimentally realized example. The system consists of a benzylic amide macrocycle mechanically locked onto a thread featuring two potential hydrogen bonding stations, a succinamide (*succ*) and a 3,6-di-tert-butyl-1,8-naphthalimide (*ni*) unit separated by a C<sub>12</sub> alkyl spacer. The system, which has been studied experimentally,<sup>[81]</sup> exhibits extremely fast and fully reversible shuttling motion.

The computational procedure consists of three main steps: 1) conformational searching over the full torsional space of the rotaxane; 2) single-point semiempirical calculations for all coconformations in their neutral singlet, triplet, and anionic doublet states; and 3) statistical analysis to correlate the structural features with energy in each state. Results were checked by repeating the analysis on a subset of coconformations (~1%) that were subjected to full geometry optimization.

Constructing the profile of structure vs. energy from a large sample of semiempirical single-point energy calculations is dramatically less expensive computationally than carrying out full structural optimizations at the semiempirical level for each trial structure. For large structures such as rotaxanes and catenanes, which require 1000 or more optimization steps, the computational expense decreases on the order of  $\times 10^3$ . Zheng and Sohlberg<sup>[80]</sup> proposed that as long as the trial structures generated from the systematic conformational search are “chemically reasonable,” the use of single-point calculations will produce a structure-vs.-energy profile that is qualitatively consistent with what would be obtained if each structure were fully optimized. The mathematical basis of their argument is as follows and is shown schematically in Fig. 6:

**Fig. 6** Schematic density of conformational states (DOCS) resulting from the exact potential energy curve (PEC) and from evaluation of energy on the exact curve using coordinates from an approximate PEC.

Suppose that the molecular potential energy function is  $f(\alpha_i)$ , where  $\alpha_i$  represents the independent internal coordinates, of which there are  $M$ . (The potential energy function is shown on the left panel in Fig. 6, where the upper curve is the approximate one and the lower curve is the exact one.) The local minima are indexed  $n$ . In the harmonic approximation (widely used in computational chemistry)<sup>[82]</sup> in the vicinity of any particular minimum  $n$ , the function can be expanded in a quadratic polynomial in the parameters  $\alpha_i$

$$f(\alpha_i^n) \approx c^n + \sum_i [\alpha_i^n - \alpha_i^{0n}]^2 \frac{k_i^n}{2} \quad (1)$$

where  $c^n$  and  $k_i^n$  are constants, and  $\alpha_i^{0n}$  are the values of coordinates  $\alpha_i$  at the true minima  $n$ . The superscripts  $n$  refers to an expansion about the  $n$ th minimum. There are four minima shown in Fig. 6; in practice there are thousands.

The function  $G(f)$  is then defined as the number of minima of  $f(\alpha_i)$  with function value  $\leq f$ .  $G'(f) = [dG(f)]/df$  is the density of conformational states function (DOCS).

When minima  $n$  are approximately located (as by conformational searching with MM), mathematically this means that the  $\alpha_i^{0n}$  are determined with finite accuracy. (In Fig. 6, the evaluation of the energy on the exact curve using the minima on the approximate curve translates the uncertainty in the coordinates into uncertainty in the energy.) The uncertainty in  $\alpha_i^{0n}$  translates by propagation of errors into uncertainty in  $f(\alpha_i)$  at the minimum  $n$ , and ultimately into uncertainty in  $G'(f)$ . Error propagation analysis can then be used to find the influence of error in prediction of  $\alpha_i^{0n}$  on error in the energy profile of the system  $G'(f)$ .

By the definition of the derivative,  $G'(f)$  may be written

$$G'(f) = \left. \frac{G(f + \Delta f) - G(f)}{\Delta f} \right|_{\lim \Delta f \rightarrow 0} \quad (2)$$

where,

$$\begin{aligned} f(\alpha_i^n) &\approx c^n + \sum_i [\alpha_i^n - \alpha_i^{0n}]^2 \frac{k_i^n}{2} \\ &= c^n + \sum_{i=1}^M [(\alpha_i^n)^2 - 2\alpha_i^n \alpha_i^{0n} + (\alpha_i^{0n})^2] \frac{k_i^n}{2} \end{aligned} \quad (3)$$

In Eq. (3), the uncertainties in  $c^n$  and  $k_i^n$  are zero. Writing,  $(\alpha_i^{0n} = \alpha_i^{0n} \pm \delta_i^n)$ , the uncertainty in function  $f(\alpha_i)$  is the sum over  $i$  ( $i = 1 \rightarrow M$ ) of the uncertainty in  $(\alpha_i^n)^2$  which is 0, in  $2\alpha_i^n \alpha_i^{0n}$ , which is  $\pm \delta_i^n$ , and in

$(\alpha_i^{on})^2$ , which is  $\pm 2\alpha_i^{on}\delta_i^n$ . This may be written,

$$\begin{aligned}\Delta f &= \sum_{i=1}^M [4(\alpha_i^{on})^2(\delta_i^n)^2 + (\delta_i^n)^2]^{1/2} \\ &= \sum_{i=1}^M \delta_i^n [4(\alpha_i^{on})^2 + 1]^{1/2}\end{aligned}\quad (4)$$

Suppose the upper limit on the uncertainties in  $\alpha_i^n$  ( $i = 1 \rightarrow M$ ) is  $\pm\delta_i^n$ . The operation of the summarization in Eq. (4) becomes:

$$\Delta f = \delta_i^n \sqrt{M} [4(\alpha_i^{on})^2 + 1]^{1/2} \quad (5)$$

As long as  $G'(f)$  is slowly varying, the formula

$$\Delta G = \Delta f G'(f) \quad (6)$$

holds. It follows from Eq. (2) that the uncertainty in  $G'(f)$  is

$$\Delta G'(f) = [(\Delta f G'(f))^2 + (\Delta f G'(f))^2]^{1/2} \quad (7)$$

$$= \sqrt{2} \Delta f G'(f) \quad (8)$$

Finally, based on formula (4), where  $\Delta f = \delta_i^n \sqrt{M} [4(\alpha_i^{on})^2 + 1]^{1/2}$ ,

$$\frac{\Delta G'(f)}{G'(f)} = Q \delta_i^n \quad (9)$$

where

$$Q = \sqrt{2} \sqrt{M} [4(\alpha_i^{on})^2 + 1]^{1/2} \quad (10)$$

Because  $Q$  is independent of the uncertainties, *the relative uncertainty in the DOCS is linearly proportional to the uncertainty in the values of the independent parameters at the minima.* (In Fig. 6, this is shown as the DOCS based on the approximate energies being skewed to higher energy from the correct DOCS.) Zheng and Sohlberg concluded that if values of the  $\alpha_i^{on}$  are “chemically reasonable,” as long as  $f(\alpha_i^n)$  is computed accurately at these *approximate* minima, the resulting DCOS will be chemically reasonable as well.

In their studies of a photo-induced redox-switchable rotaxane, Zheng and Sohlberg<sup>[80]</sup> computed single-point energy and radius of gyration for 10,118 rotaxane structures. It was found that coconformations with ring binding at the *succ* site predominate in the low-energy regime for singlet and triplet species, with preference for the shaft component being extended.<sup>[80]</sup> Doublet species prefer to adopt coconformations with ring binding at the *ni* site in low-energy structures, with coiled and extended shaft conformations being energetically competitive. Effectively, the same results

were obtained by geometrical optimizations of a subset of coconformations, and were also in excellent agreement with previous experimental observations.<sup>[81]</sup>

## Computation as an Aid to Rotaxane Synthesis

Raymo, Houk, and Stodart<sup>[83]</sup> studied a series of  $[n]$ rotaxanes, each consisting of a bipyridinium-based backbone, encircled by one or more dioxyarene-based macrocyclic components. One of the structures is presented in Fig. 7. Syntheses were attempted for various functional R groups. Systematic variations in the R group attached to one of the phenyl rings of the tetraarylmethane-based stopper considerably affected the yields. When certain R groups are used, no rotaxane was isolated leading to the observed “all-or-nothing” substituent effect. A computational study was undertaken to explain this substituent effect, and to search for the transition state of the slipping-off process. The four compounds were constructed with Macromodel<sup>[49]</sup> 5.0, and followed individually by energy minimization using the Polak–Ribiere conjugate gradient (PRCG) algorithm.<sup>[84]</sup> The AMBER\* force field<sup>[85]</sup> was used with the GB/SA H<sub>2</sub>O model<sup>[48]</sup> to resemble a polar solvent. The study revealed two main energy barriers for the slipping-off of the macrocycle over the stoppers.<sup>[86]</sup> (The fact that the ring can slip off the shaft without breaking any chemical bonds means that these systems could be classified as pseudorotaxanes, but given a sufficiently large barrier to slipping, such a distinction is merely semantic.) Note also that if stabilization occurs upon assembly, i.e.,  $\Delta E < 0$ , the activation energy barrier to dissociation will be greater than that for association, and dissociation may therefore be kinetically forbidden even if the assembly process has an appreciable rate. The trend in calculated energy barriers agreed with experimental yields of the corresponding rotaxanes, and the abrupt substituent effect was a result of steric hindrance. This work provides an example of theory and computation yielding qualitative trends and insight that allows for targeted synthesis, thus accelerating the development process.

**Fig. 7** The rotaxane system studied by Raymo et al. *Source:* Reprinted with permission from Ref.<sup>[83]</sup>. © 1998, American Chemical Society.

**Fig. 8** Schematic layout of Schalley et al.'s rotaxane system. Source: From Ref.<sup>[87]</sup>.

Schalley et al.<sup>[87]</sup> synthesized a set of rotaxanes with shafts of varying lengths. As in the work of Raymo, Houk, and Stodart,<sup>[83]</sup> they also reported that during the synthesis of these rotaxanes, the yield depends on the nature of the stopper. To examine the steric requirements of the stopper–ring complexes in detail, Schalley et al.<sup>[87]</sup> carried out force-field calculations of the rotaxane molecule shown in Fig. 8, using the Amber\* force field<sup>[85,88,89]</sup> incorporated in the MacroModel 7.1 program package.<sup>[90]</sup> Monte Carlo simulations were performed, and results suggested that rotaxane ring “acts as a noncovalently bound ‘protecting group’ for the stopper nucleophile.”<sup>[87]</sup> The findings based on the modeling suggested an improved synthetic scheme.

### Peptide Rotaxanes

There have been several descriptions of rotaxanes and molecular shuttles based on dipeptide threads and benzylic amide macrocycles.<sup>[59,91–94]</sup> Asakawa et al.<sup>[95]</sup>

reported hydrogen bond-assembled chiral peptide rotaxanes constructed by threading an achiral benzylic amide macrocycle onto a chiral dipeptide shaft. To elucidate the effect of external stimuli on the magnitude and sign of the chiral optical response for peptide rotaxanes, with the general structure GlyX, where X is a chiral amino acid, they performed modeling of the rotaxane circular dichroism (CD) spectra.<sup>[95]</sup> Optimized geometries for each rotaxane were obtained by taking X-ray crystal structures as starting geometries and optimizing with the MM3<sup>[36–38]</sup> method as implemented in the TINKER<sup>[39–42]</sup> program. MM techniques were used for structural optimization, but CD is a purely electronic structure effect, requiring an explicit electronic structure description of the system. The CD spectra were simulated by using the semiempirical INDO/S<sup>[96,97]</sup> procedure. The simulation reproduced the shape of the experimental curves of CD spectra. The expression of chirality was shown to be a non-linear effect that can be transmitted over long distances.

Asakawa et al.<sup>[95]</sup> made the bold claim that, “. . . the switching ‘on’ and ‘off’ of the expression of chirality in peptide rotaxanes by controlling intercomponent interactions, i.e., through the ‘mechanical bond,’ may be a general phenomenon, not limited to a simple optical response.” This novel insight could be conceivably far-reaching. It might be applicable to other areas where chiral transmission from one molecule to another can be beneficially used, such as for asymmetric synthesis.

### Metal-Containing and Metal-Templated Rotaxanes

Organometallic chemistry is finding use in the production of novel rotaxanes and catenanes.<sup>[98–102]</sup> Whelan et al.<sup>[103]</sup> modeled the adsorption of the prototypical benzylic amide macrocycle on a [2]rotaxane onto a gold surface. Molecular mechanics calculations with charge equilibration were performed. Intramolecular interactions, gold–gold interactions, and gold–adsorbate interactions were taken into account. The MM3 model,<sup>[36–38]</sup> as implemented in the Tinker package,<sup>[39–42]</sup> was used for the molecular mechanics aspect of the calculations. Whelan et al. showed that the initial stages of film growth proceed by chemisorption of the amide functions onto the metal surface with the bonding interaction located in two carbonyl groups. They also found that macrocycle–macrocycle interactions are responsible for the difference in the behavior of two carbonyls with respect to the other two.

Li et al.<sup>[98]</sup> noted three sources of broad interest in the complexes of copper: 1) their roles in the catalytic

**Fig. 9** Schematic of a dimeric copper-complexed rotaxane. Source: Reprinted from Ref.<sup>[98]</sup>. © 2003, with permission from WILEY-VCH, STM-Copyright & Licenses.

reduction of dioxygen,<sup>[104]</sup> 2) their ability to transfer energy,<sup>[105,106]</sup> and 3) their activity in biological systems.<sup>[107,108]</sup> Li et al. carried out molecular dynamic calculations on three copper-complexed rotaxanes and catenanes,<sup>[98]</sup> one of which is presented in Fig. 9, to identify the lowest energy conformers. The Macro-Model program and the MM2 force field implemented in the CACHE 5.0 program were employed in the calculations. The compounds were predicted to take conformations that are flexible enough to enable the rotation of the four amide groups into an “in” or an “out” conformation, without the occurrence of large energy differences between different conformers. These findings from the molecular modeling studies supported the structural assignments made experimentally.

## CONCLUSION

Despite the very considerable computational challenge, theoretical and computational investigations of switchable rotaxanes are emerging at an accelerating pace. Good success has been reported in modeling structural properties and switching mechanisms. These studies are contributing to a substantially improved understanding of the fundamental nature of these topologically nontrivial molecular complexes. Complementary

application of computational and experimental methods is especially powerful. Inelastic neutron scattering coupled with molecular dynamics simulation is one such synergistic marriage of theory and experiment for the study of switchable rotaxanes. Close on the heels of these successes, examples of theory-accelerated synthesis of molecular shuttles by design are starting to emerge. The development of robust computational approaches to the modeling of such systems will undoubtedly facilitate new research on these systems, and ultimately the design of true molecular and nanodevices.

## ACKNOWLEDGMENT

Our molecular devices research is funded in part by the NSF–NER program, startup funds from Drexel University, and Dupont Corp. in the form of a Dupont Young Professor award to KS.

## INTRODUCTION

Nanotechnology is an emerging field that studies fundamental nanoscale processes and the exploitation of those processes in the development and function of nanodevices.<sup>[1]</sup> To date, development has been hampered by the need for materials and processes that can perform reproducibly at the nanometer scale. Although at present nanodevice development is dominated by materials made from SiO<sub>2</sub> or metals, these materials can suffer from a lack of processability.<sup>[2]</sup> As an alternative that has met with some success, organic-based materials can be easily processed by a variety of methods including spin coating, evaporation, and printing.<sup>[3]</sup> Organic and organic/inorganic hybrid materials have been developed for organic light-emitting diodes (OLEDs), field-effect transistors, and other devices.<sup>[4–6]</sup> However, organic devices usually suffer from a short lifetime as a consequence of poor mechanical and thermal stability associated with small organic molecules.<sup>[5]</sup> Although organic/inorganic hybrid materials have better mechanical and thermal stability,<sup>[7–9]</sup> there still exists an inherent lack of component compatibility, leading to difficulties in processing, and intercomponent communication.<sup>[9]</sup>

A promising class of materials for nanodevice application is conducting polymers (Fig. 1). Their thermal and environmental stability facilitates use in devices for photochemical and electrochemical applications,<sup>[10–12]</sup> and their physical and chemical properties can be easily tailored for specific functions.<sup>[13,14]</sup> When conducting polymers were first introduced, their poor solubility in common processing solvents limited their versatility.<sup>[11]</sup> However, this issue has been addressed through modifying the backbone of the polymer with side chains, such as alkyl and alkoxy groups. With this approach, processing of these materials in either aqueous or organic media has expanded the utility of conducting polymers in OLEDs, electrochromic displays, and coatings for more sensitive materials.<sup>[6,15–17]</sup> Numerous articles are found in the literature reporting

devices in the micrometer regime made with conducting polymers.<sup>[2,3,18–21]</sup>

Although Moore's law predicts a doubling in the number of transistors per chip approximately every 18 months,<sup>[22]</sup> the limits of traditional patterning techniques are threatening to hinder this advancement. The feature size required to continue this trend is in the <100 nm regime, where control over feature size is critical and difficult to achieve. New procedures and variations on current methods need to be developed to break this regime barrier. In this article, we will review current approaches to creating conducting polymer nanopatterns, from "template synthesis" to lithography. We discuss the advantages and disadvantages of each method and highlight the unique nanostructures formed with these techniques. These materials are likely to enhance the emerging field of nanoelectronics, while complementing current technology.

## TEMPLATE SYNTHESIS

The first reported patterning of conducting polymer nanostructures used template synthesis, a method developed by Penner and Martin<sup>[23]</sup> in the mid-1980s. They reported the electrochemical polymerization of pyrrole in the pores of a polycarbonate membrane. Template synthesis, as the name implies, utilizes the microporous or nanoporous structure of materials as a template for the electrochemical or oxidative synthesis of conducting polymer nanotubules and nanofibrils.<sup>[24]</sup> This technique can also be used to form nanotubes and nanofibrils of metals, carbon, and semiconductors.<sup>[24,25]</sup>

### Template Materials

The most common template materials used are "track-etch" membranes and alumina membranes.<sup>[26]</sup> Track-etch membranes are formed by bombarding a

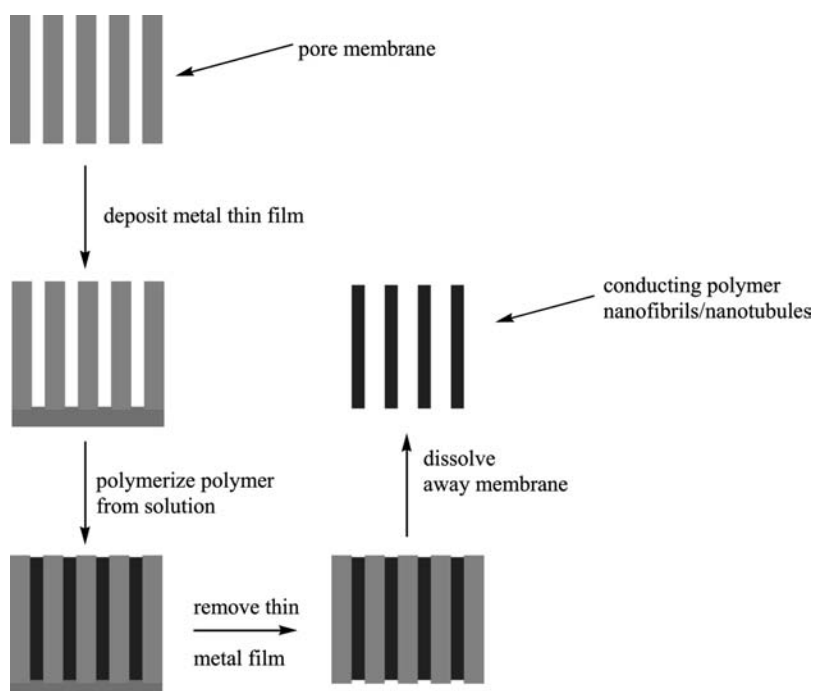

**Fig. 1** Examples of conducting polymers.

nonporous membrane with nuclear fission fragments.<sup>[27]</sup> These membranes are typically polycarbonate or polyester. The tracks that are formed are subsequently chemically etched to produce pores in the material. The size of the uniform pores can be as small as 10 nm in diameter with pore densities as high as  $10^9$  pores/cm<sup>2</sup>.<sup>[26]</sup> The bombardment occurs randomly, which, at small pore diameters and high pore densities, can cause intersections of the pores.<sup>[26]</sup> If these intersections are not desired, alumina or other membranes can be used because the processes used to form these membranes are more controlled.

Porous alumina membranes are formed from the anodization of Al metal in acidic solution. The uniform pores are cylindrical, with pore densities as high as  $10^{11}$  pores/cm<sup>2</sup> and a size range from >100 down to <5 nm.<sup>[26]</sup> Because of the nature of pore formation in the alumina membranes, interconnects do not develop between pores,<sup>[25]</sup> affording a template material that can form isolated nanostructures. Membranes, including SiO<sub>2</sub>, zeolites, and other nanoporous solids, have also been used as template materials, although to a lesser extent.<sup>[25]</sup>

### Mechanism for Template Synthesis

The polymerization mechanism for conducting polymers using template synthesis is either electrochemical or oxidative. The most common electrochemical method is to plate one surface of the membrane with a conducting metal thin film and use this film as the anode in an electroplating process.<sup>[28]</sup> The polymer first nucleates on the walls of the pore, and subsequent deposition yields a well-ordered polymer outer layer that becomes more disordered as the tubule wall thickens.<sup>[29]</sup> In the oxidative method, the template is immersed in a solution containing monomer and a polymerization reagent, such as an aqueous iron(III) salt.<sup>[30,31]</sup> The deposition occurs in a manner similar to the electrochemical method, resulting in a similar polymer-order gradient for the nanostructures (Fig. 2).

**Fig. 2** Schematic of template synthesis.

### Physical Properties of Conducting Polymer Nanotubules/Nanofibrils

Early studies of polypyrrole chain order in nanofibrils (closed tubules) used polarized infrared absorption spectroscopy (PIRAS) to examine a range of fibril diameters from 30 to 600 nm. In addition, X-ray diffraction was used to observe 30 and 400 nm fibrils.<sup>[32]</sup> In the X-ray diffraction studies, 400-nm fibrils showed diffractograms similar to amorphous conducting polymer, while the 30-nm fibrils exhibited diffractograms similar to stretched polymer, suggesting an alignment of the polymer chains in these small-diameter fibrils.<sup>[32]</sup>

The PIRAS experiment supported the X-ray diffraction evidence that polymer chain alignment in a fibril increases as the diameter decreases. In a typical PIRAS experiment, the absorbance is measured for light polarized parallel and perpendicular to the major axis of a material (Fig. 3). In the case of a polymer fibril, if the polymer chain alignment is completely random, then the absorbance of light parallel to the pore axis will be the same as the absorbance of light perpendicular to the pore axis and will give a dichroic ratio (ratio of absorbances parallel and perpendicular to the pore axis) of 1. Smaller fibrils had dichroic ratios significantly different from 1, with the fibrils preferentially absorbing one polarization over another.<sup>[32]</sup> Amorphous polymer and large-diameter fibrils do not absorb polarized light preferentially, giving dichroic values very close to 1.<sup>[32,33]</sup>

Polarized infrared absorption spectroscopy experiments were also performed on polycarbonate membranes; the polycarbonate was also found to be stretch-oriented.<sup>[32]</sup> Studies have shown that conducting polymers can be induced to align with the orientation of the substrate.<sup>[34–36]</sup> This orientation is lost as the thickness of the deposited polymer film grows. Similarly, the outer walls of conducting polymer

tubules and fibrils deposited in stretch-oriented polycarbonate membranes align with the axis of the membrane, but this alignment is slowly lost as polymerization continues and the walls thicken. Wall thickness is controlled by the polymerization time.<sup>[25]</sup>

The thickness of the polymer walls is also correlated with the conductivity of the tubule. While thick-walled nanotubules had conductivities similar to bulk material, the narrow-walled nanotubules had significantly higher values.<sup>[35]</sup> One explanation for this phenomenon is that the alignment in the polymer chains increases the conjugation length of the polymer, enhancing the electronic properties of the material. As the walls thicken, the overall randomness of the structure increases, decreasing the conjugation length and hence the conductivity.<sup>[35]</sup> This method provides a means to control the conductivity of the material through polymerization time. It has been postulated that the walls in a polycarbonate membrane nucleate the ordered polymer in two ways: 1) as the polymerization commences, the polycationic oligomers forming are not as soluble as the monomer units and 2) there is a coulombic attraction between the anionic walls of the membrane and the forming cationic polymer.<sup>[26]</sup>

Recently, this “greater ordering” claim has been disputed. Most of the above studies of polypyrrole nanotubules were performed with a polycarbonate membrane; Mativetsky and Datar<sup>[37]</sup> used an alumina membrane to form nanotubules of polypyrrole oxidatively and found the tubules to have a highly irregular morphology. Indeed, PIRAS studies with alumina membranes have shown no preferential polarized absorption (dichroic ratios near 1).<sup>[37]</sup> Because there are no charged sites in an alumina membrane, the nucleation occurs more randomly in the alumina pores. Polypyrrole then grows radially outward from each nucleation site until it encounters an obstacle: that of the pore wall or another “polypyrrole mass,” disrupting

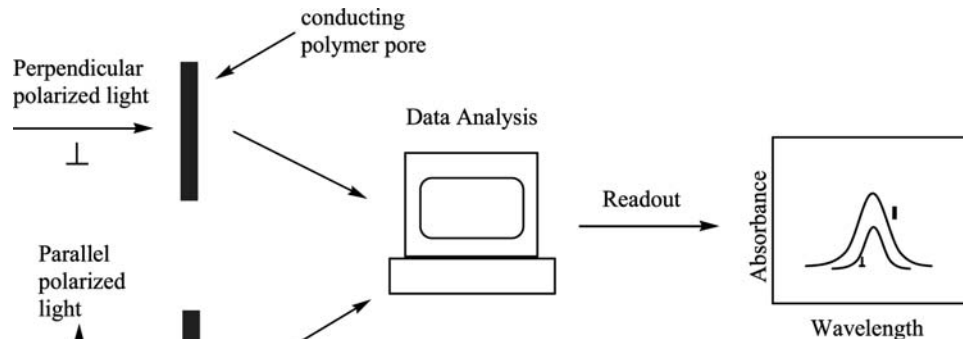

Fig. 3 Schematic of a typical PIRAS experiment.

order. Although Mativetsky and Datars<sup>[37]</sup> were not able to measure conductivity directly, their measurements suggest that the conductivity of these random fibrils is comparable to the fibrils of similar size formed from a polycarbonate membrane. They therefore concluded that the enhanced conductivity of these nanotubules is not a result of increased order imposed by the polycarbonate walls.

### Applications of Template Synthesis

Conducting polymer nanofibrils and nanotubules have a wide variety of potential applications. They are highly permeable, and studies have shown that they can be highly selective for certain gas mixtures; the high-density conducting polymer fibrils could be used as a gas permeation membrane.<sup>[38]</sup> Conducting polymer nanotubules are also well suited for encapsulated sensors because the polymerization process can be stopped at any time, thus controlling the size of the cavity. Researchers have encapsulated a variety of enzymes and chemical species in thin-walled tubules and have found that their activity is greater than that of enzymes trapped in a thin polymer film.<sup>[30,39,40]</sup> These reactions could be carried out in aqueous or organic solvents because the conducting polymer “microreactor” is isolated from the environmental surroundings by the walls of the conducting polymer, utilizing the relative insolubility of the polymer in common solvents.<sup>[30]</sup> The surface area for enzyme/substrate interaction can be adjusted by changing the porosity of the membrane, producing a microreactor with a high loading capability.<sup>[30]</sup>

With the enhanced conductive properties of these materials, numerous groups have reported using nanotubules to form a variety of novel systems. For example, Granstrom, Berggren, and Inganas<sup>[41]</sup> polymerized 3,4-ethylene-dioxythiophene (EDOT) in polycarbonate membranes with pore sizes of 10 nm and 100 nm for the preparation of a hole-injection contact in a polymeric light-emitting diode (PLED). An electroluminescent layer was spin-coated on the surface of the membrane, followed by an Al/Ca layer for the electron-injecting contact. Although the PLED tested had a very low efficiency, with optimization, the authors believed that increased efficiencies up to 1–10% could be obtained.<sup>[41]</sup> The advantage of this technique is in the sheer quantity of nano-LEDs that can be formed at one time.

In other applications, polyaniline tubules have been studied for use as microscale/nanoscale transistors and for field emission because of their excellent switching properties and mechanical stability (Fig. 4).<sup>[42,43]</sup> Polymer composites have been made to blend physical properties, and many have been found to enhance

**Fig. 4** Scanning electron microscope image of polyaniline nanofibrils formed from a porous alumina membrane using template synthesis. *Source:* From Ref.<sup>[42]</sup>. © (2001), with permission from Elsevier Science.

desirable characteristics, such as conductivity and “rectification effect.”<sup>[31,44–46]</sup>

### Inverse Opal Formation

A variation of template synthesis is to use microspheres and nanospheres of polymers as templates for the formation of macroporous 2-D and 3-D polymer structures, called inverse opals. A typical experiment involves assembling a template of colloidal microspheres or nanospheres on a conductive metal electrode surface by slow evaporation from a weight percent solution of colloidal particles on an electrode surface. The particles of materials such as poly(styrene) or silica will assemble themselves as the solvent evaporates. Once the structure is dry and mechanically immobilized, it is immersed in a solution containing the desired monomer units. Electropolymerization of the conducting polymer has been favored in the literature over the oxidative method, with many groups citing a greater control over the polymer growth rate and deposition than with the oxidative method (Fig. 5).<sup>[47,48]</sup> The templates are then etched (silica) or dissolved away (colloidal polymer), leaving conducting polymer patterned into a “honeycomb” structure.

This technique has been used to create nanostructures of polypyrrole,<sup>[47–49]</sup> polyaniline,<sup>[49–51]</sup> polythiophene,<sup>[47,49]</sup> and poly(phenylenevinylene) (PPV).<sup>[52]</sup> Nanostructure sizes as low as 50 nm have been reported with polypyrrole,<sup>[48]</sup> where it was found that the pore size can be controlled by the amount and time of applied voltage and by the size of the colloidal

Fig. 5 Schematic of “inverse opal” synthesis.

particle utilized. Han et al.<sup>[50]</sup> used polystyrene nanospheres that were coated with increasing layers of a polyelectrolyte (PE) to see what effect the size of the nanoparticle would have on the resulting conducting polymer film (Fig. 6). The pore size actually decreased upon increasing the number of PE layers, leveling off after 4 PE layers, and the structure shrank less upon extraction of the template, improving mechanical stability.<sup>[50]</sup>

Fig. 6 A) Assembly of PS particles with 2 PE layers on a Au surface. B) Polyaniline honeycomb nanostructure formed in the interstitial voids of the particles. Source: From Ref.<sup>[50]</sup>. © (2002) American Chemical Society.

The tunability of these systems has attracted interest in the field of photonic bandgap crystals.<sup>[47,51,52]</sup> They have been shown to exhibit the property of reflecting certain wavelengths of light, spanning the visible and near-infrared (NIR) regions of the spectrum. The conductivities of these 2-D and 3-D structures are similar to those of bulk conducting polymer.<sup>[49]</sup>

## LITHOGRAPHY AND MASK TECHNIQUES

Lithography is the process of writing a free-form or replicated pattern on a surface by electrical (applied voltage), photochemical (UV, X-ray beam), or physical (diamond etching) means. Lithography has been very successful at creating structures at the micrometer scale, but there are significant challenges and obstacles to forming structures of <100 nm in dimension. Ultimately, the lithography techniques developed must be reliable, accurate, and efficient. Development over the past 10 years has dealt with these issues, and the next few sections describe these advances. As nanolithography is still a relatively young field, many of the techniques described below are unoptimized.

## Solvent-Assisted Micromolding

Solvent-assisted micromolding (SAMIM) is a “soft lithography” technique that provides a simple, fast way to form patterns on a surface. The mold is made out of an elastomeric material [usually poly(dimethylsiloxane) (PDMS)]; it is coated by wetting the mold itself with a thin layer of a solvent appropriate for the polymer or precursor substrate. The mold is then brought into contact with the substrate, and the solvent dissolves (or swells) the substrate, allowing the substrate to flow into the recesses of the mold.

As the solvent evaporates, the polymer hardens, but maintains the shape of the mold (Fig. 7).<sup>[53]</sup> Kim et al.<sup>[54]</sup> first utilized this method to form features down to 50 nm in height and 60 nm in width on polymeric photoresists. Solvent-assisted micromolding was used to create polymeric light-emitting diodes (PLEDs) using a precursor to poly(phenylenevinylene) (PPV) and methanol as a solvent.<sup>[55]</sup> Although the features formed were larger than 100 nm, the potential of this technique to form very small devices of interest has been demonstrated.

### Micromolding in Capillaries

Micromolding in capillaries (MIMIC) is a technique related to SAMIM. A prepatterned stamp made out of an elastomer such as PDMS is placed on a clean, flat substrate and a drop of solution of the desired patterning material is placed at the edge of the stamp. Through capillary action, the drop migrates into the grooves of the stamp. As the solution dries, the material is patterned on the substrate, and the stamp is subsequently removed.<sup>[53]</sup> This technique has been used to form nanowire and nanodot patterns of poly-(3,4-ethylenedioxythiophene) (PEDOT) doped with poly(4-styrenesulfonate) (PEDOT-PSS).<sup>[56]</sup> By varying the size of the capillary channel and the solution concentration, nanowires of 6 nm in height and nanodots of 10 nm in height were formed on the substrate.<sup>[56]</sup>

### Scanning Tunneling Microscopy Lithography

Scanning Tunneling Microscopy (STM) and related techniques have been used for surface modification for about 15 years. The first example of conducting polymer deposition was reported by Wu, Fan, and Bard<sup>[57]</sup> using a scanning electrochemical microscope (SECM), “which maintains a constant faradaic current between a tip electrode and a metal surface electrode.” In this procedure, Nafion<sup>®</sup> film was first deposited on the Pt surface and immersed in an anilinium sulfate solution to saturate the film. In this system, the platinum is the surface electrode and tungsten is used as the tip electrode. A positive potential was applied to the Pt surface to oxidize the aniline at the Pt / Nafion interface, and deposition of the resulting polymer was localized around the tip electrode (Fig. 8). The features formed were larger than 100 nm, which was attributed to tip size, thickness of the Nafion film, and electric field distribution. Control over these parameters was predicted to give smaller features.<sup>[57]</sup> Borgwarth et al.<sup>[58]</sup> utilized SECM to form polythiophene by oxidizing bromide to bromine, which locally diffused to the conductive substrate and oxidatively polymerized the thiophene monomer.

Using a gold electrode, Yang, Evans, and Hendrickson<sup>[59]</sup> reported the formation of polypyrrole nanostructures from a tetrafluoroborate/pyrrole solution. The Pt/Ir STM tip was coated with Apiezon<sup>®</sup> to insulate most of the tip, helping to control the size

Fig. 7 A) Schematic of MIMIC. B) Schematic of SAMIM. Source: From Ref.<sup>[53]</sup> by Annual Reviews.

of the nanofeature deposited on the surface. Polymer dots were deposited on the surface, and then the ability to remove the polymer dots was demonstrated by “blasting” the polymer dot from the surface with higher voltage.<sup>[59]</sup> This technique was used to “write” the word *science* using dots of 5–10 nm in diameter (Fig. 9). The variation in diameter was attributed to thermal evaporation and consequent concentration of monomer solution during operation, and to the local variation of surface roughness, affecting the movement of the tip as it maintains a constant distance above the surface.<sup>[59]</sup> A polymer line with a width of 10 nm and a circle with a diameter of 6 nm were formed by controlling the translation of the tip on the surface using a simple computer program.<sup>[59]</sup>

Highly oriented pyrolytic graphite (HOPG) has also been used as the conductive surface for forming conducting polymer nanostructures with an STM tip. Yaniv and McCormick<sup>[60]</sup> reported nanofeatures as small as 50 nm in diameter and 4 nm in height, formed from a 0.1 M KCl/0.1 M pyrrole solution. They found that no deposition occurred with potentials below 7.5 V, and control of the features could only be achieved with pulses below 100 nsec. Above this pulse duration, deposition became scattered over the scanned area.<sup>[60]</sup> Nyffenegger and Penner<sup>[61]</sup> studied qualitatively the mechanism of nanostructure formation using a similar setup. They concluded that the bias pulse forms defects in the basal plane of the HOPG within a few microseconds, and then aniline monomer diffuses to the edge of the defect and is oxidized.

As this process proceeds, the cationic aniline oligomers become insoluble and nucleate in the defect.<sup>[61]</sup>

### Atomic Force Microscope Lithography

The first example of atomic force microscopy (AFM) being used for patterning conducting polymer nanostructures was reported by Cai et al.<sup>[62]</sup> The electrochemical polymerization of pyrrole and aniline on an HOPG substrate was locally altered using an AFM tip. Depending on when the AFM scanning was activated, the amount of polymer could be decreased or enhanced in the scanning area. When the AFM tip is scanned over the surface before the application of a potential, any oligomers that are formed once the potential is applied are “swept” to the edges of the scanning area. Indeed, there is an enhancement in the amount of polymer at the edges of the scanning area. When the AFM tip is scanned after polymerization has commenced, the vertical force exerted on the developing polymer both creates a denser film and forces oligomers downward toward the polymer, increasing the local concentration of oligomers and thus the rate of polymerization.<sup>[62]</sup>

Dip-pen nanolithography (DPN) was developed by Piner et al.<sup>[63]</sup> and, as the name suggests, it uses the AFM tip as a pen, dipped in the desired patterning material. The AFM tip is then brought in close proximity to the surface. A water meniscus forms, which facilitates transport of the material from the

Fig. 8 Schematic of a typical STM lithography experiment.

**Fig. 9** The word “science” formed using STM nanolithography. Source: From Ref.<sup>[59]</sup>. © (1995) American Chemical Society.

tip to the surface. This method has been utilized to pattern a variety of materials to the surface such as DNA and thiols.<sup>[63–65]</sup> The Noy group utilized this method to deposit poly[2-methoxy-5-2'-ethylhexyloxy-1,4-phenylenevinylene] (MEH-PPV) on a glass surface.<sup>[66]</sup> The method was coupled with scanning confocal microscopy to obtain luminescent images of the deposited polymer nanostructures. Although the deposition was successful, more studies are needed to determine the extent of nanowire alignment and continuity.<sup>[66]</sup>

A technique that combines aspects from previous STM tip techniques is electrochemical dip-pen nanolithography (E-DPN), which has been used to deposit metal and conducting polymer nanostructures on a surface.<sup>[67,68]</sup> The tapping mode AFM tip is dipped in the desired monomer or metal salt solution, and as the tip engages the surface in a preprogrammed pattern, a potential is applied between the tip and the surface. This potential reduces the metal salt or electrochemically polymerizes the monomer and deposits the resulting nanostructure on the surface through the meniscus (Fig. 10).<sup>[67,68]</sup> In this way, polymers of 3,4-ethylenedioxythiophene,<sup>[68]</sup> pyrrole, and aniline<sup>[69]</sup> have been formed and deposited on a Si(111) surface with feature sizes as small as 30 nm in width and up to 5 nm in height.

The size of the nanostructures formed depends on a variety of factors, including humidity, speed of translation, and applied voltage, and it has been found that these factors are monomer-dependent. For example, it is easier to draw lines of polyaniline at lower humidity, while other polymers were less affected by the humidity. Aniline has a measurable solubility in water at 25°C (1 g in 28.6-mL water), and upon formation of the water meniscus, capillary action could disperse the aniline before a voltage is applied.

The height of the line can be controlled by the speed of translation of the tip as it deposits.<sup>[68]</sup> Two lines of poly(ethylenedioxythiophene) (PEDOT) were drawn at 10 and 1 nm/sec, and the line drawn at 1 nm/sec was significantly higher than the line drawn at 10 nm/sec (Fig. 11). Applied voltage along with

humidity controls the width of the line. A larger water meniscus covers a larger surface area, leading to a larger area of deposition.

The voltage applied depends, in part, on the potential of the monomer being used and on the native oxide layer that exists on the Si wafer. As the thickness of the oxide layer increases, so does the necessity of higher voltages for polymerization and deposition. Bias voltages ranged from  $-7$  to  $-15$  V. At such a high bias voltage, it is important to ensure that polymer, and not  $\text{SiO}_2$ , is being deposited.

After depositing PEDOT, an oxide layer was formed next to the polymer, and etching studies were performed. Upon exposure to HF, the  $\text{SiO}_2$  was etched from the surface, but the PEDOT line remained. Conversely, when exposed to a strongly oxidizing solution of 1:2  $\text{H}_2\text{O}_2$ : $\text{H}_2\text{SO}_4$ , the PEDOT line was removed while the  $\text{SiO}_2$  remained. Similar etching studies were performed with polyaniline and polypyrrole, and the results were consistent with the PEDOT studies. Interconnects also have been formed with a single polymer and with two different polymers using this technique. The ability to pattern these nanostructures precisely will be important toward the development of nanodevices.

## Masks

Seo, Pyo, and Cho<sup>[70]</sup> reported a mask method for the formation of polypyrrole micropatterns and nanopatterns using domains formed from polymer blends and block copolymers as the template. It is known that in thin films of polystyrene (PS) and poly(4-vinylpyridine) (4PV), microphase-separated domains are formed, and that thin films of block poly(styrene-*b*-4-vinylpyridine) (PS-*b*-4PV) form nanometer-separated domains.<sup>[70]</sup> The mask is formed from protonating the pyridine ring and immersing in a solution of sodium dodecyl sulfate

**Fig. 10** Schematic of E-DPN.

**Fig. 11** Atomic force microscope image of PEDOT lines drawn at 10 and 1 nm/sec. Inset shows height difference of the two lines. *Source:* From Ref.<sup>[67]</sup>. © (2001) American Chemical Society.

(SDS), which will form a bilayer with the pyridine and itself through ionic and hydrophobic interactions, respectively. Although SDS forms a monolayer with the PS through hydrophobic interactions, the polypyrrole nucleates preferentially on PS and displaces the SDS monolayer, but cannot displace the SDS bilayer. Using this method, nanopatterns as small as 50 nm were obtained (Fig. 12).<sup>[70]</sup> The pattern formed is not well defined, and additional research is needed to control pattern size and alignment.

## CONCLUSION

The ability to pattern nanostructures has opened up the field of nanoelectronics, and conducting polymers will play a significant role in the development of this field. The complementarity of these techniques is already apparent and represents a strength in the field. At the nanoscale, control and quantity will be immensely important, highlighting the advantages of both template synthesis and lithography. Today, template synthesis can afford numerous repetitive nanostructures, and lithography can yield nanostructures with precise size at a specific location. Unfortunately, most of the lithography techniques that work so effectively at the micrometer scale have yet to break the nanoscale barrier because of physical limits and methods used to form lithographic masks. Template synthesis is still a “bulk synthesis” technique because it has not been demonstrated that this technique can accurately deposit one or a few nanostructures.

Numerous applications have already been demonstrated for these new materials, from encapsulators for biosensors to photonic bandgap crystals. In addition, the potential for use in fabrication of nano-device components and interconnects is great, although high-throughput methods may be some years away. The success of many research groups in circumventing the current chemical, physical, and engineering challenges has encouraged an increasing number of researchers to study fundamental nanoscale processes. Such further research and innovation will likely lead to nanoelectronics playing an integral role in the development of future commercial applications.

## INTRODUCTION

Conducting polymers with metallic and polymeric properties are indispensable materials for the development of organic electronic devices, such as batteries, light-emitting diodes, and displays. The electrochemical fabrication of conducting polymer nanostructures, especially nanotubular structures, can enhance their performance by improving charge transport rate as well as surface area. However, the understanding of the electrochemically synthesized conducting polymer nanotubes is lacking in spite of their importance and high applicability. Here, we discuss the electrochemical synthesis, synthetic mechanism, and structural characterization of the conducting polymer nanotubes. The application of conducting polymer nanotubes is also discussed in the development of ultrafast flexible electrochromic device with low power consuming features.

## BACKGROUND

One of the most exciting challenges in recent research fields is the development of organic electronic devices including batteries, organic electronic memory, organic light emitting diode, lasers, and displays.<sup>[1–9]</sup> Conducting polymers, such as polyaniline, polypyrrole, polythiophene, and poly(*p*-phenylene vinylene) classes, are indispensable material in fabricating organic electronic devices because they have the electrical, electronic, electrochemical, and optical properties of a metal as well as the mechanical properties of a conventional polymer.<sup>[1–16]</sup> In optical properties, for example, polythiophene is red (or blue) in the reduced (or oxidized) state, whereas polymethylthiophene is purple (or pale blue) in the reduced (or oxidized) state.<sup>[17]</sup> All these unique characteristics of conducting polymers offer innumerable applicability to organic electronic devices.

Usually, conducting polymers are used in organic devices in three forms: thin film, nanofibrillar form,

and nanotubular form. The film is the most popular in organic devices, acting as electrodes or light controlling materials.<sup>[3,6,7,9]</sup> Oxidative chemical polymerization method is frequently used to fabricate pinhole-free homogenous thin film by spin-coating on a conductive or even insulating surface. Nanofibrils or tubes are used in the devices, which require higher surface area and sensitivity such as sensors or batteries.<sup>[1,2,18]</sup> Template synthesis, as shown in Fig. 1, is one of the most frequently adopted techniques to fabricate nanostructures of the conducting polymers since Penner and Martin pioneered the electrochemical synthesis of polypyrrole nanofibrils using a nucleopore (polycarbonate) membrane in 1986.<sup>[18–26]</sup> Alumina membranes (Fig. 2) and track-etched polycarbonate membranes were frequently used as a template owing to their well-defined pore structures.<sup>[18]</sup> The outer shape of the deposited material is usually determined by the inner structure of the membrane pores. Most of the conducting polymer nanostructures were synthesized by the chemical oxidation method because of its simplicity.<sup>[18,21–23,26]</sup> The polymerization conditions such as polymerization time and monomer concentrations determine whether the resulting inner structures are hollow tubes or completely filled fibrils.

For the electrochemical synthesis of conducting polymer nanofibril/nanotube in the porous template, a conductive substrate should be used at one side of the membrane as an electrode to deposit the polymer in the pores.<sup>[27–30]</sup> The mechanism for the nanostructure growth is more complicated compared to the chemical method. However, the electrochemical method has advantages over the chemical method in that the nanotube length can be easily controlled by changing polymerization time. The electrochemically polymerized nanotubes have also better electrochromic properties such as color vividness and switching rates.<sup>[19,20,27]</sup> For the application of conducting polymers to sensors and organic electronic devices, the tubular form of conducting polymer provides more advantages than the film or fibrillar

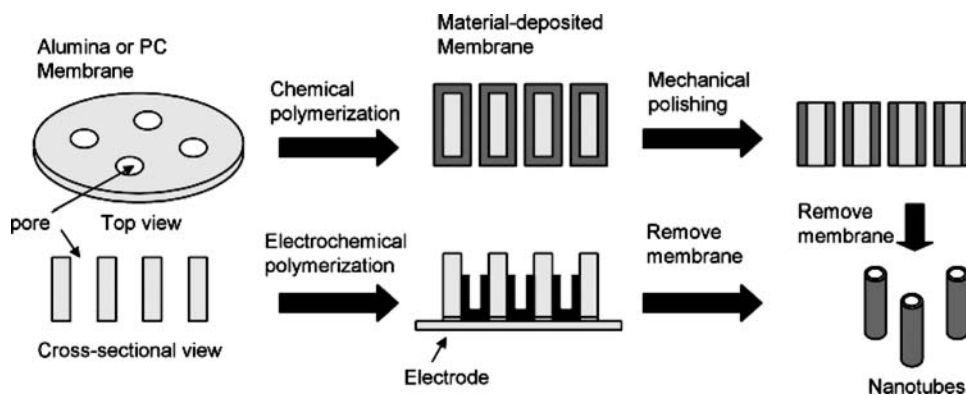

Fig. 1 Schematic of template synthesis of conducting polymer nanotubes chemically (top) and electrochemically (bottom).

form: possibility of inner modification, high surface area, fast response, etc.<sup>[18,27]</sup> Surprisingly, however, the studies on electrochemical synthesis of conducting polymer nanotubes are not many. Here, we discuss the electrochemical synthesis, synthetic mechanism,

structural characterization, and application of conducting polymer nanotubes using the template synthesis.

## METHODS OF ELECTROCHEMICAL SYNTHESIS

Electrochemical polymerization is normally carried out using a standard three-electrode configuration in a solution containing monomer and a supporting electrolyte. Three kinds of methods, potentiostatic, galvanostatic, or potentiodynamic, are used in electrochemical synthesis. Generally, potentiostatic conditions are recommended to obtain thin films, while galvanostatic conditions are recommended to obtain thick films. In the potentiodynamical method, a relatively firm polymer structure is expected because oxidation and reduction cycles are repeated during polymerization. For electrochemical synthesis, one face of the porous membrane is sputter-coated with a thin layer of conducting materials such as gold or indium-doped tin oxide (Fig. 1). This side, acting as a working electrode, is connected to a power source, the potentiostat. Electrochemical potential is defined by a reference electrode such as Ag/AgCl or saturated calomel electrode (SCE).

To make the nanotubular structure, two strategies can be used: one is the direct growth of conducting polymer nanotubes in the membrane pores and the other is the metal layer deposition on the surface of the pores and then the electrochemical growth of the conducting polymer.<sup>[21,22,26–31]</sup> The latter is useful to make nanotubes with very small diameters because the deposited metal layer reduces the inner diameter of pore. However, it is not easy to fabricate the polymer nanotubes with a good shape because the chemically deposited metal surface is very rough. On the other hand, better nanotubular structures are obtained with the direct growth method and the length of the polymer nanotube can be controlled.

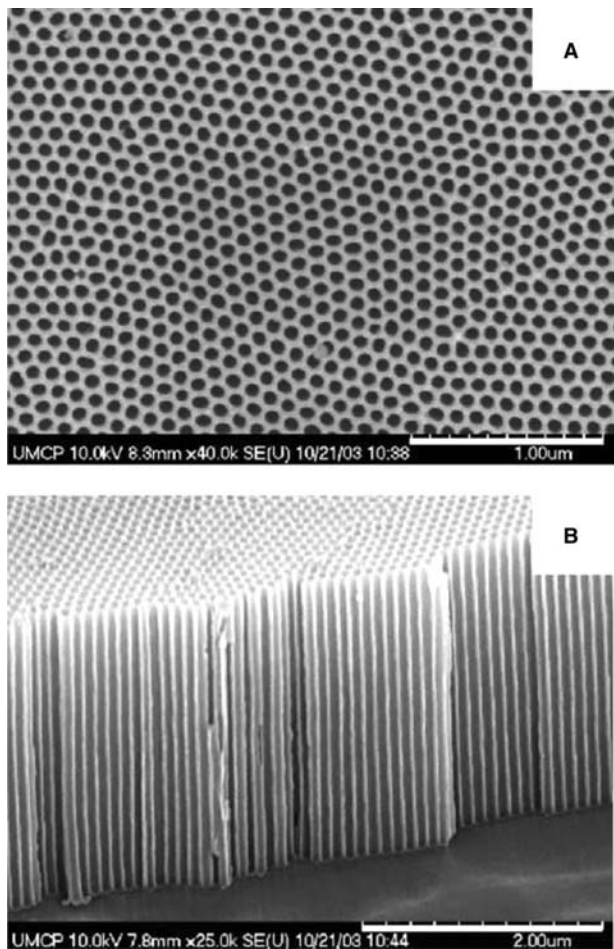

Fig. 2 Scanning electron micrographs of a porous alumina membrane (pore diameter: 60 nm): (A) top view and (B) cross-sectional view.

## CHARACTERIZATION OF NANOTUBE STRUCTURES

To characterize the tubular structures, three methods have been used: observation of end morphology of nanotubes using scanning electron microscopy (SEM), indirect observation of the microtomed section of nanotubes embedded in a membrane, or direct observation of the individual nanotube using transmission electron microscopy (TEM).<sup>[19,22,26–29]</sup> The first method, SEM, is relatively unreliable because it is very hard to differentiate the complete hollow nanotubes with the partially filled nanotubes or nanowires with small pit structures at the end. For example, Duvail et al. reported that the outer structures of poly(3,4-ethylenedioxythiophene) (PEDOT) in a SEM image for the top ends of the nanomaterials were shown like tubular forms with thick walls, while the inner structures in a TEM image were proven to be an almost filled concave shape with an open end.<sup>[30]</sup> Li et al. reported that the TEM image of  $\text{LiMn}_2\text{O}_4$  nanostructures showed tubular structures while the SEM image of their top ends showed fibrillar forms.<sup>[32]</sup> The microtoming is a useful technique to prove inner tubular structures. The nanotubes embedded in a membrane are sliced in a slanted angle. If the tubules within the membrane have a partially filled structure, the TEM image of this thin microtomed slice will show plugged pores as well as unplugged pores containing rings of conducting polymer. In this method, we do not need to remove the template but require an additional instrument to cut the membrane. Direct observation of tubular structure using TEM will be most reliable, although the template should be removed.

## ELECTROCHEMICALLY SYNTHESIZED CONDUCTING POLYMER NANOTUBES

### Polypyrroles

Martin et al. reported the first electrochemical synthesis of the tubular structure of conducting polymer with *N*-methylpyrrole in a nucleopore membrane (1.0  $\mu\text{m}$  pores) chemically or electrochemically (current density of 1.0  $\text{mA}/\text{cm}^2$ ) in 0.5 M *N*-methylpyrrole in an acetonitrile solution.<sup>[22]</sup> They proposed a mechanism for nanotube formation. The key to this process is the interaction of the nascent polyheterocyclic chain with the pore wall. The nascent cationic heterocyclic polymers are adsorbed to the anionic membrane wall by electrostatic attraction, which resulted in the preferential growth of conducting polymers as a tubular form. Demoustier-champagne and coworkers have also investigated the electrochemical synthesis of

polypyrrole nanotubes in a track-etched polycarbonate membrane (pore diameter of 35–200 nm).<sup>[28,29]</sup> The polymerization was carried out at +0.8 V SCE in 0.05–0.1 M pyrrole aqueous solution. The nanostructures were proven using the TEM images of a microtomed section of polypyrrole nanotubes.<sup>[28]</sup> They investigated the importance of the limited diffusion of monomers to nanotube formation using pulsed chronoamperometry technique. However, they concluded that the diffusion of monomer inside the pores is not the determinant parameter leading to the formation of tubes because no changes were found in tube wall thickness as the monomer concentration changed in the range of 0.05–0.35 M or pulsed polymerization was applied with various delay times. Yamada, Gasparac, and Martin prepared a gold/polypyrrole composite microtube membrane to investigate the transport properties of bottlenecked polypyrrole microtubes.<sup>[31]</sup> The pyrroles were electropolymerized by using cyclic voltammetry after electroless deposition of gold on the surface of a polycarbonate membrane. The effective inner diameter of the polypyrrole nanotubes was adjusted by controlling the number of polymerization cycles. As expected, decreasing the pore diameters reduced the transported phenols. Granstrom and coworkers have investigated the electrochemical polymerization of conducting polymer fibrillar structures including polypyrrole and polythiophenes.<sup>[33–35]</sup> The conducting polymer fibrils, synthesized in the pores of a membrane, have higher conductivity and longer conjugation length compared to a conventional polymer film. Higher conductivity was observed for conducting polymer fibrils grown at higher monomer concentration and in smaller pores, as observed by Martin's group in the chemically synthesized nanofibrils of polypyrrole, polymethylthiophene, and polyacetylene.<sup>[21,23]</sup>

### Polyanilines

Demoustier-Champagne and coworkers have synthesized polyaniline nanotubes chemically and electrochemically.<sup>[36]</sup> They used track-etched porous polycarbonate membranes with different pore diameters ranging from 20 to 220 nm. The pore diameter of the membrane is one of the important parameters to have an effect on the growth rate of the polyaniline nanotubes: as the pore diameter of a membrane was reduced, the polyaniline growth rate in the longitudinal direction (along the pore wall) was decreased owing to the limited diffusion of monomers into narrower pores. They also observed that the nanotubes, grown in a membrane with smaller pore diameters, exhibit larger values of conductivity, which has contributed to more ordered structures in smaller-diameter nanotubes.

Szklarczyk et al. investigated the mechanism for the electrochemical formation of poly(*o*-methoxyaniline) nanostructures using in situ atomic force and electron microscopies.<sup>[37]</sup> The polymerization was carried out potentiodynamically by cycling potentials between 0.0 and 1.0 V. Based on an atomic force micrograph, however, it was hard to determine whether the synthesized nanostructures were nanofibrils or end-capped nanotubes. X-ray energy dispersive spectroscopic study showed that the metallic layer, sputtered to make one surface of a membrane conductive, was also present on the walls of the pores. They proposed that this metallic layer on the wall results in the simultaneous growth of nanostructures on the pore wall and on its bottom.

### Polythiophenes

Duvail et al. tried to synthesize PEDOT nanotubes potentiodynamically (cyclic voltammetry) or potentiostatically (chronoamperometry). Unlike polypyrroles and polyanilines, PEDOT was likely to be electrochemically synthesized as nanowires instead of hollow nanotubes in a porous membrane. They remarked that the preferential growth along the pore walls in PEDOT is much less important compared to other conducting polymers.

Recently, we have synthesized PEDOT nanotubes electrochemically using an alumina membrane as a template.<sup>[27]</sup> The tubular structure of PEDOT, grown in a porous alumina film, was investigated by SEM and TEM. Polymerization was performed potentiostatically at 1.2–1.8 V vs. Ag/AgCl in an acetonitrile solution of 20 mM in 3,4-ethylenedioxythiophene (EDOT) and 100 mM in LiClO<sub>4</sub>. After completely removing the alumina template with phosphoric acid (25 wt%), nanotubes were then separated and characterized to prove their hollow tubular structures and to measure their wall thicknesses by using TEM. Key

variables in the growth of the tubular structure of PEDOT are monomer concentration and applied potential. Various nanostructures of PEDOT, including completely tubular, partially filled, and completely filled nanostructures (Fig. 3), were obtained by controlling both the applied potentials and the monomer concentrations.

These phenomena were difficult to explain using only the previous mechanism, that is, the interaction between the wall surface and polymers.<sup>[18,22]</sup> To explain the formation of hollow nanotubes as well as partially filled nanotubes, we proposed an additional mechanism as well as the mechanism by attraction between the polymers and the pore walls: The polymerization reaction of PEDOT in the pores is limited by the diffusion of monomer at highly applied potential that leads to high electrochemical reaction rate in the pores (Fig. 4).

Another important parameter in electrochemically synthesizing nanotubes is the electropolymerization time. In the beginning, very thin nanotubes are formed because of the strong interaction of the membrane wall surface and polymers, as mentioned above. Fig. 5A shows very thin tubular structures with an average length of 3 μm, synthesized at 1.5 V for 20 sec in 50 mM EDOT. As the polymer becomes long, a little voltage drop is expected because of the resistance of polymer. This leads to thickening of the tube wall rather than continuous nanotube elongation. The PEDOT tubes are almost filled in 100 sec and have about 6 μm length (Fig. 5B). Even though the electropolymerization time increased five times, the total length of nanotubes increased twice because most of the diffused monomers are consumed to fill the nanotubes. Further increasing the electropolymerization time leads to completely filled nanowires. Therefore, electropolymerization time as well as monomer concentration and applied potential have to be considered to fully understand the phenomena of nanotube formation.

**Fig. 3** Transmission electron microscopy images of the PEDOT nanotube or nanowire synthesized at the constant voltage of (A) 1.5 V, (B) 1.3 V, and (C) 1.2 V vs. Ag/AgCl in 20 mM EDOT using an alumina template (pore diameter: 200 nm). Source: From Ref.<sup>[27]</sup>.

**Fig. 4** Schematic mechanism of the electrochemical synthesis of conducting polymer nanowire (top) or nanotube (bottom) using template synthesis. Large diffusional flux (high monomer concentration) and slow reaction (low potential) resulted in nanowire structure while small diffusional flux (low monomer concentration) and fast reaction (high potential) resulted in nanotubular structure.

### APPLICATIONS

During the past decade, there have been many reports about potentially practical applications of conducting polymers to various fields such as batteries, organic electronic memory, sensors, organic light emitting diode, lasers, and organic display, etc.<sup>[1-9,15,16,38]</sup> However, the applications of the tubular shape of the conducting polymer have been reported rarely. For

example, Kanungo, Kumar, and Contractor fabricated microtubule sensors based on polyaniline microtubules, which were polymerized in the pores of track-etched polycarbonate membrane (pore diameter of 1.2  $\mu\text{m}$ ).<sup>[39]</sup> The poly(styrene sulfonate)-polyaniline was deposited by potentiostatic (+1.0 V; pH 5.0) or potentiodynamic (potential cycles between -0.2 and 0.8 V vs. SCE; scan rate of 50 mV/sec; pH 0.5) method. The enzymes were immobilized by physical adsorption

**Fig. 5** The effect of electropolymerization time on nanostructures. Transmission electron microscopy images of the PEDOT nanotubes synthesized at the constant voltage of 1.5 V (vs. Ag/AgCl) for (A) 20 sec and (B) 100 sec in 50 mM EDOT using an alumina template (pore diameter: 200 nm).

after polymerization. The sensor response was improved by about 100 times compared to conventional sensors based on polyaniline film.

One of the fascinating properties of the conducting polymer is the electrochromic effect. PEDOT of the conducting polymers has had much attraction because of its good electrochromic effect in color changes, which can be applied to electronic paper or flexible display. One of the problems in current electrochromic display is the slow color-switching rate, which is limited by the diffusion rate of counterions into the film during the redox process.<sup>[9,27,40–44]</sup> The diffusion time ( $t$ ) of ions to reach a saturation concentration in a polymer film, which implies switching time, is proportional to the square of the film thickness ( $x$ ):  $t \propto x^2/D$ , where  $D$  is the diffusion coefficient of an ion in a polymer film.<sup>[45,46]</sup> Therefore, the simplest way to overcome the slow switching rates is to decrease the diffusion distance of ions, that is, to reduce film thickness.<sup>[47–50]</sup> Based on the reported switching time of 2.2 sec for a 300 nm-thick PEDOT film, we expect the switching time to be about 10 msec for a 20 nm thick film.<sup>[40]</sup> However, the coloration of such a thin film is never sufficient for display applications. That is, there is always a trade-off between the coloration and switching time as the film thickness varies.

**Fig. 6** Schematic diagram of the ultrafast electrochromic device based on PEDOT nanotube arrays. Counteranions (negatively charged grey balls) diffuse into a thin layer of PEDOT nanotube wall (less than 20 nm in wall thickness to provide the short diffusion distance) when PEDOT nanotubes are oxidized by applying positive potential on the indium-doped tin oxide glass electrode. The color of PEDOT turns from a deep blue to a transparent pale blue. *Source:* From Ref.<sup>[27]</sup>.

To improve the color switching rate without the loss of color contrasts, we developed the electrochromic device based on the PEDOT nanotube arrays. Fig. 6 illustrates that the thin wall thickness of PEDOT nanotubes (less than 20 nm) can provide ions with short diffusion pathways, which allows very fast switching rates, while the micrometer length of the PEDOT nanotubes in an array structure can produce strong coloration for the display system.

In fact, there have been similar examples showing fast charge transport rates with nanofibrillar or nanotubular structures of conducting polymers and inorganic materials.<sup>[32,51,52]</sup> Li et al. demonstrated that the rate capabilities could be improved by reducing the wall thickness of the nanotubes, which decrease the distance for Li ion transport into nanostructured  $\text{LiMn}_2\text{O}_4$  electrodes, compared to a conventional film structure.<sup>[32]</sup> Van Dyke and Martin have reported the significantly increased charge transport rates (five times) in fibrillar polypyrrole compared to conventional polypyrrole films (1  $\mu\text{m}$  in thickness).<sup>[24,25]</sup> However, the charge transport rate was still in a second range owing to not having tubular structure but nanowire structure with 200 nm diameter. Chien and Schlenoff showed that the time to charge and discharge polyacetylene fibrils can be accelerated by reducing the fibril diameter.<sup>[2]</sup>

An electrochromic window with PEDOT nanotube arrays was designed as shown above. The device was switched from pale blue (decoupled and oxidized state of PEDOT) to deep blue (colored and reduced state of PEDOT) by applying alternating square potentials between 1.0 and  $-1.0$  V on PEDOT nanotube arrays

**Fig. 7** (A) Plots of reflectivity of electrochromic window ( $1\text{ cm}^2$ ) monitored at 530 nm for coloration (open circle) and decoloration (solid circle) upon potential-switching between  $-1.0$  and  $1.0$  V, respectively. (B) Patterned letter 'N' on the PEDOT nanotube arrayed film. The alternating square potentials between  $-1.0$  V (lower image) and  $1.0$  V (upper image) were applied on the background area after  $1.0$  V was applied on the letter "N" (decoupled state). *Source:* From Ref.<sup>[27]</sup>.

**Fig. 8** Flexible electrochromic display in (A) oxidized or (B) reduced state, which was fabricated using conducting polymer nanotubes in a polycarbonate membrane.

vs. the upper transparent electrode. The switching speed was measured optically from reflectivity responses as a function of time at the applied potentials (Fig. 7A). Both the coloring and decoloring processes show switching times of less than 10 msec. Movie film is usually played at a speed of 24 frames/sec, which corresponds to display switching times of about 40 msec. Furthermore, the patterned letter “N” showed good color contrast of 6 as shown in Fig. 7(B). Therefore, PEDOT nanotubes, exhibiting switching times of <10 msec and good contrast, are excellent candidate material for moving image displays.

The above design is not suitable for a flexible display because the alumina template is highly fragile. Thus, we used a flexible template, a porous polycarbonate membrane. PEDOT nanotubes were grown electrochemically after sputtering a thin layer of gold on one face of the polycarbonate membrane as an electrode. Fig. 8 shows a highly flexible electrochromic device in an electrolyte solution, 100 mM LiClO<sub>4</sub> in acetonitrile. The oxidized and reduced PEDOT usually shows transparent pale blue and deep blue, respectively. However, the color of the device was gold in the oxidized state (Fig. 8A) while it was dark bluish in the reduced state (Fig. 8B) because of the sputtered gold layer. Due to the high flexibility of a polycarbonate template, the electrochromic device can be rolled easily.

## CONCLUSIONS

We investigated the electrochemical syntheses of conducting polymer nanotubes. A variety of parameters influence the nanotube formations, such as applied potential, monomer concentration, pore diameters, electropolymerization time, etc. However, the more detailed mechanism still needs to be investigated.

Tubular structures have many advantages over fibrillar structures including the possibility of inner modification, the high surface area, and the fast charge diffusion. As an application of conducting polymer nanotubes, we introduced ultrafast electrochromic displays with switching speeds compatible with moving image display technology and low power consuming features. The thin wall thickness (less than 20 nm) of nanotubes renders the diffusion path length of counter-ions extremely short, which leads to ultrafast switching speed (<10 msec). The long-nanotube arrays provide a strong coloration. As only a primitive form of a flexible electrochromic display has been demonstrated, we are currently investigating the possibility of demonstrating a flexible display capable of showing color text and images on a rewritable medium by making pixelated nanotube arrays on thin plastic substrates.<sup>a</sup>

## INTRODUCTION

Molecule-based nanodevices with advanced functions have been attracting much attention, because the size of microelectronic circuit components will soon reach the scale of atoms or molecules.<sup>[1,2]</sup> The idea that one, or a few molecules, could perform the basic functions of electronics was first introduced in 1978.<sup>[3]</sup> Aviram and Ratner<sup>[3]</sup> suggested that a molecular diode should be obtained by a donor–spacer–acceptor structure, when it is placed between two electrodes. Such molecular-scale electronic devices differ radically from bulk-scale devices, because one or a few molecules work as a circuit component.<sup>[4]</sup> In addition, it should be noted that the structure and function of molecular building blocks are rationally controlled by chemical synthesis, and that each molecular component can be aggregated into a larger structure by self-assembly.

To realize molecular-scale devices, the development of new approaches should be required to construct desired molecular nanostructures on a suitable substrate. Whereas large functional molecules have been directly obtained by chemical synthesis,<sup>[5,6]</sup> supramolecular assembly is a realistic way to create nanoscale molecular structures.<sup>[7]</sup> The supramolecular approach, starting from molecular building blocks, can lead to controlled aggregates, which is achieved by selective and directional intermolecular interactions. When non-covalent attractive interactions such as hydrogen bonding are introduced into functional molecules, the selective aggregation results in the controlled formation of molecular nanostructures, which has been widely studied.<sup>[7]</sup> However, these structures have been obtained exclusively in crystals or dissolved structures. For the use of the molecular nanodevices, the supramolecule should be supported on a suitable surface. The surface-supported supramolecules should be located at suitable positions.

On solid surfaces, scanning probe microscopy, particularly scanning tunneling microscopy (STM),<sup>[8]</sup> has proven to be a powerful tool for the real-space investigation of adsorbed functional molecules, allowing to directly determine the arrangement, configuration, and conformation of adsorbed molecules with submolecular resolution. Using the technique of STM, several groups have reported on self-assembled structures of adsorbed molecules on metal surfaces.<sup>[9–11]</sup> To realize molecular nanodevices, further control of their size and shape should become an important step. Here we demonstrate the controlled supramolecular aggregation of porphyrin derivatives formed on a gold surface. First, we describe the structure of porphyrin and substrate surface used. After the adsorption properties of the porphyrin on the gold surface are described in detail, the supramolecular aggregation of cyano-substituted porphyrins is reported.

## PORPHYRIN AND GOLD SURFACE

Porphyrins and other closely related tetrapyrrolic pigments are a class of naturally occurring macrocycles, which play very important roles in various biological processes including hemes, chlorophylls, and several others.<sup>[12]</sup> Thus porphyrin derivatives have been widely studied both in basic research and for functional applications.<sup>[13]</sup> In the present work, we have used 5,10,15,20-tetrakis-(3,5-di-tertiarybutylphenyl) porphyrin ( $H_2$ -TBPP)<sup>[14,15]</sup> as a basic molecule, which is composed of a free-base porphyrin and four di-tertiarybutylphenyl (tBP) substituents (Fig. 1). Fig. 2 shows an ideal shape of  $H_2$ -TBPP obtained from molecular orbital calculations.<sup>[16]</sup> The molecule exhibits a planar macrocyclic conformation of the central porphyrin through 60–90° rotations of four phenyl rings with respect to the porphyrin mean plane. Because of the phenyl-ring

**Fig. 1** Structural formula of H<sub>2</sub>-TBPP, which includes the central free-base porphyrin and four tBP substituents.

**Fig. 2** (A) Top and (B) side views of the calculated conformation of H<sub>2</sub>-TBPP, obtained from semiempirical molecular orbital method with the AM1 Hamiltonian. The about 65° rotations of phenyl rings result from steric hindrance between the porphyrin and phenyl rings. As shown in the side view, the insulating tBP groups prevent direct interaction between the central porphyrin and substrate surface, when the molecule is adsorbed on a surface.

rotations, the insulating tBP substituents should prevent the direct interactions between the central porphyrin and the surface, even when the H<sub>2</sub>-TBPP molecule is adsorbed onto a surface. As the characteristic features of the central porphyrin should be conserved even for molecules supported on surfaces, this isolation fulfills the requirements for the molecular nanoelectronic or optoelectronic devices.<sup>[14,15]</sup>

To ensure selective molecular aggregation, we used a gold(111) surface as the substrate because of its inertness and its properties of surface reconstruction. The Au(111) was formed by deposition of gold on a mica substrate in ultrahigh vacuum (UHV) and was prepared by repeated cycles of Ar ion sputtering and annealing at 700 K. After the procedure, the starting Au(111) clean surface was obtained as shown in the STM image of Fig. 3A. This STM image was obtained at 63 K in UHV and revealed a characteristic “herringbone” surface reconstruction. As there are 23 surface atoms within 22-unit cells in the [110] direction<sup>[17]</sup> as shown in the atomic-resolved STM image of Fig. 3B,

**Fig. 3** (A) STM image (82 × 82 nm) of a Au(111) surface obtained at 63 K, in which periodic rotations of bright stripes result in the formation of herringbone pattern. (B) Atomically resolved STM image (3.5 × 8.6 nm) of the Au(111) surface. Within 22-unit cells of the bulk lattice, indicated by a white rectangle, there are 23 surface atoms, so that the bright stripes are induced by lattice distortion in the surface layer.

the reconstruction of the Au(111) surface results from alternating face-centered cubic (fcc) and hexagonal close-packed (hcp) stacking of the surface atoms with respect to the bulk lattice. In the STM image, brighter stripes correspond to the transition region between hcp and fcc stackings, and periodic rotations of the uniaxial domains result in the formation of long-range herringbone patterns.<sup>[17]</sup> Here it should be noted that a point dislocation of the surface lattice occurs at each elbow of this pattern, and the preferential nucleation of adsorbates at the elbows has been reported in various systems.<sup>[10,18]</sup> It is very important for individual molecules to be selectively positioned at specific sites of the surface.

### CONFORMATION AND ARRANGEMENT OF ADSORBED TBPP

As the conformation of adsorbed molecules is occasionally different from the ideal conformation and is responsible for the molecular functions, the detailed analysis of the conformational change upon adsorption is one of the fundamental steps to realize the selective assembly of adsorbed molecules.<sup>[15]</sup> To directly observe individual molecules using STM, H<sub>2</sub>-TBPP molecule was deposited onto the Au(111) at room temperature by sublimation from a Knudsen cell kept at about 530 K in UHV. The sample was then subsequently transferred to the cold STM stage for direct observations. Fig. 4A shows a STM image of the Au(111) surface after a small amount of H<sub>2</sub>-TBPP deposition, which reveals regular arrays of isolated single molecules. These molecules are located at the elbows of the herringbone patterns, indicating that each molecule is preferentially nucleated at the point dislocations (defects). This selective molecular positioning allows direct imaging of isolated molecules without intermolecular interactions.

Fig. 4B shows a high-resolution STM image of a single H<sub>2</sub>-TBPP molecule on the Au(111) surface, which exhibits four paired lobes surrounding two oblong protrusions.<sup>[19]</sup> From the molecular dimension, we assign each lobe as one of the tBP substituents, and the appearance of the paired lobes suggests that the phenyl rings are oriented close to the porphyrin macrocyclic plane, different from the ideal shape of H<sub>2</sub>-TBPP shown in Fig. 2 where the phenyl rings are rotated by 60–90°. By comparing the STM results with the molecular model, we have derived the dihedral angle between the porphyrin and phenyl rings to be about 20°, where the four phenyl rings are alternately rotated with respect to the porphyrin mean plane. In the STM image, the brighter lobe should correspond to the upper tertiarybutyl group within a tBP substituent. The rotations of the phenyl–porphyrin bonds have

**Fig. 4** (A) STM image (86 × 104 nm) of a Au(111) surface at 63 K after a small amount of H<sub>2</sub>-TBPP deposition. Individual molecules are selectively located at the elbows of the herringbone pattern. (B) Submolecular resolution STM image (2.1 × 2.1 nm) of H<sub>2</sub>-TBPP, which shows four paired lobes surrounding two oblong protrusions.

been reported for adsorbed Cu-TBPP molecules on several metal surfaces, which depend on the substrate structures. These results indicate that the rotational flexibility of the phenyl–porphyrin bonds allows the tertiarybutyl substituents to fit into the surface geometry, leading to the conformational changes.

The most distinguishing feature for the H<sub>2</sub>-TBPP molecules on the Au(111) surface is that the internal structure of the central porphyrin macrocycle has been resolved in the STM images, which is composed of two oblong protrusions. As the  $\pi$  electrons are expanded over the central porphyrin macrocycle, no corrugated structure is expected in the STM image of the central region when the porphyrin exhibits a planar conformation. Thus the oblong protrusions should be associated with the non-planar macrocyclic conformation (deformation) of the central porphyrin.

To confirm the non-planar deformation, we performed a semiempirical molecular orbital calculation with the AM1 Hamiltonian.<sup>[16]</sup> Fig. 5 shows the calculated conformation of H<sub>2</sub>-TBPP with fixed 20°

**Fig. 5** (A) Top and (B) side views of calculated conformation of H<sub>2</sub>-TBPP with 20° rotations of phenyl rings, obtained by semiempirical molecular orbital method with the AM1 Hamiltonian. In this structure, the dihedral angle between the porphyrin and phenyl rings has been fixed at 20°, where the four phenyl rings were alternately rotated with respect to the porphyrin mean plane. In the central porphyrin, the saddle-shaped deformation is characterized by alternate tilting of the pyrrole rings above and below the mean plane, which is induced by the steric hindrance with the rotated phenyl rings.

rotations of the four phenyl rings. The converged structure shows that the 20° rotations of the phenyl rings introduce nonplanar deformation of the central porphyrin macrocycle, whereas the ground state planar conformation is formed through 60–90° rotations as shown in Fig. 2. In this non-planar conformation, the saddle-shaped deformation of the central porphyrin is characterized by alternate tilting of the pyrrole rings above and below the mean plane, which is induced by steric hindrance with the rotated phenyl substituents. The maximum deviation of the porphyrin macrocycle from the mean plane is estimated to be about 0.95 Å, which is roughly consistent with the STM corrugation of 0.6 Å. In the high-resolution STM image of Fig. 4B, the two oblong protrusions should be associated with the tilt-up pyrrole rings of the non-planar porphyrin macrocycle, whereas the tilt-down pyrrole rings weakly appear as bridges between two oblong protrusions.

In addition to the direct imaging of molecular structures, STM is also applied for tunneling spectroscopy of adsorbed molecules, which allows probing the electronic properties on an STM resolution. Tunneling spectra  $[(dI/dV)/(I/V)]$ , which are numerically derived from current–voltage ( $I$ – $V$ ) characteristics at a typical tip–sample separation, almost represent the local density of electronic states at the tip position.<sup>[20]</sup> Fig. 6 shows the tunneling spectrum obtained on an adsorbed H<sub>2</sub>-TBPP molecule on the Au(111) surface at 63 K. In this tunneling spectrum of H<sub>2</sub>-TBPP, there are two characteristic peaks of occupied states at  $V = -1.1$  V and at an unoccupied state at 0.9 V, which should correspond to the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) states of the central porphyrin, respectively. The obtained HOMO–LUMO gap of about 2 eV is in agreement with that of the porphyrin, estimated from optical absorption spectroscopy, which indicates that the electronic properties of H<sub>2</sub>-TBPP remain mostly unchanged even after adsorption and deformation.

With increasing coverage, two-dimensional islands are formed through self-assembled aggregation of the H<sub>2</sub>-TBPP molecules on the Au(111) surface. As shown in Fig. 7A, we have observed larger islands even without thermal annealing above 300 K, suggesting that the diffusion barrier for molecules on this surface is low at room temperature. In the islands, the non-planar

**Fig. 6** Tunneling spectrum of H<sub>2</sub>-TBPP adsorbed on the Au(111) surface at 63 K, which represents the local density of the electronic states of the molecule. In this spectrum, the negative sample voltage corresponds to the occupied electronic states, whereas the positive voltage corresponds to the unoccupied states.

**Fig. 7** (A) STM image ( $33 \times 33$  nm) of a two-dimensional  $H_2$ -TBPP island formed on the Au(111) surface. The Au(111) surface is almost covered with the  $H_2$ -TBPP molecules. (B) High-resolution STM image ( $5.3 \times 5.3$  nm) and (C) its model of the  $H_2$ -TBPP island. The molecules are well ordered into an  $11 \times 5\sqrt{3}$  superstructure with respect to the surface lattice.

macrocyclic conformation of the central porphyrin remains, and the molecules are ordered into a close-packed arrangement [Fig. 7B]. A detailed analysis of the STM image indicates that the molecular arrangement exhibits an  $11 \times 5\sqrt{3}$  superstructure, commensurate with the underlying substrate lattice of Au(111).<sup>[19]</sup> Fig. 7C shows the model of the  $H_2$ -TBPP island formed on the Au(111)- $1 \times 1$  structure, where the symmetric intermolecular interaction should be governed by van der Waals forces between tBP substituents.

### SELECTIVE INTERMOLECULAR INTERACTIONS

A large number of different selective and directional intermolecular connections have been developed in

supramolecular chemistry.<sup>[7]</sup> In this work, we have used a cyanophenyl substituent to control molecular aggregation,<sup>[21]</sup> because it has a simple and symmetric structure as well as an asymmetric charge distribution at the cyano group. Within the cyano group, the nitrogen atom is negatively charged and the carbon atom is positively charged, so that the asymmetric charge distribution should induce a large dipole moment, resulting in the introduction of dipole–dipole interactions between neighboring cyanophenyl substituents. Fig. 8 shows the optimized arrangements of a cyanobenzene dimer and trimer obtained from ab initio molecular

**Fig. 8** Structure of the molecular aggregates of a (A) cyanobenzene dimer and (B) trimer, obtained from ab initio molecular orbital calculations. In the dimer structure, an antiparallel configuration is formed between cyano groups, whereas a cyclic configuration is formed in the trimer structure. These structures are formed by the dipole–dipole interactions of the cyano groups, and further stabilized by  $CN \dots HC$  hydrogen bonding.

calculations at the MP2/6-31G\* level.<sup>[22]</sup> In the aggregated structures, an antiparallel configuration of the cyano groups is stabilized in the dimer, whereas a cyclic arrangement is formed in the trimer.<sup>[23]</sup> The antiparallel and cyclic configurations are in good agreement with the classical dipole–dipole arrangements. In addition, the length of the CH...NC contacts is about 2.39 and 2.65 Å for the dimer and trimer, respectively, which is shorter than the van der Waals distance of about 2.7 Å. The interaction energies were estimated to be  $-7.12$  and  $-12.40$  kcal/mol for the dimer and trimer, respectively. These results indicate that these cluster structures are further stabilized by CH...NC hydrogen bonding.

To introduce the characteristic interaction of the cyanophenyl groups, we have synthesized cyano-substituted porphyrins. When a tBP group of H<sub>2</sub>-TBPP is replaced with a cyanophenyl substituent, (cyanophenyl)-tris(di-tertiarybutyl-phenyl) porphyrin (CTBPP) is

obtained as shown in Fig. 9A. Because of the absence of a di-tertiarybutyl group, three paired lobes appear in the STM image of a single CTBPP molecule on the Au(111) surface as shown in Fig. 9B, in agreement with the chemical structure. At low coverage, most CTBPP molecules assemble into triangular clusters on the Au(111) surface. As shown in Fig. 10A, identical clusters are located separately at the elbows of the herringbone patterns, and the high-resolution STM image of Fig. 10B shows that the triangular cluster is a CTBPP trimer. The cyanophenyl substituents are assembled into a cyclic configuration in the trimer structure, in good agreement with the cyanobenzene trimer aggregation. In addition, we observed that the trimer clusters were ordered to form two-dimensional islands by further deposition, suggesting that the trimer works as a single molecule on the surface.

Compared with the characteristic trimer aggregation of CTBPP, we have not observed such supramolecular

**Fig. 9** Structural formula of cyano-substituted porphyrins. (A) CTBPP, where a tBP substituent of H<sub>2</sub>-TBPP is replaced with a cyanophenyl substituent. (B) *cis*-BCTBPP molecule, where two cyanophenyl groups are substituted at the *cis* position. (C) *trans*-BCTBPP, where two cyanophenyl groups are substituted at the *cis* position. High-resolution STM images of (D) CTBPP, (E) *cis*-BCTBPP, and (F) *trans*-BCTBPP.

**Fig. 10** (A) STM image at 63 K of CTBPP molecules on Au(111). Identical triangular clusters are formed on the surface. (B) High-resolution STM image of a triangular cluster and (C) its model. This cluster is composed of three molecules, in which cyclic configuration of cyano groups is formed at the center.

**Fig. 11** STM image at 63 K of (phenyl)-tris(di-tertiarybutyl-phenyl) porphyrin on Au(111). In this molecule, the cyano group was removed from CTBPP. Within two-dimensional islands, the directions of the phenyl groups are randomly distributed.

clusters, when the cyano group was removed from the CTBPP molecule. Fig. 11 shows a small island of (phenyl)-tris(di-tertiarybutyl-phenyl) porphyrins formed on the Au(111) surface, in which the molecular orientations are randomly distributed on the surface, indicating no selective aggregation. This result confirms that the supramolecular aggregation is dominated by the cyano groups.

One more cyano group was substituted to further probe the supramolecular aggregation on the Au(111) surface. When two tBP groups were replaced with cyanophenyl substituents, bis(cyanophenyl)-bis(di-tertiarybutyl-phenyl) porphyrin (BCTBPP) was obtained, which forms two types of isomers (*cis* and *trans*) with respect to the configuration of two cyanophenyl substituents. Figs. 12A and 13A show STM images of single *cis*- and *trans*-BCTBPP molecule, respectively. The disappearance of paired lobes at the cyanophenyl substituents agrees well with the chemical structures. At small coverage of the *cis*-BCTBPP molecules, identical clusters appear as four-leaf clovers as shown in Fig. 12B and C, which are located at the elbows of the surface reconstruction. From the molecular model of Fig. 12C, we find that the *cis*-BCTBPP molecules are aggregated into a supramolecular tetramer on the Au(111) surface. In this structure, the antiparallel intermolecular connections of all the cyanophenyl substituents lead to a macrocyclic arrangement of the porphyrin molecules, forming a molecular ring.

**Fig. 12** (A) STM image at 63 K of *cis*-BCTBPP molecules on Au(111). Identical clusters appear as four-leaf clover. (B) High-resolution STM image of a cluster and (C) its model. This cluster is composed of four molecules, in which antiparallel configuration between cyano groups is formed.

**Fig. 13** (A) STM image at 63 K of *trans*-BCTBPP molecules on Au(111). Linear long wires are formed. (B) High-resolution STM image of a wire and (C) its model. This wire is formed by the antiparallel interaction between cyano groups.

The diameter of the macrocyclic ring is roughly estimated to be about 3.8 nm.

In contrast to the macrocyclic clusters of CTBPP and *cis*-BCTBPP, sequential aggregation was achieved for the *trans*-BCTBPP molecules, where two cyano-phenyl groups were substituted at the *trans* positions. Fig. 13 shows supramolecular wires of *trans*-BCTBPP formed on the Au(111) surface. In this structure, the antiparallel configuration between the cyanophenyl substituents results in a linear arrangement of the molecules. The maximum length of the straight wires is above 100 nm, comparable with the length scale of the present silicon devices. In addition, most of the individual wires extended across the elbows of the heringbone patterns, whereas some branches are also formed because of the three-fold symmetry of Au(111). This is because the molecules were initially nucleated at the elbows, so that it is easy to connect these molecules in the direction across the elbows.

The selective aggregation of the porphyrin molecules results from the antiparallel or cyclic configurations of the cyano substituents. From the high-resolution STM images and related models, we estimated the length of CH...NC contacts between cyanophenyl substituents to be about 2.6 and 2.5 Å for the antiparallel and cyclic configurations, respectively. These values are almost identical to those of the calculated cyanobenzene clusters, indicating that the obtained clusters are stable on the surface.

## CONCLUSION

In this work, we have presented the formation of surface-supported supramolecular structures with controlled size and shape by using the dipole-dipole interactions of the cyano group. On the Au(111) surface, monomer, trimer, tetramer, or wire-like aggregations of porphyrins were controlled only by changing the number and position of the cyanophenyl substituent. It should be emphasized that these porphyrins find one another on the surface and link together spontaneously. Because a large number of substituents have been reported for non-covalent bonding, further controls of selective aggregation should be feasible on surfaces.

In molecular electronic nanodevices, these supramolecular aggregates should be linked to the outside world through microscopic electrodes, and a semiconducting or insulating substrate should be more useful. As some substituents are likely to connect to metal atoms, selective adsorption of substituted molecules at metal electrodes will be easy to obtain on an inert insulating surface. By further selective assembly, supramolecular nanostructures (such as wires) should be constructed between metal electrodes, in which the

structures are electrically coupled with the electrodes because of the metal-substituent connections.

# Coordination Framework Topology

Neil R. Champness

Neil S. Oxtoby

School of Chemistry, University of Nottingham, Nottingham, U.K.

## INTRODUCTION

This entry describes the use of multimodal ligands in constructing solid-state molecular materials, in particular coordination frameworks. It will be demonstrated that such ligands have advantages over simpler, more traditional unimodal ligands in controlling the topology of coordination frameworks at the molecular level. This gives rise to the hope of a high degree of design of coordination frameworks for subsequent use as advanced materials.

The construction of crystal-engineered frameworks using either coordinative-bonding or hydrogen-bonding interactions is an extremely topical area of inorganic and materials chemistry.<sup>[1–3]</sup> The strong interest in this area arises because the synthetic procedure used to construct these materials allows, in principle, a high degree of design. New materials with tunable properties have been developed from coordination frameworks over recent years and as synthetic procedures become more advanced so the properties of these materials become more highly evolved.

In particular, new framework materials with host-guest properties, similar to those observed with zeolites, have been reported. The potential advantage of using coordination frameworks is that the components of the framework, metal, ligand, and anion can be readily chosen and designed to allow specific manipulation of the dimensions and shape of channels or pores. Component design gives rise to not only shape-selective inclusion but also the possibility of chemoselectivity. Recent examples include very high methane adsorption<sup>[4]</sup> within a coordination framework and also rare example of dioxygen adsorption in which the dimensions of the framework channels give rise to a highly ordered O<sub>2</sub> array.<sup>[5]</sup> Examples of new materials with interesting magnetic<sup>[6]</sup> and non-linear optical<sup>[7]</sup> properties have also been reported. It is even possible to incorporate more than one of these properties within a single material and this gives rise to highly novel and advanced materials such as a nanoporous molecular magnet with reversible solvent-induced mechanical and magnetic properties<sup>[8]</sup> and a coordination-framework-based material that exhibits coexisting ferromagnetism and metallic conductivity.<sup>[9]</sup>

## COORDINATION FRAMEWORK DESIGN: THE BUILDING BLOCK METHODOLOGY

The high degree of design in these systems arises from the coupling of the well-understood coordination properties of individual metal ions and the highly developed organic chemistry of ligand synthesis. Indeed, notable advances have been made in the synthesis of coordination frameworks and in understanding the factors that influence network topology using the building block methodology as originally advanced by Robson et al.<sup>[1]</sup> The building block methodology can be used to design molecular frameworks by using the geometric properties of the framework components. For example, by linking building blocks through simple linear rods (connecting units) the geometric properties of the building block are expressed throughout three-dimensional space. In the case of coordination frameworks one may like to consider the properties of a transition metal ion. Thus if one links metal cations with a linear coordination geometry through a simple connecting unit, a one-dimensional chain will be constructed. Similarly, a square-planar metal cation can be linked to generate a two-dimensional sheet structure. Three-dimensional architectures can be achieved by linking non-linear or non-planar metal centers. Perhaps the most commonly studied example of a three-dimensional coordination framework is that constructed from tetrahedral metal centers, such as Cu(I), and linear bridging ligands, including 4,4'-bipyridine,<sup>[10]</sup> or *trans*-1,2-bis(4-pyridyl) ethene.<sup>[11]</sup> In this case the metal nodes will be linked such that the tetrahedral geometry of the cation is expressed in three dimensions to generate a structure with a diamond-like structure (Fig. 1). The geometry of the ligand can also be readily adapted and in principle combinations of different building block geometric properties may be combined to generate increasingly complex multidimensional architectures.

This concept of using building block geometries to develop extended arrays is highly adaptable, but framework structures can be readily influenced by weaker supramolecular forces,<sup>[2]</sup> and the situation is not as simple as it may at first appear. Indeed, the

**Fig. 1** Schematic representation of a diamond-like structure which can be generated by linking tetrahedral metal nodes through bidentate bridging ligands, such that the tetrahedral geometry of the cation is expressed in three dimensions.

individual components of a network system cannot be treated separately, but the network must be thought of as a combined entity drawing upon the unified properties of the building blocks used in its construction.

The majority of coordination frameworks reported thus far have used relatively simple ligand systems using bridging ligands that provide two,<sup>[12]</sup> three,<sup>[13]</sup> or four<sup>[14]</sup> monodentate donors in a predefined geometry (Scheme 1). Such ligands give rise to a vast range of structural types but are limited in their influence of network structure in two ways.

Firstly, as the ligands use only monodentate donors they offer little control over the interaction between the ligand and the metal center. The ligand is able to occupy a single metal coordination site offering influence over the rest of the metal center only through steric crowding or through more subtle electronic effects. Secondly, the ligand can bridge metal centers in only a single manner (Scheme 1). This means that the ligand is controlling the network structure only by means of the ligand length or potentially via steric bulk or weaker supramolecular interactions.

This is not to belittle the contribution of such systems. Indeed, the chemistry of coordination frameworks has advanced so rapidly using precisely these simple ligands and it is a perfect example of how a complicated approach is not always the most useful or applicable to a given problem.

However, the principles and complexity of ligand synthesis strategies offer the supramolecular chemist the possibility of a much higher degree of building-block design. This potentially leads to a greater control of network structure, topology,<sup>[15]</sup> and ultimately functional properties. One way in which coordination network structure can be influenced is by using multimodal ligands.

## MULTIMODAL LIGANDS VS. UNIMODAL LIGANDS

Multimodal ligands differ from simpler unimodal systems in that they offer both more than one binding site, usually both monodentate and chelating bidentate donor sites and in some cases more than one bridging mode. A simple example of a multimodal ligand is 2,4-di(2-pyridyl)-6-(ethynyl-4-pyridyl)pyridine (Scheme 2), which contains both a tridentate, terpyridyl site and a monodentate pyridyl site, both of which are capable of binding to a suitable metal center.<sup>[16]</sup> The tridentate site is expected to be the most strongly coordinating unit, reflecting the simple chelate effect, and reaction with  $\text{Co}(\text{ClO}_4)_2$  affords a mononuclear complex in which the  $\text{Co}(\text{II})$  center is coordinated by two terpyridyl sites. However, in the presence of counteranion with a greater coordinating ability, such as chloride, the metal center is coordinated by two  $\text{Cl}^-$  ligands leaving four residual coordination sites at the octahedral metal center. A terpyridyl ligand and a monodentate pyridyl donor from a second ligand occupy these four sites, and this results in the formation of a one-dimensional coordination polymer (Fig. 2). Thus using appropriate design protocols the multimodal ligand can be used to assemble either a discrete complex or a one-dimensional polymeric system.

**Scheme 1** Examples of unimodal bridging ligands that provide two, three, or four monodentate donors in a predefined geometry. Source: From Refs.<sup>[12–14]</sup>.

**Scheme 2** A simple example of a multimodal ligand, 2,4-di(2-pyridyl)-6-(ethynyl-4-pyridyl)pyridine.

It is evident from this example that the combination of more than one type of coordinating mode within a single ligand offers the potential for control over the coordination sphere of a metal within a self-assembled coordination architecture. Thus when a single tridentate unit is coordinated to the metal center the number and orientation of the remaining coordination sites on a given metal are defined for other ligands. The ligand thus defines, to some extent, the orientation of ligands used in coordination polymer propagation.

Multimodal ligands also differ from simpler unimodal ligands in that they specifically control the relative positions of the donor groups with respect to each other and thus offer more than one method of bridging metal centers within an extended array. This differs from unimodal ligands in which a single bridging mode is typically observed even when using tri- or tetradentate ligands. This point will be elaborated further below.

## COORDINATION PREFERENCES OF MULTIMODAL LIGANDS

As multimodal ligands possess more than one type of coordination site there will inherently be a degree of competition between donor groups within a single ligand. This is illustrated by the example of the 2,4-di(2-pyridyl)-6-(ethynyl-4-pyridyl)pyridine–Cobalt(II) system discussed above (Fig. 2) for which the ligand exhibits two distinct coordination modes, using either just one or both of the available coordination sites.<sup>[16]</sup>

As multimodal ligands often combine both bi- or tridentate groups and monodentate donors the chelating, multidentate unit regularly dominates the

coordinating ability of the ligand following simple thermodynamic principles. This is illustrated by the reaction of pyrazino[2,3-*f*]quinoxaline (pyq) with  $\text{AgBF}_4$  in acetonitrile, which yields discrete complexes of the form  $[\text{Ag}(\text{pyq})_2](\text{BF}_4)$  in which the chelating bidentate fragment of the ligand coordinates, the Ag(I) center, and the monodentate donors remains uncoordinated (Fig. 3).<sup>[17]</sup>

However, it is not always the case that the multidentate site dominates the coordination sphere. Indeed, in one particularly rare case the ligand 2,2'-bi-1,6-naphthyridine reacts with  $\text{M}(\text{SCN})_2$  salts ( $\text{M} = \text{Co}, \text{Zn}, \text{Cd}$ ) to yield polymeric complexes,  $[\text{M}(\text{SCN})_2(2,2'\text{-bi-1,6-naphthyridine})_2]_\infty$ , in which the metal centers are coordinated exclusively by the monodentate groups of this ligand (Fig. 4).<sup>[18]</sup> Thus each metal center is coordinated by four distinct ligands, with the remaining metal sites occupied by the  $\text{SCN}^-$  ligands, and the ligands bridge metal centers to generate a two-dimensional sheet structure of (4,4) topology.<sup>[15]</sup> In this instance the bidentate units remain uncoordinated, which is surprising considering that these groups should be much better donors for the metal centers in comparison to the monodentate donors. The reason for the preference of this particular system to adopt this unexpected coordination mode is unclear, but may possibly be explained by the observed products being a kinetic rather than thermodynamic product. Such a phenomenon has been previously observed for coordination polymer structures for which insolubility of a kinetic product may be an important factor.<sup>[19]</sup> It is interesting to note that if one considers a hypothetical product in which the bidentate unit of this ligand is coordinated to the metal center, there would be a maximum of three such groups coordinated to the metal which would lead to an entirely different architecture.

In most cases the coordination preferences of the metal center will strongly influence the coordinating preferences of the ligand. Typically, a metal center will have a strong thermodynamic preference for a given geometry and ligand type, and for most metals this will result in multimodal ligands coordinating via their chelating groups in preference to a combination of donors unless a specific system is carefully designed, as is the case for the 2,4-di(2-pyridyl)-6-(ethynyl-4-pyridyl)pyridine–Cobalt(II) system discussed above.<sup>[16]</sup> However, certain metal centers do not exhibit strong coordination preferences and only small energy barriers exist

**Fig. 2** View of the one-dimensional coordination polymer formed by  $\{\text{CoCl}_2[2,4\text{-di}(2\text{-pyridyl})\text{-6-(ethynyl-4-pyridyl)pyridine}]\}_2$ . Source: From Ref.<sup>[16]</sup>.

**Fig. 3** View of the structure of  $[Ag(pyq)_2](BF_4)$  in which the chelating bidentate fragment of the ligand coordinates the Ag(I) center, and the monodentate donors remains uncoordinated, pyq = pyrazino[2,3-*f*]quinoxaline.

between multiple coordination geometries. This is particularly noticeable for Ag(I) whose  $d^{10}$  electronic configuration results in a highly flexible and coordinatively labile metal center. Ag(I) compounds are particularly susceptible to variation in reaction conditions, including reaction solvent, and also to the nature of the counteranion that is used. However, in many instances reactions between multimodal ligands and Ag(I) salts will result in the metal center adopting what may be considered a uniform coordination environment within a coordination polymer. In other words, all of the metal centers adopt the same number and types of donor and similar relative orientations. The rest of this entry will concentrate on how the use of multimodal ligands can lead to the development of interesting coordination architectures with Ag(I) cations and how the multimodal ligands contrast with simpler unimodal systems.

**Fig. 4** View of the two-dimensional coordination polymer formed by  $[M(SCN)_2(2,2'\text{-bi-1,6-naphthyridine})_2]_\infty$  ( $M = Co, Zn, Cd$ ) illustrating that the metal centers are coordinated exclusively by the monodentate groups of the 2,2'-bi-1,6-naphthyridine ligand.

## AG(I) COORDINATION POLYMERS WITH MULTIMODAL LIGANDS

Ag(I)-based coordination polymers are capable of generating one-,<sup>[20]</sup> two-,<sup>[17,21–24]</sup> or three-dimensional structures<sup>[17,21,24–28]</sup> depending on the nature of the other building blocks employed and have been particularly well studied with multimodal ligands.<sup>[17,21,23,24,29,30]</sup> For multimodal ligands, one-dimensional structures are less common, and so to illustrate the influence of such ligands this article will concentrate on three- and two-dimensional architectures.

### Three-Dimensional Architectures

The reaction of Ag(I) salts,  $AgBF_4$  or  $AgPF_6$ , with the multimodal ligand 2,2'-bipyrazine (bpyz) has been extensively studied.<sup>[17,21]</sup> When the reaction is performed using nitromethane as a solvent, three-dimensional coordination polymers are formed,  $\{[Ag(bpyz)](BF_4)\}_\infty$ <sup>[17,21]</sup> or  $\{[Ag(bpyz)](PF_6)\}_\infty$ <sup>[17]</sup> both of which crystallize in the chiral tetragonal space group  $P4_32_12$ . In both polymers the same Ag(I) coordination environment and topological arrangement are observed. The Ag(I) center adopts a “uniform” coordination sphere throughout the polymeric architecture being coordinated by three bpyz ligands, one chelating and two monodentate N-donors, in a pseudo-tetrahedral geometry. Each Ag(I) center is linked to four nearest-neighbor Ag(I) centers, two via the chelating ligand and two more through two peripheral monodentate N-donors forming a distorted diamond-like array (Fig. 5). The chirality of the framework can be most readily understood if one inspects the extended lattice along the crystallographic *c* axis. This view shows that the structure forms two distinct channels that represent different helices running through the network (Fig. 6). The larger square-shaped channel constructs a  $4_3$  helix in which each Ag(I) center is linked to the next Ag(I) center along the helix via a short, single pyrazine bridging mode. In contrast, the smaller rhomboid-shaped channel forms a  $2_1$  helix in which adjacent Ag(I) centers are linked through a longer bridging mode via two peripheral N-donors of a bpyz ligand. In contrast to a conventional diamond lattice in which adjacent helices have opposing hands and are chemically identical, in  $\{[Ag(bpyz)](BF_4)\}_\infty$  adjacent antiparallel helices are chemically distinct, displaying different bridging modes and resulting in the chirality demonstrated by these architectures.

The role of the multimodal ligand is crucial in influencing the architecture of these compounds and in inducing the chirality of the framework that is observed. To fully appreciate the role of the ligands one must consider a related structure constructed using a unimodal

**Fig. 5** View of the three-dimensional structure formed by  $\{[\text{Ag}(\text{bpyz})](\text{BF}_4)\}_\infty$  illustrating an adamantane-shaped unit which forms a portion of the extended diamond-like structure.

ligand. The closest, unimodal analogue to 2,2'-bipyrazine would be two pyrazine ligands (Scheme 3). Unfortunately, the reactions of pyrazine with Ag(I) salts are extremely complex leading to a plethora of different products, and direct comparisons are not valuable.<sup>[22,25,26]</sup> However, comparison with the highly related bridging, bidentate unimodal ligand

**Fig. 6** View along the crystallographic  $c$  axis of  $\{[\text{Ag}(\text{bpyz})](\text{BF}_4)\}_\infty$  showing the two distinct channels that represent different helices running through the network.

**Fig. 7** View of the conventional diamond structure formed by  $\{[\text{Ag}(4,4'\text{-bipyridine})_2](\text{CF}_3\text{SO}_3)\}_\infty$ , which adopts a single type of channel around which a single type of helix is observed.

4,4'-bipyridine does provide a useful evaluation of the influence of multimodal ligands. Reaction of  $\text{Ag}(\text{CF}_3\text{SO}_3)$  with 4,4'-bipyridine forms a conventional diamond-like structure,  $\{[\text{Ag}(4,4'\text{-bipyridine})_2](\text{CF}_3\text{SO}_3)\}_\infty$ , which crystallizes in the centrosymmetric, achiral space group  $Pbca$ .<sup>[27]</sup> The conventional diamond structure formed by  $\{[\text{Ag}(4,4'\text{-bipyridine})_2](\text{CF}_3\text{SO}_3)\}_\infty$  forms a single type of channel around which a single type of helix is observed (Fig. 7). The uniformity of channel periphery is a result of the unimodal nature of the 4,4'-bipyridine bridging ligand which can only coordinate metal centers through one type of donor and crucially is only capable of bridging metal centers through a single mode. Thus it can be seen that by using a multimodal ligand, such as 2,2'-bipyrazine, the three-dimensional architecture of a coordination polymer can be significantly altered, and in the example of  $\{[\text{Ag}(\text{bpyz})](\text{BF}_4)\}_\infty$  chirality can be introduced to a framework structure.<sup>[17,21]</sup>

The role of the multimodal ligand is key in this system. By possessing multiple bridging modes, 2,2'-bipyrazine can disrupt the homogeneity of channels in the diamond-like array. Such a reduction in homogeneity may prove useful in controlling the properties of materials. For example, in this example the two different channels may ultimately be useful for chemical

**Scheme 3** Comparison of the multimodal ligand, 2,2'-bipyrazine, and two unimodal pyrazine ligands.

**Fig. 8** View of the two-dimensional sheet structures formed by (A)  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  and (B)  $\{[\text{Ag}(\text{pyrazine})_2]\text{PF}_6\}_\infty$ .

separation. Reduction in homogeneity and hence symmetry is also more likely to lead to polar or chiral materials, such as  $\{[\text{Ag}(\text{bpyz})](\text{BF}_4)\}_\infty$ , an area of specific interest for crystal engineering of materials with non-linear optical properties.<sup>[7]</sup>

### Two-Dimensional Architectures

It is also possible to generate two-dimensional coordination polymer architectures using Ag(I) cations and multimodal ligands, including 2,2'-bipyrazine.<sup>[17,21]</sup> Reaction between  $\text{AgBF}_4$  and bpyz using an acetonitrile

solvent results in the formation of an extended two-dimensional sheet structure,  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$ . In  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  all of the Ag(I) cations adopt a uniform coordination sphere with one chelating bidentate bpyz ligand, two monodentate bpyz ligands, and an additional coordinated acetonitrile ligand (Fig. 8A). The acetonitrile ligand plays no role in polymer propagation but does serve to cap the Ag(I) coordination sphere allowing the adoption of a two-dimensional sheet-like structure.

In this instance a comparable pyrazine-based structure has been reported,  $\{[\text{Ag}(\text{pyrazine})_2]\text{PF}_6\}_\infty$ , although a different counteranion,  $\text{PF}_6^-$ , is employed.<sup>[22]</sup> Counteranions can have a very significant impact upon the extended structures of coordination polymers and this is most certainly the case for Ag(I)-based systems.<sup>[17,26,28,31]</sup> However, if one considers the topology of the cationic coordination polymer framework alone, valuable insight into the role of multimodal ligands is still valid. The structure of  $\{[\text{Ag}(\text{pyrazine})_2]\text{PF}_6\}_\infty$  consists of four connected Ag(I) nodes bridged by pyrazine ligands to afford an extended two-dimensional sheet of (4,4) topology that is highly undulating due to a distorted geometry at the Ag(I) center (Fig. 8B).  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  adopts a highly related structure in which each Ag(I) cation is linked to four others to give a two-dimensional structure which may be viewed as a (4,4)-grid structure if one considers solely the metal centers as nodes.

Comparison of the structures of the above examples illustrates that the multimodal 2,2'-bipyrazine ligand subtly influences the extended framework structure. In both  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  and  $\{[\text{Ag}(\text{pyrazine})_2]\text{PF}_6\}_\infty$ , individual tetranodal units comprise four Ag(I) centers and four aromatic, pyrazyl or pyrazine rings. However, in the case of  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  two pyrazine edges of the tetranodal units are linked using the interpyrazyl C–C bond of the 2,2'-bipyrazine ligands. This results in a subtle modification of the tetranodal units contracting two of the angles to make a rhomboid-shaped unit rather than a square-shaped unit (Fig. 8A). Thus it can be seen that using a multimodal ligand, 2,2'-bipyrazine, rather than the unimodal ligand, pyrazine, allows subtle control over the coordination network structure.

The principle of manipulation of two-dimensional sheets can be extended further by using more complex multimodal ligands such as 3,6-di-pyrazin-2-yl-(1,2,4,5)-tetrazine (dpztz)<sup>[23]</sup> or 2,2'-azobispyrazine (azpyz).<sup>[24]</sup> Both of these ligands have the capability to coordinate up to four metal centers, two via chelating sites and two via monodentate sites (Scheme 4), and thus can potentially manipulate the internal arrangement of a two-dimensional sheet to a higher degree.

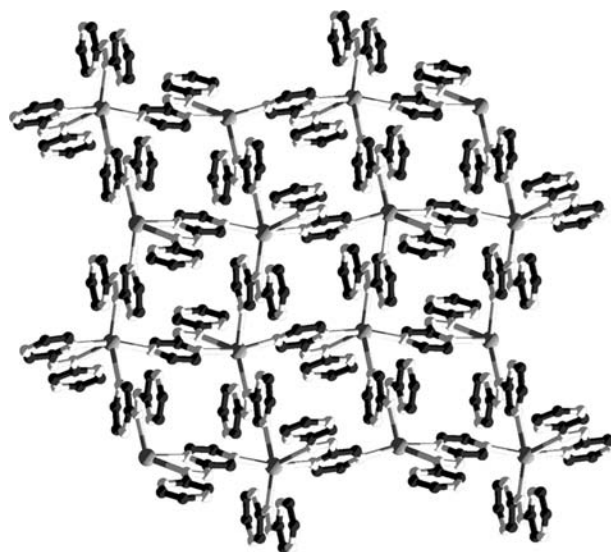

**Scheme 4** Schematic view of how more complex multimodal ligands, such as 3,6-di-pyrazin-2-yl-(1,2,4,5)-tetrazine (dpptz) or 2,2'-azobispyrazine (azpyz), can bind up to four metal centers.

The single-crystal X-ray structure of  $\{[\text{Ag}(\text{dpptz})]\text{PF}_6\}_\infty$ <sup>[23]</sup> shows each Ag(I) center adopting a five-coordinate geometry (Fig. 9), with two chelating and one monodentate dpptz ligands. Each dpptz ligand coordinates only three Ag(I) cations rather than the potential maximum of four metals, leaving a pendant, uncoordinated pyrazyl donor. The two-dimensional sheet structure can be viewed as a distorted (4,4) grid-type structure akin to those observed for  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  and  $\{[\text{Ag}(\text{pyrazine})_2]\text{PF}_6\}_\infty$ . In  $\{[\text{Ag}(\text{dpptz})]\text{PF}_6\}_\infty$  two different tetranodal units are

**Fig. 9** View of the two-dimensional sheet structure formed by  $\{[\text{Ag}(\text{dpptz})]\text{PF}_6\}_\infty$ .

**Fig. 10** View of the two-dimensional sheet structure formed by  $\{[\text{Ag}(\text{azpyz})_2]\text{SbF}_6\}_\infty$ .

observed. In the smaller ring the sides of the unit consist of two tetrazine rings and two pyrazyl rings, thus two of the angles of this tetranodal unit are “pinched” by the intraligand C–C bonds. In the other tetranodal unit the edges also consist of two tetrazine and two pyrazyl groups. However, in this larger unit none of the angles is pinched as no two edges of the tetranodal unit are linked through an intra-dpptz covalent bond. As with  $\{[\text{Ag}(\text{bpyz})(\text{MeCN})]\text{BF}_4\}_\infty$  and  $\{[\text{Ag}(\text{pyrazine})_2]\text{PF}_6\}_\infty$  the sheet is highly undulating, with a depth of ca. 13.0 Å.

Azpyz also reacts to form a structure that adopts a two-dimensional (4,4) grid sheet structure.<sup>[24]</sup> Reaction between azpyz and  $\text{AgSbF}_6$  affords  $\{[\text{Ag}(\text{azpyz})_2]\text{SbF}_6\}_\infty$  in which each Ag(I) center adopts an unusually distorted, trigonal, prismatic, six-coordinate geometry and is coordinated by two chelating azpyz ligands and two monodentate pyrazyl donors (Fig. 10). Each Ag(I) center is bridged to four other via a pyrazyl group that does not participate in a chelating coordination mode and so the tetranodal units in this structure are not distorted by the ligand and a conventional (4,4) grid is observed.

The complexity, and sometimes unpredictable nature, of systems that involve multimodal ligands is illustrated by the structure that is formed from the reaction of  $\text{AgSbF}_6$  with dpptz which forms  $\{[\text{Ag}_2(\text{dpptz})_3](\text{SbF}_6)_2\}_\infty$ .<sup>[23]</sup> As with  $\{[\text{Ag}(\text{azpyz})_2]\text{SbF}_6\}_\infty$ ,  $\{[\text{Ag}_2(\text{dpptz})_3](\text{SbF}_6)_2\}_\infty$  forms a two-dimensional sheet structure that contains Ag(I) cations in a distorted, trigonal, prismatic geometry (Fig. 11). However, in this case the Ag(I) cation is coordinated by three chelating units and the final structure does not form a (4,4) grid structure but rather a (6,3) structure which may be thought of as a brick-wall structure (topologically related to honeycomb arrangements).

**Fig. 11** View of the two-dimensional sheet structure formed by  $\{[Ag_2(dpztz)_3](SbF_6)_2\}_\infty$ .

## CONCLUSION

It is clear from the brief examples reported here that multimodal ligands can be used to influence the structure of solid-state molecular materials such as coordination frameworks. In many ways such ligands have advantages over simpler, more traditional ligands in controlling the topology of coordination frameworks at the molecular level and give rise to the hope of a high degree of design of coordination frameworks.

# Core–Shell Hydrogel Nanoparticles

Clinton D. Jones

L. Andrew Lyon

School of Chemistry and Biochemistry, Georgia Institute of Technology,  
Atlanta, Georgia, U.S.A.

## INTRODUCTION

This contribution introduces the synthesis of poly (*N*-isopropylacrylamide) (pNIPAm)-based core/shell microgels and gives an overview of investigations involving the physical properties of such systems. Core/shell microgels are created via two-stage “seed-and-feed” precipitation polymerization. Core particles serve as preexisting nuclei onto which a hydrogel-forming polymer of a different composition (the shell) is added. The physical properties of the resultant particles are then analyzed with photon correlation spectroscopy (PCS) and fluorescence resonance energy transfer (FRET). Investigations herein show how the overall particle behavior differs between core and core/shell systems. Addition of a shell impacts the swelling behavior of the core component and varies with shell thickness. Particle behavior can be explained by considering the preparation method, where a radial crosslinker density gradient is created, resulting in a distribution of polymer network densities in the core and shell components.

## ENVIRONMENTALLY RESPONSIVE MICROGELS

Responsive hydrogel nanoparticles (microgels) are crosslinked, spherical, colloids normally ranging in diameter from 10 to 1000 nm, and are individually composed of a network of randomly oriented polymer chains having the ability to exist in a swollen or collapsed state depending on local environmental conditions.<sup>[1,2]</sup> The microgels investigated in this contribution are composed of the environmentally responsive polymer poly(*N*-isopropylacrylamide) (pNIPAm)<sup>[3]</sup> and are crosslinked with *N,N*-methylene (bisacrylamide) (BIS) shown in Fig. 1. Particles of this type were first prepared by Pelton and Chibante in 1986,<sup>[4]</sup> and the field has expanded significantly in recent years.<sup>[1,2]</sup> Because of the chemical versatility and physical properties of pNIPAm-based microgels, particle design has continued to attract attention for potential applications in such fields as sensing,<sup>[5,6]</sup> drug

delivery,<sup>[7]</sup> biomaterials,<sup>[8,9]</sup> catalysis,<sup>[10]</sup> and pollution control.<sup>[11]</sup> Part of the appeal of these materials stems from the varied physical properties of pNIPAm particles that are modulated by their phase transition, including hydrophobicity,<sup>[12]</sup> particle size,<sup>[13,14]</sup> porosity,<sup>[15]</sup> refractive index, colloidal stability,<sup>[16]</sup> scattering cross section,<sup>[17,18]</sup> electrophoretic mobility,<sup>[19–21]</sup> and rheology.<sup>[22,23]</sup>

There has been a growing interest into responsive lattices possessing a more advanced architecture and are hence multifunctional. The creation of particles having differing polymer combinations in the core and shell components increases the ability of operators to manipulate the resultant properties multifold. Numerous responsive core/shell or core/corona particles have been synthesized either to introduce spatially localized chemical functionalities to the particle,<sup>[24–26]</sup> to impart thermoresponsivity to non-responsive particles,<sup>[27]</sup> or to modify a specific physical property of the latex.<sup>[22,28,29]</sup> Many of these core/shell particles contain both a responsive and a non-responsive component. However, there are many potential applications of multiresponsive core/shell particles that are composed of two or more environmentally sensitive polymers. Such materials present a potentially diverse chemo–mechanical system for study, as these particles would be expected to display very complex phase transition behavior. This is especially true in core/shell systems where one polymer has a chemical or mechanical influence over the swelling of the other polymeric component.

## CORE/SHELL MICROGEL SYNTHESIS AND CHARACTERIZATION

Crosslinked pNIPAm microgels undergo a reversible temperature-induced volume phase transition (VPT) at 31°C, the intrinsic lower critical solution temperature (LCST) of the parent polymer.<sup>[2]</sup> The particles contain ~98% water by volume below the polymer LCST and ~20% or less water by volume when phase-separated.<sup>[30]</sup> In the hydrophilic swollen state, water molecules surround and fill individual microgels, where hydrogen bonding occurs between water and

**Fig. 1** Chemical structures of the common monomers employed for these investigations. *N*-Isopropylacrylamide (NIPAm), *N,N'*-methylene(bisacrylamide) (BIS), acrylic acid (AAc).

amide groups along individual polymer chains. However, hydrogen bonding is disrupted as the local solution temperature is increased from below to above the polymer LCST. The entropically favored expulsion of water from the polymer matrix, along with hydrophobic and hydrogen bonding interactions between neighboring polymer chains, induce the particles to undergo a large-magnitude volume change.<sup>[1,31–33]</sup>

PNIPAm core/shell microgels are synthesized via two-stage precipitation polymerization in aqueous solution.<sup>[34]</sup> This synthetic approach takes full advantage of the physical properties of the polymeric system<sup>[3]</sup> to form monodisperse colloids, and is quite versatile for manipulating the resultant particle behavior. Precipitation polymerization involves the preparation of a polymer that is insoluble in its monomer, or in the presence of a non-solvent for the polymer.<sup>[35]</sup> The procedure for synthesizing core/shell microgels can be referred to as “seed-and-feed” precipitation polymerization. Collapsed core particles, produced in a prior polymerization, serve as preexisting hydrophobic nuclei (the seed) onto which precipitating polymer in solution grows (the feed) to form a shell. In fact, this protocol is fully extendable for adding multiple shells to particles by repeating the shell synthesis on core/shell particles.

First, core microgel particle formation occurs in water at 70°C upon addition of the free-radical initiator ammonium persulfate (APS). At this temperature, APS cleaves homogeneously to form free-radical species that attack olefin groups on the monomers present in the continuous water phase. Water-soluble monomers then begin to polymerize and form oligomer chains that are insoluble upon reaching a certain

critical chain length. Chains reaching this critical length undergo hydrophobically favorable coil-to-globule phase transitions.<sup>[36]</sup> These globules aggregate with one another to form precursor particles, which then have a choice of two competing processes: they can aggregate and grow to form colloiddally stable microgel particles or deposit onto existing colloiddally stable particles in solution. Free radicals located on the growing particle surface capture growing oligomer chains from the continuous phase adding to the particle size. Stabilization occurs due to both surfactant adsorption and charge incorporated on the growing particles from the initiator fragments.<sup>[2,37]</sup> The surfactant employed in these investigations is sodium dodecyl sulfate (SDS) at concentrations well below the critical micelle concentration; therefore, the role of the surfactant is only to stabilize particles during growth and not to “template” particle growth.<sup>[38]</sup> Particle synthesis is normally carried out at 70°C under nitrogen for at least 5 hr. These inert conditions eliminate a majority of dissolved oxygen molecules, which may act as free-radical quenchers.

Shell addition synthesis is performed under monomer-flooded conditions by using the same physical conditions described for the core. A monomer solution, usually differing in composition of the core, is added to the previously synthesized core component in the presence of APS to form the shell.<sup>[39]</sup> This procedure involves diluting the original core solution by 80% in the final aqueous reaction solution in the presence of SDS. The constituent shell monomers are dissolved in H<sub>2</sub>O in a separate solution. After 1 hr of degassing the core solution, the shell monomer solution is heated to approximately the same temperature (70°C) before addition. After thorough mixing and degassing for at least 15 min, APS initiator is then added to begin polymerization. At this temperature, the core particles are fully collapsed and act as preexisting hydrophobic nuclei, which capture growing polymer (the shell) from the continuous phase to form the shell. This process is illustrated in Scheme 1.

The results of core/shell synthesis can easily be realized by comparing the size differences between the original core and resultant core/shell particles via PCS. Fig. 2 shows the results of polymerizing a pNIPAm shell onto a pNIPAm core. Although this particle is not interesting from a functional standpoint, the data illustrate that core/shell particles are larger in size and exhibit the same volume phase transition (VPT) behavior as the original core. PCS analysis also reveals

**Scheme 1** Core/shell synthesis on deswollen seed particles. Source: From Ref.<sup>[39]</sup>. © 2003, Am. Chem. Soc.

**Fig. 2** PCS analysis of 2 mol% BIS crosslinked pNIPAm core (open circles) and pNIPAm core/pNIPAm shell (filled circles) particles in H<sub>2</sub>O. The core/shell particles are larger than the original core at all temperatures, showing that polymer was added during shell polymerization. Both systems undergo a volume change at approximately the same temperature of 31°C.

that the size distribution between the core and core/shell particles is the same, between 15% and 20%. Furthermore, there is no indication of a new particle population created from the second polymer synthesis step.<sup>[40]</sup> This information supports the contention that the oligoradical capture rate of the core is greater than the propensity of growing polymer chains to form new particles during shell polymerization.

The most interesting core/shell microgels are those in which the hydrogel polymer in the core and shell components differ in composition. Visualization of the core/shell structure is possible when a pNIPAm core is used for subsequent polymerization of a pNIPAm-co-acrylic acid (pNIPAm-co-AAc) shell. The results of this core/shell polymer combination can be seen in the transmission electron micrograph (TEM) image shown in Fig. 3; selective staining of the AAc groups with uranyl acetate allows for easy visualization of the core/shell structure.<sup>[34]</sup> Only one population of particles is shown in the figure, again illustrating that no new particles are formed in solution during the second step of polymerization. This image also suggests that the interface between the two materials is fairly sharp and not highly interpenetrated. It should be noted that the particle size measured by this technique is somewhat unreliable as the particles may have a tendency to flatten and spread on the TEM grid during the sample preparation. This can also lead to a larger apparent polydispersity; individual particles

**Fig. 3** Transmission electron micrograph of pNIPAm (core)/pNIPAm-co-AAc (shell) hydrogel particles. The AAc component of the particles was preferentially stained with uranyl acetate to visualize the core/shell structure of the particles. *Source:* From Ref.<sup>[34]</sup>. © 2000, Am. Chem. Soc.

are not expected to interact with the substrate in a homogeneous fashion. It is for these reasons that particle sizing is performed via the less perturbing method of PCS.

### THERMODYNAMIC PROPERTIES OF CORE/SHELL MICROGELS

The copolymer system of pNIPAm-co-AAc is considered to be a multiresponsive polymer because of its sensitivity to both temperature and pH; the  $pK_a$  value of AAc is 4.25.<sup>[41]</sup> This copolymer combination has been shown to undergo a temperature-induced volume change at much higher values ( $\sim 60^\circ\text{C}$ ) than homogeneous pNIPAm under pH conditions where the majority of acid groups are deprotonated.<sup>[42]</sup> The deswelling behavior of the pNIPAm core/pNIPAm-co-AAc shell particles shown in Fig. 3 were investigated via PCS as a function of temperature and solution pH.<sup>[34]</sup> The pH-insensitive pNIPAm core displays a volume phase transition at  $\sim 31^\circ\text{C}$ , the characteristic LCST of the parent polymer as shown in Fig. 2.<sup>[2]</sup> However, the pH-sensitive core/shell particles exhibit value-added properties, where the resultant thermodynamic properties are not a simple summation of the individual hydrogel components. At pH 3.5, where the majority of AAc groups are protonated, the VPT behavior is the same as that of pNIPAm microgels. However, when the AAc groups are deprotonated at pH 6.5, multiple phase transitions occur as a result of both components of the particle collapsing as shown in Fig. 4.<sup>[34]</sup> Size changes as a function of pH can be attributed to both an increased osmotic pressure resulting from counterion ingress, as well as

**Fig. 4** PCS data of pNIPAm core/pNIPAm-co-AAc shell particles at pH 6.5. Under these pH conditions, the acrylic acid groups are deprotonated. Deswelling of both the core and the shell leads to multiple volume phase transitions across this temperature range. *Source:* From Ref.<sup>[34]</sup>. © 2000, Am. Chem. Soc.

chain-chain Coulombic repulsion resulting in an increase in the average interchain distance.<sup>[21,42]</sup>

### MECHANICAL INTERACTIONS BETWEEN THE CORE AND SHELL

One aspect of microgel synthesis that is an essential consideration of core/shell particle behavior is the creation of a radially distributed crosslinker density gradient during particle formation. It has been shown that during particle growth, the crosslinker is statistically incorporated faster than other constituent monomers, leading to the creation of a radial distribution of crosslinks.<sup>[1,2,37,43,44]</sup> An illustrative model of the resultant particle morphology is shown in Fig. 5. Because the crosslinker is incorporated fastest, polymer chains toward the particle interior possess a greater number of crosslinking points per chain than those toward the particle exterior. However, this same population of loosely crosslinked chains will be hindered from reaching their fully extended state in the presence of added polymer (e.g., shell). The average number of chains that will be perturbed will differ according to the initial crosslinker concentration, with lower mol% crosslinked particles having a higher average number of loosely crosslinked chains near the periphery than highly crosslinked particles that do not have a gradient morphology.<sup>[45,46]</sup>

**Fig. 5** The synthesis of pNIPAm microgels via precipitation polymerization creates a radial crosslinker density gradient. Polymer chains near the particle periphery have fewer crosslinker points between chains than those located toward the interior. The various subchain lengths between crosslinking points affect particle deswelling as described in the text.

Because the synthetic conditions used for the core are the same for shell addition, a radial crosslinking density gradient is expected in the shell component as well, with the greatest network density being located at the interface of the core and shell. As illustrated in Scheme 1, collapsed core particles serve as preexisting hydrophobic nuclei and capture growing oligomers from solution that form the shell. Upon particle reswelling at 25°C following shell addition, the rigid interior (more highly crosslinked portion) of the shell component prohibits the core from expanding to its maximum volume, which it possessed prior to shell addition.

The thermodynamic and morphological impact of a hydrogel shell on a hydrogel core particle can be studied with a chosen experimental design relying on a pH- and temperature-responsive core particle, upon which a temperature-responsive, pH-innocent material is added. In this fashion, the shell-induced modulation of the pH response and thermoresponsivity of the core particle can be studied. The well-investigated pH/thermo-responsive hydrogel, pNIPAm-co-AAc, was chosen as the core material and a pH-innocent pNIPAm shell was added. The core/shell particles used for illustration are simply the inverse of those discussed above. In this previous case, the thermodynamics of particle deswelling was investigated, whereas the mechanical properties of this core/shell system are now being presented.

As shown in Fig. 6, a size decrease is observed at all temperatures and at pH 6.5 for these core particles following shell addition, suggesting that the pH-induced swelling of the core is now restricted by the presence of the shell. Indeed, below 31°C, the volume of the core/shell particle is only 40% of the parent core particle volume at pH 6.5. In addition to mediating the solvation of the core, the added pNIPAm shell also

**Fig. 6** Volume phase transition behavior of pNIPAm-co-AAc core (open circles) and pNIPAm-co-AAc core/pNIPAm shell (filled circles) microgels at pH 6.5. The size of the core/shell microgels is smaller than the parent core at all temperatures, suggesting restricted swelling of the core component by the added shell. *Source:* From Ref.<sup>[39]</sup>. © 2003, Am. Chem. Soc.

controls the overall particle deswelling behavior above the polymer LCST by forcing the charged microgel core to undergo a volume phase transition. The added shell compresses the charged core at the LCST of neutral pNIPAm, despite the resistance of the parent core particle to deswelling when the AAc moieties are deprotonated.

A depiction of this core/shell interface is shown in Scheme 2 and illustrates that the loosely crosslinked polymer chains near the core periphery are not allowed to expand to their preshell state because of the added

**Scheme 2** Impact of core and shell crosslinker density gradients on core compression. *Source:* From Ref.<sup>[39]</sup>. © 2003, Am. Chem. Soc.

presence of the highly crosslinked network in the shell. If heterogeneity were not present within both the core and shell in the form of a radial crosslinking density gradient, one would not expect to see the effects observed here, as the core and shell would have the same average and local crosslinker concentration.

## SHELL THICKNESS DEPENDENCE

The thickness of the shell component also impacts the restricted swelling and compression of the core, because it is apparently the nature of the network density in the shell that modulates such behavior. Particles having a pNIPAm-co-AAc core and a pNIPAm shell were used to investigate the effects of shell thickness variation.<sup>[40]</sup> Shell thickness can be controlled by modulating the amount of polymer added to the core during the shell synthesis, which is carried out by simply varying the total monomer concentration present in the shell monomer solution. More monomer present for polymerization directly correlates with the amount of material added and therefore the resultant thickness of the shell. As shown in Fig. 7, the particle size increases with increased shell monomer concentration providing evidence of increasing shell thickness. The average particle polydispersity index

**Fig. 7** PCS results for BIS crosslinked pNIPAm-co-AAc (core)/pNIPAm (shell) particles with varying shell thickness under pH 3.5 solution conditions. Shell thickness is controlled by the initial monomer concentration present in the shell addition synthesis: (open circles) 0 mM, (filled squares) 20 mM, (open squares) 40 mM, (filled circles) 80 mM total shell monomer. The particle size increases relative to the core as the thickness of the shell increases. *Source:* From Ref.<sup>[40]</sup>. © 2003, Am. Chem. Soc.

for all samples varied randomly between 15% and 20% as measured by PCS for all temperatures investigated. These data were taken under pH 3.5 solution conditions (0.001 M total ion), where the core component is not significantly charged. Thus the volume phase transition behavior of each particle should be nearly identical to that of typical pNIPAm homopolymer microgels. Indeed, the VPT temperature (VPTT) is approximately the same for the core and core/shell particles. Recent results using a non-responsive poly(butyl methacrylate) core with varying thickness of a pNIPAm shell also show independence of the VPTT as a function of shell thickness when interrogated via PCS.<sup>[47]</sup>

The data in Fig. 8 show the results of modulated swelling behavior of the core in the presence of increasing shell thickness. These data were collected under pH 6.5 solution conditions (0.001 M total ion), where the acidic groups are fully deprotonated and thus the core component is charged. In each case, the size decrease is greater than the apparent shell thickness observed in Fig. 7, indicating that increasing the thickness of the shell concurrently decreases the ability of the parent core to swell to its original volume. These data indicate that the network structure in the shell changes with shell thickness, thus affecting the swelling ability of the core and the entire core/shell particle. The cross-linking density gradient in thicker shells may have a more gradual persistence toward the particle periphery,

**Fig. 8** PCS results for BIS crosslinked pNIPAm-*co*-AAc (core)/pNIPAm (shell) particles with varying shell thickness under pH 6.5 solution conditions below the VPT temperature of the particles. The core/shell particles show a smaller volume than the core despite the increasing shell thickness. These data indicate that increasing the thickness of the shell directly impacts the phenomenon of restricted swelling of the core component.

thereby decreasing the overall hydrodynamic radius as interrogated via PCS.

## FLUORESCENCE ANALYSIS OF CORE/SHELL NANOPARTICLES

Complimentary to the PCS analysis of restricted swelling and compression of the core by the shell component, the FRET technique can be used to probe the swelling behavior of hydrogel polymer chains inside the core component of core/shell hydrogel nanoparticles. FRET is a distance-dependent process requiring that two fluorophores, termed the donor and the acceptor, have overlapping emission and excitation spectra, respectively. Energy transfer occurs from excited donor molecules to acceptor molecules when the two are within a certain characteristic distance referred to as the Förster radius, and is the result of long-range dipole-induced dipole interactions.<sup>[48]</sup> The Förster radius is typically in the range of 20–60 Å and the efficiency of this process is inversely proportional to the sixth power of the donor–acceptor distance ( $R_0^{-6}$ ). For these investigations, the sulfoindocyanine-based dyes Cy5 and Cy5.5 (Amersham Biosciences) were chosen as the donor and acceptor molecules, respectively.<sup>[49]</sup>

Microgels composed of a pNIPAm core and a homogeneous pNIPAm shell were employed for this study. The core was copolymerized with a small percentage of amine groups for postpolymerization modification with *N*-hydroxysuccinimidyl (NHS) ester functionalized cyanine dyes. Both the core and shell components are lightly crosslinked with 2 mol% *N,N'*-methylene(bisacrylamide) (BIS). The amount of energy transfer occurring between the cyanine FRET pair in the core component is monitored by comparing the emission intensity of the donor and acceptor molecules in the absence and presence of the added shell over a range of temperature values. In the absence of the shell, only a small degree of energy transfer is observed in the core when it is fully swollen below the pNIPAm lower critical solution temperature (LCST) of 31°C. Addition of a pNIPAm shell produces a significant degree of FRET under the same conditions, illustrating that the polymer chains in the core are in a constrained conformation relative to their fully swollen state.

Because of the VPT behavior of pNIPAm microgels, a decrease in the average donor/acceptor distances will occur as the temperature is increased, leading to energy transfer between the molecules. Fig. 9 shows fluorescence data of the donor/acceptor labeled core microgels below (23°C) and above (43°C) the LCST. The sample was excited at 646 nm in both cases. When the microgels are in the fully swollen state at 23°C,

**Fig. 9** Fluorescence emission spectra of core microgels containing both Cy5 donor and Cy5.5 acceptor dyes excited at 646 nm. In the swollen state at 23°C (solid line), there is a small degree of energy transfer, as evidenced by the non-zero Cy5.5 emission intensity. Above the phase transition temperature at 43°C (dashed line), the average donor-to-acceptor distance is decreased, resulting in an increase in the donor/acceptor intensity ratio.

there is a small amount of energy transfer occurring. A significant amount of energy transfer occurs as the temperature is raised to 43°C. The high temperature fluorescence spectrum shows a broadening because of a decrease in the donor emission intensity at 671 nm and a simultaneous increase in the acceptor emission intensity at 697 nm because of FRET.

The VPT behavior of the core microgels can be monitored with FRET by comparing the ratio of the donor and acceptor emission intensities as a function of temperature. As shown in Fig. 10, the FRET analysis exactly coincides with the change in particle size as a function of temperature. These data indicate that the two dyes are homogeneously incorporated throughout the microgel core particle. Thus the amine monomer must also be homogeneously distributed initially within the polymer matrix. Previous investigations indicate that homogeneous incorporation can be expected for this particular amine monomer at the low concentrations used in this study.<sup>[50]</sup> The accepted temperature-induced deswelling mechanism of microgels suggests that the particles collapse beginning at the periphery and continue toward the inside.<sup>[43]</sup> Because of the inverse relationship between the coil to globule phase transition temperature and chain length, loosely crosslinked subnetworks toward the periphery will undergo a phase transition at a lower temperature than highly crosslinked chains near the

**Fig. 10** A comparison of photon correlation spectroscopy analysis (circles) and fluorescence resonance energy transfer analysis (triangles) of core microgels containing both Cy5 donor and Cy5.5 acceptor molecules in deionized H<sub>2</sub>O. The donor to acceptor emission intensities were monitored at 671 and 697 nm, respectively; samples were excited at 646 nm.

center of the particle.<sup>[36,44]</sup> Accordingly, the continuous phase transition of pNIPAm microgels, such as that in Figs. 2, 4, 6 and 7, can be viewed as a collection of discontinuous phase transitions of the radial distribution of crosslinked networks existing in the particle. If the donor and acceptor groups were not homogeneously distributed inside the polymer matrix, then the FRET analysis would not overlap the PCS data. For instance, energy transfer would not occur until late in the volume decrease and the magnitude of FRET would be substantially less if the dyes were crowded toward the inner portion of the particle. If the dyes were located near the periphery, then a majority of the energy transfer would occur early in the volume decrease.

FRET analysis of the VPT behavior between the core and core/shell is presented in Fig. 11A. In comparison to the degree of FRET in the core, the core/shell particles exhibit significant energy transfer at 23°C. This behavior shows that the shell restricts the core from reswelling to its original state, as shown in Fig. 6 above. The ratio between the donor and acceptor emission intensity at 23°C for the core/shell particles is approximately the same as that for the core particles at 31°C. Fig. 11B shows a spectral comparison between these two sets of data. The two spectra illustrate that amount of energy transfer between donor and acceptor chromophores is approximately the same for each case by observing the shape of the fluorescence emission spectrum. A semiquantitative value of the amount of restricted swelling can be gathered by noting that the core alone undergoes a volume decrease of 40% at 31°C when interrogated via PCS. If

**Fig. 11** (A) Fluorescence resonance energy transfer analysis of Cy5 donor/Cy5.5 acceptor labeled core (open) and core/shell (solid) microgels in H<sub>2</sub>O. These core/shell microgels were excited at 646 nm and exhibit a greater degree of energy transfer than the original core below 33°C. (B) Fluorescence analysis of core particles at 31°C (solid line) and the core/shell particles at 23°C (dashed line). The two spectra show that approximately the same amount of energy transfer is occurring for each system at these temperatures.

the same volume change in the core produces the same amount of FRET in both the original core at 31°C and the core/shell at 23°C, then it may be assumed that the core is restricted from swelling to only 60% of its original volume in the presence of the shell. Indeed, the core is swollen to some extent in the core/shell particles, as FRET does increase as the temperature is raised above the pNIPAm VPT temperature.

## CONCLUSION

The synthesis and characterization of pNIPAm-based microgels possessing a core/shell morphology have been presented. Core particles are first synthesized via precipitation polymerization and serve as preexisting nuclei in a subsequent polymerization containing monomer of a different composition to form the shell. The core/shell structure can be visualized with electron microscopy and the physical properties of the systems are investigated via photon correlation spectroscopy and fluorescence spectroscopy. The presence of the shell impacts the swelling behavior of the core component, which is elucidated by using these analytical techniques. Fundamental understanding of the swelling properties is important for the development of applications-based materials.

## INTRODUCTION

The design and synthesis of nanoscale materials is important in the fabrication of advanced devices for optics, electronics, and biotechnology.<sup>[1–6]</sup> Over the past decade, considerable effort has been devoted to the design and controlled fabrication of nanostructured materials with functional properties. The interest in nanoscale materials comes from the fact that their properties (optical, electrical, or chemical, etc.) are the functions of their size, composition, and structural order. Colloidal particles represent attractive building blocks from which to create ordered and complex materials. They are also of widespread interest in chemical engineering, biological, and pharmaceutical applications.<sup>[7]</sup> In biotechnology, the encapsulation and delivery of proteins and DNA into cells has led to the implementation of intracellular medicinal therapies such as gene therapy.<sup>[8,9]</sup> Completion of the human genome project has ensured the former, leaving the synthesis of encapsulation and delivery materials as perhaps the single most important challenge in intracellular medicinal therapies. Recently, core-shell particles and micro- or nanosized capsules have received considerable attentions for their technological importance in many fields.<sup>[10–25]</sup> There have been many efforts to fabricate core-shell colloidal materials with tailored structural, surface, and optical properties.<sup>[26–28]</sup> The creation of core-shell colloidal particles is also of interest from a fundamental viewpoint, especially in the areas of colloid and interface science. They can be utilized as model systems to investigate factors governing colloidal interactions and stabilization and to gain valuable information on the properties of concentrated dispersions.<sup>[29,30]</sup>

## OVERVIEW

The synthesis of core-shell particles typically involves tailoring the surface properties of particles, often accomplished by coating or encapsulating them within a shell of a preferred material. The shell can alter the charge, functionality, and reactivity of the surface, and can enhance the stability and dispersibility of the colloidal core. Optical, magnetic, or catalytic functions may be readily imparted to the dispersed colloidal matter depending on the properties of the coating. Encapsulating colloids in a shell of different composition may also protect the core from extraneous chemical and physical changes.<sup>[31,32]</sup> Core-shell particles often exhibit improved physical and chemical properties over their single-component counterparts and, hence, are potentially useful in a broader range of applications. Optimization of the surface characteristics of particles through coating processes is also of primary importance for the successful application of composite particles. Recent methods offer new alternatives for the controlled synthesis of novel, stable, and functional core-shell type materials.

An important extension of core-shell particles is the subsequent removal of the core by either thermal or chemical means (selective etching with a solvent or calcination in air), forming hollow spheres. A variety of procedures currently used to fabricate a wide range of stable hollow capsules of various compositions have been reported.<sup>[33]</sup> Hollow capsules of nanometer to micrometer dimensions constitute an important class of materials that are employed in various technological applications, such as encapsulate agents for delivery of cosmetic, drug, catalysis, and protecting sensitive agents. They may also provide some immediate advantages over their solid counterparts because of their

relatively low densities and as fillers with low dielectric constant in electronic components. Using various chemical and physicochemical methods nowadays routinely produces hollow capsules comprising polymer, glass, metal, and ceramic.

As particular examples, hollow spheres with mesoporous wall have been synthesized from gel composite;<sup>[34,35]</sup> however, large entities such as macromolecules usually cannot penetrate such microspheres. It would be desirable to leave a hole on the shell surface for transporting various molecules. Lin and coworkers synthesized a vesicular hollow microspheres that possess a pair of holes of submicron size on exactly opposite sides.<sup>[36]</sup> Recently, our group obtained the nanobottles through the removal of template functional polymer and silica cores through programmed calcination at high temperature and solution etching, respectively. Because there is an opening on the hollow cavity of silica nanobottle, it can afford both a channel for transmission and a container for storage. So the nanobottles can be used as an extremely small container for encapsulation, as well as a nano-sized carrier and reactor for catalysis and microreaction. Furthermore, the encapsulation of rare earth complex in the nanobottles reveals a potential application for nanotechnology.

This entry provides an overview of the various methods used to synthesize core-shell particles, hollow capsules, and bottles in the nanometer to the micrometer size range, detailing early and very recent developments in the above area.

## NANOSIZED CORE-SHELL SPHERES

### Nanosized Core-Shell Spheres with Polymer Shell

Polymer-coated spheres offer interesting prospects in a broad spectrum of applications, ranging from catalysis to additives and dyes, where they are exploited in the manufacture of cosmetics, inks, and paints. The synthetic routes that have been developed in order to produce polymer-coated spheres fall into two main classes: polymerization at the sphere surface or adsorption onto the spheres. Hofman-Caris has comprehensively reviewed the processes used to obtain spheres that consist of an inorganic core and a polymer shell through polymerization and chemical coupling procedures prior to 1994.<sup>[28]</sup> We will deal with more recent strategies used to coat spheres with polymers, polymerization approaches, and the self-assembly of polymers from solution.

A number of polymerization-based methods have been employed to produce spheres that consist of solid cores coated with a shell of polymeric materials. These include monomer adsorption onto spheres followed by

subsequent polymerization,<sup>[37–42]</sup> heterocoagulation-polymerization,<sup>[43]</sup> and emulsion polymerization.<sup>[28,44]</sup> In the first approach, one of the most frequently employed to achieve polymer coatings on solid spheres, the polymerization reaction can be catalyzed either by an initiator to promote the process or by the colloidal spheres themselves.

Atom transfer radical polymerization (ATRP) is a versatile technique, which offers several advantages over other polymerization routes including control over molecular weight and molecular weight distribution.<sup>[45,46]</sup> Also, the polymers can be end-functionalized or block copolymerized upon the addition of other monomers.<sup>[46]</sup> Not only does this feature offer tailorability of the polymer coating with a variety of compositions and functionalities, but also this feature may be important in biomedical applications to modify the polymer shell with biological moieties for specific cellular interactions. ATRP has been able to form PMMA and PS shells on silica nanoparticles,<sup>[45]</sup> and provides magnetic core-shell nanospheres with size <15 nm. Magnetic studies show a decrease in coercivity, which is consistent with the reduction of magnetic surface anisotropy upon polymer coating. Certainly the magnetic core of these core-shell nanospheres can be selected, depending upon the desired super paramagnetic properties for specific applications such as in data storage and MRI contrast enhancement.<sup>[47]</sup> Moreover, the resulting core-shell nanospheres are within the biological size restrictions and may potentially be modified for a particular biospecificity.

Matijevic et al. reported the coating of aluminum hydrous oxide-modified silica spheres with poly(divinylbenzene) (PDVB) layers by pretreatment of the inorganic cores with coupling agents such as 4-vinylpyridine or 1-vinyl-2-pyrrolidone, followed by subsequent admixing of divinylbenzene and a radical initiator.<sup>[37]</sup> Polymer layers of poly(vinylbenzyl chloride) (PVBC), copolymers of PDVB–PVBC, and double shells of PDVB and PVBC were also synthesized around inorganic spheres using a similar approach.<sup>[38]</sup>

The use of electrochemical or soluble initiators can be eliminated by utilizing catalytically active cores to effect the polymerization of monomers adsorbed on the surface of spheres. This approach was employed to obtain poly(pyrrole) coatings on a range of inorganic cores by using the active sites on the metal oxide surfaces to initiate the polymerization of pyrrole.<sup>[39]</sup> Hematite, silica-modified hematite, and cerium(IV) oxide (CeO<sub>2</sub>) were coated with poly(pyrrole) by exposing the inorganic cores to the polymerization medium of pyrrole in an ethanol/water mixture and heating to 100°C.

Möller et al. presented a work directed toward the formation of core-shell particles consisting of a nanocrystal of Au surrounded by a shell of conducting polymer, e.g., polypyrrole.<sup>[48]</sup> Because of the different

chemical nature of the two materials, charge transfer might be expected at the interface and the optical functions of both materials should be drastically different from the corresponding bulk materials.<sup>[49]</sup> Preliminary experiments using solutions of tetrachloroauric acid (HAuCl<sub>4</sub>) and pyrrole, without diblock copolymer, have demonstrated the formation of PPY and Au. However, in this case it was not possible to prevent the macroscopic segregation of the polymer and the metal phase. Macroscopic segregation can be prevented efficiently if the composite particles are formed within the cores of the micelles of a diblock copolymer. Fig. 1 shows the micrograph recorded after annealing the film at 130°C. Uniform Au particles with a diameter of 7 nm formed within the micelles. The figure indicates that the originally indistinct ultrasmall clusters of elementary gold coalesced upon treatment above the glass transition temperature of both blocks. When the same annealing procedure was applied to an Au-loaded micellar film that had not been treated with pyrrole, larger Au particles were formed and the micellar organization was destroyed. Thus the presence of polypyrrole or pyrrole oligomers is essential to yield a single Au particle within each spherical microdomain.

**Fig. 1** TEM micrograph of a colloidal polymer film ([PY]/[HAuCl<sub>4</sub>] = 3.0) after annealing at 130°C for 140 min, exhibiting 7 nm wide Au clusters in each micelle encapsulated by PPY. *Source:* From Ref.<sup>[48]</sup>.

Methods to coat a polymer shell with a controllable thickness on magnetic nanoparticles may aid in the development of ordered arrays of magnetic nanoparticles. The formation of polymeric shells is essential for biomedical applications of magnetic nanoparticles such as magnetic targeting drug delivery and magnetic resonance imaging (MRI) contrast enhancement. Many methods usually create micrometer-sized magnetic polymer spheres, which are large for in vivo applications.<sup>[50]</sup> A less than 20-nm size has been suggested for the efficient diffusion of nanoparticles through tissue in MRI applications.<sup>[51]</sup> An emulsion polymerization of poly(methyl methacrylate) (PMMA) on ~10-nm core of mixed-phase iron oxides has made improvement; the particle size is still >130 nm.<sup>[52,53]</sup> Polystyrene (PS) is easy to synthesize for testing various strategies of coating nanoparticles with polymer shells. Zhang et al. reported the formation of magnetic MnFe<sub>2</sub>O<sub>4</sub> PS nanoparticles using ATRP yielding a core-shell nanoparticle with size <15 nm.<sup>[54]</sup> Most polymer-coating studies on magnetic nanoparticles form the nanoparticle core (typically Fe, Fe<sub>2</sub>O<sub>3</sub>, or Fe<sub>3</sub>O<sub>4</sub>) at the same time as that of polymerization.<sup>[55]</sup> The MnFe<sub>2</sub>O<sub>4</sub> nanoparticles as the magnetic core were separately prepared by a reverse micelle microemulsion procedure.<sup>[56]</sup> Polymerization initiators are chemically attached onto the surface of nanoparticles. The modified nanoparticles are then used as macro-initiators in the subsequent polymerization reaction. This approach provides great flexibility in the selection of magnetic core. Consequently, magnetic tunability can be introduced into these core-shell nanosphere systems to achieve the desired super paramagnetic response.<sup>[57]</sup>

Inspired by the nanosized, amphiphilic core-shell structure of lipoproteins, shell cross-linked nanoparticles with a hydrophobic core, contained within a hydrogel network, were prepared by the self-assembly of amphiphilic block copolymers followed by intramolecular cross-linking between the polymeric chains located within the shell.<sup>[58]</sup> The control over size, shape, and composition of these nanoparticles holds great potential in drug delivery applications.<sup>[59,60]</sup> Intracellular cross-linking of the polymer chains within the shells of polystyrene-*b*-poly(acrylic acid) micelles by reaction with difunctional poly(ethylene oxide) afforded unimolecular amphiphilic core-shell nanospheres (50 nm hydrodynamic radius).<sup>[61]</sup>

The controlled release of polymer chains from the core by adjusting the cross-link density of the shell opens the possibilities of designing polymeric nanoparticles with specific shell permeabilities, capable of delivery of large guests. This approach may provide a solution to some of the delivery problems posed by biologically active molecules, such as peptides and proteins, genes and oligonucleotides. The results of this study also provide a foundation for better understanding

**Fig. 2** TEM images of silica-PMMA (left), silica-PS core-shell spheres (right). *Source:* From Ref.<sup>[64]</sup>.

of the porosity of the cross-linked shell.<sup>[62]</sup> This represents a methodology to probe the permeability of nanoscopic membranes and a means for applications in the controlled release of macromolecular species.

Our group described a flexible method for preparing monodisperse silica-PS core-shell microspheres. In this method, silica nanoparticles grafted with 3-(trimethoxysilyl) propyl methacrylate (MPS) was employed in an emulsion polymerization as seeds. The thickness of the shells could be changed through varying the amount of monomer and emulsifier. The monodispersity and diameters of the core-shell microspheres were found to depend on the size of grafted silica nanoparticles and the concentration of emulsifier.

The monodisperse silica microspheres with average radii ranging from 35 to 90 nm were prepared in ethanol according to the Stöber method<sup>[63]</sup> at ambient temperature. In order to obtain a functionalized surface, MPS with C=C bond was added and reacted with the Si-OH group on the surface of the silica by hydrolysis. Monodisperse silica-polymer core-shell microspheres were obtained through emulsion polymerization of styrene (St) or methyl methacrylate (MMA), while grafted silica particles dispersed in ethanol, which acts as “seeds” in the polymerization process.<sup>[64]</sup>

Fig. 2 shows the TEM images of the resulting silica-PMMA (left) and silica-PS (right) core-shell microspheres. The spherical particles show obvious core-shell structures, light shells (PMMA or PS) coat the dark grafted silica microspheres cores, and over about 90% of these core-shell microspheres have only one single core. The average radius of the monodisperse core-shell microspheres varies from 45 to 150 nm for silica-PMMA and from 80 to 210 nm for silica-PS, which have been confirmed by the TEM.

A series of TEM images of core-shell microspheres prepared by increasing the amount of styrene (St) prove that the grafted silica nanoparticles act as “seeds” in the emulsion polymerization.<sup>[64]</sup> The “raspberry” morphology of core-shell microspheres was seen, and it was clearly visible that the surfaces of shells became smoother and the shells thickened with increasing the amount of monomer; the core-shell microspheres were still monodisperse.

### Nanosized Core-Shell Spheres with Inorganic and Composite Shell

Various procedures have been employed in the fabrication of inorganic/hybrid coatings on particles, allowing a broad range of materials with different properties to be prepared. The specific methods of solid-core inorganic/hybrid-shell sphere preparation can be classified into two general categories: precipitation and surface reactions, and the controlled deposition of preformed inorganic colloids.

Previous investigations have demonstrated that polymeric and inorganic particles dispersed in aqueous solutions can be coated with layers of various inorganic materials either by precipitation of the coating materials onto the cores or by direct surface reactions utilizing specific functional groups on the cores to induce coating.<sup>[17,27,31,65–76]</sup> The inorganic coatings prepared using these approaches include silica,<sup>[17,27,31,65–73]</sup> yttrium basic carbonate, titania,<sup>[74–76]</sup> and polyelectrolytes onto particles via the layer-by-layer (LbL) and LB techniques. Early work focused on the coating of titania microparticles with silica layers; however, significant particle clumping and coalescence took place

during silica deposition. Using the precipitation method, in which the coating material is precipitated directly onto the core, Ohmori and Matijevic optimized the coating conditions and coated spindle-shaped hematite ( $\alpha$ - $\text{Fe}_2\text{O}_3$ ) particles with silica layers by hydrolysis of the alkoxide tetraethoxysilane (TEOS) in 2-propanol.<sup>[31,65,77]</sup> Uniform silica coatings on individual  $\alpha$ - $\text{Fe}_2\text{O}_3$  particles were obtained when the kinetics of the TEOS hydrolysis was properly controlled. Dispersions of uniform sub-micrometer spherical particles consisting of silica cores and yttria coatings, as well as yttria cores with silica coatings, were also prepared by a similar method.

Electrostatic interactions between nanoparticles and larger particles via solution self-assembly have been widely exploited to prepare core-shell materials.<sup>[66,78–82]</sup> Homola et al. reported the coating of  $\gamma$ - $\text{Fe}_2\text{O}_3$  particles with preformed smaller silica particles by combining the particle mixtures under conditions where the two types of particles are oppositely charged. This resulted in better dispersion and less aggregation of the magnetic particles. Similarly, nanosized silica was deposited on a range of larger inorganic particles, thus forming a protective layer. Nanocomposite multilayers can be assembled on particle surfaces by using the LbL method based on colloidal templates.

Lu et al. described a sol-gel approach for the coating of super paramagnetic iron oxide nanoparticles with uniform shells of amorphous silica.<sup>[83]</sup> The coating process has been successfully applied to particles contained in a commercial ferrofluid and those synthesized through a wet chemical process. The thickness of the silica coating could be conveniently controlled in the range of 2–100 nm by changing the concentration of the sol-gel solution. Fluorescent dyes could also be incorporated into these silica shells through a covalent coupling between these organic dyes and the sol-gel precursor. Also, they and Liz-Marzan et al. demonstrated that gold nanoparticles could be directly coated with uniform shells of amorphous silica using a sol-gel process (Fig. 3).<sup>[27,83,84]</sup> The thickness of such a conformal coating could be changed from tens to several hundred nanometers by controlling the concentration

of TEOS precursor or the deposition time. The potential use of these spherical, core-shell colloids in fabricating photonic devices has been illustrated with two examples: photonic crystals and plasmonic waveguides. These demonstrations suggest that Au-SiO<sub>2</sub> core-shell particles with well-controlled sizes are promising building blocks for nanoscale integrated optics, in which the dimensions of structures for guiding and modulating photons will no longer be limited by the wavelength of light.

Stable colloidal core-shell particles consisting of a PS core and a titania coating were prepared in one step by the hydrolysis of a titanium alkoxide in the presence of a cationic PS latex.<sup>[85]</sup> Although this study used PS as a core, it should be possible to replace it with other polymer colloids that can be given cationic surface groups or with negatively charged particles that can be made positive by coating with a polyelectrolyte. This results in unusually smooth and uniform titania shells that can be made as thin as a few nanometers. This is attributed to a very rapid collection of the negatively charged titania oligomers by the positively charged surfaces. The coatings are very smooth and uniform and can be varied in thickness from just a few nanometers to at least 50 nm. Thicker coatings should also be possible but only through a multistep seeded growth process. The coated spheres have the same monodispersity as the starting latex, allowing them to form colloidal crystals.

Novel fine polymer particles containing ultrafine Pd, Pt, or Rh metal dispersed on the core-shell-type sphere were prepared by the emulsifier-free emulsion polymerization, followed by the addition of a mixture of  $\text{Ln}(\text{NO}_3)_3$  and  $\text{NaH}_2\text{PO}_4$ .<sup>[86]</sup> Rogach et al. and Caruso et al. report on the fabrication of 3-D colloidal photonic crystals by the self-organization of submicrometer-sized PS latex spheres covered via the consecutive electrostatic adsorption of charged polyelectrolytes and luminescent semiconductor nanocrystals (Fig. 1).<sup>[82]</sup> CdTe and CdTe(S) nanocrystals,<sup>[87]</sup> capped on the surface with different thiols and with sizes ranging from 2.5 to 5 nm, have been prepared by a wet

**Fig. 3** (A) TEM image of gold nanoparticles with an average diameter of 50 nm. (B,C) TEM images of such gold nanoparticles after their surfaces had been coated with amorphous silica shells of  $\sim 20$  and  $\sim 80$  nm in thickness, respectively. *Source:* From Ref.<sup>[83]</sup>.

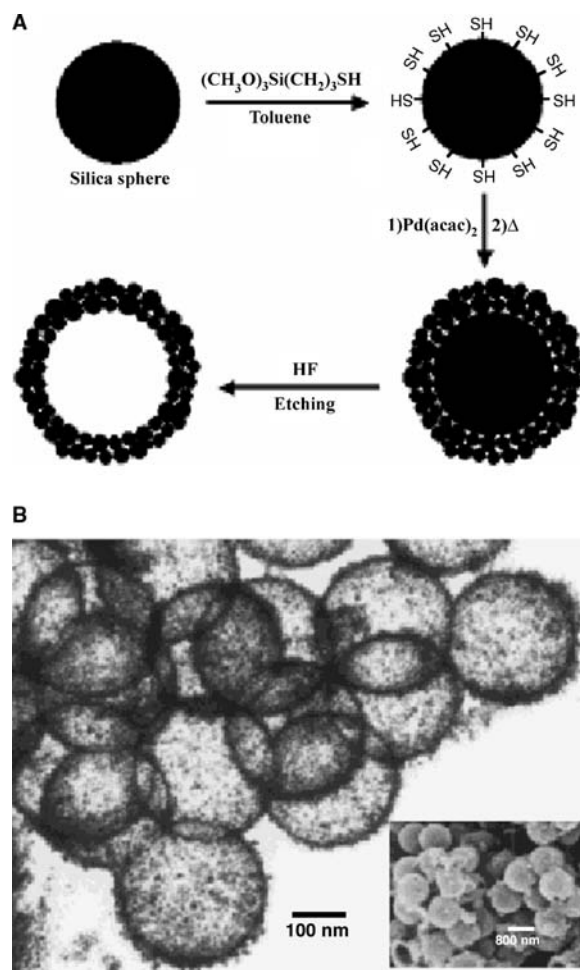

chemical route.<sup>[88]</sup> They show a pronounced size dependence on the position of their electronic transitions and luminescence maxima due to the quantum confinement effect. Relatively narrow and reasonably strong “excitonic” luminescence occurs close to the onset of absorption and is tunable between 530 and 680 nm.

Highly monodispersed CdSe–CdS core-shell nanoparticles have been prepared by a novel route involving thermolysis in TOPO in a one-pot synthesis.<sup>[89]</sup> This route is a simple and convenient route to produce reasonable quantities of high-quality, monodispersed core-shell nanoparticles. The precursors are easy to synthesize and store and give high yields of TOPO-capped quantum dots.

Submicrometer-sized anionic PS latexes have been coated with uniform layers of iron compounds by aging, at elevated temperature. Dispersions of the polymer colloid in the presence of aqueous solutions of ferric chloride, urea, hydrochloric acid, and polyvinylpyrrolidone have been produced.<sup>[25]</sup> The thickness of the deposited layers could be altered by suitable adjustment of the reactant concentrations, and they could also be increased by further aging of the coated particles in the presence of aqueous solutions of ferric chloride. Hollow colloidal spheres of iron compounds were obtained by calcinations of the so-coated PS latexes at elevated temperature in air. Different chemical compositions of hollow colloidal spheres were obtained by heating them in hydrogen.

## HOLLOW CAPSULES AND NANOBOTTLES

Hollow spheres are useful in a variety of areas. They can be used in catalysis, delivery of drugs, development of artificial cells, or protection of biologically active agents (such as proteins, enzymes, or DNAs). Hollow spheres may also provide some immediate advantages over their solid counterparts because of their relatively low densities. In a typical procedure, hollow spheres are prepared by the removal of the “cores” (via selective etching with a solvent or calcination in air) from core-shell structure nanospheres. There are a variety of methods currently used to fabricate a wide range of stable, hollow spheres of various compositions. These methods include nozzle reactor systems,<sup>[90–92]</sup> emulsion/phase separation techniques coupled with sol-gel processing,<sup>[73,93,94]</sup> sacrificial core procedures,<sup>[77,95–97]</sup> and LbL technique (consecutively assembling inorganic nanoparticles and polymer onto colloids and subsequently removing the templated colloid).<sup>[1,10–15,98–102]</sup> There have been some successful examples for the preparation of different kinds of hollow microsphere materials (such as silica,<sup>[12,16–21,80]</sup> zirconium<sup>[16]</sup> hydroxide, yttrium compounds,<sup>[15,22,23]</sup> titania,<sup>[75,99–101]</sup> copper

**Fig. 4** TEM and SEM (inset) of hollow palladium spheres. *Source:* From Ref.<sup>[105]</sup>.

compounds,<sup>[102]</sup> zeolite,<sup>[103]</sup> and magnetic nanoparticles.<sup>[17,24,25,104]</sup> Yin et al. synthesized mesoscopic hollow microspheres of ceramic materials with functionalized interior surfaces.<sup>[96]</sup> Kim et al. fabricated hollow palladium microspheres and successfully applied them to the recyclable heterogeneous catalyst for Suzuki coupling reactions (Fig. 4).<sup>[105]</sup> Caruso and coworkers prepared many kinds of inorganic and hybrid hollow spheres (SiO<sub>2</sub>, TiO<sub>2</sub>, Fe<sub>3</sub>O<sub>4</sub>, luminescent polyelectrolyte, etc.) by consecutively assembling inorganic nanoparticles and polymer onto colloids (LbL technology) and subsequently removing the templated colloid (Fig. 5).<sup>[106]</sup>

## Polymer Hollow Capsules and Nanobottles

Recent advances in supramolecular chemistry have given chemists unprecedented control over the composition and shape of nanoscopic objects. An example of such development is the synthesis of nanometer-sized organic hollow spheres, which can find numerous

**Fig. 5** Illustration of procedures for preparing inorganic and hybrid hollow spheres. The scheme is shown for PS latex particles. Source: From Ref.<sup>[106]</sup>.

applications in drug delivery/targeting, extraction and as nanoreactors. Sun et al. described a new strategy for synthesizing nanometer-scale organic hollow spheres using Au colloids as templates.<sup>[107]</sup> The whole structure is held together by S–S bonds. Oxidation of gold nanoparticles protected by thiolated cyclodextrin molecules leads to the formation of water-soluble polycyclodextrin nanocapsules held together by S–S bonds. They are currently working on broadening the described strategy to other substrates/templates and probing the encapsulation properties of the hollow spheres.

Marinakos et al. described new methods for synthesizing nanometer-sized hollow capsules of poly(pyrrole), poly(*N*-methylpyrrole), and polyalkenes.<sup>[41,42]</sup> These methods utilized nanometer-sized gold particles as templates from which to grow polymer shells. Dissolution of the template particles yielded structurally intact hollow polymer capsules with interior volume and shell thickness governed by the diameter of the template particle and the polymerization time, respectively. Moreover, they showed that alkanethiols were encapsulated in the hollow polymer core by attaching them to the gold template particles prior to polymerization and particle etching, and small molecule diffusion rates through the pyrrole-based polymer capsules depended on polymer oxidation state. They also described a method for converting alkylthiolate monolayers on gold particles into hollow polymer capsules.<sup>[108]</sup> The synthetic design of the tripodal ligand provides the potential to ultimately control the functionality present on the surface of the particle as well as that present internally.

Marinakos et al. show that small molecules and enzymes can be trapped inside poly(pyrrole), poly(*N*-methylpyrrole), and poly-(3-methylthiophene) capsules synthesized using the gold particle template method.<sup>[1]</sup> Diffusion coefficients of small molecules through the capsule shell were found to vary by almost 3 orders of magnitude depending on the polymer, polymer oxidation state, and counter anion incorporated

during polymer synthesis. A small molecule (anthraquinone) and an enzyme (horseradish peroxidase) were trapped inside hollow capsules by attaching them to the template particle prior to polymerization and particle etching. A thin poly(pyrrole) shell protected the enzyme two times longer in neat toluene compared to unencapsulated enzyme. Finally, the potential for using conductive polymer nanoparticles for intracellular delivery or diagnostics was examined by administering particle suspensions to 3T3 murine fibroblasts. Particles ranging in size from 25 to 100 nm were engulfed by fibroblasts without compromising cell viability.<sup>[1]</sup>

Hollow polymer spheres synthesized from a vesicle-directed polymerization can be dried and redispersed in water using a variety of non-ionic ethoxylated alcohol surfactants as stabilizers.<sup>[109]</sup> The final dispersions consist of both polymer shells and surfactant micelles, which remain together in colloidal suspension for at least several months. Small-angle neutron scattering (SANS) is used to measure the polymer shell thickness (6.3 nm) and core radius (56 nm) of the surfactant-stabilized hollow polymer spheres in the presence of surfactant micelles.

Hollow polymer microsphere latexes were synthesized according to polymer–polymer core-shell emulsion polymerization then removing the core by selective solvents.<sup>[41]</sup> Kamata et al. have demonstrated a practical route to the facile synthesis of spherical hollow colloids of PBzMA that contained movable cores of Au nanoparticles (Fig. 6).<sup>[110]</sup> This procedure should be extendable to many other systems that involve the use of different combinations of materials for the core and the shell. These core-shell colloids may also find use as building blocks to form colloidal crystals with photonic band gap properties different from those of conventional core-shell or hollow particles.

Water-soluble polyelectrolyte nanocapsules as pH-sensitive nanocontainers can be synthesized by vesicular or emulsion polymerization via core-shell latexes.<sup>[111]</sup> These particles show a reversible pH and

**Fig. 6** (A,B) Backscattering SEM and (C,D) TEM images of Au-SiO<sub>2</sub>-PBzMA particles before (A,C) and after (B,D) HF etching. The polymerization time was 4 hr, and the polymer shell was ~22 nm thick. (E,F) TEM images of Au-Air-PBzMA particles synthesized using different polymerization times: (E) 3 hr and (F) 6 hr. The polymer shells were ~12 and ~32 nm in thickness, respectively. *Source:* From Ref.<sup>[110]</sup>.

ionic strength-dependent swelling transition causing a considerable increase (decrease) of their radius. During this transition, gated pores are opened (closed) in the spherical polymer shells, which enable free molecular exchange between the interior of the hollow sphere and the bulk medium. This pH-switchable control of the permeability of the polyelectrolyte envelopes can be used to trigger the release of encapsulated materials from their central cavity.

### Inorganic Hollow Capsules and Nanobottles

Previous studies have provided successful procedures for the preparation of composite particles consisting of inorganic and organic cores covered with shells of other inorganic materials by controlled surface precipitation processes.<sup>[85,112–114]</sup> Such composite particles may be useful in many applications because the properties (magnetic, optical, electric, adsorptive, etc.) of these particles can be altered by appropriate coatings. Other studies have also shown that these procedures can be used for the preparation of polymer particles covered with yttrium, zirconium, iron, and titanium compounds by controlled surface precipitation processes, which makes it possible to extend the use of these colloids to different areas of high technology.

Owing to their lower density, large specific surface area, and optical properties, hollow particles have been of interest as fillers, coatings, catalysts, capsule agents, etc. In a novel approach, it was shown that hollow inorganic colloidal spheres of narrow size distribution could be obtained by thermal decomposition of the polymer core of PS particles coated with yttrium,

zirconium, iron, and titanium compounds. Kawahashi and Shiho described the application of these processes to other systems. Thus, under certain conditions, copper compounds can be deposited uniformly on PS latexes by precipitation using solutions of the corresponding salts in the presence of urea. Hollow metallic copper and copper oxide particles of a narrow size distribution can be obtained by calcination of particles coated in this manner at elevated temperatures in nitrogen and air, respectively.<sup>[102]</sup>

Calcination of sulfate-stabilized PS latexes coated with nanoparticle/polymer multilayers results in the production of hollow silica spheres.<sup>[11,84]</sup> The calcination process removes the organic matter (the colloidal core and bridging polymer) during heating to 450°C, as confirmed by thermogravimetric analysis.

Hollow spheres of zeolite b and silicalite-1 with different sizes were fabricated efficiently and conveniently through LbL self-assembly of nanozeolite-polymer multilayers on PS latex, coupled with the removal of the core by calcination.<sup>[103]</sup> The pH and ionic strength of the colloidal solution, crystal size of nanozeolites, and size of PS latex templates are factors affecting the fabrication of hollow zeolite spheres. Hollow spheres of other zeolites such as ZSM-5 and TS-1 have also been successfully fabricated in the same manner. Currently, the application of these novel materials in catalysis, separation and delivery systems is in progress in our laboratory.

Fowler et al. prepared hollow silica microspheres in high yields by a one-step facile synthesis under ambient conditions.<sup>[34]</sup> By controlling the rate of TEOS hydrolysis specifically at the droplet/water interface, intact microspheres with uniform wall thickness and thermal stability can be routinely synthesized. The

procedure can be readily extended to the synthesis of organo-functionalized silica shells, microspheres with encapsulated organic pigment, and hollow silica capsules with submicrometer dimensions. Such materials could have a wide range of uses in diverse materials applications. And they reported the facile synthesis of thermally stable hollow spherical shells with ordered mesoporous walls, approximately 20 nm or less in thickness. The structures were synthesized at room temperature by hydrolysis and condensation of TEOS in an aqueous solution of cetyltrimethyl ammonium bromide (CTABr), which was subjected to rapid quenching by dilution followed by pH neutralization after an induction period.<sup>[35]</sup>

Novel fine polymer particles containing ultrafine Pd particles dispersed on the surface of core-shell [core, poly(styrene-*co*-acrylic acid); shell, PrPO<sub>4</sub>]-type microspheres were prepared by the emulsifier-free emulsion polymerization of styrene with acrylic acid followed by the addition of PdCl<sub>2</sub> and a mixture of Pr(NO<sub>3</sub>)<sub>3</sub> and NaH<sub>2</sub>PO<sub>2</sub>. Pyrolysis of the resulting polymer particles at 900°C provides organic polymer-free hollow capsules composed of Pd metal and PrPO<sub>4</sub>.<sup>[115]</sup>

Most work in this area has been focused on the development of synthetic methodologies. Very little attention has been directed toward the functionalization of the interiors of these hollow particles. In addition, there are only limited sets of reports that address the diffusion of chemical reagents across the shells of hollow particles. Yin et al. described a method based on template-directed synthesis for generating ceramic hollow spheres whose interior surfaces could be functionalized with the prespecified, nanoscopic objects.<sup>[96]</sup> The templates involved in this process were crystalline lattices of monodispersed polymer beads whose surfaces had been derivatized with functional objects such as nanoparticles, quantum dots, or other nanoscale objects. These nanoscopic objects were left behind on the interior surfaces of the hollow spheres when the templates were selectively removed through etching or calcination (Fig. 7).

On the other hand, nanosized hollow inorganic spheres with a hole in the wall (denoted as nanobottle) had been successfully prepared from the assembly of functional polymer nanosphere with tetraethoxysilane or tetrabutyl titanate, coupled with the removal of the cores by programmed calcination. Cross-linked polymer nanospheres with quaternary ammonium species on the surface were synthesized using an emulsifier-free emulsion copolymerization. The polymerization and purification were carried out according to a published procedure,<sup>[116]</sup> and cross-linked polymer nanospheres with a uniform size of about 45 nm were obtained. As-synthesized silica-coated polymer nanospheres were hydrothermally prepared from chemical assembly of TEOS with the functional polymer nanospheres.

**Fig. 7** Schematic outline of the experimental procedure. The polymer template could be either dissolved with a solvent or burnt out through calcination at elevated temperatures. *Source:* From Ref.<sup>[96]</sup>.

After calcination at 550°C, the polymer template was removed and hollow silica spheres were obtained (named as silica nanobottles). Figure 8 shows the TEM images of functional polymer nanospheres from emulsion polymerization process, as-synthesized silica microspheres, and calcined hollow silica samples. After the self-assembly of the silica gel with the functional polymer nanospheres, the as-synthesized silica microspheres also show a very uniform size at 52–55 nm (B), which are nearly 10 nm thicker than the polymer nanospheres.<sup>[117–120]</sup> Calcination of the as-synthesized silica spheres results in the complete removal of the polymer nanospheres, forming hollow nanospheres with the size of 50–53 nm (C). As shown in Fig. 8D, a hole with the size of 5–8 nm can be seen on the surface of some hollow silica microspheres. These results may suggest that the holes in the silica hollow microspheres are formed in the following steps: Calcination at 550°C leads to decomposition of polymer nanospheres to smaller gas molecules, which have high pressure in the closed hollow microspheres. Then the gaseous molecules with high pressure break through the shells of the hollow microspheres, and the hole in the silica hollow microsphere is formed (scheme as

**Fig. 8** TEM images of (A) polymer spheres, (B) silica spheres before calcination, (C) hollow silica spheres after calcinations, and (D) magnification of silica nanobottles. *Source:* From Ref.<sup>[121]</sup>.

Fig. 9). Therefore these silica hollow microspheres with the hole are referred to as *silica nanobottles*.<sup>[121]</sup>

The AFM observation of functional polymer nanospheres, as-synthesized silica microspheres, and calcined silica samples were carried out. Similar to the TEM images, the functional polymer nanospheres have a uniform size of 52–56 nm and as-synthesized silica microspheres show a bigger size of 58–62 nm (not shown here). In addition, it can be seen clearly in Fig. 10 that the surface of every shell contains one hole of 9–12 nm in diameter. Obviously, the sample size characterized by AFM is slightly larger than that by TEM technique, which could be explained by assuming that the probe does not follow the microsphere's surface precisely because of the blunt scanning tip. Interestingly, the AFM images also show that there are holes on the hollow microspheres and each hollow microsphere possesses only one hole, which is in good agreement with the images observed by TEM. These results further confirmed that the sample is a kind of *silica nanobottles*. The nitrogen adsorption–desorption isotherms of silica nanobottles and uncalcined silica-coated polymer microspheres are well measured.

The comparisons of adsorption results suggest that the calcined sample is a kind of opening hollow nanosphere (nanobottles). The relatively larger pore volume of silica nanobottles may be potentially useful for the encapsulation of functional compounds in the silica nanobottles.

### Composite Capsules

Hollow inorganic–organic composite spheres can be obtained by selection of a solvent that decomposes the templated core but leaves the polymer bridging the nanoparticles in the shell. The choice of solvent depends on the type of core employed; for example, acidic or dimethyl sulfoxide solutions cause the removal of MF polymer latex core templates, tetrahydrofuran the removal of some PS cores, and highly oxidizing solutions decompose proteinaceous cores.

Similar to the pure polymer shells, the nanoparticle/polymer multiplayer shell assembled onto MF particles obtained upon decomposition of the MF core by acid assumes a rather flat confirmation on the substrate

**Fig. 9** The procedure for preparation of silica nanobottles. *Source:* From Ref.<sup>[121]</sup>.

**Fig. 10** AFM height and amplitude images of silica nanobottles. *Source:* From Ref.<sup>[121]</sup>.

when dried.<sup>[84]</sup> Confocal microscopy images of the hollow composite microspheres again show that the shells often maintain their spherical shape in solution. Interestingly, permeating the nanoparticle/polymer shell still readily expels the oligomers produced as a result of decomposing the MF particles. Higher magnification TEM reveals that the shell is composed of nanoparticles embedded in the polymer matrix.

Nanoparticle/polymer-coated biocolloids (gluteraldehyde-fixed echinocytes) can also be utilized for the production of composite hollow structures. The template has a jagged and highly structured surface. After the removal of the core by exposure to deproteinizer, hollow composite silica/polymer capsules are obtained. Unlike the polymer or nanoparticle/polymer shells produced by the removal of MF-templated cores by acid solutions, these hollow structures mimic the original shape, including the secondary structure (spikes) of the templates, and do not significantly spread-out on the surface when dried. This is most probably due to the gelation of the silica particles as a result of the decomposing solution. SEM experiments confirmed that these structures were hollow.

### ENCAPSULATION OF RARE EARTH COMPLEX IN NANOBOTTLES

The abovementioned silica bottles are nanosized materials and there is a hole on the surface of it, which may be useful for further encapsulations. Rare earth (RE) complex  $\text{Eu}(\text{TTA})_3(\text{TPPO})_2$  (TTA: 1-(2-thenoyl)-3,3,3-trifluoroacetate, TPPO: triphenyl phosphineoxide) was selected as a guest molecule. After the modification of silica nanobottles with APTES ( $\text{NH}_2-(\text{CH}_2)_3\text{Si}(\text{OC}_2\text{H}_5)_3$ ),<sup>[122]</sup> the RE complex was mixed

with the silica nanobottles in chloroform, followed by filtering and washing with chloroform until the filter liquors gave no luminescence under UV radiation.

After RE complex encapsulation, the SEM images of silica nanobottles give most like morphology as before encapsulation, indicating that the silica nanobottles still remained after the encapsulation of RE complex. Furthermore, the encapsulation of  $\text{Eu}(\text{TTA})_3(\text{TPPO})_2$  in nanobottles was characterized by energy dispersive X-ray analysis (EDX). The results indicate that RE complex still exists in silica nanobottle samples after careful washing. Fig. 11 shows UV-visible absorption

**Fig. 11** UV-Visible absorption spectra for (A) the modified silica nanobottles itself, (B) the assembly of  $\text{Eu}(\text{TTA})_3(\text{TPPO})_2$  in modified silica nanobottles, (C)  $\text{Eu}(\text{TTA})_3(\text{TPPO})_2$  absorbed on the outer surface of as-synthesized silica-coated polymer spheres (after washing with chloroform many times), and (D) RE complex  $\text{Eu}(\text{TTA})_3(\text{TPPO})_2$ . *Source:* From Ref.<sup>[121]</sup>.

spectra of silica nanobottles, RE complex  $\text{Eu}(\text{TТА})_3(\text{TPPO})_2$  encapsulated in silica nanobottles, and  $\text{Eu}(\text{TТА})_3(\text{TPPO})_2$  adsorbed on the outer surface of as-synthesized silica-coated polymer microspheres (after washing with chloroform many times) as well as RE complex  $\text{Eu}(\text{TТА})_3(\text{TPPO})_2$  itself. The spectrum of silica nanobottles does not show any absorption in the region of 200–800 nm (a); the sample spectrum of RE complex encapsulated in silica nanobottles shows clear peaks at near 255, 292, 330, and 348 nm (b); the spectrum of RE complex adsorbed on the outer surface of silica nanobottles only shows very weak absorptions after careful washing, and is similar to that of RE complex (c); the spectrum of  $\text{Eu}(\text{TТА})_3(\text{TPPO})_2$  shows typical peaks at 241, 325, and 436 nm (d). From the contrast of the above spectra, it can be confirmed that RE complex adsorbed both the inner and outer surface of the hollow microspheres. In addition, the peaks of RE complex are shifted to a lower wavelength in silica nanobottles. This phenomenon is possibly assigned to the encapsulation of RE complex in silica nanobottles, which is consistent with those of RE complex entrapped in mesopores of MCM-41 and in microcages of zeolite Y.<sup>[123,124]</sup>

## CONCLUSION

Research efforts over the last decade have led to a host of new strategies being developed for the modification of particle surfaces. Earlier methods have primarily focused on achieving single-component coatings on particles through surface chemical modification and conventional polymerization and precipitation reactions. More recent approaches, particularly those based on solution self-assembly, have been shown to be highly effective in producing multicomposite, nanostructured coatings. These methods permit remarkable control over the coating uniformity and thickness, and thus the assembled components and experimental conditions can be readily manipulated to prevent the aggregation of the coated colloids. Although the method of choice highly depends on the coating required and the end use of the composite particles, the synthetic approaches outlined provide a high level of flexibility, thus allowing the design, structure, and properties of the resultant particles to be varied tremendously. In addition, combinations of these methods are likely to allow new functional and composite layers to be manufactured on the surfaces of particles. Accordingly, nanoengineered core-shell particles are expected to find new and exciting applications in the chemistry, bioscience, and materials science fields. Core-shell particles have already been assembled into colloidal crystals for photonic

applications, used as heterogeneous catalysts and multienzyme biocatalysts, and in surface enhanced Raman scattering applications.

An interesting extension of the composite particles is the production of hollow capsules by the removal of the core particle; these hollow materials may find applications in drug delivery, or as reactor or specific recognition systems. The successful production of such hollow capsules opens many new and exciting avenues in the areas of chemistry, biotechnology, and materials science. They are potentially suitable for a variety of applications including the loading of drugs, as confined environment reactor systems, and for targeting by utilization of the surface functionalities on the capsule walls to attach specific receptors. Controlling the thickness and composition of the capsule walls should allow selective and switchable permeation for the encapsulation and release of various substances. The use of cross-linkable, pH- or temperature-sensitive polymers as capsule wall constituents are attractive candidates for controlling and varying the permeability, while the incorporation of specific reactive groups inside the capsule walls would allow specific chemistry to be carried out in these systems. Coupling of biospecies to the surfaces of the capsules through functional groups would provide biofunctionalized capsules.

Some experiments demonstrate that it is possible to coat the outer and inner surfaces of hollow polymer capsules with phospholipid bilayers. The polymer capsules are permeable to small low molecular weight dyes, but not to polyelectrolytes with molecular weights greater than 4000 or molecules larger than 5–10 nm in diameter. The phospholipid coating reduces the permeability to small organic dyes. The precipitation of small organic dye molecules inside polymer capsules has been achieved, as has the solubilization of various organic solvents. Functional biomolecules have also been encapsulated at a very high loading capacity in polymer capsules; these systems are expected to be used in enzyme catalysis applications. The coating technique is currently being extended to inorganic templates to create novel hollow capsules of nanometer size and to emulsion-based systems. A luminescent RE complex is successfully encapsulated in silica nanobottles, showing this material has potential nanotechnology applications.

# Cubosomes: Bicontinuous Liquid Crystalline Nanoparticles

Patrick T. Spicer

Complex Fluids Research, Procter & Gamble Company,  
West Chester, Ohio, U.S.A.

## INTRODUCTION

Surfactants, lipids, and polymer molecules that have both polar and non-polar components are termed amphiphilic. The hydrophobic effect drives amphiphilic molecules in polar solvents to spontaneously self-assemble into a rich array of thermodynamically stable lyotropic liquid crystalline phases with characteristic lengths on the nanometer scale. Liquid crystalline phases possess a sufficient average degree of molecular orientational order to be characterized by their structural symmetry, despite their liquid state, and often form in aqueous surfactant systems at relatively high amphiphile concentrations. An interesting example of contemporary interest is the bicontinuous cubic liquid crystalline phase.

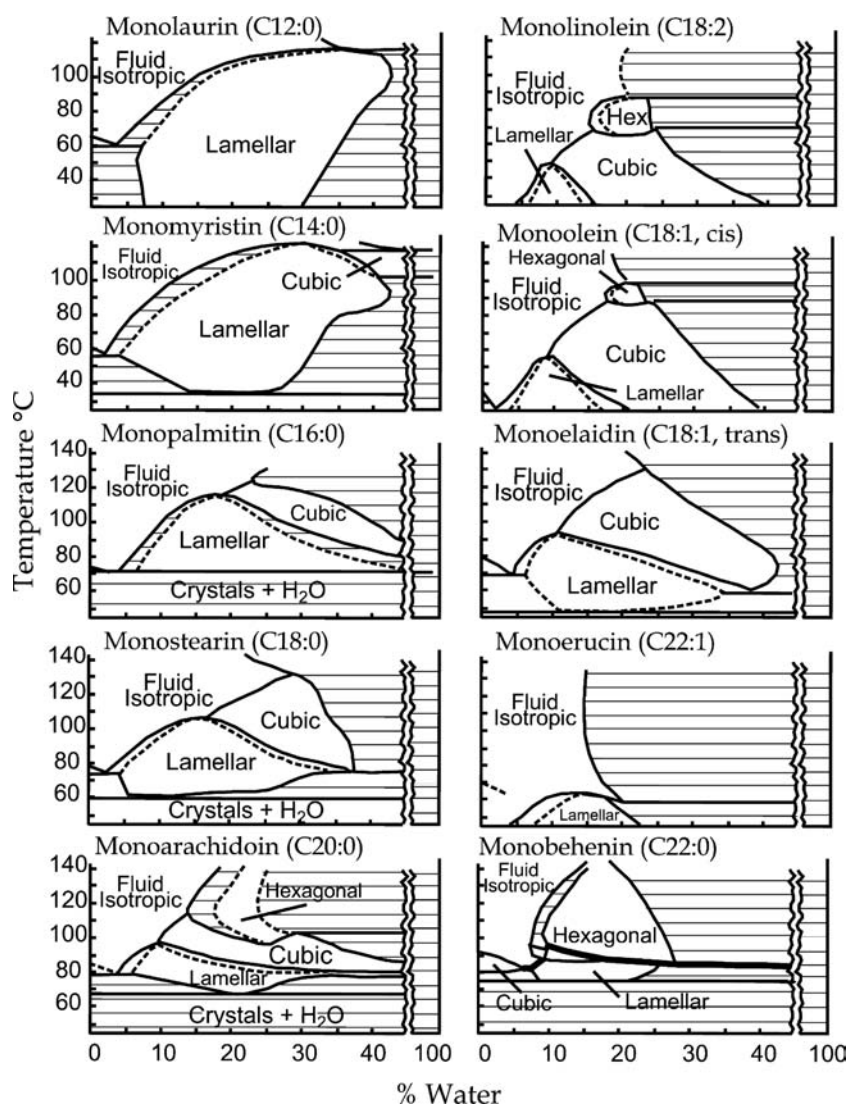

Bicontinuous cubic phases are optically isotropic, very viscous, solidlike liquid crystals with cubic crystallographic symmetry. Prior to their structural characterization, these phases were termed “viscous isotropic phases” and considered quite a nuisance in industrial processes. Bicontinuous cubic phases consist of two separate, continuous but non-intersecting hydrophilic regions divided by a lipid bilayer that is contorted into a periodic minimal surface with zero average curvature. The phase’s regular structural connectivity results in a very high viscosity, whereas its tortuosity is useful for slowing diffusion in controlled transport applications. The bicontinuous nature of such cubic phases distinguishes them from the so-called micellar or discontinuous cubic phases containing micelles packed in cubic symmetry. In this work, all references to cubic phases refer to bicontinuous cubic phases, unless otherwise noted.

The last several decades have brought about a great understanding of the properties of cubic phases and a realization of their relevance in areas such as medicine, biology, and chemistry. An intriguing property of the cubic phases formed by certain classes of amphiphiles is their ability to be dispersed into particles, termed cubosomes. Cubosomes are liquid crystalline nanostructured particles with the same unique properties of the bulk cubic phase, although cubosome dispersions have much lower viscosity. Although fundamental research has been focused sharply on bulk cubic phases, it is commercial applications that drive much

of the existing and still very active research into cubosomes. This entry reviews historical research into cubic phases and cubosomes, describing the initial discovery and the realization that differential geometry allows the mathematical characterization of cubic phase structures. Cubosome properties are reviewed in the context of particle formation and applications. Where appropriate, interesting open problems are cited and discussed.

## CUBIC PHASE STRUCTURE

Luzzati and Husson<sup>[1]</sup> and Luzzati et al.<sup>[2]</sup> first recognized the existence of cubic phases in lipid–water systems using x-ray scattering measurements. Fontell, Mandell, and Ekwall<sup>[3]</sup> drew similar conclusions regarding cubic phases in ternary systems of amphiphiles, oils, and water. In parallel, although without apparent awareness of the lipid work, biologists began documenting structures with cubic symmetry in plant leaf plastid membranes,<sup>[4]</sup> identical to what is now accepted as cubic liquid crystalline phase structures. Around the same time, Lutton<sup>[5]</sup> published a comprehensive study of the aqueous phase behavior of monoglycerides. Monoglycerides are polar lipids with poor water solubility that exhibit aqueous phase behavior, reflecting their structural similarity to nonionic surfactants. Fig. 1 shows a schematic of Lutton’s results for monoglycerides with hydrocarbon chain lengths between  $C_{12}$  and  $C_{22}$ . Of particular interest is the large region of cubic phase exhibited by each of the aqueous monoglyceride systems, with the largest being that of monoolein, the unsaturated  $C_{18}$  monoglyceride (Fig. 2). Cubic phases are often found sandwiched between lamellar and hexagonal liquid crystalline phases, especially in nonionic surfactant systems.<sup>[6]</sup> However, the monoolein–water system uniquely possesses a cubic phase region spanning large compositional and temperature ranges. It is not entirely clear why monoolein forms cubic phases in such broad compositional and temperature ranges, but surfactant packing concepts offer some conceptual approaches. Monoolein has a slightly larger cross-sectional area of its hydrophobic tail region, leading to a ratio of the hydrophobic tail group area to the

**Fig. 1** Schematic of the aqueous phase behavior of the monoglycerides showing the regions of cubic phase formation. Source: From Ref.<sup>[5]</sup>. © American Oil Chemists' Society, 1965.

hydrophilic head group area slightly larger than one ( $\sim 1.03$ ,<sup>[7]</sup>). As a result, the cubic phases are often referred to as reversed or inverse cubic phases, indicating the curvature of the constituent bilayers toward the polar medium. Shortly after Lutton's study, Larsson began to systematically examine the structure of aqueous monoglyceride cubic phases using x-ray diffraction. He found, using nuclear magnetic resonance (NMR) and x-ray, that the cubic phases have continuous regions of both hydrophobic and hydrophilic nature<sup>[8]</sup> leading to the conclusion that the cubic phase structures can be described using the concepts of differential geometry and periodic minimal surfaces.<sup>[9]</sup>

Minimal surfaces are best described by analogy with their most readily observed natural form: soap films. The surface formed by a soap film between two rings is a catenoid, a simple form of minimal surface whose two principal curvatures are equal but opposite in sign at every point, resulting in an average curvature of zero and a negative Gaussian curvature.<sup>[10]</sup> Fig. 3 shows approximate plots of the three most commonly studied minimal surfaces in cubic phases. The surfaces in Fig. 3 are particularly fascinating because their discovery was purely mathematical, prior to knowledge of the structures' existence in cubic phases. The P-surface (or primitive surface) and the D-surface (or diamond surface) were both discovered mathematically by Schwarz

**Fig. 2** Molecular structure of monoolein, the lipid most commonly used to form cubosomes.

**Fig. 3** Unit cubes of the P-surface, G-surface, and D-surface formed in bicontinuous amphiphilic systems.

in 1890, whereas the G-surface (or gyroid surface) was only discovered by Schoen<sup>[11]</sup> in the 1960s. In cubic phases, the minimal surface is formed by the self-assembled bilayer that occurs as the hydrophobic or hydrophilic portions of the surfactant molecules line up to minimize their interaction with their opposites. The three structures are all bicontinuous (i.e., they divide space into two continuous but non-intersecting regions); in the case of cubic phases, two separate regions of hydrophilic material (water channels) form. Following suggestions by Scriven<sup>[12]</sup> that minimal surfaces could explain liquid crystal structure, Larsson, Fontell<sup>[9]</sup> applied the minimal surface description to the cubic phase observed in the monoolein–water system and noted the connection to the structures formed in plastid systems. However, Longley and McIntosh<sup>[13]</sup> found evidence of an alternative symmetry in the monoolein–water cubic phase, leading Larsson<sup>[14]</sup> to realize that two cubic phases are formed, both with minimal surface structures. The monoolein–water system forms the D-surface at high water levels and the G-surface at lower levels, as shown in the phase diagram in Fig. 4.<sup>[15]</sup> Qiu and Caffrey<sup>[16]</sup> later updated

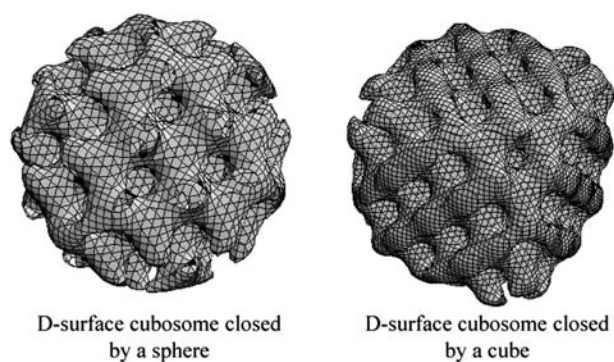

**Fig. 4** Aqueous phase behavior of the monoolein–water system, updated to reflect the existence of two cubic phases. Source: From Ref.<sup>[23]</sup>. © American Chemical Society, 1989.

elements of the monoolein–water phase diagram, but the version put forth by Larsson (Fig. 4) remains the benchmark. The P-surface is formed in the monoolein–water system, but only when a third component, such as caseins<sup>[17]</sup> or amphiphilic block copolymers,<sup>[18]</sup> is added. The strength of the minimal surface approach to cubic phase characterization is its quantitative mathematical basis. Unfortunately, the analytical representation of minimal surfaces in Fig. 3 is still mathematically very difficult. A significant advance came in the discovery that nodal surfaces are closely related to minimal surfaces and offer a simple equation that can be used to plot and study cubic phase structures.<sup>[19]</sup> The structures plotted in Fig. 3 are generated using nodal surfaces and the equations used are also shown. Extensive reviews of the history and mathematical description of bicontinuous phases are given in Refs.<sup>[20]</sup> and <sup>[21]</sup>, whereas a more recent review<sup>[22]</sup> generally discusses bicontinuous geometry in amphiphilic systems. Contemporary with the discovery of minimal surface applicability to cubic phases was the realization that, in certain cases, the cubic phases can exist in a particulate form, possessing the same bicontinuous structure as the bulk cubic phase.

## CUBOSOMES—DISPERSED CUBIC PHASE PARTICLES

Dispersed particles of bicontinuous cubic phases were first observed during studies of fat digestion that simulated stomach contents by combining oil with lipase and bile salts.<sup>[23]</sup> Olive oil droplets, mainly triolein, in contact with lipase formed small particles of cubic phases as the enzyme broke the triglyceride down into monoolein that then hydrated. Lindstrom et al.<sup>[24]</sup> studied the phenomenon further, observing that sodium cholate bile salts provided dispersion and colloidal stability of the cubic phase particles formed by monoolein and water, and that such particles formed in other ternary systems as well. One of the first published instances of the word “cubosome” appears in a review by Larsson<sup>[25]</sup> of the implications of bicontinuous cubic phases to biological membranes. Later research on cubosomes focused on the ternary phase behavior of the Poloxamer 407 (a PEO<sub>99</sub>–PPO<sub>67</sub>–PEO<sub>99</sub> block copolymer)–monoolein–water system because of the polymer’s utility at providing colloidal stability to cubosomes against recoalescence to bulk cubic phase.<sup>[18]</sup> The PPO region of the block copolymer exists either at the surface of the cubic phase particles, or within the bilayer structure, whereas the PEO chains remain in the bulk water phase. Landh<sup>[18]</sup> observed cubosome formation in a three-phase region including disordered bicontinuous ( $L_3$  or sponge) phase, cubic phase, and water. Cubosome structures,

**Fig. 5** Calculated nodal surface representations of a D-surface cubosome closed off on its surface with a sphere and a cube.

such as bulk cubic phases, are critical elements of some biological processes and occur naturally in bacterial cells, for example.<sup>[26]</sup>

Just as bulk cubic phases can be mathematically characterized using nodal surface approximations, so, too, can cubosomes. Andersson et al.<sup>[27]</sup> model different cubosome structures by extending nodal surface descriptions<sup>[19]</sup> to describe closed-off surfaces such as those formed by cubosomes. Fig. 5 shows two examples of such simulated cubosomes, in this case a D-surface that has been closed off on its surface by a sphere and by a cube. A comprehensive overview of the structures that can be simulated by such techniques is given by Jacob and Andersson.<sup>[28]</sup> Many experimental studies of cubosomes utilize cryo-transmission electron microscopy (TEM) micrographs that allow the visualization of cubosome particles and the verification of their lattice symmetry, although x-ray measurements are required to confirm phase structures. Cryo-TEM allows the visualization of hydrated phase structures by vitrifying, instead of freezing, the sample in a thin film suspended between polymer-coated grid struts.<sup>[29,30]</sup> Insight into bulk cubic phase structure has also been gained in some cases by freeze-fracture electron microscopy.<sup>[31,32]</sup> More recent work has shown the possibility of *in situ* study of cubosomes using atomic force microscopy.<sup>[33]</sup>

Although small amounts of cubosomes are apparently produced by simple addition of dispersing agents such as sodium cholate to bulk cubic phase,<sup>[24]</sup> mechanical dispersion of bulk cubic phase is the most studied and most direct cubosome formation technique. Gustafsson et al.<sup>[34,35]</sup> formed cubosomes by high shear microfluidization and ultrasonication of bulk cubic phase in contact with aqueous Poloxamer 407. The cubosomes produced exhibit the P-surface structure based on x-ray diffraction and, interestingly, resemble cubes despite their nonsolid nature. The molecular-scale cubic symmetry of the lipid bilayer comprising

**Fig. 6** Cryo-TEM micrograph of cubosomes and vesicles formed by ultrasonic dispersion of bulk cubic phase in aqueous Poloxamer 407 solution. *Source:* From Ref.<sup>[36]</sup>. © American Chemical Society, 2001.

cubosomes is thus manifested in the nanometer-scale cubosome particles, although their appearance is often orientation-dependent.<sup>[34,36]</sup> An example of the different types of particles formed by ultrasonication of bulk cubic phase in aqueous Poloxamer 407 solution is seen in Fig. 6, a cryo-TEM micrograph of the dispersion. The particles range in size from about 10 to 500 nm in diameter. Cubosomes are immediately identifiable as square particles with a well-defined cubic lattice of dots. Each dot corresponds to the presence of a pore-containing aqueous phase. Along with well-formed cubosomes, more disordered cubosomes that have a more spherical shape are also visible. Gustafsson et al.<sup>[34]</sup> point out that the absence of grain boundaries in the cubosomes indicates they are single-crystal structures. Unilamellar vesicles, dispersed lamellar liquid crystalline phase particles, are also visible in Fig. 6. Increased polymer-to-monoolein ratios lead to the formation of larger ratios of vesicles to cubosomes. Such vesicles often form during the dispersion of bulk cubic phase, despite the fact that the lamellar phase is not an equilibrium phase at these conditions. Ultrasonication of bulk cubic phase produces mostly vesicles<sup>[34]</sup> that, over the course of several weeks, transform into cubosomes, likely via membrane fusion. Such metastability is characteristic of cubosome systems because of the slow transport processes involved in forming the high-viscosity crystalline structure and the high-energy input required to fragment bulk cubic phase. Distinct from the dispersed vesicles, the surfaces of some of the cubosome particles have

hemispherical vesicle structures that are thought to block the exposure of the hydrophobic bilayer at the termination of the cubosome edge structure but may also aid in colloidal stabilization of the cubosomes.<sup>[35,37]</sup> Gustafsson et al.<sup>[35]</sup> were able to shift the cubosome structure between the P-surface and the D-surface by varying Poloxamer 407 concentration. Although cubosomes have been feasibly produced in various laboratory settings for years, the desire to apply cubosomes in various commercial products spurs current research interest in cubosome production.

## CUBOSOME MANUFACTURE

At its most basic, the production of cubosomes entails the formation of nanoparticles. Two distinct nanoparticle production routes exist: top-down and bottom-up techniques. Most cubosome research over the last two decades has focused on top-down techniques, whereby bulk cubic phase is first produced and then dispersed by high-energy processing into cubosome nanoparticles. No systematic study exists of the effect of power input on bulk cubic phase dispersion, but existing rheological work offers some insight into the energy required to form cubosomes.

Bulk cubic phase resembles a clear rigid gel formed by water-swollen cross-linked polymer chains, but cubic phases differ in that they are a single thermodynamic phase and display periodic liquid crystalline structure. Studies<sup>[38,39]</sup> of the P-surface and D-surface cubic phases formed by several didodecyldimethylammonium bromide (DDAB)-oil-water systems found the phases to behave as viscoelastic fluids that exhibit relatively constant modulus values until the lattice structures break down around 1–5% strain. Rupture of the cubic phases occurs in a direction parallel to the shear direction and the energy required is proportional to the number of tubular network branches that rupture. Warr and Chen<sup>[40]</sup> found that rupture of the cubic phase occurs as the bilayer breaks under applied shear stresses and flows along slip planes. The cubic phases exhibit a yield stress that increases with increasing amounts of bilayer-forming surfactants and oils, and that is inversely proportional to the crystalline unit cell dimension.<sup>[40]</sup> Warr and Chen<sup>[40]</sup> also suggested but could not confirm that cubic phases may behave as lamellar phases do during dispersion with increasing shear: dispersed liquid crystalline particles form at intermediate shear rates, whereas a defect-free bulk phase re-forms at higher shear rates. At high oscillatory frequencies, cubic phases become highly elastic<sup>[38]</sup> and may be more apt to fracture than deform. A worthwhile study would be the correlation of energy input with the cubic phase breakage

mechanism most feasible for a given deformation rate. Different breakage mechanisms could correlate with cubosome yield.

Unfortunately, most existing studies provide little insight into the mechanisms underlying cubosome formation by energetic dispersion of bulk cubic phases. Comparison of the dispersions produced by sonication and high-pressure homogenization suggests the formation of complex dispersions containing vesicles and cubosomes with time-dependent ratios of each particle type. Coarse cubosomes on the micron scale possess the same D-surface cubic structure as their originating bulk cubic phase,<sup>[41]</sup> but after homogenization, the P-surface dominates, either because of the added polymer or other factors.<sup>[34]</sup> Based on such studies, it has been suggested that high-energy dispersion processes destroy the structure of bulk cubic phases, creating vesicles that then must fuse their bilayers to form ordered cubosomes.<sup>[41]</sup> However, no quantitative conclusion can be drawn without a systematic study of the effects of the fundamental parameters of a dispersion process. Fluid shear stresses, temperature changes induced by sonication, and pressure<sup>[42,43]</sup> all affect cubic phase and thus cubosome formation in different ways.

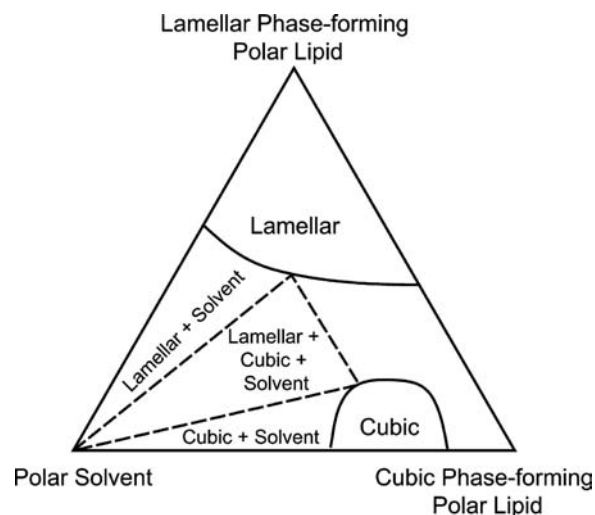

More recent work has examined the development of bottom-up methods of cubosome formation, allowing cubosomes to form and crystallize from precursors on the molecular length scale. Almgren et al.<sup>[30]</sup> discuss the formation of cubosomes by dispersion of L<sub>2</sub> or inverse micellar phase droplets in water at 80°C, then by slow cooling to allow the droplets to gradually crystallize into cubosomes. Large-scale production of cubosomes and products containing them requires more robust processes. Spicer et al.<sup>[36]</sup> developed a room temperature process to produce cubosomes by simply diluting monoolein-ethanol (or other hydrotrope) solutions with aqueous Poloxamer 407 solutions. The cubosomes have been shown to form by spontaneous emulsification,<sup>[44]</sup> producing nanoparticle dispersions in the near absence of energy input beyond that required for simple blending of the two liquids. Smaller and more stable cubosomes are produced than those by high-energy processes, but some vesicles are also produced.<sup>[36]</sup> A second process was also developed to allow cubosome production from a powdered precursor.<sup>[45]</sup> Spray-dried powders comprising monoolein coated with starch or dextran form cubosomes on simple hydration. Colloidal stabilization of the cubosomes is immediately provided by the polymers. An example of a cubosome formed in such systems is shown in Fig. 7. The large unfolded bilayers that form in such cases may be stabilized by polymer-induced osmotic, steric, or viscous forces,<sup>[45]</sup> identical to the higher fraction of surface vesicles observed in the Poloxamer 407-Monoolein-water system.<sup>[35]</sup>

**Fig. 7** Cryo-TEM micrograph of cubosome formed by hydrating starch-encapsulated monoolein particles. *Source:* From Ref.<sup>[45]</sup>. © Kluwer Academic Publishers, 2002.

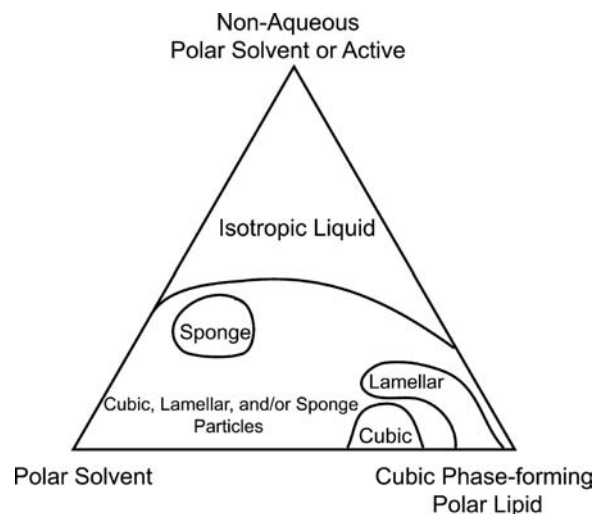

## SYSTEMS FORMING CUBOSOMES

The formation of cubosomes is possible in binary and ternary systems with a sufficiently large miscibility gap between the cubic phase and the solvent. Colloidal stabilization of cubosomes is good when Poloxamer 407 is used to provide steric stabilization against aggregation and coalescence, but other suitable polymers can be used as well. Earlier studies<sup>[37]</sup> advocate mixing vesicles and cubosomes produced by fragmentation of bulk lamellar and cubic liquid crystalline phases in excess water, respectively. The coating of cubosomes with lamellar bilayer “caps” covers the cubic bilayer openings formed by fragmentation, preventing exposure of hydrocarbon chains to water and providing limited colloidal stability. Coating the cubosomes with solid crystalline bilayers provides superior colloidal stability to lamellar liquid crystalline coatings, although such rigid coatings limit the lowest diameter of the cubosomes to 100 nm, rather than the absolute minimum of 50 nm, because of curvature restrictions.<sup>[37]</sup> In addition, coatings of the sponge phase have been proposed as a stabilizing coating for cubosomes.<sup>[37]</sup> Figs. 8 and 9 show schematics of the two general forms of ternary phase diagrams exhibited by systems forming cubosomes. For ternary systems of lamellar phase-forming polar lipids, cubic phase-forming polar lipids, and water (Fig. 8), cubosomes form in the two-phase region of equilibrium between the cubic phase and water or solvent, whereas vesicles form in the two-phase region between the lamellar phase and water. The three-phase region between the lamellar,

**Fig. 8** Schematic of the typical ternary phase diagram exhibited by systems containing a lamellar phase-forming polar lipid, a cubic phase-forming polar lipid, and water. *Source:* From Ref.<sup>[37]</sup>.

cubic, and water phases is likely to contain both vesicles and cubosomes. Similarly, for ternary systems containing cubic phase-forming polar lipids, a non-aqueous polar solvent or an active ingredient (such as a drug), and water, a sponge phase often forms in the general area indicated in Fig. 9.<sup>[46]</sup> In such cases, cubosomes form in the two-phase region of equilibrium between the cubic phase and water or solvent, whereas cubosomes, vesicles, and/or sponge phase particles may form in the multiphase regions between the cubic phase, sponge phase, lamellar phase, and water.<sup>[36]</sup> Currently, the only well-documented instances of cubosome formation are in systems containing monoolein. There is no reason why other

**Fig. 9** Generalized ternary phase diagram for systems containing a cubic phase-forming polar lipid, a non-aqueous polar solvent, and water.

**Fig. 10** Molecular structure of phytantriol, the second most commonly used amphiphile for forming cubosomes.

similar surfactant systems should not form cubosomes, provided that a sufficient miscibility gap exists between the bicontinuous cubic phase and the solvent. One molecule with great potential for cubosome formation is phytantriol (Fig. 10), a commonly used additive in consumer products such as sunscreens. Several patents have emerged citing the formation of cubosomes in phytantriol–water systems,<sup>[47–49]</sup> but no published phase diagram is known. However, a simple swelling experiment offers insights into the aqueous phase behavior of phytantriol. Figs. 11 and 12 show partially polarized light micrographs of the interfaces formed on contacting a small droplet of monoolein (Fig. 11) and phytantriol (Fig. 12) with excess water. In both cases, interfaces that separate the amphiphile from the optically birefringent lamellar phase, and two distinct optically isotropic cubic phase regions are visible. Although such experiments are qualitative, the similarity between monoolein and phytantriol is striking and fortuitous, suggesting the need for more quantitative assessment (e.g., using the Diffusive Interfacial Transport (DIT) technique<sup>[50]</sup>) of the phytantriol–water system. Some glycolipids<sup>[51,52]</sup> also exhibit the cubic–water miscibility gap required for cubosome formation, and confirmation should be relatively simple. Ultimately, much of the future work on

cubosomes will be driven by the most financially compelling applications.

## APPLICATIONS

### Controlled-Release Drug Delivery

Controlled release of solubilized actives is the most popular application pursued by cubosome researchers, and excellent reviews exist of attempted delivery applications as well as pharmaceutical actives that have been solubilized in bulk cubic phase<sup>[53]</sup> and cubosomes.<sup>[54]</sup> Cubic phase is attractive for controlled release because of its small pore size (ca. 5–10 nm); its ability to solubilize hydrophobic, hydrophilic, and amphiphilic molecules; and its biodegradability by simple enzyme action.<sup>[55]</sup> Cubic phase is strongly bioadhesive<sup>[56]</sup> and is thought to be a skin penetration enhancer,<sup>[57]</sup> suggesting excellent compatibility with topical and mucosal deposition and delivery of active ingredients. Recent studies<sup>[58,59]</sup> have emphasized similarities between the bicontinuous structures formed in human skin layers and those comprising cubic phases, offering the promise of better skin transport understanding and treatment. The tortuous structure of cubic phase lends itself well to slowing diffusive release of solubilized actives. Theory predicts the minimum reduction of a solute's free solution diffusivity by 33%.<sup>[60]</sup> Experimental measurements of small molecule diffusivity in cubic phases give values on the order of  $10^{-10}$  m<sup>2</sup>/sec.<sup>[61]</sup> No commercial applications of cubic phase delivery vehicles are known other than a treatment developed for periodontal disease that is based on triglyceride–monoolein mixtures combined with

**Fig. 11** Polarized light micrographs of the aqueous phase progression exhibited by monoolein in excess water.

**Fig. 12** Aqueous phase progression of phytantriol in excess water. The sequence of phases is qualitatively identical to that of monoolein (Fig. 11).

the drug metronidazole.<sup>[62]</sup> The lipid–drug mixture forms a low-viscosity liquid that, when applied to the gums and placed in contact with saliva, hydrates to form a bulk cubic phase that then delivers the drug to the gum. Despite the potential of bulk cubic phase as a delivery vehicle, some applications are not compatible with the extremely high viscosity of the bulk cubic phase and require the use of cubosomes.

Cubosomes prepared in dispersions possess a nanometer-scale structure identical to bulk cubic phase, but the dispersion itself has a much lower, waterlike viscosity. Compared to liposomes or vesicles, cubosomes possess much higher bilayer area-to-particle volume ratios as well as higher viscous resistance to rupture. Although bulk cubic phase has sufficient length scale to allow controlled release of solutes, cubosomes are too small and have too high a surface area for such performance, exhibiting instead burst release.<sup>[63]</sup> Turning this concept around, cubosomes should be quite useful for *uptake* instead of release because they can rapidly absorb pollutants (e.g., for water treatment or cosmetic skin protection) and retain an amount determined by the solute partition coefficient.<sup>[47–49]</sup> For example, oleic acid-containing cubosomes change from cubic phase to hexagonal phase with a drop in pH, indicating a relatively rapid response of the cubosome interior to the outer fluid environment.<sup>[64,65]</sup> Although the above controlled-release limitations exist for small molecule solutes and unmodified cubosomes, other routes may still exist for controlled-release applications of cubosomes. For example, large poly(amidoamine) dendrimer molecules exhibit a 100 × reduction in free diffusivity when entrapped in cubic phases.<sup>[66]</sup> Modification of the cubic

phase environment is also a potential method of regulating solute transport. Puvvada et al.<sup>[67]</sup> find that aqueous alginate molecules can be gelled in cubic phase pores by ionic strength changes, increasing local viscosity and drastically slowing active release. Other studies have found that the partitioning and release kinetics of ionic solutes in cubic phases are significantly altered by incorporating oppositely charged surfactants into the cubic bilayers.<sup>[68,69]</sup> In such cases, the functionalizing surfactant must be chosen carefully to avoid disturbing the cubic phase structure, but guidelines exist for additive selection.<sup>[69]</sup> The contorted but regular structure of the cubic phases is also of interest to material science researchers as a template for complex solid materials.

## Materials Synthesis

From a materials science perspective, the creation of ordered structures with nanoscale pore geometries is of great interest to numerous fields including electronics, photonics, catalysis, and medicine. The creation of solid structures using cubic phases as a template usually entails either polymerization or reaction to form solids from precursors that are solubilized in, or comprise, the cubic phase matrix. One of the earliest and most successful materials formed in a cubic phase template is the aluminosilicate zeolite MCM-48,<sup>[70]</sup> used for catalytic processing of petroleum. Yang, O'Brien, and Marder<sup>[71]</sup> successfully carried out polymerization inside cubosomes, yielding a solid nanostructured particle with cubic symmetry. Such particles hold promise for use in photonic and

semiconductor applications.<sup>[72]</sup> Lu et al.<sup>[73]</sup> have developed novel aerosol processes that create particles with nanometer-scale structure by evaporation of solvent from isotropic phase liquid droplets, simultaneously driving them into cubic phase structures and solidifying the particles. As sophistication in the cubic phase template area builds, optimization of the structures will be a leading interest area. Along these lines, Larson<sup>[74]</sup> suggests the possibility of aligning the cubic phases by steady or large-amplitude oscillatory shearing prior to templating, forming materials with unique and highly anisotropic properties. Beautiful structures have been formed using careful growth of faceted cubosomes in the  $C_{12}E_2$ -water system,<sup>[75]</sup> offering future promise of multiple-decade length-scale control over the morphology of particles formed from such templates.

## OPEN PROBLEMS

The creation of cubosomes and other liquid crystalline nanoparticles is still an open and active area of research. Numerous applications as well as fundamental insights into behavior and performance regularly emerge. As a result, many open problems remain to be examined and solved by intrepid researchers, including some described in the above sections. An especially interesting area is the formation of dispersions of other liquid crystalline phases besides cubosomes. Studies of such dispersions, excluding vesicles, are sparse. Dispersions of hexagonal liquid crystalline phase<sup>[35]</sup> and sponge phase<sup>[76]</sup> have been reported, usually in coexistence with cubosomes. Such dispersion mixtures may provide multiple modes of controlled release, whereas their structures are compelling templates for solid nanoparticle synthesis, but more work is needed. As more becomes known about bicontinuous mesh and intermediate phases,<sup>[77,78]</sup> it may become possible to find stable, dispersed forms of these structures as well, liberally broadening liquid crystalline nanoparticle applications. Probably the most compelling direction of research into these systems seeks to understand the interactions between bicontinuous structures and biological systems in general. Enormous potential exists for the expansion of the current understanding of biological processes and medical treatment.

## CONCLUSION

Cubosome nanoparticles formed from cubic liquid crystalline phases are a unique and intriguing self-assembled material with enormous potential in areas as diverse as medicine, materials science, and consumer products. The relatively recent discovery of cubosomes has spurred a broad level of investigation that, as proposed

applications become financially attractive, will continue to narrow and fill in many of the current gaps in our knowledge of cubosome formation and performance. Interdisciplinary research in engineering, biology, medicine, and chemistry will be especially crucial to tie together existing cubosome research and to provide a consistent understanding of these fascinating particles.

## ACKNOWLEDGMENTS

I am indebted to my collaborators at the Procter & Gamble Company, Matthew Lynch and Janet Burns (Corporate Research), and Kristin Hayslip, Bill Small, and David Piatt (Corporate Engineering). Invaluable advice and mentoring have been and continue to be received from Stig Friberg (Clarkson University, retired), Eric Kaler (University of Delaware), Robert Prud'homme (Princeton University), and Robert Laughlin (Procter & Gamble Company, retired). The support of management at the Procter & Gamble Company, in particular Richard Owens, has been crucial throughout our work in the area of cubosomes.

## INTRODUCTION

Small particles with high surface-to-volume ratio composed of bimetallic alloys are extensively used as catalysts<sup>[1,2]</sup> and magnetic recording media<sup>[3,4]</sup> in the chemical and information technology industries. Current research has been focused on reducing particle size, preferably to the nanometer scale, to achieve both improved catalytic activity<sup>[5]</sup> and higher areal density for information storage.<sup>[6]</sup> Both physical and chemical methods have been developed for such purpose, albeit with many shortcomings. Gonsalves, Rangarajan, and Wang<sup>[7]</sup> have provided an excellent review of those methods, with emphasis on chemical approaches. Physical methods such as gas condensation or mechanical deformation are very energy-intensive and tend to produce heterogeneous size populations.<sup>[7,8]</sup> Chemical approaches offer better control over alloy composition and homogeneity. Chemical reduction of metallic salts is the most generally applied approach. Reducing agents based on borohydrides have been extensively used,<sup>[7]</sup> while recently, organic reducing agents are receiving more attention.<sup>[9,10]</sup> Nanosized alloys can also be prepared through thermal decomposition reactions.<sup>[7]</sup> In its finer form, the thermal treatment is performed sonochemically in numerous minute reactors created through supersonic radiation.<sup>[11]</sup> Chemical preparations of nanoalloys usually suffer from tough, demanding environments (airless and water-free conditions in some reactions), contamination from reducing agents, and the limited choice of starting agents (metal carbonyls for thermalization and supersonication). In addition, chemical reduction routes are flawed by an intrinsic limit that the reduction rates of both metal cations need to be similar; otherwise, a core-shell structure rather than real alloys will prevail.<sup>[12]</sup>

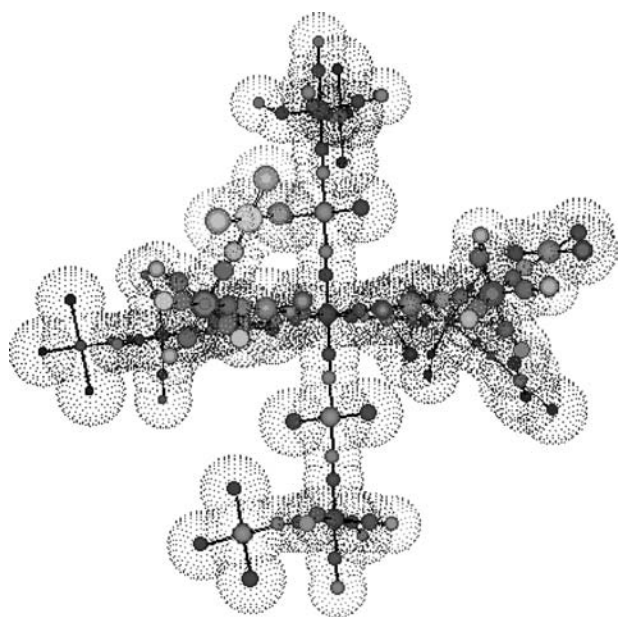

Sol-gel processing has been widely used to prepare nanomaterials, especially composites.<sup>[13–15]</sup> However, to date, this approach has not been applied to the formation of nanoalloys. This method offers the advantage of high chemical purity as well as product homogeneity. Moreover, this technique excels in fabricating thin films, which are actually preferred in the

forementioned applications. However, current sol-gel processing is based on the hydrolysis of metal alkoxides, a method applicable to only  $d^0$  transition metal cations.<sup>[16]</sup> More importantly, a large amount of oxygen exists in the backbone of the gel polymer, from which only ceramics can be prepared through subsequent sintering treatment. We have found two cases<sup>[13,14]</sup> that consider the synthesis of nanometal alloys through sol-gel processing. In fact, in both studies, it was the silica matrix that underwent the sol-gel process and the alloys were prepared through hydrogen reduction.

The transition metal cyanogel polymers introduced in the following section are proposed to have a star polymer structure given in Fig. 1. For the case of a palladium/cobalt cyanogel as shown in the model, a  $Pd^{II}$  center is coordinated by two cyano groups and two chlorides in a trans configuration, while every Co center is coordinated octahedrally by six cyano groups. Usually synthesized in aqueous media, nascent cyanogel polymers are hydrogels containing 98 wt.% water. The water is not chemically bound and therefore evaporates when cyanogels are oven-dried ( $\sim 90^\circ C$ ) to produce a solid-state xerogel having no oxygen element in or near the polymer network. The sol-gel processing of cyanogels has been proven to be a very convenient method to prepare various bulk materials.<sup>[17–19]</sup> It is also an extremely versatile route as cyanogels containing almost all the transition metals can be prepared.<sup>[20,21]</sup> These attributes render the sol-gel processing of cyanogels ideal for nanoalloy fabrication.

## BACKGROUND

Sol-gel processing of metal-oxo polymers has developed into a standard technology for the formation and mechanical shaping of ceramics and metal oxide glasses.<sup>[16]</sup> Here we suggest that a similar approach using hydrogels based on novel transition metal coordination polymers provides an attractive route to the formation of metal alloy particles in the nanometer size range. The sol-gel approach offers

**Fig. 1** Proposed tar polymer structure model of the Pd/Co cyanogel based on elemental analysis, FTIR data, and TGA.

advantages of low processing temperatures and improved chemical homogeneity of the product when compared with standard high-temperature solid-state synthesis techniques. In addition, because simple molding of the gel state allows formation of a “green-body” product (i.e., a mechanically soft intermediate structure that can be annealed to form a product having the density of the crystalline state), machining to form a technologically useful shape can often be minimized or eliminated. Central to sol-gel processing is the formation of a hydrogel as the key intermediate product. This material consists of two continuous intermingled phases: an aqueous phase and a continuous network or polymeric phase. Both phases completely fill the container utilized forming a macroscopically homogeneous material.

In general, sol-gel processing has been limited to the formation of inorganic “polymers” having metal-oxygen linkages as the defining polymer structure

motif. Most typically, the metalloid species involved is silicon and the final product is a silica-type glass. For example, in the case of silica gel, an initial polymer phase can be generated by the acid catalyzed reaction of  $\text{Si}(\text{OCH}_2\text{CH}_3)_4$  [tetraethoxysilane-TEOS] in an aqueous alcoholic solvent (Eq. (1), below). This reaction leads to a hydrogel system containing a continuous polysiloxane phase and a continuous aqueous phase. Upon heating, one observes the loss of the aqueous phase and fracture of the remaining solid-state polymer phase to generate a xerogel composed of particulates of the initial polymer. Continued heating of the xerogel causes loss of ethoxy moieties as ethanol from the silane centers forming a solid-state silica. Thus from a simple stoichiometric point of view, sol-gel processing of metal-oxo polymers is just the densification of a metal oxide system via loss of chemically bonded solvent molecules. That is, there is no significant change in chemical composition as the systems move from a molecular state to a solid-state product. Most typically, the metalloid species involved is silicon leading to the formation of a silica-type glass, although several other ceramic materials based on early transition metal-oxo polymers, such as those of titanium and vanadium, have also been utilized to produce dense ceramic materials. The science and engineering of such systems has been carefully reviewed in Brinker and Scherers’s<sup>[16]</sup> text, “Sol-Gel Science.”

In contrast to this chemistry, we have reported that a sol-gel system can be generated by the reaction of  $[\text{M}'\text{Cl}_x]^{m-}$  complexes (where  $\text{M}' = \text{Pt}, \text{Pd}, \text{Ru},$  or  $\text{Ir}$ ) with  $[\text{M}(\text{CN})_x]^{n-}$  complexes (where  $\text{M}$  is a transition metal,  $x = 4, 6,$  or  $8$ ) in aqueous solution.<sup>[22]</sup> This reaction forms an oxygen-free polymer utilizing bridging cyanide linkages for the bonding motif as illustrated by Eq. (2) (below). Upon formation, the aqueous polymer undergoes a classic sol-gel transition to form a hydrogel that is referred to as a “cyanogel” to highlight the central role of the cyanide ligand and the lack of an oxygen-based polymer. Likewise, the sol phase is referred to as a “cyanosol.”

Cyanogels can be thermally processed to generate a wide variety of solid-state materials including alloys, nitrides, sulfides, and ceramics.<sup>[17,19]</sup> When compared with classic sol-gel processing, one intriguing aspect of cyanogel processing is that the solid-state product can have a different chemical composition from the starting polymer. Thus, for example, if a cyanogel formed from  $[\text{PdCl}_4]^{2-}$  and  $[\text{Co}(\text{CN})_6]^{3-}$  is thermalized in the presence of oxygen, the ceramic  $\text{PdCoO}_2$  having the delafossite structure is obtained. Thus in this system, one observes both the loss of an integral polymer component ( $\text{CN}^-$ ) and the addition of gas phase oxygen to the final product.<sup>[17,20,23]</sup> Broad-based experience with cyanogel systems indicates that this is a general property of such systems. Therefore unlike classic sol-gel processing, cyanogel processing is not limited to densification of the initial polymer, but gives rise to a rich and extensive materials chemistry that allows for the synthesis of a wide variety of materials. Of particular interest to the present discussion is the finding that thermal processing of a cyanogel under an inert atmosphere leads to the formation of pure metallic alloys. For instance, previous research has indicated that a Pd/Co alloy<sup>[17]</sup> is formed by sintering of the cyanogel noted above at temperatures as low as 375°C under an argon atmosphere, although a 650°C reaction temperature is found to be more convenient because only a short reaction time is needed. The traditional alternative is to co-mix the two metals at 1800°C.<sup>[4]</sup>

If the polymer system is trapped in the cyanosol state and then thermally processed, a new methodology for the synthesis of nanocrystalline metal alloys is accomplished. In the present study, Pd/Co cyanosols were spin cast to form thin films, which were then sintered to prepare nanometer-scale alloys. The Pd/Co cyanogel thin film was found to have an intrinsic thickness of approximately 40 nm. Infrared spectroscopy indicated that only bridging cyano groups exist inside the cyanogel thin film, in contrast to the bulk gel counterpart. Transmission electron microscopy revealed that the films were composed of uniform size (2–3 nm) gel particles which formed either clusters or superlattices. Sintering of this thin film under an inert atmosphere produced nanosized Pd/Co alloys. By manipulating polymerization and thin film fabrication conditions, one is able to control the size and distribution of prepared nanoalloys. Currently, nanosized Pd/Co alloy particles (10-nm mean diameter) with near monodisperse size distribution (20%) can be prepared through this method. To the best of our knowledge, this is the first example of the controlled preparation of nanosized metal alloys through sol-gel processing and is by far the simplest method for such purpose.

## EXPERIMENTAL

### Preparation

Aqueous solutions using deionized, reverse osmosis purified water of 0.06 M  $\text{Na}_2\text{PdCl}_4$  (Pressure Chemical Corporation) and 0.06 M  $\text{K}_3\text{Co}(\text{CN})_6$  (Aldrich) were mixed in a 3:1 ratio to form a cyanosol solution at the designated temperatures. Immediately after mixing, the cyanosol solution was quickly spin-coated onto a substrate using a Chemat Tech. KW-4A spin-coater to form a thin film. These films were sintered under Ar using a Carbolite 2416-cm<sup>3</sup> three-zone furnace. A variety of substrates were employed including Pyrex glass, pyrolytic graphite, nickel TEM grids, single crystal calcium fluoride, and single crystal silicon.

*Warning:* Hazardous gases, HCN and  $(\text{CN})_2$ , can be evolved during the heating of the gels above 200°C. Therefore while doing the thermogravimetric and calorimetric analyses, it is important to trap all product gases using two dispersion bubblers in series; the first one should contain bleach, while the terminal one should contain aqueous sodium hydroxide.

### Film Characterization

Fourier transform infrared (FTIR) spectra of sol-gel thin films coated on optical quality  $\text{CaF}_2$  disks (International Crystal Laboratories) were taken using a Nicolet 730 spectrometer. Multilayer (up to 9) cyanogel thin films were prepared by repeated spin coating and characterized by IR spectroscopy after each new layer was added. The surface and cross-section morphology of Pd/Co cyanogel thin film coated on microcover glasses (VWR Scientific) were characterized by scanning electron microscopy (SEM) using a Philips XL30 FEG-SEM. The thickness of the Pd/Co cyanogel thin film coated on single crystal silicon wafer was measured by ellipsometric analysis (laser wavelength: 632.8 nm) using an AutoEL III ellipsometer (Rudolph Technologies, Inc.). Sintered films were characterized by transmission electron microscopy (TEM) using either a Philips CM200 FEG-TEM or a Zeiss 910 TEM.

## RESULTS AND DISCUSSION

Figure 2 shows the IR spectrum of a Pd/Co cyanogel thin film prepared at room temperature. The absorption at 2200  $\text{cm}^{-1}$  is assigned to the stretching vibration of bridging cyano groups. This feature confirms the formation of the coordination polymer under spin-coating conditions. The bonding situation in the thin film is significantly different from that found in bulk

**Fig. 2** The FTIR spectrum of a Pd/Co cyanogel thin film showing no terminal cyanide stretches but intense bridging cyanide.

Pd/Co cyanogels. Bulk gels exhibit both terminal and bridging cyano groups. During the gelation reaction, the nitrogen end of a cyano ligand in the  $[\text{Co}(\text{CN})_6]^{3-}$  complex coordinates to the Pd center of a  $[\text{PdCl}_4]^{2-}$  complex through the displacement of a chloride ligand. On average, two chlorides are lost per Pd center allowing the formation of bridging cyanide ligands in a trans configuration about the palladiums. This forms a chain structure of metal centers (Pd and Co) bridged by cyano groups. Because the Co(III) center is coordinated octahedrally by six cyano groups, the same chain pattern branches into six directions from the Co(III) center forming a star polymer structure. Essentially no terminal cyano groups can be detected by IR spectroscopy; this suggests  $O_h$  geometry. The highly ordered ideal structure shown in Fig. 1 is difficult to achieve in reality. Small-angle X-ray scattering analysis indicates the surface fractal nature of bulk cyanogels.<sup>[18]</sup> This implies that short-range order rather than long-range order prevails in the bulk cyanogel polymer, and this situation is expected to apply in the thin film systems considered here. Infrared spectroscopy of bulk gel structures always indicates a fair amount of terminal cyano groups. Therefore the IR of the Pd/Co cyanogel thin film shown in Fig. 2 is surprising and suggests that the thin film environment is much more ideal from a structural point of view than the bulk gel environment.

The as-prepared Pd/Co cyanogel thin film is transparent and visually indistinguishable from the substrate. The surface morphology of the thin film is homogeneous at the level of SEM observation (Fig. 3A). A cross section of a thin film membrane is shown in Fig. 3B. Because of the strong electron scattering property of high atomic number elements, the palladium content of the thin film causes it to appear as the bright fine line at the top of the cross section. Measurement of this feature yields a film thickness of 40 nm. Ellipsometric analysis indicates the thickness to be  $14 \pm 1$  nm as detailed in Table 1. Both thickness and refractive index from three different points are self-consistent, again demonstrating the homogeneity of the thin film. The thickness obtained through ellipsometric analysis is of the same magnitude as SEM measurement. The discrepancy between these two measurements may be explained by the different choices of substrates when the thin films were prepared. The SEM measurements are obtained by forming a cyanogel thin film on a borosilicate glass substrate, while the ellipsometric measurements utilize a single crystal silicon substrate. Examination of multilayer cyanogel thin films formed on a  $\text{CaF}_2$  substrate by IR indicates that the same thickness per layer ( $\sim 40$  nm) is reproduced during repeated spin coating of cyanogel layers on top of each other for at least 10 layer thickness ( $\sim 400$  nm). This is demonstrated in Fig. 4 by a plot of IR absorbance corresponding to bridging cyano

**Fig. 3** Scanning electron micrograph of the surface (A) and cross-section (B) morphology of a cyanogel thin film.

groups vs. the number of layers showing a linear dependence. Based on this data, a Beer's law plot yields an absorption coefficient for the vibration of the bridging cyano groups of  $1000 \text{ cm L mol}^{-1}$ , which agrees with the literature value.<sup>[24]</sup>

Transmission electron microscopy characterization furnishes more information on the microstructure of the thin film. Fig. 5A provides a nanometer-resolved image of a Pd/Co cyanogel thin film. On this length scale, the film is observed to be composed of uniform size (3 nm) cyanosol particles, which form both clusters and superlattices. The formation of a superlattice is often observed with nanoparticles when a monodispersed distribution is

present. In the current study, we believe that Coulomb repulsions between the negatively charged sol particles are also a factor.

It is worth pointing out that the spin-coating technique plays a rather unconventional role in this study. As noted earlier, the thin films were fabricated immediately after the mixing of reactant solutions. During spin coating, the solvent (water) is rapidly removed, effectively "freezing" the reaction. Therefore the polymerization reaction is truncated when compared with bulk cyanogel synthesis, leaving isolated sol particles as the final product. Consequently, in addition to serving as a thin film fabrication technique, the spin-coating method also intervenes and alters the chemistry of cyanogel formation. The Pd/Co polymer thin film is therefore both physically and chemically different from its bulk counterpart.

It was demonstrated previously in our lab that bulk Pd/Co alloys could be prepared by sintering 3-D samples of Pd/Co cyanogels.<sup>[17]</sup> A novel process for alloy preparation, the sol-gel processing of cyanogels is actually very intuitive. Within the framework of the cyanogel, Pd and Co cationic centers are homogeneously mixed at the atomic level. As shown in reaction 3, subsequent heat treatment induces a redox reaction between the metal ions and the cyanide ligands, producing bulk alloy systems and gas phase cyanogen. This reaction initiates at temperatures as low as  $\sim 350^\circ\text{C}$  and proceeds at fairly rapid rates above  $\sim 500^\circ\text{C}$ .

Figure 6A shows alloys prepared by sintering at  $650^\circ\text{C}$  a 60 mM Pd/Co cyanogel thin film that was

**Fig. 4** Plot of IR absorbance at  $2200 \text{ cm}^{-1}$  vs. number of layers of Pd/Co cyanogel thin films spin-coated. The plot is well fit by Beer's law (solid line) yielding a molar extinction coefficient of  $10^3 \text{ cm L mol}^{-1}$ .

Scale bar represents 100nm.

**Fig. 6** Transmission electron microscopy analysis of nanoalloys prepared by sintering Pd/Co cyanogel thin films synthesized under conditions as follows: (A) Room temperature, 60 mM reactants, 3000 rpm spin-coating rate; (B) 0°C, 60 mM reactants, 3000 rpm spin-coating rate; (C) 0°C, 1 mM reactants, 4000 rpm spin-coating rate; (D) Size distribution analysis of the nanoalloy particles presented in micrographs A–C.

formed by spin coating at 3000 revolutions per minute (rpm) at room temperature. The Pd–Co alloy crystallites show clean crystal symmetries, bearing hexagonal or trigonal shapes. The sizes of the observed alloy particles are widely distributed, ranging from 10 to 80 nm with a median size of 32 nm. The sol–gel processing can be divided roughly into two steps: thin film fabrication and sintering. The sintering temperature and time are predetermined because exact conditions in bulk cyanogel processing are used. On the other hand, thin film fabrication through spin coating can be influenced by at least three variables: reactant concentration, reaction temperature, and spin-coating rate. During sintering, gel particles coalesce to form alloy particles while losing non-metal elements. To prepare smaller and more homogeneous nanoalloys, it is desirable to prepare cyanosol thin films composed of well-dispersed colloidal particles. In such thin films, there are similar numbers of particles in any given area, which tend to form alloy particles of similar sizes. In addition, because there will be few areas with higher than usual particle density, extremely large alloy particles are less likely to be produced. Such cyanosol thin films can be prepared by either increasing the spin rate or slowing down the polymerization rate, which can be realized by lowering reaction temperature or reactants concentration. Therefore we prepared a 60 mM Pd/Co cyanogel thin film by coating at 3000 rpm a cyanosol solution cooled to 0°C in ice–water mixture. Figure 6B shows the nanoalloy prepared by sintering this thin film at 650°C. Sizes of these alloy particles range from 6 to 25 nm with a median value of 14 nm, significantly smaller than those found in Fig. 6A. These alloy particles are, for the most part, spherical because of the minimization of surface energy. A further decrease in polymerization rate can be obtained by lowering the reactant concentration; Fig. 6C shows a nanoalloy prepared by sintering a 1 mM Pd/Co cyanogel thin film prepared at 0°C and 4000 rpm. The spherical alloy particles range from 6 to 12 nm with the median at 10 nm. The size distribution plots of nanoalloy particles prepared from three different cyanogel thin films are shown in Fig. 6D. They clearly indicate that smaller and more uniformly sized alloy particles are yielded when cyanogel polymerization rate is slowed or spin rate is increased, approaching monodispersed samples when the polymerization rate is minimized and the water removal rate is maximized.

## CONCLUSION

A novel method was developed for the fabrication of nanosized bimetal alloys utilizing sol–gel processing of cyanogel thin films. Two exceptional advantages are associated with this method: access to most transition metals via cyanometalate reagents and easy

control of alloy size distribution. In addition, this is by far the simplest method for such purpose.

## ACKNOWLEDGMENT

We thank Mr. Allan Chang and Prof. Steven Chow for ellipsometry measurements; This work was supported by the National Science Foundation under award number CHE-0079169.

# Cyclic Peptides: Self-Assembly in Hydrogen-Bonded Nanotubes

Roberto J. Brea

Juan R. Granja

*Department of Organic Chemistry, Universidad de Santiago de Compostela, Santiago de Compostela, Spain*

## INTRODUCTION

The numerous potential applications of tubular molecules or supramolecules in such fields as biosensing, pharmacology, or catalysis continue to drive the search for new strategies for their construction. This entry reviews the design, preparation, characterization, and application status of nanotubular structures obtained from cyclic peptides by self-assembly.

## OVERVIEW

### Nanotubes and Supramolecular Chemistry

The novel properties of nanostructures have given rise to enormous current interest in the development of nanostructured devices and materials for equally novel applications.<sup>[1–3]</sup> Nanotubes<sup>[4,5]</sup> are of particular interest because of their potential applications—sometimes inspired by the biological roles of natural tubules—in fields including ion sensing, molecular inclusion and separation, catalysis, nanocomposites, optics, electronics, chemotherapy, transmembrane transport, and drug delivery. In these contexts, nanotubes have been constructed that consist of, or are based on, zeolites, graphite, inorganic, lipids, and cyclodextrins.<sup>[6–11]</sup> In most cases, however, it is not yet possible to guarantee uniform prespecified internal tube diameter, a property that, together with its length, will be essential for success in many potential applications.

Nanotubes composed of the materials mentioned above are mostly covalently bonded. Although great advances have been made in this area, non-covalently bonded nanotubes offer significant advantages, including high synthetic convergence, built-in error correction, control through unit design, and, most importantly, self-organization. In non-covalently bonded nanotubes the component molecules are held together by mechanisms such as hydrogen bonding,

$\pi$ - $\pi$  stacking, electrostatic or van der Waals forces, and hydrophobic interactions.<sup>[12,13]</sup> These interactions are much weaker than covalent bonds but determine many of the physical properties of molecules, such as solubility and organization in aggregates, and their exploitation for the formation of structures with well-defined composition, shape, and chemical, physical, and biological properties can constitute a viable alternative to covalent synthesis. Lehn coined the term “supramolecular chemistry” for this field,<sup>[14]</sup> which is beginning to have an enormous impact on materials science and nanotechnology. In supramolecular chemistry, molecules are designed and synthesized for their ability to interact specifically with more or less well-specified target molecules (“molecular recognition”) or spontaneously to form larger aggregates with well-defined pattern or structure (“self-assembly” or “self-organization”).<sup>[15–17]</sup>

In this entry we review the history and current situation of one of the most successful approaches to the preparation of non-covalently bonded self-assembling nanotubes, to wit, the aggregation of cyclic polypeptides in stacks stabilized by hydrogen bonds.

### Nanotubes Designs and Peptide Nanotubes

Programs for the preparation of non-covalently bonded self-organizing nanotubes have aimed at a variety of different structures (many inspired by natural structures), including hollow bundles of rod-like units, helically folded linear species, rolled-up sheets, helically juxtapositioned truncated wedges, and stacked rings (Fig. 1A–E, respectively).<sup>[11]</sup> The last of these schemes (Fig. 1E) is particularly attractive in that the internal diameter of the nanotube is determined solely by that of the unit rings, and can therefore be controlled more easily than in the other cases.

Self-assembling peptide nanotubes (SPN)<sup>[18]</sup> are formed by stacking cyclic peptides, the stacking interactions being backbone–backbone hydrogen bonds

**Fig. 1** Various strategies for the self-organization of simple components as tubular structures.

(Fig. 2). Suitable peptides are those in which the ring can adopt a flat conformation in which all the amino acid side chains have a pseudo-equatorial outward-pointing orientation and the carbonyl and amino groups of the peptide bonds are oriented perpendicular to the ring, the carbonyl of each peptide bond on one side of the ring and the corresponding N-H group on the other (Fig. 3). Achievement of this kind of conformation depends on the number of amino acid residues per ring and on their kind ( $\alpha$ ,  $\beta$ , etc.) and

chirality (R, S); it perfectly positions the carbonyl and amino groups of neighboring rings for the formation of hydrogen bonds that link the rings into tubes like rolled-up  $\beta$ -sheets. Appropriate cyclic peptides can be synthesized by connecting the ends of a linear peptide constructed by successive addition of either individual amino acids or small peptide sequences.<sup>[19]</sup>

The cyclic peptide approach to nanotubes has two crucial advantages over all others that have so far been tried: firstly, the diameter of the polypeptide rings, and

**Fig. 2** Schematic representations of the general strategy for nanotube formation stacking cyclic peptides.

**Fig. 3** Schematic representations of nanotubes (bottom) formed by self-assembly from cyclic D,L- $\alpha$ - or  $\beta$ -peptides (top left and top right, respectively) (for clarity most side chains are omitted).

hence the internal diameter of the nanotube, is easily controlled by varying the number of amino acid residues in each ring; and secondly, the properties of the outer surface of the nanotube can easily be modified by varying the amino acid side chains. For example, self-assembly in lipidic or aqueous media can be promoted by endowing the cyclic units with hydrophobic or hydrophilic groups, respectively, so as to stabilize the flat conformation required for ring stacking. Appropriate unit design and optimization of conditions for self-assembly allows the properties of the resulting nanotubes to be tailored for specific applications. Thanks to this, SPN can be used as or in porous solid materials, soluble cylindrical supermolecules, ion channels and other transmembrane pores, solid-supported ion sensors, antimicrobial and cytotoxic agents, and nanocluster composites.<sup>[11,20]</sup>

## TYPES OF PEPTIDE NANOTUBE

### Introduction

The assembly of nanotubes by stacking cyclic peptides was first suggested in 1972 by Hassall, who envisaged that cyclic tetrapeptides composed of alternating  $\alpha$ - and  $\beta$ -amino acid residues would assemble through backbone-backbone hydrogen bonding.<sup>[21]</sup> This hypothesis was verified in 1975 by the analysis of the crystal structure of the tetrapeptide *cyclo*[L-Ser(O-*t*-Bu)- $\beta$ -Ala-Gly-L- $\beta$ -Asp(OMe)].<sup>[22]</sup> However, although the peptide rings were found to adopt the required conformation and stack above one another in the crystal lattice, neighboring rings were linked by only two hydrogen bonds instead of four. The use of hybrid rings composed of mixed  $\alpha$ - and  $\beta$ -amino acid residues is currently in

abeyance, and in this review we concentrate on cyclic D,L- $\alpha$ -peptides, cyclic  $\beta$ -peptides, and other peptide rings.

## Tubular Ensembles of Cyclic D,L- $\alpha$ -Peptides

### Preliminary studies

In 1974, on the basis of theoretical analysis, De Santis et al. concluded that peptides composed of an even number of alternating D- and L-amino acid residues would form closed rings capable of stacking through backbone-backbone hydrogen bonding.<sup>[23]</sup> The resulting supramolecular tubes would be closely related to the  $\beta$ -helical conformations adopted by linear D,L-peptides. Initial attempts to verify these predictions experimentally were inconclusive because of the poor solubility of the peptides employed.<sup>[24]</sup> For example, in 1989 an X-ray crystallographic study of diverse cyclic peptides by Lorenzi and coworkers failed to find the expected associations between the basic units, each peptide instead being hydrogen-bonded to several cocrystallized solvent molecules.<sup>[25]</sup> However, in 1993 Ghadiri and coworkers took advantage of the pH-dependent ionization of the glutamic acid side chain to control nanotube formation, as described in the next subsection.<sup>[18]</sup>

### Solid-state ensembles: microcrystalline peptide nanotubes

The first well-characterized peptide nanotube was prepared using the octapeptide *cyclo*-[(L-Gln-D-Ala-L-Glu-D-Ala)<sub>2</sub>], which was chosen because it would favor solubility in basic aqueous solution, where coulombic repulsion among its negatively charged carboxylate side chains would prevent premature ring stacking.<sup>[18]</sup> Controlled acidification of the basic solution of this peptide led to microcrystalline aggregates that were characterized by transmission electron microscopy (TEM), electron diffraction, Fourier transform infrared spectroscopy (FT-IR), and molecular modeling. These analyses showed, as expected, ordered hollow tubes formed by cyclic units stacked through antiparallel  $\beta$ -sheet-type hydrogen bonding, the between-ring distance being 4.73 Å and the internal tube diameter 7.5 Å (Fig. 4).

Proton-controlled self-assembly also allowed the preparation of microcrystalline aggregates of nanotubes with an internal diameter of 13 Å composed of *cyclo*-[(L-Gln-D-Ala-L-Glu-D-Ala)<sub>3</sub>] units,<sup>[26]</sup> which confirmed that the internal diameter of the nanotube could be determined just by varying the number of amino acid residues in the cyclic unit. Ghadiri's group has also prepared solid nanotubular assemblies using

**Fig. 4** Dimensions of *cyclo*-[(L-Gln-D-Ala-L-Glu-D-Ala)<sub>2</sub>]-based nanotubes in crystal arrays, as deduced by TEM, electron diffraction, FT-IR, and molecular modeling.

various uncharged cyclic octapeptides to explore the effects of intertubular hydrophobic packing interactions on crystal formation; FT-IR, cryoelectron microscopy, and electron diffraction analyses show the expected cylindrical structures, with between-ring distances of about 4.8 Å and all the characteristic features of an antiparallel  $\beta$ -sheet-like structure.<sup>[27]</sup> More recently, Lambert and coworkers have employed pH-controlled self-assembly to synthesize nanotubular microcrystals of the cyclic D,L- $\alpha$ -octapeptide *cyclo*-[(L-Asn-D-Phe-L-Asp-D-Phe-)]<sub>2</sub>.<sup>[28]</sup>

### Solution-phase studies of dimerization

The basic step in all the above self-assembly processes, the association of cyclic peptides by antiparallel- $\beta$ -sheet-type hydrogen bonding, has been investigated in water by fluorescence quenching methods, which confirm that ring–ring association with the previously reported stacking parameters occurs in solution and is not just a consequence of crystallization.<sup>[29]</sup> To obtain a better understanding of this stacking interaction, and to carry out preliminary exploration of various ways of stabilizing the resulting nanotube structures, toy systems were designed and studied in

which complications associated with unlimited stacking (such as poor solubility) are avoided by allowing only the formation of two-ring structures (hereinafter, “tubelets”). This restriction is achieved by selective alkylation of the amino groups on one face of the peptide ring (those of amino acid residues with the same chirality).<sup>[30]</sup> For example, in deuteriochloroform *cyclo*-[(L-Phe-D-<sup>Me</sup>N-Ala-)]<sub>4</sub> associates as dimeric tubelets with an association constant of about 2540 M<sup>-1</sup>, but these structures grow no further because their *N*-methyl groups prevent hydrogen bonding to a third peptide ring (Fig. 5).<sup>[31]</sup> X-ray analysis shows that crystals obtained in methylenechloride/hexanes are composed of similar dimers, the hydrophilic nature of the cavity of which is confirmed by their containing water molecules. Solution-phase nuclear magnetic resonance (NMR) and FT-IR studies of this and other *N*-methylated peptides support the proposed structures and have begun to elucidate the thermodynamics of nanotube formation. These studies suggest that each hydrogen bond contributes 0.5–0.8 kcal mol<sup>-1</sup> to the enthalpy of formation. *N*-Methylated cyclic hexapeptides such as *cyclo*-[(L-<sup>Me</sup>N-Leu-D-Leu-)]<sub>3</sub> dimerize with smaller association constants,<sup>[32]</sup> but deca- and dodecapeptides fail to do so because of the difficulty to adopt the required flat conformation.<sup>[29–31]</sup> *N*-Propyl

**Fig. 5** Parallel (*p*–*q*) and antiparallel (*p*–*p* and *q*–*q*)  $\beta$ -sheet structures of dimeric tubelets composed of *cyclo*-[(L-Phe-D-<sup>Me</sup>N-Ala-)]<sub>4</sub> (*p*) and/or *cyclo*-[(D-Phe-L-<sup>Me</sup>N-Ala-)]<sub>4</sub> (*q*), with the corresponding dimerization constants.

and allyl groups can also be used to prevent ring stacking from proceeding beyond the dimer stage.

Studies of sidechain–sidechain interactions have shown that  $\gamma$ -branched side chains are more favorable for dimerization than unbranched chains. Recently, aromatic side chain–side chain interactions in cyclic peptides containing homophenylalanine were used to induce crystal growth orthogonal to the tubulet axis through the prevalent effect of dimer formation in the crystal nucleation.<sup>[33]</sup>

Dimeric tubelets have also allowed easy comparison of the stabilities of parallel and antiparallel  $\beta$ -sheet structures in solution.<sup>[34]</sup> Using the enantiomeric cyclic peptides *cyclo*-[(L-Phe-D-MeN-Ala)<sub>4</sub>] and *cyclo*-[(D-Phe-L-MeN-Ala)<sub>4</sub>], it was found that antiparallel  $\beta$ -sheet structures (*p-p* and *q-q* in Fig. 5) are more stable than parallel structures (*p-q*) by 0.8 kcal mol<sup>-1</sup>.

Finally, further confirmation of  $\beta$ -sheet-type hydrogen bonding has been obtained by covalent consolidation of non-covalently constituted cyclic peptide dimers. In non-polar solvents the olefin-bearing peptide *cyclo*-[(L-Phe-D-MeN-Ala-L-Hag-D-MeN-Ala)<sub>2</sub>] (X = CH<sub>2</sub>-CH=CH<sub>2</sub> in Fig. 6; Hag = homoallylglycine)

forms equal proportions of two kinds of dimer, one of which undergoes selective hydrogen-bond-mediated olefin metathesis to afford covalently stabilized  $\beta$ -sheet peptide tubelets (see legend in Fig. 6).<sup>[35]</sup> Subsequent work has extended this general strategy to other covalent links, such as disulfide bonds:<sup>[36]</sup> for example, with *cyclo*-[(L-Phe-D-MeN-Ala-L-Cys-D-MeN-Ala)<sub>2</sub>] (X = SH in Fig. 6) S-H...S hydrogen bonds appear to stabilize the reactive dimer prior to formation of the disulfide bond. Studies of this kind, using dimers as toy systems, are paving the way for the preparation of stable polymeric nanotubes composed of cyclic peptides with backbone-unalkylated amino groups.

### Artificial transmembrane ion channels

As was emphasized above, the major advantage of peptide nanotubes over others is the ease with which their external surface properties and internal diameters can be controlled by the use of cyclic peptides with appropriate side chains and numbers of amino acid residues. In 1994, Ghadiri's group created the first

**Fig. 6** Consolidation of cyclic peptide dimers by covalent bonding between their constituent rings using olefinic or thiolic side chains. Of the two dimers formed by *cyclo*-[(L-Phe-D-MeN-Ala-L-Hag-D-MeN-Ala)<sub>2</sub>] (Hag = homoallylglycine; X = CH<sub>2</sub>-CH=CH<sub>2</sub> in the figure), only the isomer in which CH<sub>2</sub>-CH=CH<sub>2</sub> groups of different peptide rings face each other can undergo covalent stabilization.

transmembrane nanotube to self-assemble in a lipid bilayer, a feat that depended on the hydrophobic side chains of the cyclic  $D,L$ - $\alpha$ -peptide *cyclo*-[L-Gln-(D-Leu-L-Trp)<sub>3</sub>-D-Leu-] (Fig. 7,  $x = H$ ).<sup>[37]</sup> Since then, several similar structures have been studied by liposome-based proton transport assays, computational methods, FT-IR spectroscopy, grazing-angle reflection/absorption, polarized attenuated total reflectance (ATR), and single-channel conductance measurements.<sup>[38,39]</sup> In all cases, when the amino acid sequence is dominated by hydrophobic amino acids, the resulting nanotube is oriented nearly parallel to the lipid alkyl chains, as required for a transmembrane channel.<sup>[39]</sup> While peptide nanotubes formed from amphipathic cyclic peptides lay parallel to the membrane plane. Increasing the size of the cyclic peptide, for example by using *cyclo*-[L-Gln-(D-Leu-L-Trp)<sub>4</sub>-D-Leu-], provides channels with larger pores. Both *cyclo*-[L-Gln-(D-Leu-L-Trp)<sub>3</sub>-D-Leu-] and *cyclo*-[L-Gln-(D-Leu-L-Trp)<sub>4</sub>-D-Leu-]-based channels have prodigious alkaline ion transport activities. Molecular dynamics simulations suggest that these high rates of transport may be due largely to the way in which water molecules are ordered in the lumen.<sup>[38]</sup> However, even larger cation conductances (10–15% larger for 20 mM  $K^+$ ) can be achieved by oriented heterodimer-based nanotubes in which the

ring at the end facing the  $K^+$  source, *cyclo*-[(L-Glu-D-Leu)<sub>4</sub>], is negatively charged at the working pH.<sup>[40]</sup>

Ab initio calculations have suggested that band conduction may occur through the between-ring hydrogen bonds of peptide nanotubes as a result of delocalization of electrons and holes toward the tube axis.<sup>[41]</sup>

### Tubular Ensembles of Cyclic $\beta$ -Peptides

$\beta$ -Peptides are an emerging class of non-natural biopolymers that in solution adopt a variety of secondary structures analogous to those of  $\alpha$ -peptides, including pleated sheets, turns, hairpins, and a variety of helical conformations of differing chirality and radius.<sup>[42]</sup> Their ability to resist enzymatic degradation and their favorable conformational properties suggest that  $\beta$ -peptides may have interesting applications. Molecular modeling and X-ray crystallography have shown that in the solid state, cyclic tetrapeptides composed of chiral  $\beta^3$ -amino acid residues can adopt flat-ring conformations and stack to form nanotubes in the same way as cyclic  $D,L$ - $\alpha$ -peptides, and that in the case of  $\beta$ -peptides this is possible with peptide rings composed of homochiral  $\beta$ -amino acid residues as well as with rings of residues of alternating chirality (Fig. 3).<sup>[43]</sup>

**Fig. 7** Schematic representation of a peptide nanotube self-assembled in a lipid bilayer by association of cyclic peptide units. Peptides used by Ghadiri and coworkers in transport experiments are shown at the left ( $x = H$ ). Source: From Ref.<sup>[38,39]</sup>

Like their D,L- $\alpha$  counterparts, cyclic  $\beta^3$ -peptides with appropriate hydrophobic side chains can associate in lipid bilayers to form efficient self-assembled artificial transmembrane ion channels.<sup>[44]</sup> In the cases of *cyclo*-[( $\beta^3$ -HTrp-)<sub>4</sub>]- and *cyclo*-[( $\beta^3$ -HTrp- $\beta$ -Hleu-)<sub>2</sub>]-based channels assembled in planar lipid bilayers, single-channel conductance measurements have shown activities similar to those of D,L- $\alpha$ -peptide-based channels, with K<sup>+</sup> transport rates of  $1.9 \times 10^7$  ions sec<sup>-1</sup>, greater than that of gramicidin A under similar conditions. It is thought that the unnatural backbones of channel-forming cyclic  $\beta^3$ -peptides will have interesting consequences for the corresponding channels and channel formation processes. In particular, as linear  $\beta$ -peptides resist digestion by proteases because of their unnatural backbone, the same is expected to be true of cyclic  $\beta^3$ -peptides, which should therefore be able to

form ion channels with potential antimicrobial effects in the presence of these enzymes; a mechanism of this kind is thought to be responsible for the known antimicrobial activity of helical linear  $\beta$ -peptides.<sup>[45]</sup>

### Tubular Ensembles of Cyclic Peptides Containing $\gamma$ -Amino Acid Residues

The inner faces of D,L- $\alpha$ - and  $\beta$ -peptide-based nanotubes are hydrophilic (and some of their potential applications depend on this). It is not possible to modify their pore properties by introducing functional groups on their inner faces, because all their amino acid side chains point outward and substitution at C $_{\alpha}$  or C $_{\beta}$  would interfere with nanotube assembly. However, this shortcoming disappears if cyclic hybrid

**Fig. 8** A cyclic peptide composed of alternating  $\alpha$ -amino acids and *cis*-3-aminocyclohexanecarboxylic acid ( $\gamma$ -Ach) that can stack to form nanotubes with hydrophobic regions in the lumen around the cyclohexane  $\beta$ -methylenes. A) The two types of hydrogen bond involved in nanotube formation (left, a and b) and their separate realizations in N-methylated dimeric tubelets (right). B) Silicon representations (1, top view; 2, side view) of the crystal structure of dimeric *cyclo*-[(D-Phe-(1R,3S)-<sup>Me</sup>N- $\gamma$ -Ach-)<sub>3</sub>], which crystallized in association with five molecules of chloroform, one of them occupying the central cavity of the dimer.

$\alpha,\gamma$ -peptides are used as the basic units for nanotube construction. Our group has recently designed, synthesized, and characterized a new cyclic peptide, composed of alternating  $\alpha$ -amino acids and *cis*-3-aminocyclohexanecarboxylic acid ( $\gamma$ -Ach), that can adopt the flat conformation required for the formation of nanotubes consisting of hydrogen-bonded stacks of alternately oriented rings (Fig. 8).<sup>[46]</sup> In these rings the  $\beta$ -methylene of each cyclohexane projects into the lumen, creating a hydrophobic region. That these rings can indeed stack as desired was verified by using the backbone methylation strategy (see “[Solution-Phase Studies of Dimerization](#)”) to prepare hydrogen-bonded dimers of each of the two types required for nanotube formation (one bonded via the  $\alpha$ -amino acid residues of each component cyclic peptide, the other via their  $\gamma$ -Ach moieties; Fig. 8A, frames a and b). Nuclear magnetic resonance, Fourier transform infrared spectroscopy, and X-ray diffraction studies conclusively confirmed the formation of these dimers and showed that the dimer bonded via  $\alpha$ -amino acid residues are extremely stable in non-polar solvents, with  $K_a$ 's  $> 10^5$ . It should be possible to functionalize the inner surface of nanotubes composed of these hybrid  $\alpha,\gamma$ -peptides by introducing substituents on the  $\beta$ -methylene, something that, as noted above, is impossible for nanotubes based on cyclic  $\alpha$ - or  $\beta$ -peptides. The ability to functionalize nanotube cavities would give the chemist greater capacity to design selective ion channels, selective molecular inclusion devices, or molecular and catalytic containers.

### Tubular Ensembles of Other Cyclic Peptides

The  $\alpha$ -,  $\beta$ - and  $\gamma$ -amino-acid-based peptides discussed above do not exhaust the kinds of cyclic peptide that

have already been examined as potential basic units for nanotube construction. Dori and coworkers synthesized a tripeptide that crystallized as bundles of nanotubes.<sup>[47]</sup> It is composed of  $\alpha,\beta$ -unsaturated  $\delta$ -amino acid residues that, because of the *trans* geometry of the vinyl group, adopt the flat conformation required for self-assembly of nanotubes (Fig. 9). Because the peptide backbone has an even number of atoms between the carbonyl and amino groups of each residue, all the carbonyl groups are oriented in the same direction (as in the  $\beta$ -peptide-based nanotube of Fig. 2), which gives the nanotubes a large dipole moment resulting in highly anisotropic crystals.

Guichard and coworkers have reported the design, synthesis, and structural analysis of cyclic oligopeptides consisting of homochiral residues with proteinogenic side chains.<sup>[48]</sup> These units crystallize as hydrogen-bonded polar nanotubes with electron density in the tubular cavity.

Macrocyclic bisureas prepared from cystine have been used by Ranganathan and coworkers, as well as the analogous bisamides (Fig. 10A).<sup>[49]</sup> Despite their flexibility, these molecules crystallize in tubular arrays of uniform shape and internal diameter, adjacent rings being bound together by two hydrogen bonds in the bisamides and four in the bisureas. The tubular structure may additionally be stabilized by the hydrophobic collapse of the alkyl bridge.

Finally, Ranganathan and coworkers have also explored the nanotube-forming possibilities of a quite different kind of cyclic unit, cyclodepsipeptides in which the amide groups lie in the ring plane and solid-state ring–ring stacking is due to  $\pi$ – $\pi$  interactions between phenyl and carbonyl rings included in the depsipeptide backbones of the rings of neighboring tubes, which interdigitate as shown in Fig. 10B.<sup>[50]</sup>

**Fig. 9** Self-association of a rigid lactamic  $\gamma$ -tripeptide as a nanotube.

**Fig. 10** Self-assembled nanotubes investigated by Ranganathan and coworkers. A) Self-assembly by association of cysteine-based macrocyclic bisureas. B) Self-assembly through  $\pi$ - $\pi$  interactions between interdigitating aromatic rings included in the backbones of the cyclodepsipeptides constituting neighboring nanotubes.<sup>[49,50]</sup>

## APPLICATION STATUS OF PEPTIDE NANOTUBES (FIG. 11)

### As Selective Transmembrane Transport Channels

Naturally occurring transmembrane channels are chemically diverse molecules performing molecular transport and selection and ion-flow trafficking.<sup>[51,52]</sup> Synthetic peptide nanotubes that are internally hydrophilic and externally endowed with appropriate characteristics can mimic certain transmembrane channel functions. As noted above, the first such nanotubes, designed to explore the possibility of self-assembly in lipid bilayers, were composed of *cyclo*-[L-Gln-(D-Leu-L-Trp)<sub>3</sub>-D-Leu-] units (Fig. 7) and had ion conductivities greater than  $10^7$  ions  $\text{sec}^{-1}$ .<sup>[37]</sup> The incorporation of the constituent peptide rings into lipid bilayers was shown by absorption and fluorescence spectroscopy, and their spontaneous assembly into hydrogen-bonded nanotubes by FT-IR spectroscopy, while ion conductance studies using patch clamp techniques found  $\text{K}^+$  and  $\text{Na}^+$  transport rates about three times faster than those of the naturally occurring channel gramicidin A (Fig. 12).

These artificial peptide transmembrane channels are naturally size selective. For example, the passage of glucose, which is estimated to require a pore diameter somewhat larger than 9 Å, is not allowed by the octapeptide nanotubes described above, but nanotubes built of the decapeptide *cyclo*-[(L-Trp-D-Leu)<sub>4</sub>-L-Gln-D-Leu-], which have an internal diameter of 10 Å, pass

both glucose and glutamic acid very efficiently.<sup>[53,54]</sup> These decapeptide nanotubes also transport ions with similar efficiency, but with mean opening times that are shorter than with octapeptide channels because of their greater conformational freedom. Potential applications of these artificial transmembrane channels include biosensing and size-selective molecular delivery.

Recently, a heterodimeric peptide nanotube architecture that displays altered conductance and rectification properties has been described, (Fig. 7, e.g.,  $x = \text{CH}_2\text{COOH}$ ).<sup>[40]</sup> by taking advantage of the different properties (mode of interaction and microenvironment in which they reside) of the two subunits that reside at the ends of the channel assembly (caps). The local electrostatic perturbations brought by the cap subunits bearing ionizable functionalities were used to modulate the ion selectivity and conductance of the transmembrane channel. For example, an increase in conductance (10–15% in 20 mM KCl) was observed when a negative charged (*cyclo*-[(L-Glu-D-Leu)<sub>4</sub>]) cap was used because of the inherent cation selectivity of the resulting channel.

Likewise as noted above, the cyclic  $\beta^3$ -peptides *cyclo*-[( $\beta^3$ -HTrp)<sub>4</sub>] and *cyclo*-[( $\beta^3$ -HTrp- $\beta$ -HLeu)<sub>2</sub>] can also associate tubewise in lipid bilayers (Fig. 13), forming channels with  $\text{K}^+$  transport rates of  $1.9 \times 10^7$  ions  $\text{sec}^{-1}$ .<sup>[44]</sup> It is worth pointing out that these channels are anisotropic, as all the component rings of  $\beta$ -peptide nanotubes stack with the same orientation. This leaves all the amide NH groups pointing toward one end of the nanotube and all the C=O groups pointing toward the other end, giving

**Fig. 11** Potential applications of peptide nanotubes that are currently being investigated.

the entire tube a dipole moment that should result in its being oriented parallel to an applied electric field and in its exhibiting voltage-gating behavior. Moreover, the formation of the nanotube itself should also be facilitated by the application of an electric field, which should cause all the peptide rings to adopt the correct orientation for stacking.

### As Antibiotics

The proliferation of antibiotic-resistant bacteria in recent years has intensified the need for new antibiotics with novel modes of action.<sup>[55,56]</sup> Many naturally occurring peptide antibiotics act by creating pores in bacterial membranes, which kills the bacterium by

**Fig. 12** Micro-patch-clamp measurements of ion conduction by nanotubes self-assembled from *cyclo*-[L-Gln-(D-Leu-L-Trp)<sub>3</sub>-D-Leu] in lipid bilayers. The figure shows a 140-sec continuous record of single-channel K<sup>+</sup> conduction under an applied voltage drop of 50 mV. Closure of the ion channels is due to thermal disruption of their constituent hydrogen bonds. *Source:* From Ref.<sup>[37]</sup>; © 1993, Macmillan Magazines Ltd.

**Fig. 13** Schematic representation of a transmembrane ion channel self-assembled in a lipid bilayer from *cyclo*-[( $\beta^3$ -HTrp-)<sub>4</sub>].

destabilizing electric potential and ion gradients.<sup>[57]</sup> Approaches to novel antibiotics mimicking this mode of action include the use of peptide rings capable of stacking in the membrane to form transmembrane pores (Fig. 14).<sup>[58,59]</sup> In particular, amphipathic cyclic D,L-octa- and hexapeptides with at least one positively charged amino acid residue (included to interact with negatively charged bacterial membranes) have been shown to infiltrate the bacterial membrane and

associate as nanotubes oriented at an angle of 20° to the membrane plane, suggesting the formation of nanotube “carpets” causing extensive membrane damage.<sup>[58]</sup> An important aspect of this approach is that peptide rings can be designed to associate as nanotubes selectively in bacterial rather than mammalian membranes. Such peptides exhibit significant antibacterial activity *in vitro*, and their preferential action against bacterial cells has been demonstrated in mice, in which

**Fig. 14** Schematic representation of the formation of lethal ion channels in bacterial membranes. A) Proposed carpet-like mode of action of peptide nanotube, showing the greater potential for membrane discrimination due to its polyvalent display of surface-exposed hydrophilic side chains to interact with various membrane constituents. B) Schematic representation of multiple nanotube assemblies formation with different surface presentation from a given cyclic peptide.

they exhibit activity against a broad spectrum of bacteria, including methicillin-resistant *Staphylococcus aureus*.

The design of new supramolecular drugs based on the principles shown for these antibiotic peptides may be the 21st century drugs and a step toward combating the development of drug-resistance. The actual molecular approach to drug design of lead compounds based on the narrow sequence space between the pharmacophore and the molecular target (receptors, enzymes, or nucleic acids) makes very easy its inactivation just by only a few structural changes. The supramolecular approach would have a large sequence space, maintaining their mode of action despite gross structural changes. The potential of the supramolecular approach to drug design is illustrated in Fig. 14; from a given cyclic  $D,L$ - $\alpha$ -peptide sequence it is possible to generate several different nanotube assemblies with different surface presentations through variations in the relative rotations of the cyclic subunits.

### As Biosensors

The feasibility of diffusion-limited size-selective ion sensing using supported nanotubes has been shown in studies using a cyclic  $D,L$ - $\alpha$ -octapeptide that self-associated as nanotubes embedded in self-assembled organosulfur monolayers supported on gold films (Fig. 11).<sup>[60,61]</sup> The functional properties of this arrangement were studied by cyclic voltammetry and impedance spectroscopy, showing, for example, selective redox activity for the smaller  $[\text{Fe}(\text{CN})_6]^{3-}$  complex compared to  $[\text{Mo}(\text{CN})_8]^{4-}$ , because of the presence of peptide channels. The studies have demonstrated the feasibility of diffusion-limited size-selective ion sensing based on supported tubular biomaterials. Variations in the type of cyclic peptide, diameter, and their channel selectivity toward different species, along with the differences in the chain length of the alkyl group of the organosulfur adsorbates, are expected to increase the repertoire of the sensor applications.

## As Biomaterials

Inspired by natural mineralization processes thought to involve interaction with oriented groups on natural polymers, Ghadiri's group has also investigated the formation and stabilization of metal nanoclusters on the surface of SPN crystals composed of *cyclo*-[(L-Gln-D-Ala-L-Gln-D-Ala-)<sub>2</sub>]-based nanotubes (J.D. Hartgerink, M.R. Ghadiri, personal communication).<sup>[11,62]</sup> The array of carboxyl groups on the outer nanotube surface served to nucleate the deposition of copper(I) oxide. The resulting nanocomposite material was characterized by high-resolution TEM and electron energy loss spectroscopy (EELS). It is thought that regular nanotube-borne functional group arrays may also serve to nucleate mineral crystallization processes.

## As Photoresponsive Materials

Molecules that can be reversibly switched between two states using light have been extensively studied in

recent decades,<sup>[63–65]</sup> especially with a view to their application as optical data storage devices. Ghadiri and coworkers have investigated a system in which *N*-methylated cyclic D,L-peptide dimers can be switched between one state in which the two rings in each dimer are connected covalently by an azobenzene link in *Z* conformation and another in which the *E* conformation of this link connects neighboring dimers (Fig. 15).<sup>[66,67]</sup> Interconversion between the two states can be effected both in solution and in thin films at the air–water interface; the *E*–*Z* isomerization is the faster process. Further research in this direction may lead to materials capable of modifying their macroscopic properties in response to light.

## Other Potential Applications

The ease with which the size and external properties of peptide nanotubes can be controlled, and the fact that their outer surfaces present regularly oriented arrays of functional groups, suggests that other fields in which these supermolecules may find application include

**Fig. 15** An azo-linked cyclic peptide dimer that can be reversibly switched between isolated-dimer and interconnected-dimer forms using radiation of different frequencies.

catalysis, anticancer therapy, and electronic, optical, and molecular engineering.<sup>[68,69]</sup>

## CONCLUSION

Although covalent bonds constitute the strongest kind of connection between atoms, weaker interactions such as hydrogen bonds, hydrophobic interactions, and salt bridges can be decisive for molecular organization and properties, as first became apparent in studies of biological systems. Supramolecular chemistry, the study of supramolecular structures formed by non-covalent interactions among covalently bound components, investigates, inter alia, the behavior of simple component units designed to self-associate non-covalently to form ordered supramolecular structures with prespecified properties. In this entry we have surveyed aspects of the supramolecular chemistry of cyclic peptides, which under appropriate conditions interact via hydrogen bonds to form nanoscale tubular structure–peptide nanotubes. Crucial for this interaction is the adoption of a flat conformation in which the amino acid side chains of the peptide rings have a pseudo-equatorial outward-pointing orientation and the carbonyl and amino groups of the peptide bonds are oriented perpendicular to the ring, the carbonyl on one side of the ring and the corresponding amino group on the other. This conformation can be achieved by cyclic peptides with a variety of amino acid compositions, including alternating D- and L- $\alpha$ , alternating  $\alpha$  and  $\gamma$ ,  $\beta$ , and  $\delta$ . Peptide rings composed of amino acid residues with an even number of carbons between the amino and carboxyl groups stack with all rings having the same orientation, so creating nanotubes with strong dipole moments, while rings composed of  $\alpha$ - and  $\gamma$ -amino acids stack with alternating orientations and lack this natural directedness. In all cases, the resulting nanotubes have well-defined uniform internal diameters and external surfaces that can be easily endowed with specific properties by modification of the amino acid side chains; to quote Ghadiri, “a reliable repeat unit can be exploited to place functionality in a supramolecular lattice with molecular precision.”<sup>[70]</sup> Once the nanotube has been formed, it can be consolidated by the formation of covalent bonds between adjacent peptide rings. Recent work has also paved the way to the modification of the properties of the inner nanotube surface, which in previous peptide nanotubes had always been bare and hydrophilic. Peptide nanotubes are currently being actively investigated with regard to their application as selective transmembrane ion or molecular transport channels, antimicrobial and cytotoxic devices, ion sensors, porous solid materials, nanocluster composites, and photoresponsive materials.

## INTRODUCTION

Dendrimers are three-dimensional, highly branched, monodispersed macromolecules,<sup>[1,2]</sup> which are obtained by an iterative sequence of reaction steps, giving precisely defined branching structures. The possibility of designing these well-defined macromolecules (e.g., by choosing specific functional end groups, or certain multifunctional monomers) is a very powerful tool that enables the exploration and development of a wide variety of applications. One of the most promising applications of dendrimers is in catalysis.<sup>[3,4]</sup> In general, organometallic dendrimers offer potentials in combining the advantages of both homogeneous and heterogeneous catalyses<sup>[5–8]</sup> because of their structurally well-defined and specific number of active sites, as well as their advantage of facile recovery by nanofiltration<sup>[9,10]</sup> or solvent precipitation.<sup>[11]</sup>

Active sites can be introduced specifically at: a) the surface, b) the core, c) branches, and d) inner cavities of dendrimers in a controlled manner (Fig. 1), although it is difficult to control the number and location of active metal species in traditionally supported metal catalysts using linear or cross-linked polymers. The active sites at the periphery of dendrimers are readily available for catalytic reactions because of their globular shapes. However, when catalytic species are incorporated at the core of dendrimers, these dendrimers are applied as shape-selective, size-selective, or enantioselective catalysts. Catalytic groups can be anchored to the branches of the interior, giving rise to catalysts with both high loading of catalytic sites and control of the nanoenvironment around the active species. Moreover, dendrimers serve as host-type “nanoreactors” for metal guest molecules. Encapsulation of catalytic sites into the cavities of dendrimers leads to both active site isolation and substrate size selectivity.

We describe here the unique catalytic properties of both periphery-functionalized dendrimer-bound Pd(II)<sup>[12]</sup>

and Pd(0)<sup>[13]</sup> complexes, and dendrimer-encapsulated Pd(0) nanoparticles<sup>[14]</sup> based on poly(propylene imine) dendrimers. The dendrimer-bound Pd(II) complex has higher catalytic activity for selective hydrogenation of conjugated dienes to monoenes, than those of the corresponding low-molecular-weight Pd complex. Moreover, the dendrimer-bound Pd(II) complex is easily recovered and reused without any loss of activity. The dendrimer-bound Pd(0) complex showed high stereoselectivity in the allylic substitution reaction. Facile recovery of dendritic Pd complexes can be achieved by the use of a thermomorphic system.<sup>[8]</sup> The size-selective and substrate-specific hydrogenation of olefins is achieved by dendrimer-encapsulated Pd(0) nanoparticles. Unique catalysis is attributed to hydrogen bonding between the internal amino groups of the dendrimers and substrates.

## APPLICATION

### Dendrimer-Bound Pd(II) and Pd(0) Complexes

Surface functional groups on dendrimers can be easily modified with various ligands capable of binding metal complexes to give a number of metal-containing dendrimers.<sup>[15]</sup> Transition metal complexes at the surface of dendrimers will be readily available for catalytic reactions. The high local concentration of catalysts greatly affects catalytic performance in either a positive or a negative sense.

### Preparation and Characterization of the Dendrimer-Bound Pd(II) and Pd(0) Complexes

Double phosphinomethylation of primary amino groups on the first, third, fourth, and fifth generations

	A	B	C	D
metal loading	high	low	high	low / high
control of solubility	difficult	easy	easy	easy
control of environment around active sites	difficult	easy	easy	easy

**Fig. 1** Comparison of different types of metal-functionalized dendrimer catalysts: (A) periphery, (B) core, (C) interior branches, and (D) inner cavities of dendrimers.

of poly(propylene imine) dendrimers was carried out, giving 4, 16, 32, and 64 chelate phosphines on the periphery (**1a–d**), respectively, as shown in Scheme 1.<sup>[11]</sup> Treatment of the dendrimers **1a–d** with  $\text{PdCl}_2(\text{PhCN})_2$  afforded dendrimer-bound  $\text{PdCl}_2$  complexes **2a–d**. Subsequently, the reduction of **2** with hydrazine monohydrate in the presence of two equivalents of  $\text{PPh}_3$ <sup>[16]</sup> led to the formation of dendritic  $\text{Pd}(0)$  complexes **3a–d**, respectively, with retention of parent dendritic structures.  $\text{PhN}(\text{CH}_2\text{PPh}_2)_2\text{PdCl}_2$  (**4**) as a low-molecular-weight analogue of **2** was synthesized by literature procedure.<sup>[17,18]</sup> These dendritic Pd complexes were characterized by  $^1\text{H}$ ,  $^{13}\text{C}\{^1\text{H}\}$ ,  $^{31}\text{P}\{^1\text{H}\}$  nuclear magnetic resonance (NMR), Fourier transform infrared spectroscopy (FTIR), and X-ray photoelectron spectroscopy (XPS). The  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum of **2** did not show any signal for the residual free phosphine at  $\delta -27$  but only one singlet at  $\delta 8$ . The infrared spectrum of **2** had broad bands at  $294\text{ cm}^{-1}$  assigned as terminal *cis* Pd–Cl stretching bands, which were

similar to those observed in **4**.<sup>[19]</sup> Elemental analysis of **2** gave a Pd:P:Cl ratio of 1:2:2, which strongly supports the complete complexation of the chelate phosphine to Pd in a *cis* form. After the reduction of **2**, the above  $^{31}\text{P}$  NMR resonance at  $\delta 8$  was fully replaced by a new one around  $\delta 27$ . XPS analyses of **2** showed two bands at 343 and 338 eV because of Pd  $3d_{3/2}$  and  $3d_{5/2}$ , respectively, and the binding energy of Cl 2p was 198 eV. In the case of **3**, the binding energies of 341 and 336 eV for  $3d_{3/2}$  and  $3d_{5/2}$ , respectively, were observed. The above values of binding energies were comparable with those of **4**, typical Pd complexes of  $\text{PdCl}_2(\text{PPh}_3)_2$  and  $\text{Pd}(\text{PPh}_3)_4$ . From these results, the structure of dendritic Pd complexes **2** and **3** can be determined as shown in Scheme 1, respectively.

### Selective Hydrogenation of Conjugated Dienes to Monoenes with Dendrimer-Bound Pd(II) Complex Catalyst

The catalytic activity of **2** was examined in the hydrogenation of cyclopentadiene under an atmospheric pressure of  $\text{H}_2$  in EtOH, compared with those of **4**, Pd/C, and Pd/ $\text{Al}_2\text{O}_3$ . The time courses of hydrogen uptakes are shown in Fig. 2. In the case of **2**, hydrogen uptake drastically dropped after cyclopentadiene was consumed completely. At that time, high selectivity for the formation of cyclopentene was observed; cyclopentane was the only product without cyclopentane. Using Pd/C and Pd/ $\text{Al}_2\text{O}_3$  catalysts, rates of hydrogenation remained constant after perfect consumption of the diene without such a turning point of hydrogen uptake. The rate of hydrogenation of **4** was extremely low among the Pd catalysts used. It has been reported that such a selective hydrogenation of dienes to monoenes using homogeneous Pd catalysts required high pressures of  $\text{H}_2$  and  $\text{SnCl}_2$  as activating agents.<sup>[20,21]</sup>

**Scheme 1** Preparation of dendritic Pd(II) complexes **2** and Pd(0) complexes **3**. Reagents and conditions: (1) HCHO, HPPH<sub>2</sub>, toluene, 60°C; (2) PdCl<sub>2</sub>(PhCN)<sub>2</sub>, toluene, room temperature; and (3) H<sub>2</sub>NNH<sub>2</sub>·H<sub>2</sub>O, PPh<sub>3</sub>, EtOH, room temperature.

Fig. 2 Time courses of  $H_2$  uptakes using various Pd catalysts in the hydrogenation of cyclopentadiene.

Presumably, an active species for this hydrogenation may be a Pd(II) hydride species derived from the following scheme (Eq. (1))

based on hydrogenation using the polystyrene-bound Pd(II) catalyst.<sup>[22]</sup> According to the above equilibrium equation, the generation of Pd–H can be accelerated by the presence of bases. In a separate experiment, addition of triethylamine to the corresponding low-molecular-weight catalyst **4** increased rates of hydrogenation, as shown in Fig. 2. The high catalytic performance of **2** would be because of the dendrimer structure containing many amino moieties, compared with **4**. It has been also reported that dendritic metal complex catalysts had lower activities than analogous monomeric complexes in many organic reactions.<sup>[23–25]</sup>

Interestingly, the solubility of **2** in various solvents did not strongly influence catalytic activities. Hydrogenation was very efficient in EtOH in which **2** was insoluble, whereas it was slow in *N,N*-dimethylformamide (DMF) in which it was soluble. Because all active sites of **2** are located on the dendrimer surface, substrates easily gain access to active sites on the surface without steric hindrance and diffusion limitation, which might lead to efficient hydrogenation even in the heterogeneous system using an EtOH solvent. Generally, heterogenization of metal complexes using organic polymers has disadvantages such as lowered reactivity induced by diffusion limitation of substrates, catalyst leaching, steric hindrance, and inability to totally mimic reactivity and selectivity attainable with the corresponding homogeneous ones.<sup>[8]</sup>

Initial rates of  $H_2$  uptake in the hydrogenation of various cyclic conjugated dienes are summarized in Fig. 3. Notably, the rates increase in the order of  $C_5 < C_6$ – $C_8$ . The fact that the molecular size of dienes did not affect the hydrogenation rate could be explained by the above unique character of the functionalized dendrimer ligand. These phenomena are a sharp contrast to the results of our previous hydrogenation using the polystyrene-bound Pd complex;<sup>[22]</sup> to swell polystyrene support, a mixed solvent of benzene and ethanol must be used because many Pd active sites exist within the polystyrene matrix.

Recycling of **2** was carried out in the heterogeneous hydrogenation of 1,3-COD in EtOH. After hydrogenation, the dendritic catalyst was separated from the reaction mixture by centrifugation and washed with EtOH in air, then dried in vacuo.<sup>a</sup> The spent Pd catalyst was used in the hydrogenation for the second run while keeping the activity and selectivity for hydrogenation.

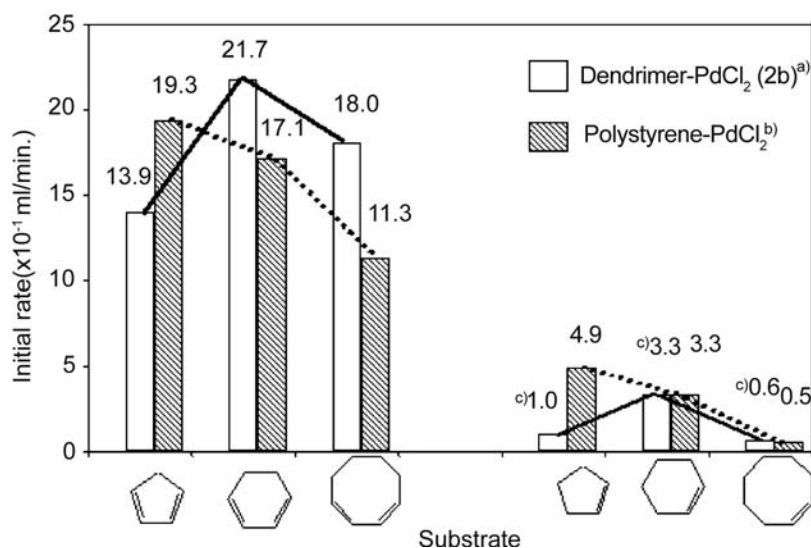

### Stereoselective Allylic Amination Reactions with Dendrimer-Bound Pd(0) Catalysts

The prominent catalysis of dendritic Pd(0) complexes **3** was investigated in the allylic amination<sup>[26,27]</sup> of *cis*-3-acetoxy-5-carbomethoxycyclohex-1-ene with morpholine. Notably, the stereoselectivity for a *cis* product increased with increasing generation (third to fifth) of dendrimers, as depicted in Fig. 4: A high *cis* selectivity of 94% was obtained with **3d**, whereas Pd(PPh<sub>3</sub>)<sub>4</sub> as a typical monomeric Pd(0) catalyst led to a slight excess of *cis* products. The first and third generations of the dendritic catalysts **3a** and **3b** showed moderate *cis* selectivity, respectively. To clarify the origin of stereoselectivity, <sup>13</sup>C spin–lattice relaxation times ( $T_1$ ) of the phosphinated dendrimers **1a–d** were measured (Fig. 4).<sup>b</sup> The  $T_1$  value of peripheral phenyl groups on **1a–d** decreased with increasing generation of dendrimers, and this phenomenon shows that the dendrimer surface becomes more congested for higher generations.<sup>[28,29]</sup> In the case of **3d**, attaining high stereoselectivity of substitution reactions can be explained by steric steering of nucleophilic attack to a surface ( $\pi$ -allyl) Pd intermediate (i.e., the active sites would be strongly shielded from the *endo* attack of the nucleophile). The moderate selectivity with **3a** and **3b** might be due to the loosely packed dendrimer surface, which would allow the partial dissociation of chelate phosphine ligands.<sup>[30]</sup> Trost and Keinan,<sup>[31]</sup> Trost and

<sup>a</sup>In the case of homogeneous hydrogenation in DMF solvents, **2** could be recovered as precipitates by adding an excess of ether to the reaction mixtures.

<sup>b</sup>Because of the low solubility of dendrimers **3**,  $T_1$  for dendrimers **1** in place of **3** was measured by the inversion–recovery method.

**Fig. 3** Substrate size dependence on initial rate in the hydrogenation of cyclic dienes and monoenes using the dendrimer PdCl<sub>2</sub> and the polystyrene PdCl<sub>2</sub>. (A) Reaction conditions: substrate, 1.3 mmol; EtOH, 5.0 mL; catalyst 2, 0.01 mmol Pd; H<sub>2</sub>, 1 atm; 25 ± 1°C. (B) Reaction conditions: substrate, 4.3 mmol; benzene–EtOH (1:1), [13 – (volume of substrate)] mL; catalyst, 0.04 mmol Pd; H<sub>2</sub>, 1 atm; 25 ± 1°C. Source: From Ref.<sup>[26]</sup>. (C) Reaction temperature, 40 ± 1°C.

Verhoeven,<sup>[32]</sup> and Bäckvall, Granberg, and Heumann<sup>[33]</sup> have also reported similar stereoselective performances in allylic amination because of the steric hindrance of solid supports with polystyrene-bound and silica-bound Pd(0) complex catalysts.

Recycling of dendritic metal complex catalysts was attempted by membrane filtration<sup>[9,10]</sup> or solvent precipitation,<sup>[11]</sup> which often results in some losses of catalytic activities during the recovery and reuse processes. Fortunately, our dendritic Pd(0) catalysts **3** could be easily recycled by using a biphasic system of DMF and heptane, and the system does not need any special procedures such as membrane filtration.

**Fig. 4** Generation dependence on stereoselectivity in the allylic amination of *cis*-3-acetoxy-5-carbomethoxycyclohex-1-ene with morpholine. Stereoselectivity for *cis* isomers was compared at 30% conversion of the substrate. Selectivity (%) = [(*cis* – *trans*)/(*cis* + *trans*)] × 100. T<sub>1</sub> values were calculated for the C<sub>4</sub> carbon (128 ppm) in the phenyl groups of corresponding dendrimers **1**, respectively.

**Fig. 5** shows a thermomorphic biphasic system containing **3**. An extremely low solubility of **3** in the heptane solvent meant that the catalysts were completely transferred to DMF and the catalyst solution could be recycled after decantation of the heptane phase containing products. For example, in the allylic substitution of *trans*-cinnamyl acetate with dibutylamine, the high catalytic activity was retained during three reuse experiments: Yields of the allylic amine in the heptane phase were 66%, 99%, 99%, and 99% for the first, second, third, and fourth runs, respectively. In the above reactions, no Pd leaching in the heptane phase was observed during recycle experiments. This is the first application of surface-functionalized dendritic catalysts in a thermomorphic system.

### Dendrimer-Encapsulated Pd Nanoparticles

The unique architecture of dendrimers provides special opportunities for host–guest chemistry<sup>[34]</sup> initially proposed as the concept of the dendritic box in which organic dyes are encapsulated through electrostatic interactions.<sup>[29]</sup> Ooe et al.<sup>[14]</sup> Crooks et al.<sup>[35]</sup> Balogh and Tomalia,<sup>[36]</sup> and Esumi et al.<sup>[37]</sup> reported on the preparation of transition metal nanoparticles such as Cu, Pt, Ag, Au, and Pd within the definite internal cavity of dendrimers to prevent the agglomeration of metal nanoparticles. In catalysis, dendrimers act as nanoreactors containing metal nanoparticles.<sup>[14,35,38]</sup>

### Preparation and Characterization of Dendrimer-Encapsulated Pd(0) Nanoparticles

Third-generation to fifth-generation PPI dendrimers were selected to construct nanocapsules because of

**Fig. 5** Schematic illustration of thermomorphic allylic amination using dendrimer-bound Pd(0) complex **3**.

their compact molecular sizes and the high density of amino groups within their dendritic structures. Treatment of the above PPI dendrimers with 3,4,5-triethoxybenzyl chloride gave surface-functionalized dendrimer **5** (**5a** = G3, **5b** = G4, and **5c** = G5), as illustrated in Fig. 6.<sup>[14]</sup> Pd nanoparticles were prepared within **5** by the following sequence: A predetermined quantity of aqueous Pd<sup>2+</sup> was extracted into the interior of **5** to give preorganized Pd<sup>2+</sup> dendrimers **6**, which were reduced with KBH<sub>4</sub> to yield Pd nanoparticles encapsulated within the dendrimers **7**.

The <sup>1</sup>H NMR spectrum of **6b** in chloroform showed that the signals of  $\alpha$ -methylene protons of amino groups were broadened. In <sup>14</sup>N NMR spectra, the broad signal of amino groups for **5b** shifted from  $-348.5$  to  $-347.2$  ppm after treatment with Pd<sup>2+</sup>, whereas amide signal at  $-278.8$  ppm remained unchanged.<sup>[39,40]</sup> These results suggest that Pd ions are coordinated to amino groups within dendrimers. The incorporation of Pd ions into dendrimers was also confirmed by the color change of liquid phases: When an aqueous solution containing 10  $\mu\text{mol}$  Pd<sup>2+</sup> ions was added to 0.72  $\mu\text{mol}$  **5b** in chloroform, the light brown color of aqueous Pd<sup>2+</sup> solution completely disappeared and then shifted to the chloroform solution. Using a 30:1 molar ratio of Pd<sup>2+</sup> to **5b**, a pale yellow color remained in the aqueous phase. Inductively coupled plasma (ICP) measurements of the aqueous phase revealed that the number of extracted Pd ions per dendrimer was 24.<sup>c</sup> The number of extracted Pd<sup>2+</sup> corresponds to the total number of N<sup>3</sup> and N<sup>4</sup> nitrogen atoms, where tertiary amino groups in  $n$ th shell were labeled as N <sup>$n$</sup>  ( $n = 1-5$ ) from the core to the  $n$ th shell, as shown in Fig. 6. The above phenomena were also observed in the case of **5a** and **5c**, respectively.

Treatment of **6** with KBH<sub>4</sub> in chloroform gave homogeneous dark brown solutions. XPS spectra of **6** showed two bands at 343.0 and 337.9 eV because of Pd 3d<sub>5/2</sub> and 3d<sub>3/2</sub>, respectively. After reduction with

**Fig. 6** Structure of triethoxybenzamide dendrimer (**5b**).

KBH<sub>4</sub>, the above two bands shifted to 340.6 (Pd 3d<sub>5/2</sub>) and 335.3 eV (Pd 3d<sub>3/2</sub>), which provides evidence for the complete reduction of Pd<sup>2+</sup> to Pd<sup>0</sup> species. A transmission electron microscopy (TEM) image of **7c** in Fig. 7 reveals the formation of roughly spherical and nearly monodispersed Pd nanoparticles. For **7a**, **7b**, and **7c**, the Pd particle diameters were  $2.6 \pm 0.6$ ,  $2.4 \pm 0.6$ , and  $2.3 \pm 0.4$  nm, respectively, which are smaller than the diameters of **5a** (3.9 nm), **5b** (4.3 nm), and **5c** (4.9 nm), respectively. All the above Pd(0) nanoparticles were so stable that no aggregates of Pd particles were observed for several months in the solution.

By comparing the size of dendrimers with that of Pd(0) nanoparticles, we found that the dendrimers,

**Fig. 7** High-resolution transmission electron microscopy image of **7c** nanocomposites. The average particle size and distribution of Pd particles were determined by counting 100 particles.

<sup>c</sup>The amount of Pd ions extracted with **4b** in chloroform was calculated from the difference of Pd concentrations in the aqueous phase between that before and that after the extraction.

especially **5c**, encapsulate the Pd(0) nanoparticles. Yeung and Crooks<sup>[41]</sup> have also prepared Pd(0) nanoparticles 2–3 nm in diameter by the chemical reduction of Pd<sup>2+</sup> species within the perfluorinated polyether-derivatized PPI dendrimer.

### Substrate-Specific Hydrogenation of Dendrimer-Encapsulated Pd(0) Nanoparticles

The catalytic performance of the dendrimer-encapsulated Pd(0) nanoparticles **7** was tested in the hydrogenation of various olefins, as shown in Table 1. Hydrogenation rates decreased with increasing generation of dendrimers from G<sub>3</sub> to G<sub>5</sub>. A conjugated diene of 1,3-cyclooctadiene was selectively hydrogenated to cyclooctene in >99% yield, and its initial hydrogenation rates using **7a**, **7b**, and **7c** were 5.4, 4.1, and 2.9, respectively (entry 1). In the case of Pd/C catalyst, cyclooctene was formed together with a 19% yield of cyclooctane as an overhydrogenation product at a complete consumption of 1,3-cyclooctadiene. High selectivity for the monoene has been also reported in the catalytic hydrogenation using poly-(amido amine) (PAMAM) dendrimer-encapsulated Pd nanoparticles<sup>[35]</sup> and poly(*N*-vinyl-2-pyrrolidone)-stabilized Pd colloids.<sup>[42]</sup> The ring size effect of substrates on hydrogenation rates was remarkable in the case of **7c**. Initial rates for the hydrogenation of cyclic conjugated dienes decreased in the order of cyclopentadiene > 1,3-cyclohexadiene > 1,3-cyclooctadiene (entries 1–3). The substrate size effect was also observed for the hydrogenation of acrylates and allylic alcohols (entries 6, 7, 9, and 10). However, using Pd/C catalysts, the hydrogenation

**Table 1** Hydrogenation of olefins using dendrimer-encapsulated Pd nanoparticles<sup>a</sup>

Entry	Substrates	Initial rate [ $\times 10^{-1}$ mL/min]			
		<b>7a</b>	<b>7b</b>	<b>7c</b>	Pd/C
1		5.4	4.1	2.9	12.0
2		9.8	8.7	7.2	11.8
3		9.2	9.0	8.3	10.3
4		0.92	0.80	0.70	2.8
5		9.5	9.0	7.6	10.0
6		5.5	4.5	3.1	9.1
7		1.5	1.2	0.86	2.4
8		12.1	11.5	11.2	11.6
9		5.8	4.2	3.8	9.3

<sup>a</sup>Reaction conditions: catalyst, 5.0  $\mu$ mol Pd; substrate, 1.0 mmol; toluene, 12.5 mL; H<sub>2</sub>, 1 atm; 30°C.

rates were not strongly affected by substrate size. A similar ring size effect using **7** was also obtained in our previous hydrogenation catalyzed by the polystyrene-bound Pd complex, where the active sites are buried within the polystyrene matrix.<sup>[22]</sup> On the contrary, when the phosphinated dendrimer-bound Pd(II) complex catalyst having active species located on the periphery of the dendrimers was used, hydrogenation rates were not strongly dependent on substrate size.<sup>[12]</sup> Thus it can be concluded that the surface congestion of dendrimers, especially for **5c**, suppresses the penetration of large substrates into encapsulated Pd nanoparticles.

Notably, in the hydrogenation of an equimolar mixture of 3-cyclohexene-1-methanol and cyclohexene using **7c**, cyclohexanemethanol was obtained exclusively without the formation of cyclohexanes. However, the selectivity for cyclohexanemethanol decreased in the case of **7a**; cyclohexane was obtained in 7% yield at a complete consumption of 3-cyclohexene-1-methanol. The use of Pd/C resulted in the formation of 60% yield of cyclohexanemethanol together with cyclohexane in 10% yield. A similar substrate specificity for polar substrates was also obtained in a competitive hydrogenation between *N*-methyl-3-cyclohexene-1-carboxamide and cyclohexene; an olefinic bond of the carboxamide was exclusively reduced to give *N*-methyl-cyclohexanecarboxamide without contamination of cyclohexane. These results are summarized in Scheme 2. To the best of our knowledge,

**Scheme 2** Competitive hydrogenation of (A) 3-cyclohexene-1-methanol and cyclohexene (B) *N*-methyl-3-cyclohexene-1-carboxamide and cyclohexene using various Pd catalysts. (A) Reaction conditions: 3-cyclohexene-1-methanol, 0.5 mmol; cyclohexene, 0.5 mmol; catalyst, 5.0  $\mu$ mol Pd; toluene, 12.5 mL; H<sub>2</sub>, 1 atm; 30°C. (B) Reaction conditions: *N*-methyl-3-cyclohexene-1-carboxamide, 0.5 mmol; cyclohexene, 0.5 mmol.

this is the first example of substrate-specific catalysis on dendrimer-metal nanocomposites reported to date.

The interaction between dendrimers and substrates was examined by NMR and FTIR. The  $^1\text{H}$  NMR spectra show that the  $\alpha$ -methylene proton signal of the tertiary amino groups for **5c** at 2.17 ppm shifted downfield to 2.20 ppm in the presence of 3-cyclohexene-1-methanol, whereas there was no change in the proton signals of **5c** in cyclohexene. In FTIR spectra of 3-cyclohexene-1-methanol, the free hydroxyl band at  $3621\text{ cm}^{-1}$  disappeared when **5c** coexisted. These data clearly show that hydrogen bonding between the hydroxyl group of the substrate and the amino group exists within the dendrimers. Hydrogen bonding plays an important role in the preferential penetration of polar substrates into the dendrimers, which could lead to the above remarkable substrate specificity. We think that complete encapsulation of Pd nanoparticles within the  $G_5$  dendrimer can promote substrate specificity for 3-cyclohexene-1-methanol and *N*-methyl-3-cyclohexene-1-carboxamide. The lower selectivity observed for the polar substrates in the case of **7a** could be attributed to partly exposed Pd nanoparticles that bulged out from the polar nanoenvironment inside the dendrimers.<sup>d</sup>

## CONCLUSION

This study demonstrated the preparation and catalyses of both periphery-functionalized dendritic catalysts and dendrimer-encapsulated metal catalysts. The location of catalytic sites and their spatial separation are very important for unique catalyses. Various dendritic effects in catalysis have been observed, including increased/decreased activity, selectivity, and stability. The high local concentration of catalytic active sites on the periphery can lead to accessibility of substrates to active metallic sites without the influence of substrate size. Moreover, these dendritic catalysts enable the easy recovery of catalysts from reaction mixtures by centrifugation and reuse without loss of activity. On the contrary, the encapsulation of catalytic species gave not only the stability of the active species but also the size selectivity by nanofiltration. Moreover, the nanoenvironment inside the dendrimers provided substrate-specific selectivity based on H-bonding. We believe that the dendrimers can contribute to the development of tailor-made catalysts with high substrate selectivity as obtained by enzymes based on molecular recognition.

<sup>d</sup>Large aggregates of Au and Pt were observed when low-generation PPI dendrimers were used (see Ref.<sup>[43]</sup>).

## INTRODUCTION

Nanometer-sized particles of II–VI semiconductors and their size-dependent physical and chemical properties are currently an object of interest in various areas of chemistry and physics.<sup>[1–8]</sup> The high luminescence (quantum yield 15–20%) of CdTe nanoparticles, stabilized with thioglycolic acid (TGA), along with their size-dependent optical properties, makes them a promising material for the engineering of nanoelectronic devices. CdTe nanoparticles have already been found to be useful as components of X-ray and  $\gamma$ -detectors,<sup>[9]</sup> photodiodes,<sup>[5]</sup> and solar cells.<sup>[10]</sup> For any possible use of such particles in thin films, especially for LED devices, it is necessary to obtain a high density of particles to facilitate charge transfer between them.<sup>[11,12]</sup>

## OVERVIEW

Simplicity and high universality of the layer-by-layer (LBL) assembly method along with the possibility to control the structure of growing films at each deposition step allows for the preparation of stratified thin composite materials with specific predetermined order of the inner nanometer-thick layers.<sup>[13–36]</sup> This method consists in cyclic deposition of oppositely charged species from their aqueous colloidal solutions. Each deposition cycle results in the formation of bilayer or two monolayers bounded together mainly due to electrostatic attraction of opposite charges. At the optimized conditions of the LBL deposition the packing and thickness of nanoparticles (NP) is reproduced from layer to layer, and there is little (if any) restructuring of the NP layer during the polyelectrolyte deposition. These conditions should change a little or not change at all when NP of different sizes are used. This makes possible the

preparation of thin films with an asymmetric internal structure by varying the LBL deposition sequence. The order of the layers can be used as a powerful tool for optimizing the diverse functional properties of the layered nanostructured materials from biological to electronic. However, the interpenetration of layers and relatively small size of most semiconductor NP (2–6 nm) may not give the possibility to distinguish separate layers inside of the film. To visualize them, one can deposit strata by assembling several bilayers of the same type of particles before assembling the next type of particles to satisfy the resolution limits of the microscopy equipment and to overcome a substantial degree of disorder in each adsorption layer.

The preparation of graded semiconductors with the methods commonly used for this task, such as molecular beam epitaxy and plasma-enhanced chemical vapor deposition,<sup>[37,38]</sup> is difficult, expensive, complex, and sometimes hazardous. The simple and universal LBL deposition method makes it possible to build graded semiconducting materials from a stable aqueous dispersion of semiconductor NP.

The objective of the current work was to apply the regularities of the LBL assembly to the optimization of the conditions for the LBL deposition of thiol-stabilized CdTe nanoparticles and to prepare graded film, based on these particles. Because of their size-dependent luminescence and, supposedly, size-independent assembly conditions, they are one of the best choices for the preparation and characterization of one-dimensionally graded films. Graded films, prepared by sequential assembly of thiol-capped CdTe nanoparticles will also be discussed in this chapter. Such films demonstrate the possible use as photodetectors, bipolar transistors, waveguides, light-emitters, and non-linear optical, magneto-optical, and high-speed devices.<sup>[38]</sup> These types of materials also reveal new phenomena in charge injection, charge carrier dynamics, and light trapping.<sup>[37]</sup>

## EXPERIMENTAL PROCEDURE

### Materials

Poly(dimethyldiallylammonium chloride) (PDDA,  $M_w = 200,000$ – $350,000$ ; 20 wt.% in water) and poly(acrylic acid) (PAA,  $M_w = 450,000$ ) used as organic components in the LBL assembly as well as cadmium perchlorate hydrate ( $\text{Cd}(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$ ), sodium hydroxide (NaOH), and thioglycolic acid (TGA), needed for CdTe nanoparticles synthesis, were bought from Aldrich (Milwaukee, WI). Aluminum telluride ( $\text{Al}_2\text{Te}_3$ ), used in the same synthesis, was purchased from Gerao Inc. (Milwaukee, WI). Sulfuric acid ( $\text{H}_2\text{SO}_4$ ) was obtained from EM Science (Gibbstown, NJ).  $\text{N}_2$  gas was obtained from Airgas (Stillwater, OK). LR-white embedding resin, used for transmission electron microscopy (TEM) sample preparation, was obtained from London Resin Company Ltd. (Berkshire, England). All chemicals were used without further purification. De-ionized water ( $> 18.0 \text{ M}\Omega \text{ cm}$ , Barnstead, E-pure system), with an unadjusted pH of approximately 5.5, was exclusively used in all solutions and rinsing procedures.

### Synthesis of CdTe Nanoparticles

Cadmium telluride (CdTe) NP, stabilized with TGA, were prepared according to the procedure described elsewhere.<sup>[4,5]</sup> Briefly, they were prepared by adding a NaHTe solution to a  $\text{Cd}(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$  aqueous solution in the presence of TGA as the stabilizing agent. The molar ratio of  $\text{Cd}^{2+}/\text{Te}^{2-}/\text{TGA}$  was 1:0.47:2.43. The 0.05 M solution of NaHTe was prepared by titration of a 0.05 M NaOH solution with an excess amount of hydrogen telluride ( $\text{H}_2\text{Te}$ ) at  $0^\circ\text{C}$  under an inert atmosphere.  $\text{H}_2\text{Te}$  gas, needed for this reaction, was generated by the direct reaction of  $\text{Al}_2\text{Te}_3$  with a 0.5 M  $\text{H}_2\text{SO}_4$  solution. After the titration was complete, the excess amount of hydrogen telluride was removed by bubbling the reaction mixture with  $\text{N}_2$  gas for 30 min. All initial components of the reaction mixture were saturated with  $\text{N}_2$  to obtain an oxygen-free media.

After the reaction was complete, the resulting solution was heated at  $96^\circ\text{C}$ . Such a treatment allows for the tuning of the size of the obtained CdTe nanoparticles by varying the heating time. For example, heating the reaction mixture for 30 min yielded nanocrystals with a luminescent maxima at 485–505 nm with an average particle size of 2.0–3.0 nm, while extension of the heating time to several hours produced a 5.0–6.0-nm nanoparticles with a luminescent maxima at 605–620 nm. CdTe nanocrystals with emission peaks at 485–505, 530–545, 570–585, and 605–630 nm display green, yellow, orange, and red luminescence, respectively, and will be denoted so accordingly.

### Layer-by-Layer Assembly of CdTe Nanoparticles

As substrates for CdTe nanoparticles LBL assembly, glass slides, silicon wafers, and cellulose acetate (CA) films were used. Transparent substrates were needed for UV-visible spectroscopy and luminescence measurements. Because glass does not absorb light at wavelengths higher than 320 nm, it was suitable as a substrate for such types of measurements. Silicon wafer substrates were used for the atomic force microscopy (AFM) study of the LBL-assembled films. Both the silicon wafers and glass slides were cleaned with a hot Nochromix solution in concentrated  $\text{H}_2\text{SO}_4$  followed by a rinsing with DI water. The surface of a flexible cellulose acetate film, needed for the TEM study of the graded film, was partially hydrolyzed with 0.1 M NaOH for 5 min to facilitate the LBL assembly, and then thoroughly rinsed with DI water.

As organic components of a LBL assembly system, positively charged PDDA and negatively charged PAA were used. A typical deposition step consisted of 1) deposition of the PDDA from its 1% aqueous solution (pH = 9) for 10 min; 2) two rinses with DI water for 1 min each; 3) deposition for 20 min of CdTe nanoparticles from as-synthesized dispersion (pH = 9–10); and 4) two rinses with DI water for 1 min each. To enhance the LBL assembly of the CdTe NP, the precursor bilayer of the PDDA/PAA was deposited on a clean substrate surface in the same fashion that was used for the LBL assembly of magnetic NP. This layer formed a uniform surface coating, providing better adsorption for subsequent NP layers. Poly(acrylic acid) was assembled from its 1% aqueous solution (pH = 3.5).

The graded LBL assembled films were prepared on glass slides and cellulose acetate substrates from “green,” “yellow,” “orange,” and “red” nanoparticles to produce a model of NP rainbow. Typically, 5–10 PDDA/NP bilayers of each of four luminescent colors were deposited. The precursor bilayer of PDDA/PAA was assembled before carrying out the preparation of the graded film. The surface of the cellulose acetate film was partially hydrolyzed with NaOH to add additional charges to it.

### Luminescence Spectroscopy

The progress of nanoparticle growth in the reaction media as well as the progress of their LBL assembly was monitored with Fluorolog 3 and Fluoromax 2 from JY SPEX by registering the luminescence spectra of the particles. During the nanocrystal growth step, the spectra were taken every 15–20 min. To check the growth of the graded CdTe film, fluorospectra were taken after the deposition of PDDA/CdTe bilayers of each color. The right-angle registration mode with no intermediate filters was utilized in these measurements.

## Transmission Electron Microscopy

Transmission electron microscopy and high-resolution transmission electron microscopy (HRTEM) images were taken on a Philips CM 12 instrument, equipped with super twin high-resolution lenses and Zeiss digital camera. The instrument was operated at 120 kV. A graded CdTe film was embedded in a LR-white embedding resin according to the specifications recommended by the manufacturer. The embedded film was cross sectioned utilizing a Reichert Ultracut E ultramicrotome (Leica) with "Diatome" diamond knife. The obtained 25–30-nm sections were placed on a 200-mesh copper grid coated with formvar and then dried in a desiccator for 30 min before being placed in the microscope.

## Confocal Laser Scanning Microscopy

The graded CdTe film was checked with a confocal laser scanning microscopy. The micrographs were taken with a Leica TCS SP microscope, equipped with 63 × Plan APO 1.32 NA water immersion and 100 × Plan APO 1.4 NA oil immersion objectives. The CdTe nanoparticles of the film were excited with an Ar-UV laser. The images were processed with Leica TCS NT software.

## RESULTS AND DISCUSSION

### Synthesis of CdTe Nanoparticles

The aqueous solutions of nanoparticles obtained according to the procedure described in the experimental part of this entry have narrow and symmetric peaks ranging from 495 nm for "green" CdTe to 620 nm for "red" CdTe NP (Fig. 1). The set of vessels, shown in Fig. 1A, contain solutions of TGA-stabilized CdTe excited with a UV lamp ( $\lambda_{\text{ex}} = 368$  nm). The average particle size gradually increases from 2.0–3.0 nm for "green" NP to 5.0–6.0 nm for "red" NP as determined by HRTEM. The arrows indicate the solutions from which the luminescence spectra (Fig. 1B) were taken. A wider peak for the "yellow" CdTe solution can be attributed to the higher polydispersity of CdTe nanoparticles compared to "green," "orange," and "red" solutions.

### Layer-by-Layer Deposition of CdTe Nanoparticles

The LBL deposition of CdTe nanoparticles was performed on glass slides and silicon wafers. The progress of the assembly was monitored by UV-visible spectroscopy and AFM. Fig. 2 shows the UV-visible spectra of a growing film of "green" CdTe nanoparticles. The spectra show the UV-visible adsorption peaks

**Fig. 1** (A) Optical image of vessels, containing aqueous dispersions of CdTe nanoparticles excited with UV lamp. The average particle size changes gradually from 2.0–3.0 nm for the solution exhibiting green luminescence (emission peak at 495 nm) to 5.0–6.0 nm for the solution exhibiting red luminescence (emission peak at 620 nm). Arrows indicate the solutions from which the luminescence spectra (B) were taken.

**Fig. 2** (A) UV-visible adsorption spectra of "green" nanoparticles with glass slide as a substrate. (B) Dependence of O.D. at 475 nm of growing film on the number of absorbed PDDA/CdTe bilayers. Only NP absorb light at this wavelength.

**Fig. 3** AFM phase (A) and topography (B,C) images of PDDA/CdTe (A,B) and PDDA/CdTe/PDDA (C), adsorbed on precursor PDDA/PAA bilayer.

coinciding with those for the CdTe nanoparticles in the film. As in the case of the assembly of the magnetic nanoparticles the linear dependence of the increment of optical density with the number of adsorption cycles was observed (Fig. 2B). The linear dependence correlates with data published elsewhere for the LBL assembly of the semiconductor NP.<sup>[6,12]</sup> Observation of the growing film with AFM revealed a completely covered surface with a dense packing of CdTe nanoparticles after the deposition of one PDDA/CdTe bilayer, adsorbed on a precursor PDDA/PAA bilayer (Fig. 3A,B). When a layer of PDDA was adsorbed on top of the CdTe NP (Fig. 3C), the roughness of the growing film was reduced. This can be attributed to a greater number of the negative charges in the spaces between the closely packed nanoparticles, which leads to the preferential polymer adsorption (Fig. 3D).

#### Graded Films From CdTe Nanoparticles: Preparation

The assembly of a graded CdTe film started with a deposition of a precursor PDDA/PAA bilayer on

a substrate. This procedure resulted in a uniform coating, which resulted in a successful LBL growth of the film. The assembly of the NP started with an adsorption of five bilayers of PDDA/“green” CdTe NP, followed by five bilayers of PDDA/“yellow,” “orange,” and “red” CdTe NP, respectively. A sketch of the structure of the obtained film, along with the corresponding band-gap progression of the CdTe NP inside of the film, is shown in Fig. 4. With the complete addition of new layers of bigger nanoparticles, a luminescence spectrum of the LBL stack was taken (Fig. 5). When CdTe nanoparticles of a bigger size were added to the film, the luminescence of the assembly broadened and shifted toward the red part of the electromagnetic spectra. Finally, after the addition of NP of each of four colors, the luminescence spectra of the film had a plateau appearance with almost equal emission intensity in a wide range of wavelengths. The red shift of the fluorescence in comparison to the original spectra of CdTe nanoparticles (Fig. 1) can be attributed to the excitation energy transfer from smaller NP to larger ones.<sup>[39,40]</sup>

**Fig. 4** Schematic view of (A) a gradient film and (B) corresponding band-gap progression.

**Fig. 5** Luminescence spectra of thin films obtained after the sequential deposition of five bilayers of (1) “green,” (2) “yellow,” (3) “orange,” and (4) “red” CdTe nanoparticles.

### Graded Films from CdTe Nanoparticles: Evaluation of the Internal Structure

To evaluate the internal structure of a gradient CdTe film, it was assembled on a flexible CA substrate. Then the LBL stack along with substrate was embedded into epoxy resin and then cross sectioned. The choice of a CA substrate can be rationalized by the fact that it does not require a complicated slicing procedure. This makes a thin and flexible CA film preferable to those of traditional glass or silicon wafers. The surface of the CA was pretreated by partial hydrolysis with 0.1 M NaOH. Such pretreatment resulted in greater adsorption rate during the LBL assembly process.<sup>[28]</sup> A graded film consisting of five bilayers of PDDA and each of “green,” “yellow,” and “red” CdTe nanoparticles was assembled in the manner described above. Embedding and cross sectioning of the LBL stack resulted in 25-nm-thick slices, which were analyzed with TEM.

The asymmetry of the obtained film is visualized as the difference in image density on the “red” and “green” sides of the LBL stack. The side of the film containing bigger “red” CdTe nanoparticles appears to be darker. This is explained by a greater percentage of heavier elements (Cd and Te) on this side of the assembly, leading to the stronger electron beam

scattering (Fig. 6A). HRTEM images of the “green,” “yellow,” and “red” parts of the film (Fig. 6B–D) show the presence of CdTe nanoparticles inside of a polyelectrolyte matrix with an average diameter of 2–4 nm for the “green” and “yellow” and 5–6 nm for the “red” sides of the assembly. This correlates with the emission wavelength of the particles. The low contrast of HRTEM micrographs, as well as the impossibility of distinguishing the differences in sizes of the “green” and “yellow” CdTe nanoparticles inside of the LBL stack, should be attributed to a stacking of at least 3–4 “red” and 6–10 “green” and “yellow” nanoparticles on top of each other inside of the slice.

The gradient nature of the resulting CdTe film was confirmed using confocal laser scanning microscopy. The sample consisting of 10 bilayers of PDDA and each of “green,” “yellow,” “orange,” and “red” nanoparticles was assembled on a CA film. The stacks of multilayers, made from NP of the same color, were separated from each other by additional interbilayers of PDDA/PAA. A series of luminescence images were obtained at different focus depths inside the assembly when the CdTe nanoparticles in the film were excited with a UV laser. The images were processed with standard Leica TCS NT software and a cross-sectional image was obtained without physical sectioning of the film (Fig. 7A). The gradual change of luminescence

**Fig. 6** (A) TEM image of cross sections of a graded CdTe film made from five bilayers of “green,” “yellow,” and “red” nanoparticles. (B–C) HRTEM images of “green” (B), “yellow” (C), and “red” (D) parts of LBL assembly.

**Fig. 7** (A) Cross-sectional confocal microscopy image of the graded film, made from 10 bilayers of “green,” “yellow,” “orange,” and “red” CdTe nanoparticles. Additional interlayers of PDDA/PAA separate stacks made of nanoparticles of the same size. (B) Dependence of green (1) and red (2) luminescence signals intensity on focus depth during cross-sectional analysis.

color from green on one side to red on the other side of the film, as the corresponding size of the NP inside of the film increases, can be clearly seen. The absence of well-separated color layers inside of the obtained “nanorainbow” results mainly from the low resolution of the technique used. There is a certain degree of interpenetration of the separate nanoparticle layers, which may also influence the cross-sectional image.

By the difference in the positions of the maxima for the red and green channels of intensity vs. the Z-position (focus depth) plot (Fig. 7B) the thickness of the obtained CdTe assembly was estimated to be  $220 \pm 20$  nm. This correlates quite well with the expected thickness of the film. One dipping cycle during an assembly results in the formation of a 3–7-nm-thick PDDA/CdTe bilayer depending on the size of the particles used. The average thickness of a PDDA/CdTe bilayer can be estimated to be 5 nm. Poly(acrylic acid), assembled on top of PDDA, forms a 5-nm-thick bilayer as determined by ellipsometry. The thickness of graded film can be estimated by adding up these numbers:  $5 \times 40 + 3 \times 5 = 215$  nm, which matches surprisingly well the thickness estimate from the confocal study. It is important to mention that because the maximum possible magnification of the confocal microscope was  $100 \times$  with an oil immersion objective, the correct thickness estimation for the CdTe-graded film can be done for relatively thick samples.

## CONCLUSION

Layer-by-layer assembled multilayers of luminescent CdTe nanoparticles have been prepared on a number of substrates. UV–visible monitoring of the assembly process shows a linear dependence of the optical density on the number of deposited bilayers. Nanoparticles completely covered the substrate surface and formed uniform closely packed layers as was

demonstrated by AFM. Sequential assembly of the CdTe nanoparticles of different sizes, ranging from 2–3 to 5–6 nm, opens the possibility of preparing films with the gradient structures utilizing the LBL assembly method. The combination of quantum-size effects with the gradient nature of the obtained CdTe films gives the opportunity to study new physical and optical effects, as well the optimization of existing applications using nanoparticle thin films based on charge transfer. At the same time it should be mentioned that the characteristic distance for CdTe LBL films, at which a change in properties can be programmed, should exceed 100 nm. This number is significantly greater than the average thickness of one bilayer or the diameter of nanoparticles. However, this observation does not prevent the organization of the NP on a much smaller scale. It is possible to tune some parameters, such as polarizability and the refractive index, on the molecular level in such asymmetric assemblies, which may lead to the discovery of unique photonic and electronic devices.

## ACKNOWLEDGMENTS

The authors are grateful to Dr. Michael Giersig (Hahn-Meitner-Institut, Berlin, Germany) for assistance with TEM and Jim Henthorn (Oklahoma University Health Sciences Center, Oklahoma City, OK, USA) for aid with confocal microscopy.

# Dip-Pen Nanolithography: Applications and Functional Extensions

Björn T. Rosner

Linette M. Demers

Nanolnk Inc., Chicago, Illinois, U.S.A.

## INTRODUCTION

In many areas of modern technology, from biotechnology to solid-state device fabrication, two-dimensional patterning techniques are used to define structures and boundaries. These patterning techniques ultimately determine features size and density and thus unit performance and price. Much is developed upon the well-known techniques of resist lithography, yet to achieve extreme spatial resolution or chemical versatility other techniques are better suited.

Dip-Pen Nanolithography (DPN<sup>TM</sup>) is a widely used scanning probe lithography (SPL) method. Here, a sharp tip is coated with a functional molecule (the “ink”) and brought into contact with a surface where it deposits ink via a water meniscus. The DPN process is a direct-write pattern transfer technique with nanometer resolution and is inherently general with respect to usable inks and substrates.

This entry serves to outline the basics of DPN writing and discusses its most important applications as well as new technological advances in DPN instrumentation.

## BACKGROUND

The invention of scanning tunneling microscopy (STM) in the early 1980s by Binnig and Rohrer<sup>[1]</sup> and the subsequent development of other scanning probe microscopy (SPM) techniques, most notably atomic force microscopy (AFM),<sup>[2]</sup> made much of nanotechnology accessible. The field of nanotechnology can be split into three major components: One is based on the ability to directly observe structures at atomic and molecular dimensions; another is involved in the direct measurement of a myriad of physical properties at the smallest scale; and the third deals with the fabrication of nanoscale structures with unique properties. Among the many techniques to produce nanoscale features, SPL techniques are of particular interest because of their inherent flexibility.<sup>[3–5]</sup> In all

instances of SPL, a proximal probe is used to locally modify the surface. These surface modification techniques can be further divided into categories found in their molecular-scale chemical synthesis counterparts<sup>[6]</sup>—that is, additive lithography (e.g., oxidation lithography<sup>[7–9]</sup>), subtractive lithography (e.g., scratching lithography<sup>[10–12]</sup>), and substitutive lithography (e.g., nanografting<sup>[13,14]</sup>).

The most intuitive type of additive lithography is the direct deposition of material from a solid stylus.<sup>[15]</sup> Indeed, writing with pen on paper is one of the oldest methods to create patterns. In 1999, researchers of Chad Mirkin’s group in Northwestern University succeeded in controllable deposition of dots and lines and invented the DPN process as a result.<sup>[16,17]</sup> DPN patterning is now a patented<sup>[18–20]</sup> and commercialized<sup>[21]</sup> process.

## POSITIONING OF DPN

An overview comparison between most popular patterning techniques is shown in Table 1. Today’s most commonly employed patterning technique is photolithography, which has very high throughput due to its parallel nature but it is also very expensive if small to medium quantities of each design are desired: Exposure of a photoresist is facilitated through a photomask that—depending on required resolution—can command up to a six digit US dollar price tag. Other techniques directly borrow concepts from photolithography, enabling their convenient use as a replacement tool, however giving them the same disadvantage regarding operation costs due to mask fabrication. These techniques include nano-imprint lithography (NIL)<sup>[22]</sup> and micro-contact printing ( $\mu$ CP).<sup>[23–25]</sup> Because of the need for molds or stamps, these techniques also show little patterning flexibility and long turnaround time from pattern inception to pattern creation. On the other hand, probe- and beam-based techniques such as electron beam patterning, STM-based lithography and DPN writing allow

**Table 1** Comparison of popular nanolithography techniques

Nanopatterning technique	Serial/parallel	Material flexibility	Patterning operation flexibility	Resolution	Registration accuracy	Speed	Cost	
							Equipment	Use
Photolithography	Parallel	No	No	~90 nm	High	Very fast	\$10M++	High
E-Beam lithography	Serial	No	Yes	~15 nm	Very high	Medium	\$500k–\$5M	High
Nanoimprint lithography (NIL)	Parallel	No	No	~10 nm	High	Fast	\$1.6M	High
Dip-pen nanolithography (DPN)	Serial or parallel pens	Yes	Yes	14 nm	Extremely high	Slow, but highly scalable	\$200k	Low
Microcontact printing ( $\mu$ CP)	Parallel	Yes	No	~100 nm	Low	Fast	~\$300k?	High
Scanning tunneling microscopy (STM)	Serial	Limited	Yes	Atomic/molecular	Extremely high	Very slow	~\$200k–\$1M	Low

for a very flexible and transparent hand-off between design and patterning. E-beam lithography, which also exposes a resist as masking material, is often used instead of photolithography for concept and low-volume work and is the most commonly used method for producing high-resolution masks for mask-based techniques. E-beam lithography is reasonably fast and well developed and offers a metrology aspect in the same instrument comparable to DPN printing, but it is specialized to high-vacuum operation and resist patterning. On the other hand, the DPN process has the unique combination of material flexibility, extremely high registration accuracy<sup>[26]</sup> between patterns consisting of multiple inks, low overall cost, and ambient environmental operation. This makes DPN writing often the choice for applications involving rapid prototyping and patterning with biomolecules at the nanoscale, while its parallel probe capability holds the promise of substantially increased throughput, when required. Its excellent registration accuracy of better than 50 nm not only allows very exact registration between multiple layers, possibly with multiple inks, it also allows alignment of DPN patterns with ultrahigh precision to previously existing surface structures (e.g., microelectronic structures produced via photolithography). In the last years, an array of good review articles on general nanoscale patterning and imaging has been published.<sup>[3–5,27,28]</sup> Therefore, the following discussion focuses exclusively on DPN methods.

## BASICS OF DPN

DPN patterning is a direct deposition technique where one or more chemically coated “pens” (usually a scanning force microscopy tip) deposit a material (“ink”) with nanometer precision to form a stable pattern

feature onto a substrate (the “paper”),<sup>[16]</sup> see Fig. 1. Typically, contact mode is used for the underlying AFM operation although patterning in AC mode (e.g., non-contact mode) has also been demonstrated.<sup>[29]</sup> In a typical DPN experiment, a conventional AFM probe tip is coated with a molecule, or “ink,” by dipping the tip in a solution of the molecules. The AFM probes used are typically made of single crystal silicon or a thin film of silicon-rich silicon nitride. They have a sharp conical or pyramidal tip that ends in an apex with an effective radius of only 10–15 nm. By contacting the tip with the surface, molecules are deposited via a water meniscus that naturally condenses at the tip–substrate contact under ambient conditions. Because so many different inks can be processed via DPN printing, as explained elsewhere in this entry, it is not possible to give a clear set of deposition control parameters for all possible chemistries. However, for all processes that are fully or

**Fig. 1** The principle of DPN. A sharp pen, coated with a functional ink, is scanned across a surface and deposits material through a water meniscus.

partially based on chemical diffusion, longer tip-substrate dwell times lead to larger pattern spot areas or wider lines, see Fig. 2.<sup>[16,30,31]</sup> Lines and dots of 14 nm width or diameter have been demonstrated using 16-mercaptohexadecanoic acid (MHA) on polycrystalline gold while a clear connection between tip sharpness and achievable patterning resolution was observed.<sup>[32]</sup> Besides contact time, environmental humidity and temperature are the most important factors that change ink deposition characteristics.<sup>[33–36]</sup> Among others, an entry in this encyclopedia treats these effects in detail.<sup>[37]</sup> Because DPN ink transport onto the surface is due to highly complex yet reproducibly controllable interactions between ink and surface molecules as well as the environment, DPN printing can be used not only as a patterning technique but also as a research tool for material interactions at the nanoscale.<sup>[38–40]</sup> After patterning an ink, the same instrument can be used as an AFM in contact or AC mode to inspect the written patterns, either by using the writing tip at high scanning speeds, such that ink deposition is negligible, or by using a special reading pen in a multipen array, as described later in this entry. It is in these passive multipen array applications, as well as multi-ink writing scenarios, that the extremely high registration accuracy of scanning-probe-based instruments adds value. Another possibility to image previously written features is by mounting a fresh, un-inked probe. As features get smaller and smaller on samples that still must be easy to handle, finding the nanoscale features with a new probe becomes equivalent to searching for a pin in a haystack, especially if prototype work involves writing only a few features. In the instance of the dedicated DPN instrument NSCRIPTOR by NanoInk Inc., a two-level

**Fig. 2** A calibration run using an alkanethiol on gold substrate and the InkCal software by NanoInk. Longer dwell times and slower scan speeds result in bigger spots and wider lines, respectively.

routine allows alignment of a new scanning tip to features on the surface, first on the microscale and then on the nanoscale. With this and other useful routines, such as semiautomated ink diffusion calibration, the DPN process becomes a reliable and easy-to-use lithography technique that does not require expert knowledge to produce results.

## APPLICATIONS

### DNA Patterning

Microarrays, especially genetic arrays, are gaining acceptance as an important tool in many areas of medical research and are becoming the discovery tool of choice in the pharmaceutical community.<sup>[41]</sup> The use of microarrays can potentially save money and time in bringing a therapeutic to market by accelerating the cycle of target discovery, candidate lead validation, and toxicity studies. Genomic and proteomic microarrays are particularly powerful in this context because they facilitate high-throughput screening of vast libraries of molecules. Further developing microarrays into nanoarrays brings with it various advantages;<sup>[42]</sup> for example, reduced cost due to less usage of reagents and analytes, and higher information content on the same sample area. Balancing these improvements is the challenge of developing appropriate high-resolution screening tools. Among patterning techniques that have the potential for operation at sub-micrometer dimensions, there are two major strategies for the fabrication of bioarrays. One method employs indirect patterning by locally altering the chemical or physical properties of a surface in order to selectively immobilize or build up biomolecules. In the other method one locally deposits the molecules or materials of interest using a nanoscale delivery device. In the past, these delivery devices have taken the form of a pin, pipette, or a non-contact jetting device and typically produce spots many micrometers in diameter. This technique is preferred because several different kinds of molecules can be deposited without exposing the patterned molecules to harsh solvents, chemical etchants, ultraviolet, or electron radiation and vacuum conditions and without risking cross-contamination—the desired chemistry is carried out exactly, and only where it is desired. DPN writing is the only technology that can directly deposit biological molecules to form multiple, sub-micrometer chemically diverse patterns with ultrahigh precision and registration. DNA patterning via DPN writing can be highly controllable in terms of pattern size and shape, resulting in immobilized DNA that is functional and accessible to specific binding of labeled targets.<sup>[43]</sup> Initial studies showed that in addition to tip-coating

and humidity, a judicious choice of ink–substrate combination can facilitate the DPN process. For example, hexanethiol-modified oligonucleotides were used to directly pattern gold substrates with features ranging from 30 nm to several micrometers in size. For nanoarrays on oxidized silicon wafers or glass surfaces, acrylamide-modified oligonucleotides were deposited directly via DPN patterning onto activated (mercaptopropyl-trimethoxysilane) substrates where subsequent reaction formed a covalent link to the surface, Fig. 3A. Non-specific binding of target oligonucleotides was minimized by passivating the unpatterned regions of the substrate by reaction with buffered acrylic acid monomer at pH 10. The feature size of individual DNA spots was controllable over a range of several orders of magnitude via the tip–surface dwell time and by tuning the relative humidity inside the patterning chamber. For micrometer-sized features on silicon substrates, the binding selectivity and function of patterned oligonucleotides was verified by hybridizing complementary fluorophore-labeled DNA.<sup>[43]</sup> For example, a two-component DNA pattern was characterized by binding complementary

fluorophore-tagged complements under hybridization conditions. Importantly, the only epi-fluorescence signals detected on the sample corresponded to the complementary targets on the patterned area. An overlay of the red and green images shows the positions of the two different sequences, Fig. 3B. In a second experiment involving sub-micrometer sized features, two different DNA sequences were identified by selectively binding two different sizes of DNA-modified gold nanoparticles to the respective patterns of DNA. AFM topography was used to show that the gold particles reacted only with the correct oligonucleotide spots. Thus, the patterned oligonucleotide was accessible for hybridization and the hybridization was selective. In these preliminary experiments, spot shape, size, and emission intensity were extremely uniform within individual features and from spot to spot. With this technique, DNA spots with diameters as small as 50 nm were prepared, i.e., 10,000 times smaller (in terms of area density) than those in conventional microarrays formed by robotic spotting. With this resolution, arrays with  $\sim 100,000$  oligonucleotide spots can be generated within an area the size of a typical AFM scanner ( $100 \times 100 \mu\text{m}^2$ ), making it possible to investigate scanned probe methods of microarray readout.

**Fig. 3** (A) Surface and oligonucleotides functionalization for covalent attachment. (B) Epi-fluorescence image of an area containing two different DNA sequences. *Source:* Reprinted with permission from Ref.<sup>[43]</sup>. © 2002 AAAS.

### Protein Patterning

The DPN technique has also been extended to direct deposition of proteins. Kaplan and Mirkin were the first to directly pattern thiolated collagen and collagen-like peptides onto gold surfaces.<sup>[44]</sup> The researchers concluded that the DPN deposition process promotes the formation of native collagen fiber on the surface. Further reports of direct protein patterning include deposition of human chorionic gonadotropin antibody onto (3-glycidioxy-)propyltrimethoxysilane modified glass surfaces as well as a number of immunoproteins, enzymes, and viruses<sup>[45–51]</sup> Although DPN writing is an extremely gentle lithographic technique, surface interactions and covalent or non-covalent attachment chemistry could potentially denature some classes of proteins. Therefore, significant effort has been directed toward studying the complex issues involved in preserving the biological activity of immunoproteins such as IgG during a DPN experiment.<sup>[47]</sup> Additives such as glycerin were used in the protein patterning solution to enhance patterning capabilities when depositing human IgG and rabbit IgG nanostructures. The activity and identity of the immobilized proteins were confirmed by binding fluorescently tagged antibodies specific for the two different nanopatterns.<sup>[47]</sup> The resulting two-color fluorescence images revealed specific biological activity and indicated that the patterns

exhibited acceptable amounts of rabbit–human cross-reactivity. In these and other initial studies,<sup>[37,48]</sup> researchers used fluorescence microscopy to detect the patterned molecules. For dot spacing below 500 nm such optical detection technologies are no longer appropriate due to resolution limits imposed by the diffraction of light. In these cases other methods of detecting binding interactions must be developed. As shown for the DNA nanopatterning work presented in the previous section, nanoparticle probes can be particularly useful for selectively labeling proteins in nanoscale binding assays.<sup>[52]</sup> The binding of metal nanoparticles in particular can be detected optically, electrically, or using AFM topographic imaging.<sup>[53–55]</sup> Nanoarrays printed via DPN present another exciting opportunity: label-free screening. Monitoring label-free signals such as height, friction, and electrostatic changes can lead to high-sensitivity detection methods based on AFM imaging and on-chip electronic circuitry. Researchers at Northwestern University showed that selective binding of antibodies to these protein nanoarrays can be detected without the use of labels by monitoring small (5–15 nm) topographical height increases in AFM images,<sup>[45]</sup> see Fig. 4. A two-component array consisting of nanoscale spots of rabbit IgG protein and lysozyme enzyme was deposited on a gold substrate. When the patterned substrate was exposed to a solution containing anti-IgG and then scanned by AFM, a height increase of 5.5 nm was observed in the position of the IgG features while no height increase was observed at the site of the lysozyme features used as control, see Fig. 5.

## Other Applications

DPN writing has become a diverse research tool in the past years.<sup>[56]</sup> Thus, it comes as no surprise that the

**Fig. 4** Contact AFM images of protein nanodot arrays prepared via DPN patterning: (A) image of lysozyme nanodot array; (B) image of IgG nanodot array. *Source:* Reprinted with permission from Ref.<sup>[45]</sup>. © 2003 American Chemical Society.

**Fig. 5** Two-component DPN-generated protein pattern after reaction with anti-IgG. Top, scheme showing label-free detection method; Bottom, a height increase of  $5.5 \pm 0.9$  nm in the IgG features is observed by tapping mode AFM. Note that no height increase is observed on lysozyme pattern. *Source:* Reprinted with permission from Ref.<sup>[45]</sup>. © 2003 American Chemical Society.

materials deposited and applications pursued with DPN patterning are equally diverse. Here, a look at the main application fields of DPN writing besides the biotech sector discussed above, namely polymers, hard materials, and etch resist applications, should suffice as a starting point for further literature research by the inclined reader. Finally, recently developed advanced DPN techniques are discussed as well.

## Polymer patterning

Starting in 2002, a series of papers was published that explored patterning of various polymeric materials using DPN. It was found that it is not necessary to rely on covalent bonding between ink and substrate as driving force for ink diffusion and dependable ink transfer. Instead, DPN writing also works on molecules that use weaker attraction forces to the substrate such as electrostatic attraction<sup>[57]</sup> and possibly even van der Waals forces.<sup>[48,58]</sup> Writing electrically conductive lines on the nanoscale is a significant step for nanotechnology, especially if the materials used merge electric conductivity with optically active behavior. The group of J. De Yoreo was able to pattern a luminescent conductive polymer, MEH-PPV,<sup>[37,48]</sup> using DPN deposition and observed its optical activity using its fluorescence response. Using optical intensity rather than topographic line width, the group demonstrated a

diffusion curve similar to those observed when using alkanethiol inks on gold. These and other researchers<sup>[59]</sup> also demonstrated writing and optical imaging of various organic dyes. Conducting polymers were also deposited by Lim and Mirkin.<sup>[57]</sup> Here, two different materials, self-doped sulfonated polyaniline (SPAN) and doped polypyrrole (PPy), were deposited using water as solvent. It was found that the negatively charged SPAN polymer could be patterned in a controlled fashion on a positively charged surface, modified with diethylene-triamine, while positively charged PPy showed similar behavior on negatively charged piranha-treated substrates. It was not possible to produce controlled deposition when switching the substrate between the two polymers or when using unmodified silicon surfaces. It was therefore concluded that the electrostatic interaction served as driving force for DPN patterning for the materials. Another approach was chosen by Maynor et al.<sup>[60]</sup> where electrically biased DPN deposition, further explained below, was used to deposit polythiophene nanowires, a polymeric material that possesses interesting electrical and electrooptical properties. Unfortunately, because of the small size of the deposited structures, none of the above-mentioned researchers attempted to measure electrical characteristics of the patterned materials. The group of V. Dravid at Northwestern University has gone one step further<sup>[61]</sup> and was able to measure a distinct electrooptical response from the deposited material. In short, the researchers developed an ink containing pyrrole monomer and a polymerizing agent and patterned the ink onto an electrode gap. After curing, the patterned features exhibited clear photosensitive behavior, documented by measured  $I$ - $V$  curves with and without illumination and temporal resistance profiles with changing illumination, see Fig. 6. McKendry et al.<sup>[62]</sup> studied writing with dendrimers on silicon surfaces and produced lines down to 100 nm width. These versatile materials have potential applications, for example, in the fields of chemical sensors and photosensitive materials. The researchers investigated DPN patterning with two different classes of dendrimers and dendrimers of varying molecular weight. They found that molecular weight is an important factor in material delivery rate when comparing equally functionalized molecules. In addition, the type of surface functionalization is an important parameter for ink delivery as well. Finally, the group of C. Mirkin also demonstrated a DPN technique to produce small but diverse libraries of nanoscale polymer brushes that comprise large numbers of structurally distinct compounds.<sup>[63]</sup> This technique using surface and site-specific ring-opening metathesis polymerization is a formidable example of the use of DPN writing to produce combinatorial libraries of many different materials.

### Hard material patterning

In addition to polymers, so-called “hard” materials have received much attention in recent years from the DPN community. Typically, “hard” materials as defined for the purpose of this review have Young’s moduli near and above 80 GPa and are patterned not in a single-molecular layer but in some form of bulk deposition or discrete particle attachment. One of the most exciting techniques of particle patterning is to use structures patterned by DPN as templates for subsequent particle self-assembly. As mentioned above, Demers et al.<sup>[52]</sup> used alkylamine-modified DNA linked to DPN-patterned MHA as templating material and nanoparticles functionalized with complementary DNA in a solution as self-assembly agent. Two differently sized and functionalized types of nanoparticles were used to assemble on the respective complementarily modified areas. A most important realization stemming from this work was that it is indeed possible to create orthogonal assemblies of nanoparticles using the specificity of DNA as linking agent, resulting in small amounts of non-specific binding. The technique of templating was also ported to patterning magnetic nanostructures. Several publications exist in this field with obvious potential applications in magnetic high-density data recording. Using templating of magnetically active iron oxide ( $\text{Fe}_3\text{O}_4$ ) particles with 4–16 nm particle diameter on MHA templates, Liu et al.<sup>[64]</sup> were able to create sub-100 nm magnetic dots. Other researchers<sup>[65]</sup> used a sol containing  $\gamma\text{-Fe}_2\text{O}_3$

nanocrystals as ink and produced lines of less than 200 nm width by direct patterning on multiple substrate materials. Fu et al.<sup>[66]</sup> also used a sol-gel-based technique to produce magnetic nanostructures. Here, a BaFe precursor solution was written via DPN and then cured at 950°C. The resulting barium hexaferrite nanostructures contained polygonal single-crystalline particles with 35 nm mean diameter. Lines of less than 100 nm linewidth could be drawn while the annealed crystals were shown to have reasonably high coercivity and remnant magnetization. Su et al. were able to further make use of their development work on sol-based ink patterning<sup>[67]</sup> and produced a functional chemical sensor array.<sup>[68]</sup> The individual chemical sensors consisted of two current-carrying electrodes and a DPN-patterned dot of metal-doped SnO<sub>2</sub> connecting the electrodes. Chloroform, toluene, and acetonitrile were introduced into the atmosphere and were clearly distinguishable due to the characteristic resistance changes on the eight different sensor materials. Importantly, the sensor exhibited rapid response and fast recovery due to the small size and nanoporous structure of the patterned material.

As a last field of “hard” material DPN, patterning of metallic structures should be surveyed here. Metals have been patterned with DPN using a multitude of approaches. The group of J. Liu developed electrochemical DPN (E-DPN)<sup>[69]</sup> where an electric field is supplied between the patterning tip and the substrate. In this instance, the water meniscus that carries the ink also acts as a miniature electrochemical cell and allows for example for reduction of metal salts and deposition as elemental metal. This technique was not only used on conducting polymers<sup>[60]</sup> as mentioned above, but also to pattern a variety of metals and semiconductors including Pt, Au, Ag, and Cu using a corresponding metal salt as starting material. The same group also showed<sup>[70]</sup> that a gold metal salt can be deposited as elemental gold without the use of E-DPN on certain surfaces such as silicon, through surface-induced reduction. Such metal salts were also used to pattern catalyst sites for GaN nanowire growth.<sup>[71]</sup> Another approach to metal patterning, viable also on insulating materials, is the direct deposition of a metal precursor ink that can be converted to a metallic film at relatively low annealing temperatures. NanoInk-internal development work has yielded encouraging results<sup>[72]</sup> using this approach, see also Fig. 7. In particular, it was possible to measure electrical properties of such lines: A 5 μm wide version of the trace shown in Fig. 7 exhibited a resistivity of only 4.3 μΩ cm, making this ink formulation a good candidate for further studies into miniaturization. It is also possible to deposit metallic nanoparticles as was shown by Ben Ali et al.<sup>[73]</sup> using thiol-capped gold nanoclusters. In a further refinement of this approach, the

**Fig. 7** A metallic line deposited via DPN writing. It is 2 μm wide (see AFM scan on top) and 6 nm high (line scan below).

group of C.N.R. Rao used aqueous metal nanocrystal dispersions<sup>[74]</sup> with particle sizes of about 3 nm and produced lines of width as small as 30 nm with one to three layers of nanocrystals in height.

### Etch resist patterning

DPN patterning can also be used in a more traditional way to selectively mask an underlying material for certain further processing steps, equivalent in function to a layer of exposed and developed photoresist in traditional photolithographic microfabrication. In the first publication reporting this application by Weinberger et al.<sup>[75]</sup> 1-octadecanethiol (ODT) was patterned via DPN onto a gold-coated silicon substrate. The monolayer formed by this alkanethiol is known to protect the underlying Au from etching during certain chemical wet etching procedures.<sup>[23]</sup> Thus, using a standard ferri/ferrocyanide etchant, only the gold layer unprotected by the patterned ODT is removed. In a subsequent wet etching step, KOH attacks the silicon wafer where it is not protected by gold. This dual-resist technique results in a three-dimensional relief structure etched into the silicon with height 55 nm and top line width down to 50 nm, see Fig. 8. Importantly, this basic technique can be used to quickly and inexpensively produce molds or stamps used for NIL or μCP. Using this approach but omitting the second etch step, it is also possible to produce

**Fig. 8** (A and B) AFM topography images of DPN-patterned and wet etched silicon wafer. (C) Cross-sectional topography trace taken from image (B). *Source:* Reprinted with permission from Ref.<sup>[75]</sup>.

metal nanostructures, very similar to the way photoresist can be used together with chemical wet etchants on an underlying continuous metal thin film. Such nanoscopic structures are of interest for the study of surface-enhanced Raman spectroscopy, plasmon optical coupling, and nanoparticle-based biodiagnostics. Zhang et al. have perfected this patterning technique to produce gold structures in the sub-50 nm regime and nanogaps from 12 to 100 nm.<sup>[76]</sup> They also extended the patterning and etch protocols to include silver and palladium<sup>[77]</sup> structures in addition to gold. Finally, the group of Chad Mirkin also introduced an electrochemical desorption strategy<sup>[78]</sup> that reduces the size of already patterned structures by “whittling” them down in size from the outside. It was found that by holding the potential of a gold-patterned substrate at a value of  $-750$  mV against an Ag/AgCl electrode, DPN-generated MHA patterns were slowly reduced in size by electrochemical desorption, resulting in dots as small as 30 nm in diameter. There are indications that this technique can be well combined with the

aforementioned dual-resist technique in order to increase feature resolution.

## FUNCTIONAL EXTENSIONS OF DPN

### Passive Pen Arrays

One of the most valuable properties of DPN writing for high-volume applications is its force independence. It was shown<sup>[17]</sup> that the tip contact force for single-pen writing has no or little effect on the ink diffusion speed in the case of alkanethiol inks. This could well be an effect of binary on-off behavior due to the capillary force acting through the water meniscus, which can be orders of magnitude larger than the “contact force” of the AFM cantilever probe. Thanks to this effect, slight variations of contact force across an array of writing probes that is introduced by minute misleveling of the array with respect to the sample surface does not affect the writing process. Writing identical structures in parallel with a multipen array becomes possible as demonstrated by Hong and Mirkin<sup>[17]</sup> In this first report, a series of standard AFM probes were used together in parallel. One pen was used with AFM feedback while the others followed passively, thus the term “passive pen array.” In order to fill a large area with parallel-written features without gaps, the individual pens must be spaced not wider than the AFM scanner range, which is typically 100  $\mu\text{m}$ . Thus, microfabricated pen arrays are needed. Such microelectromechanical systems (MEMS) based parallel cantilevered pen arrays were pioneered by the group of C. Quate and used for both imaging and lithographic applications.<sup>[79,80]</sup> In recent years, the group of Chang Liu worked closely together with the original inventors of DPN to produce such passive probe arrays and report on parallel writing.<sup>[81]</sup> The same group also reported on conductivity-based contact sensing to improve probe leveling.<sup>[82]</sup> Independently, NanoInk also developed passive pen arrays customized for DPN patterning requirements and the NSCRIPTOR instrument, using 2–26 parallel pens. Among the features offered are dedicated reader and writer probes, a variety of cantilever-to-cantilever gaps, and multiple spring constants for use with different inks and substrates. Fig. 9 shows an SEM image of such an array. To increase the level of parallel DPN writing even more and make good use of the linear scaling of throughput with number of pens, two-dimensional arrays of probes are of great interest. However, they pose unique challenges in terms of leveling and contact force management. MEMS fabrication of such devices has already been demonstrated by different research groups.<sup>[83,84]</sup> NanoInk produced a 1.3 million cantilever array on a 4 in. wafer footprint using conventional

**Fig. 9** SEM micrograph of NanoInk passive pen array A-26. Twenty-four writer pens are equally spaced and flanked by one wider reader tip and an additional cantilever used for array leveling.

fabrication techniques also used for NanoInk's commercial offerings of silicon nitride cantilevers, see Fig. 10A. This array was used with a fluorescent ink formulation described elsewhere<sup>[59]</sup> to pattern a large area by repeating a manual "stamp and translate" process several times. Imaging of these dots using a fluorescence microscope showed large areas of uniformly patterned dots as seen in Fig. 10B and some defect sites as well.

**Fig. 10** (A) SEM images of a 1.3 million pen array fabricated by NanoInk, showing multiple double-rows of cantilevers. (B) A zoom-in on opposing pens. (C) Fluorescence image acquired after stamp-and-repeat operation with the inked array.

## Ink Delivery

In the most basic DPN process, the entire AFM pen is submerged and then removed from the ink solution. In many cases excess ink and solvent are removed with a high-pressure blast of air or gas. While this technique can produce good results in skilled hands, it is advantageous to have a more reproducible approach to inking the pen. Various research groups have worked on developing a writing pen with continuous ink supply as it can be found in a macroscopic fountain pen.<sup>[85–87]</sup> However, these probes cannot produce line widths of less than a few hundred nanometers and are quite limited in the types of ink that can be transported. The other possibility is to introduce the ink by dipping the pen into an inkwell. For reproducible ink transfer, it is advantageous to only let the sharp tip get in contact with the liquid and not submerge the entire cantilever. This also reduces feedback laser reflection problems because spilled ink on the top side of the cantilever can reduce reflected laser intensity and produce interference effects. Most importantly, it also paves the way for inking multiple pens with different inks to allow writing multiple inks in the same session. NanoInk's approach, inspired by early work by Chang Liu at UIUC, is to produce microfabricated devices (inkwells) that carry ink and can be brought in contact with the pen to transfer ink onto the pen. These inkwells have the same lateral spacing as existing multipen arrays and consist of large ink reservoirs and distribution channels so that adjacent pens can be supplied with different inks without cross-contamination, as shown in Fig. 11. One additional and important use for microfluidic ink delivery is to not supply ink to specified probes while adjacent

**Fig. 11** SEM image of a NanoInk passive pen array A-11 aligned to an inkwell. Ten manually fillable larger reservoirs lead through microfluidic channels to 10 microwells that can ink the tips. The wider reader probe at the bottom remains uninked.

probes receive ink, as explained in the following: In the case of single-pen DPN operation, the inked probe is also used for inspection of the written pattern. While it is commonly assumed that ink transfer is negligible at very high probe scan speed, it can be very advantageous to use an adjacent, non-inked probe for pattern inspection. This allows for slower scan speed with possibly better image quality and less contamination onto the finished pattern. The inkwells were designed to deliver at least four different aqueous inks (e.g., for genomic applications) into an appropriately spaced inkwell array. Fluid transport occurs by open channel meniscus driven flow (wicking) in microchannels, which distribute liquid from reservoirs into an array of terminal inkwells connected by tributaries. The flow rates in the microchannels were calculated from a balance of the capillary and viscous forces (neglecting inertial forces).<sup>[88,89]</sup> It is important to note that proper ink containment is a function of the wetting properties of the various surfaces as well as the overall three-dimensional geometry of the pen-inkwell system. Correctly chosen parameters result in well-contained ink delivery as seen in Fig. 12. The pens could be used immediately for patterning, Fig. 13.

### Active Pens

The next advance in DPN technology, after adding the capability of using multiple parallel pens and the use of various different inks in parallel, is the move from arrays of passive probes to individually actuated pens. Passive probe arrays are limited to writing the same structure with all pens. This increases throughput  $n$ -fold with  $n$  pens if the desired final pattern is a repetition of any single pen pattern, each pattern spaced from each other by the probe pitch. For more complex and large-scale patterns, active pens are the enabling technology to use: If the actuated probes are spaced

**Fig. 12** (A) Video image of a probe array leveled and rotationally aligned with filled microwell array below. (B) Video image of the same setup during inking process. Here, cantilevers that are positioned on top of microwells are deflected toward the liquid filled microwells. This changes the apparent brightness since light reflects off-axis. *Source:* Reprinted with permission from Ref.<sup>[89]</sup>.

**Fig. 13** (A) Original bitmap used as source for the pattern. (B) After conversion to DPN instructions, this pattern was written using a NanoInk NSCRIPTOR, immediately after inking the probe in an inkwell as shown in Fig. 12.

apart as far as the scanner area is across, the patterning area is effectively increased by a factor of  $n$ . If they are closer together, they have an overlapping area where multiple inks can be overlaid into a single writing space (i.e., the scanner range). In contrast to passive pens, active probe arrays can be used to produce arbitrarily complex patterns of multiple inks over large areas. In particular, complex patterns can be drawn with a succession of single adjacent linear paths. In this “raster write” approach, the complexity of the pattern rests in the programming and timing of pen actuation rather than the complicated movement of a single pen or a passive multiprobe array.

Various actuation principles were explored, but most research to date focuses on thermal actuation. Thermal actuation of a cantilever is readily implemented using a bimorph design, where heating of a double layer of thin films of different materials will result in bending if the materials have sufficiently different thermal expansion coefficients. Furthermore, thermal bimorphs have already been used previously in MEMS design, with applications ranging from data storage<sup>[90]</sup> to AC-mode AFM<sup>[91]</sup> to wafer probe cards.<sup>[92]</sup> On the downside, thermal actuation can lead to increased cross-talk between adjacent pens as well as detrimental

**Fig. 14** Lateral force microscopy scans,  $8 \mu\text{m}^2$ , of 10 simultaneously generated ODT patterns on a gold surface, using thermomechanical active pens. Writing speed was  $1 \mu\text{m}/\text{sec}$ . *Source:* Reprinted with permission from Ref.<sup>[94]</sup>.

**Fig. 15** SEM micrograph of a NanoInk active pen array aligned to an inkwell. On top of the cantilever, the serpentine resistive heater and large area heat spreader can be clearly seen.

heating of the ink; so particular care has to be taken in the design of the pen array with these issues in mind. Sheehan et al. have shown that the heated tip can also be used to advantage.<sup>[93]</sup> Using tip temperature control, they demonstrated “thermal DPN,” or tDPN, the controlled deposition of an ink that only becomes liquid and deposits once the tip is heated. When using active pens for non-thermal DPN writing, the goal is nonetheless to keep the tip at the lowest temperature possible. Therefore, the bimorph should be kept as far away from the tip as possible. The group of Liu produced a body of work<sup>[94–96]</sup> describing the fabrication, integration, and application of a 10-pen active parallel array. The group used rigorous analytical and numerical thermomechanical modeling to optimize the design. They produced active pen arrays based on silicon nitride<sup>[95]</sup> and silicon<sup>[96]</sup> cantilevers. Notably, the group was able to write 10 numerals, each one with one active pen, using ODT as ink,<sup>[94]</sup> see Fig. 14. NanoInk also produces commercially available active pen arrays that also use thermal bimorph actuation. Notably, the two designs differ in that they have opposite actuation directions. NanoInk active pens actuate toward the substrate, which is particularly useful if the duty cycle of each single pen is expected to be less than 50%. The NanoInk bimorph design consists of the silicon nitride cantilever and an evaporated Cr/Pt/Au thin film. Fig. 15 shows such an array aligned to and approached into an inkwell array.

## CONCLUSIONS

In this review, we presented the basics of the DPN process as well as the positioning of DPN writing with

regards to other popular nanolithography techniques. Applications of DPN were surveyed, starting with biomolecule patterning, such as DNA and protein writing. Polymer and hard material patterning were also reviewed, as was the use of DPN writing to produce structures that can act as etch resists. Finally, technology developments specific to DPN methods such as passive pen arrays, active pen arrays, and inkwells were discussed.

DPN is a nanolithography technique with excellent potential. Besides continued use in research laboratories worldwide, to investigate nanoscale patterning of almost any material, it is expected that DPN writing will also find success in industrial use. Its ink-general nature, high resolution, and direct-write operation make it a good candidate for defect repair applications such as photomask repair. At the same time, it can be envisioned that DPN printing finds use in patterning applications such as producing nanoimprint lithography masters because of its scalability and fast turnaround from design to finished pattern. Continued research on inks and methods by the international research community will see these and other applications become reality.

## ACKNOWLEDGMENTS

The authors gratefully thank all employees at NanoInk Inc. for their contributions and support. In particular, thanks are due to Jason Haaheim for nanolithography technique comparisons and Dr Nabil Amro for work and images on inkwell-inked pens.

## INTRODUCTION

Many capillarity-related phenomena originate from the well-documented formation of water films on surfaces.<sup>[1]</sup> Thin water films have been studied by a variety of techniques including ellipsometry,<sup>[2]</sup> adsorption isotherms,<sup>[3]</sup> and atomic force microscopy (AFM).<sup>[4]</sup> These investigations have shown that the films are often just a few monolayers in thickness. When a water meniscus forms between an AFM tip and a surface, it has a profound effect on tip-sample interactions, both degrading image quality and interfering with force measurements.<sup>[5]</sup> However, the meniscus formed between the tip and surface has been proposed as the crucial feature that enables the AFM tip to be used as a tool for controlled deposition of molecules on surfaces in dip-pen nanolithography (DPN),<sup>[6,7]</sup> while other groups have suggested that the meniscus plays no or little role in the DPN process.<sup>[8,9]</sup>

We investigated the effects of humidity, tip speed, and dwell time on feature size during DPN using alkanethiol “ink” on gold “paper.” Our results indicate two distinct deposition regimes. The dwell time at which the transition between the two regimes occurs is independent of ambient humidity. In addition, while the feature size increases with humidity, the relative increase is independent of dwell time. The observed behavior is described using a deposition model that takes into account the kinetics of alkanethiol detachment and attachment at the tip. The model suggests that, at short dwell times and high tip speeds, the most important parameter controlling the feature size is the activation energy for detachment of the ink molecules. Additional results will be presented for luminescent molecules on a combined atomic force/scanning confocal microscope. We show that this method can be used successfully to push the limits of DPN down to controlled deposition of single molecules. We also demonstrate that this method is able to create and

visualize protein patterns on surfaces. Finally, we show that our method can be used to fabricate polymer nanowires of controlled size using conductive polymers.

## FACTORS AFFECTING DIP-PEN NANOLITHOGRAPHY

To perform DPN, an AFM tip is “inked” with a chemical of interest and brought into contact with a surface. The ink molecules flow from the tip onto the surface analogous to the actions of a fountain pen. This method is capable of producing nanostructures down to 15 nm in diameter and separated by as little as 5 nm.<sup>[10]</sup> While, in principle, nearly any ink or paper can be used, as has been demonstrated with dendrimers, conducting polymers, organic dyes, antibodies, and gold on silicon,<sup>[11–13]</sup> by far the most common application of DPN is the patterning of thiol “inks” on gold “paper.”

A variety of factors could determine the feature size achieved during DPN. These factors include dwell time, writing speed, temperature, concentration of the ink, interfacial tension, and humidity.<sup>[14]</sup> Thus a complete picture of the physical processes and materials parameters that control transfer and deposition has not yet emerged. Here we report the results of an experimental investigation of the effects of humidity, tip speed, and dwell time on feature size during DPN using mercaptohexadecanoic acid (MHA), a carboxyl-terminated alkanethiol. We analyze these results using a model that accounts for both the effect of humidity on meniscus height and the dissolution dynamics at the tip. We show that there is a transition from a dissolution-dominated to a diffusion-dominated regime, that the dwell time at which the transition occurs is independent of meniscus height, and that, for fabrication of small features, the most

important materials parameter controlling feature size is the activation energy of detachment from the tip.

## EXPERIMENTAL

### Humidity Dependence of MHA

Experiments were performed with a Digital Instruments multimode AFM enclosed in a custom-built humidity controlled box. The relative humidity was increased by ultrasonic evaporation of water or decreased by flowing dry air through the chamber. Sharpened microlever AFM probes were used as supplied by TM Microscopes. Gold substrates were prepared by sputtering 2–5 nm of titanium on silicon for improved adhesion followed by sputtering of 100 nm of gold. Inking of the cantilevers was accomplished by bringing them in contact with a soft membrane inoculated with the MHA solution under an optical microscope. All experiments were conducted at room temperature between 22°C and 23°C.

### Optically Active Inks

For the optical studies, our instrument combines AFM and scanning confocal microscopy. A bioscope AFM head (Digital Instruments, Santa Barbara, CA) is mounted on a Nikon Eclipse 300 inverted microscope equipped with a custom-built stage that incorporates a closed-loop piezo scanner (PolytecPI, Germany). The scanning stage is used in both the lithography procedure and confocal imaging. The fluorescence excited by a 514 line of Ar-Ion laser (Coherent Innova-70) is collected with  $100 \times 1.4$  NA lens, passed through a 50- $\mu\text{m}$  pinhole to reject stray light and then detected by an avalanche photodiode (Perkin Elmer Optoelectronics, Santa Clara, CA). Excitation light was rejected by a long-pass filter (Omega Optical, VT).

For both MHA and optical inks, arrays of dots and lines were fabricated by bringing an inked cantilever into contact with a freshly prepared gold surface. To minimize the transfer of ink from the tip to the substrate, the sample was rastered at speeds greater than 4 Hz. To make a dot, the raster scanning was stopped and the tip allowed to dwell at a specific location for a given time. The tip was then moved quickly to the next position and the process was repeated. In order to image the resulting pattern, the sample was rastered while recording the friction (lateral force) signal from the AFM. Fig. 1 shows a typical friction image for an array of MHA dots deposited on gold. In addition to the friction signal, for optical inks, the confocal arrangement provides a method of imaging fluorescent molecules (Fig. 2).

**Fig. 1** Friction-force image of MHA dots on gold fabricated with the indicated dwell times. *Source:* From Ref.<sup>[14]</sup>.

## RESULTS

### Model of Ink Transfer (MHA)

The first experiments performed were to determine whether the applied force on the tip could affect the patterning behavior and feature size. Experiments were conducted by varying the force from a few micro-Newtons down to negative forces. In order to obtain a negative force, the tip was first brought into contact with a positive force and then the set point was adjusted to a point below the resting position of the cantilever. No effect of contact force on feature size was observed, even at negative forces. The reason for this is that the water meniscus that forms at the tip–surface contact causes a substantial capillary force between the tip and the sample surface. In fact,

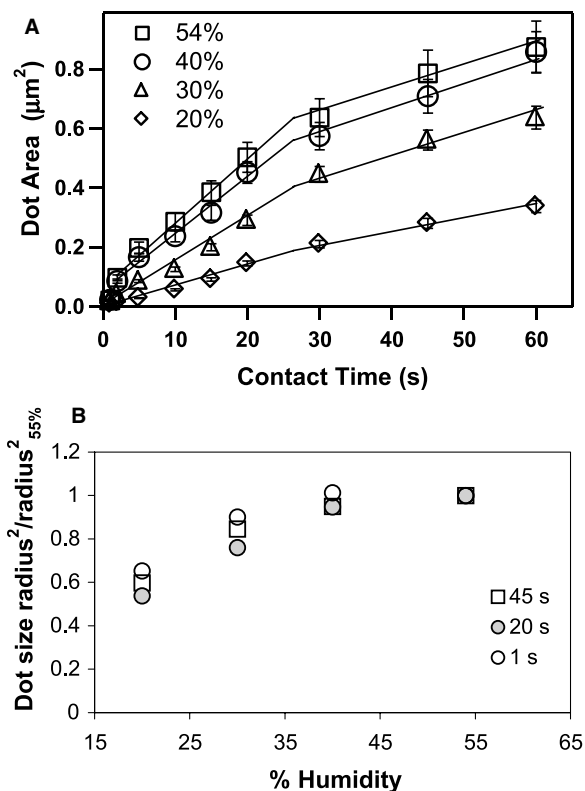

**Fig. 2** Scanning confocal image of Rhodamine 6G patterned with DPN on a glass substrate.

capillary adhesion is much larger than the force applied by the AFM cantilever and, consequently, capillarity dominates the total load force. The measured capillary adhesion force was typically  $\sim 120$  nN, as compared to the externally applied load, which was typically on the order of 10 to 20 nN. We can estimate the typical tip-sample contact area using a Hertz model of contact mechanics. For the contact of a sphere with a flat plate the contact area is given by:

$$\text{Area} = \pi a^2 = \pi \left( \frac{RP_0}{K} \right)^{2/3}$$

where  $a$  is the radius of the contact area,  $R$  is the probe radius of curvature,  $P_0$  is the applied load, and  $K$  is the elastic constant for the contact of gold and silicon nitride. For our experiments,  $R$  typically ranges from 20 to 40 nm.  $K$  can be estimated as  $8.85 \cdot 10^{10}$  Pa. For these values, the contact area at the applied load of 130 nN will be equal to  $39 \text{ nm}^2$ , which corresponds to the radius of 3.5 nm. Both values are small compared to our typical values for dot area and line width. Tip convolution did not affect the measurements of feature size except at the smallest sizes because of the small contact radius.

To determine the effects of humidity on size we placed the AFM in an environmental chamber and fabricated MHA dots at a relative humidity,  $H$ , varying between 15% and 55%. At a relative humidity at or below 15% reproducible features were not observed for the shortest contact times (0.5 sec and below), while for longer contact times we were able to produce features systematically. We initially proposed that at that humidity the meniscus does not form between the tip and the sample, thus the ink transport to the surface is inhibited. However, subsequent experiments have shown that the meniscus takes time to form and that a meniscus can form even at low humidity. Another possible explanation is that the gold used in these experiments was sputtered making grains that are larger than the smallest patterned features. Because we do not have complete data sets for the shortest contact times at low humidity, our results will be presented from 20% relative humidity. Fig. 3A shows the dependence of the dot area on dwell time for times between 0.5 and 60 sec and humidities ranging from 20% to 54%. Fig. 3B shows the dependence of dot size on humidity for three different dwell times. Three features are evident. First, the dependence of the square of the dot radius on dwell time is well fit by two linear regions separated by a sharp transition zone which occurs over the same range of dwell times for all humidities. Second, from 20% to 45% the spot size increases while above 45% there is little change in the diameter of the spot. Third, the dependence of feature size on humidity

**Fig. 3** (A) Dependence of radius squared on dwell time as a function of relative humidity. (B) Dependence of dot radius squared on humidity for three different dwell times normalized by the maximum radius squared at  $H = 55\%$ . Source: From Ref.<sup>[14]</sup>.

is the same for all dwell times. However, we observed that at the highest humidity, the precision of the measurements decreased and the edges of the dots became less well defined.

These results are consistent with those observed by Xu et al.<sup>[15]</sup> while investigating force distance curves on wet mica surfaces. In the low humidity range ( $< 20\%$ ) only a relatively small and uniform adhesion force was observed. This indicates that capillary forces did not play an important role likely because of an incomplete coverage of water on the surface. Between 20% and 45%, a steep increase in the adhesion was measured as the surface coverage of the water increased and a meniscus formed between the tip and sample. Above 45%, water formed on the surface became more “bulk-like,” showing evidence of flow dynamics and adding complexity to the measurements. Similar results have been observed with lateral force microscopy.<sup>[16]</sup>

In addition to dot fabrication, DPN can be used to write lines. In contrast to the case of dot generation where the tip is held stationary for the deposition time, during the fabrication of lines the tip continuously moves along the sample. In order to make a

comparison between the controls on dot size and line width, we fabricated a series of lines such as those shown in Fig. 4A at tip speed,  $v$ , ranging from about 0.1 to 1  $\mu\text{m}/\text{sec}$ . The dependence of line width,  $W$ , on inverse speed,  $1/v$ , is presented in Fig. 4B. The data show a linear increase down to a speed of about 0.2  $\mu\text{m}/\text{sec}$  where the dependence weakens significantly. Data on line widths for the lines of poly-[2-methoxy-5-(2'-ethyl-hexyloxy)-*p*-phenylene-vinylene] (MEH-PPV),<sup>[17]</sup> a luminescent polymer, drawn on  $\text{SiO}_2$  are also given in the inset to show that this behavior is not peculiar to MHA.

To understand our experimental results we consider the following model for ink transfer to the surface (Fig. 5). The tip moves at constant speed,  $v$ , which is zero for fabrication of dots, through a water film of thickness,  $\delta$ , on the surface. Because of a nonzero contact angle at the tip, the height,  $h$ , of the meniscus at the tip is different from  $\delta$ . Thiol molecules dissolve from the tip into the meniscus, diffuse through the meniscus, and attach to the surface making a continuous self-assembled monolayer (SAM). After a time,  $\tau$ , the tip is removed from the water film. At this time, thiol molecules are both attached to the surface and dissolved in the meniscus. Through diffusion, the

**Fig. 4** (A) Friction-force image of MHA lines on gold fabricated at tip speeds between 0.1 and 1  $\mu\text{m}/\text{sec}$ . (B) Dependence of line width on inverse tip speed for both MHA and MEH-PPV (inset). Source: From Ref.<sup>[14]</sup>.

**Fig. 5** Schematic of the physical model for molecular transfer from AFM tip to substrate through meniscus of height  $h$ . Source: From Ref.<sup>[14]</sup>.

dissolved thiols will eventually reach the edge of the SAM and attach to the substrate, contributing to the final feature size. Regardless of the tip-meniscus geometry, the magnitude of the diffusion constant, or the dissolution rate, the total number of molecules,  $N$ , transferred to the surface will be given by the integral of the transfer rate over the total tip-surface contact time  $\tau$ .

We start by considering the case of dot fabrication. Two terms contribute to  $dN/dt$ : First, molecules dissolve from the tip through thermal activated detachment at a rate:

$$\left(\frac{dN}{dt}\right)_+ = \frac{A}{\pi a^2} \beta_+ = \frac{A}{\pi a^2} \nu e^{-E_D/kT} \quad (1)$$

where  $A$  is the contact area between the tip and the meniscus,  $\pi a^2$  is the average area per thiol ink molecule,  $E_D$  is the activation energy for ink detachment,  $k$  is Boltzmann's constant,  $T$  is the temperature, and  $\nu$  is an attempt frequency. In this case, the ink molecules are not detaching from the surface of a silicon nitride tip, rather they are detaching from the surface of a bulk alkanethiol solid that has precipitated onto the tip during the inking process. Second, molecules return to the tip simply because of impingement and attachment at a rate given by:

$$\left(\frac{dN}{dt}\right)_- = A\beta_- C_0 \approx A \left(\frac{kT}{2\pi m}\right)^{1/2} e^{-E_A/kT} C_0 \quad (2)$$

where  $m$  is the mass of a thiol,  $E_A$  is the activation energy for attachment, and  $C_0$  is the concentration of thiols in solution adjacent to the tip. The right-hand side of Eq. (2) assumes a gas kinetic expression for the impinging flux. A more complicated description would modify the factors in  $\beta_-$ , but will not change the dependence on  $C_0$ . (Note that in the absence of diffusion,  $C_0$  will simply increase until it reaches the equilibrium solubility,  $C_e$ , at which time,  $(dN/dt)_+ = (dN/dt)_-$ .)

The dot radius is related to  $N$  through  $\pi R^2 = N\pi a^2$ . Combining this relationship with Eqs. (1) and (2)

and integrating gives:

$$R^2 = A \left( \beta_+ \tau - \pi a^2 \beta_- \int_0^\tau C_0(t) dt \right) \quad (3)$$

Similar arguments lead to an expression for the dependence of line-width on tip speed. Assuming the tip moves over a distance  $l$  at a speed  $v$ , we write:

$$N = \int_0^l \left( \frac{dN}{dt} \right) \left( \frac{dt}{dx} \right) dx = \frac{1}{v} \int_0^l \left( \frac{dN}{dt} \right) dx \quad (4)$$

The expressions for  $(dN/dt)_+$  and  $(dN/dt)_-$  remain the same as for dots, except that  $C_0$  is now expressed as a function of  $v$  instead of  $t$ . Recognizing that  $C_0(v)$  and  $\beta_-$  are both independent of  $x$  and that the line width  $W = N\pi a^2/l$ , Eq. (4) becomes:

$$W = \left( \frac{A}{v} \right) (\beta_+ - \pi a^2 \beta_- C_0(v)) \quad (5)$$

For both dots and lines, the exact form of  $C_0$  depends on a number of factors including the tip-meniscus geometry, surface attachment probability and the diffusivity, but because  $C_0$  is small at short contact times or high tip speeds, two regimes emerge. For small  $\tau$  (high  $v$ ),  $C_0 \approx 0$  and the dot size (line width) is given by the first term in Eq. (3).<sup>[5]</sup> That is  $R^2 \sim A\tau$  and  $W \sim A/v$ . This is the regime in which surface kinetics dominates the transfer process. For long contact times/slow tip speeds,  $C_0$  reaches a limiting value  $C_0$  that is less than  $C_c$ . Once again,  $R^2 \sim A\tau$  and  $W \sim A/v$ , but the slopes of these linear relationships are reduced. In this regime the transfer process is controlled by diffusion. We observed very similar dependencies in our experiments for both dot and line fabrication (Figs. 3 and 4).

The effect of humidity comes into this model through the impact of meniscus height,  $h$ , on contact area,  $A$ . The tip can be approximated by a cone terminated by a hemisphere of radius  $\rho$ . If  $h \gg \rho$ ,  $A$  is approximately equal to that of a conical tip with half-cone angle  $\phi$ , and height  $h$ , which is  $\pi h^2 \sin \phi$ . In contrast, for  $h < \rho$ ,  $A = 4\rho^2 \cos^{-1}(1 - h/\rho)$ .

For  $h \ll \rho$ , this has an  $h^{0.5}$  dependence, while for  $h \approx \rho$ , it is linear in  $h$ . Consequently, as the humidity is increased from 15% to 50%, we expect the dot size to increase with a dependence that ranges from  $h^{0.5}$  to  $h^2$ . Furthermore, because  $A$  is a multiplicative factor for both terms in Eqs. (3) and (5), in agreement with our measurements, the transition from dissolution-dominated to diffusion-dominated deposition should be independent of the humidity and the functional form of the dependence of dot radius on humidity should be the same for all dwell times (Fig. 3B).

An investigation of water film thickness performed on gold surfaces using scanning tunneling microscopy<sup>[18]</sup> concluded that the film consisted of 30–50-nm islands that increased in thickness from about 2 nm at  $H = 20\%$  to 10 nm at  $H = 45\%$ . Coincidentally, the increases in film thickness from that study, which are about a factor of four between  $H$  of 20% and 30% and about 1.4 between  $H$  of 30% and 40%, match our measured increases in dot size with humidity assuming an  $h^{0.5}$  dependence in the low range, and an  $h^2$  dependence in the high range.

Some questions remain on the height of the meniscus formed when the AFM tip is brought in contact with the surface. By using the Kelvin equation, the meniscus height predicted is only 2 nm at 60% relative humidity and a tip radius of 20 nm.<sup>[8]</sup> Because this proposed meniscus height is less than the height of MHA monolayer, it does not seem that a meniscus can facilitate transport. However, by imaging an AFM tip in an environmental scanning electron microscope (ESEM) in contact with a surface, we can directly visualize the height of the meniscus formed (Fig. 6). The results clearly show that the meniscus height is far greater than expected from the Kelvin equation alone.

We can quantitatively test the sensibility of this model to some degree by examining the low  $\tau$ /high  $v$  dependence of dot size and line width. In this regime, the slopes of  $R^2$  vs.  $\tau$  and  $W$  vs.  $1/v$  are both given by  $A\beta_+$ . An upper limit for the attempt frequency,  $\nu$ , is given by  $kT/h_p$ , where  $h_p$  is Planck's constant. This value is appropriate for simple atomic solids. In the case of chain-like molecules such as alkane thiols, the

**Fig. 6** ESEM images of an AFM tip in contact with a gold substrate. The relative humidity is noted in each image. The same tip was used for all images. The meniscus formed at 60% is approximately 400 nm high while at 100% is nearly 2  $\mu\text{m}$ . We cannot verify whether a meniscus forms at the low humidity range because of the resolution limit of the ESEM (approximately 75 nm under these conditions).

attempt frequency is smaller. Although no detailed calculations of the appropriate frequency factor for these systems exist, models of idealized chain-like molecules lead to an estimate for  $\nu$  which is one to two orders of magnitude smaller. Taking the data for 20% to 54% relative humidity, using a range for  $n$  of  $10^{10}$  to  $6 \times 10^{12} \text{ sec}^{-1}$ , and assuming the film thickness of 2 to 10 nm from Freund, Halbritter, and Horber<sup>[18]</sup> gives  $E_D = 45\text{--}60 \text{ kJ/mol}$  for both the dots and the lines. This number should be greater than or equal to the heat of solution for MHA in water. Literature values for the heat of solution of a number of alkanes range from 25 to 40 kJ/mol.<sup>[19,20]</sup>

Other than the comparison between the predicted value of  $E_D$  from the short-time data with the heat of solution, the other potential comparisons include 1) direct comparison of Eq. (3) with the experimental data; 2) comparison of the observed crossover time to the prediction of Eq. (3); and 3) comparison of the predicted slope of the second term in Eq. (3) with the measured slope from the long-time data. The first two involve an estimate of both  $\nu$  and  $E_D$ . As  $E_D$  goes in the exponential term, even an error of a factor of two would produce a discrepancy of an order of magnitude. As  $\nu$  is also known only to within an order of magnitude, the comparisons stated in 1) and 2) are only good to within about two orders of magnitude. The final comparison also has errors, but at least some estimate is possible. At long times, the slope should be given by  $A\pi a^2 \beta_- C_0$ . Taking  $\beta_-$  to be given by the Brownian flux (on the right-hand side of Eq. (2)), with  $T = 298 \text{ K}$ ,  $m = 4.79 \times 10^{-22} \text{ g}$  per MHA molecule,  $A = 220 \text{ nm}^2$  (meniscus height of 10 nm at 45% humidity), and  $C_0$  to be given by the equilibrium concentration of MHA in water (estimated to be  $10^{-7} \text{ M}$ ), the slope from the long-time data predicts a value for the sticking coefficient,  $e^{-E_A/kT}$  of 0.005, or  $E_A = 0.13 \text{ eV/molecule}$ . The uncertainties in the terms that define the flux as well as our lack of knowledge about the detailed tip-meniscus geometry and diffusivity in nanometer-scale films make this comparison of limited value. Although this appears to be a reasonable number, there is no literature value with which to compare it.

## Optical Inks

### Deposition of single molecules

Conventional DPN with alkanethiol inks relies on the formation of a chemical bond between the ink and the substrate to facilitate the ink transfer from the tip to the sample surface. However, recent works demonstrated that even weaker interactions such as van der Waals interactions are often sufficient to facilitate the

transfer of matter from the tip to the sample.<sup>[11,12]</sup> We have used dilute solutions of Rhodamine 6G (R6G) dye as the writing “ink” to create luminescent nanoscale patterns. Lithography was performed immediately after the “inking.” R6G has strong affinity for negatively charged glass surfaces; therefore we did not use any surface treatments to promote the transfer of the “ink.” All patterns were fabricated at ambient humidity.

Fig. 7 shows a fluorescent confocal microscopy image of a pattern of R6G deposited on glass. Several features of this image are noteworthy. First, the apparent width of the lines in the image does not reflect the actual line width of the deposited dye. Rather, image line width is determined by the size of the confocal microscope probing beam (in our case  $\sim 600 \text{ nm}$ ). Second, several features in the optical image do not show a continuous line but rather are composed of a number of spots. Moreover, these spots showed features that are characteristic of a single molecule emission pattern, such as a striped pattern and abrupt emission cessation that is indicative of a dye molecule going in and out of dark states and finally photobleaching.<sup>[21]</sup> Likewise, as we continued to image our pattern, it rapidly degraded from photobleaching. From these observations we concluded that our pattern was composed of a number of isolated single molecules deposited in a straight line by the AFM tip. Notably, we did not observe any evidence of the pattern in normal or lateral force AFM images. Therefore the amount of the material deposited on the surface was not sufficient to cause a height change or an appreciable surface free energy change. This observation is also consistent with a pattern that is composed of only a number of single molecules. It is

**Fig. 7** Scanning confocal microscopy image of a Rhodamine 6G patterned in a series of lines on glass surface. Probe translation speed was  $0.2 \mu\text{m/sec}$ . Source: From Ref.<sup>[13]</sup>.

impossible to say how well the single molecules are aligned within the pattern line because the optical image does not provide nearly enough resolution to answer this question. However, we can speculate that the dye molecules are confined laterally at least within the typical line width attainable with alkanethiol DPN. Such width is  $\sim 30$  nm in our case, but other groups have reported the patterns with line widths as small as 15 nm.<sup>[8]</sup> However, this limit may simply reflect the fact that lateral force microscopy cannot visualize thiol lines smaller than 15 nm, even if they can be fabricated by DPN. Changing the concentration of the dye solution used for inking along with careful adjustment of ambient humidity can control the average spacing between the molecules along the written line. For our sample we estimated this spacing to be  $566 \pm 210$  nm. We expect that further improvements in the deposition process such as smaller probes, rigorous humidity control, and careful choice of the writing ink will result in smaller line widths and more regular deposition patterns. These improvements will permit better alignment of single molecules on the sample for studies of the proximity effects in single molecule interactions.

### Protein patterns

One of the promising potential applications of nanolithography is fabrication of ultrahigh density protein patterns for use in “biochips.” Some of the current approaches use soft lithography or “nanografting” to create reactive sites in a SAM.<sup>[22]</sup> Proteins then attach to these reactive sites via a chemical reaction. Both of these methods are complex multistage processes and use chemical attachment, which is always complicated by the problem of nonspecific adsorption. Dip-pen nanolithography provides a simple and straightforward way for creating protein patterns as features can be directly written onto the surface. Significantly, this method provides a route to avoid the complications associated with nonspecific binding in many instances. If the protein is tagged by a specific fluorophore, then the pattern can be easily identified and verified using optical imaging. To demonstrate the feasibility of this approach we fabricated patterns of human chorionic gonadotropin (HCG) antibody tagged with tetramethylrhodamine (TMR) dye on the glass surface (Fig. 8). A glass surface was pre-treated with 3-glycidoxypropyltrimethoxysilane to introduce the epoxy groups that facilitate protein adhesion to the surface. Reliable fabrication of protein chips will require the ability to deposit proteins at high surface concentration. To demonstrate this capability, we used a high concentration of the protein “ink” [ $\sim 2 \cdot 10^{-5}$  M (1 mg/ml) solution in PBS buffer] for fabrication of the pattern in Fig. 7. In addition, each line

**Fig. 8** Scanning confocal microscopy image of a HCG antibody pattern fabricated on glass. Probe translation speed was  $0.2 \mu\text{m}/\text{sec}$ . Each line in the pattern was overwritten 10 times to maximize the protein surface density.

in the pattern was overwritten 10 times to enhance the surface concentration of the protein. The lines in the optical image on Fig. 7 appear continuous and no sufficient photobleaching was observed during scanning. The absence of single molecule behavior suggests that we have achieved large protein density in our lines.

Optical detection of a written pattern provides a straightforward way to generalize the process for creating patterns that incorporate many different proteins. Such patterns can be successfully fabricated and imaged by using a set of protein inks tagged with different fluorophores in a manner analogous to DPN with multiple inks.

### Fabrication of polymer nanowires

We have used our apparatus to fabricate and image nanowires of luminescent conductive polymers. These materials have long been under investigation as potential components of polymer light-emitting diodes (LEDs)<sup>[23]</sup> and fabrication of nanometer-scale polymer structures is a potentially significant step for creating nano-LED device prototypes. In addition, nanowires of these polymers present an ideal system for studying photoluminescence and electron transport in organic one-dimensional materials. Polymer nanowires have previously been fabricated using template-directed synthesis<sup>[24]</sup> and stretching of polymer bridges.<sup>[25]</sup> However, these methods do not allow good control over the size and position of a nanowire, or any way to assemble these nanowires in a predetermined configuration. Dip-pen nanolithography with its ability to create surface patterns is ideally suited for solving these problems. We demonstrated controlled deposition procedure by writing a series of polymer lines

**Fig. 9** Scanning confocal microscopy image of a series of MEH-PPV polymer nanowires fabricated on glass surface. A plot of the average fluorescence intensity of a polymer wire vs. inverse probe translation speed used can be found in Fig. 4B. Source: From Ref.<sup>[13]</sup>.

on a glass surface (Fig. 9) using a  $10^{-7}$  M solution of MEH-PPV in chloroform as ink. Only the following three factors limit the length of these nanowires: 1) the available range of the force microscope scanner; 2) the amount of material on the probe tip; and 3) the ability of the tip to deliver continuous ink flow. As in the two experiments that we discussed earlier, the apparent width of the structure in the image does not correspond to the real width of the nanowire; instead, it is determined by the size of the confocal microscope excitation beam. Besides the tip size, the major variable in controlling the nanowire thickness is the tip translation speed. We found that the amount of material deposited in the line during nanolithography decreases with the increase in tip translation speed. The observed trends confirm that at constant humidity the amount of material deposited on the surface is effectively controlled by the probe translation speed (Fig. 4B).

## CONCLUSION

In summary, we have used dip-pen nanolithography combined with scanning confocal optical microscopy to create and image luminescent surface patterns of arbitrary shape. We demonstrated that this method affords a robust and versatile way to pattern a variety of photoluminescent materials on the surface. Significantly, we showed that dip-pen nanolithography could be used to deposit increasingly small amounts of material down to single isolated molecules. We also showed that a combination of dip-pen nanolithography

and optical detection could be used to create and identify protein patterns on the surface, while avoiding the problem of non-specific adsorption. We demonstrated that dip-pen nanolithography affords a direct and flexible route to creating polymer nanowires of a predetermined size and shape on surfaces. We also presented a simple kinetic model that captures the main physics of the deposition process. Our model takes into account the kinetics of dissolution as well as the effect of humidity on the thickness of the adsorbed water layer. This model predicts the dependencies of feature size on dwell time and tip speed that are in agreement with the measured dependencies, as well as a transition from a kinetic to a diffusive regime. Below that transition, the fundamental material parameter that controls the feature size for a given contact time or tip speed is the activation energy for detachment of the ink into the meniscus.

These results open up several possibilities for fundamental and applied research. Further refinements in the control of the spacing between isolated single molecules will present an ideal model system for studying proximity effects in the interactions between isolated fluorophores. The ability to fabricate arrays of single molecules with controlled spacing will allow studies of collective behavior in such systems. Patterning optically tagged proteins could provide a direct route to fabrication of prototype “biochips” once the protein surface attachment chemistry is refined. In addition to significant reduction in the feature size, dip-pen nanolithography simplifies the fabrication process because it eliminates the multiple protection/deprotection steps necessary for conventional lithographic manufacturing of such chips. Finally, fabrication of conductive polymer nanowires could open up numerous possibilities for fundamental studies of electron transfer and photoconductivity in such structures. In addition, fine control over the size and shape and position of these wires will greatly facilitate their incorporation into prototype optoelectronic devices.

## Abstract

Half-way between molecular and materials chemistries lies the field of colloidal chemistry where the shape, the size, and the morphology of supramolecular assemblies are key parameters that determine their intrinsic properties, such as their interfacial behavior, surface chemistry, density, and so on. In this review, we aim to gather some of the most significant works carried out within the last few years and dealing with particles wherein the spatial distribution of these properties is not isotropic. Therefore, we present some interesting synthetic routes suggested by researchers all around the world and leading to dumbbell-like, snowman-like or Janus-like nanoparticles whose potential remarkable properties are also discussed.

## INTRODUCTION

Probably since the very first days of the mankind, symmetry has been considered as an evidence of aestheticism and harmony and consequently as a main criteria for beauty, not only in arts, but also in science. To give a single example of a field where symmetry has played and still plays a major role, one can consider the case of chemistry and highly recommend the reading of books from Magdolna and Istvan Hargittai who have thoroughly studied the matter.<sup>[1]</sup> Given all the positive influences of symmetry in so different areas of knowledge, it may be surprising that some people could be attracted by the mysteries of dissymmetry. In 1848, Louis Pasteur was probably the most famous scientist to raise the question while studying what he called the “molecular dissymmetry,” later recognized as the foundation of the stereochemistry. One of the main conclusions of his works was that only natural substances are dissymmetrical and optically active, what he summarized by “la vie est fonction de la dissymétrie de l’Univers (life is a function of the dissymmetry of the Universe).”<sup>[2]</sup> A few years later, around 1880, Pierre Curie began to study the relationship between symmetry and properties of crystals. From his early observations, he concluded that a physico-chemical phenomenon, like piezoelectricity, could not occur without a change in the symmetry elements of the system, and he summed up the idea saying that “c’est la dissymétrie qui crée le phénomène (dissymmetry creates the phenomenon).”<sup>[3]</sup>

Since these pioneering studies, dissymmetry at the molecular or crystalline scale has been thoroughly explored. Until recent years, this has not been extended to supramolecular systems and particularly colloids. In this entry, we aim to demonstrate that the specific geometry or design of dissymmetrical sub-micrometer particles should be as worthy of interest as symmetrical particles in several applications of the modern physical and chemical sciences.

## DISSYMMETRY AGAINST SYMMETRY

As quoted before, dissymmetry was historically first studied at the molecular level and this research led to tremendous applications, mainly in the field of drugs. The interest in the matter remains strong, however, and the origin of the homochirality—and therefore dissymmetry—of the biomolecules is one of the current main issues in prebiotic chemistry. As an example, the reasons why proteins comprise almost entirely “left-handed” amino acids, whereas nucleic acids contain “right-handed” sugars, are still an intriguing problem.

At the macromolecular scale, many advances have been carried out recently in the field of dendrimers and several syntheses of “unsymmetrical” structures resulting from the combination of two chemically different dendrons have been reported.<sup>[4,5]</sup> Elaboration of unimolecular micelles made of a cross-linked core

**Fig. 1** Schematic representation of some symmetrical particles (with outside views, top, and cross-sections, bottom): spherical (A), void or hollow (B), golf ball-like (C), core-shell (D), composite (E), and raspberry-like (F).

and a hairy shell with two different hemispheres also proved to be a novel amphiphilic system able to reorganize in supermicelles<sup>[6]</sup> whereas asymmetric star-block copolymer architectures have also been described.<sup>[7]</sup> Although interesting, these studies are, however, a limit case in the matter of interest of this entry since the so-formed objects are intermediate between molecules and colloidal particles.

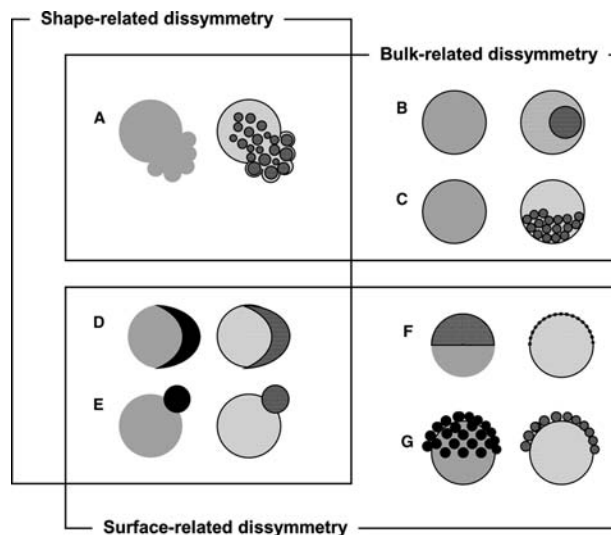

Whereas the terms asymmetrical, unsymmetrical, or dissymmetrical are intuitive enough for a molecule, this is no more the case when dealing with particles and no effort has been made, until now, to standardize the nomenclature. So far, few authors were indeed interested in the elaboration of such “non-symmetrical” particles. The main aim of this entry is to collect these works and to classify the so-formed objects, describing and comparing their synthetic routes and discussing about their current and potential applications in chemistry, physics, biology, or medicine. To make it clear, only particles deriving from spherical and isotropic objects will be discussed in the rest of this paper.

Three main parameters should be taken into account to determine whether a particle is symmetrical or not. First, the particle shape, the more evident since the term “symmetry” is commonly associated to geometric considerations, second, the chemical composition of the particle bulk, and third, the chemical composition of its surface. In Fig. 1 are presented several examples of particles previously described in the literature and that should be considered as symmetrical. They are monophasic or not, solid or hollow, homogeneously surface-modified by chemical functions or again surface-decorated by smaller particles and their morphology is often described through very colorful terms such as core-shell, golf ball-like, raspberry-like particles, etc.

In comparison, the classification of dissymmetrical particles is more complex because their dissymmetry may be related to the shape, or the chemical composition of the bulk, or the chemical composition of the surface, or any combination of these three modes. This variety is illustrated in Fig. 2 where literature examples are classified according to these criteria.

The few researchers who have reported the synthesis and the properties of such particles have also used the terms asymmetrical, unsymmetrical, non-symmetrical, non-centrosymmetrical, or they just talked about anomalous morphologies or shapes. Nevertheless, these terms are most of the time inadequate since asymmetry, for instance, which means a complete lack of symmetry, is sometimes used to describe a particle that still retained symmetry elements after the modification process.

From the viewpoint of the applications, dissymmetrical particles should be very promising when compared with symmetrical ones. Indeed, such objects may present original properties such as (i) an amphiphilic character if a hydrophilic hemisphere may be combined with a hydrophobic one, (ii) a giant dipole moment if the surface charges may segregate onto separate poles, or (iii) a discriminatory reactive behavior if two types of chemical functions may be concentrated onto separate hemispheres. So, synthesis and properties

**Fig. 2** Examples of dissymmetrical particles (outside views and cross-sections) classified according to their dissymmetry modes: octopus ocellatus-like (A), decentered core-shell (B), loaded dice-like (C), half moon-like (D), snowman-like (E), Janus-like (F), and half-raspberry-like (G).

of dissymmetrical particles will be more extensively described in the following sections.

## SYNTHESIS AND CHARACTERIZATION

In the most general case, dissymmetrical particles are prepared from symmetrical ones and several dissymmetrization procedures, i.e. chemical or physico-chemical processes altering the symmetry elements of a precursor particle, are available. In the following paragraphs, different surface modification processes as well as one-pot chemical syntheses and polymerization reactions, which historically led to surface-dissymmetrical or bulk-dissymmetrical particles, are being discussed.

### Surface-dissymmetrical Particles through Toposelective Surface Modification Techniques

#### Partial contact with reactive media

As far as we know, the oldest and most intuitive way to elaborate a dissymmetrical particle is to place a pristine symmetrical particle along an interface, where it may most likely undergo different chemical reactions or physico-chemical processes, depending on the nature of the media separated by this interface and the position of the particle at this interface.

The very first example was reported in 1988 by Casagrande and Veyssié,<sup>[8]</sup> who described the elaboration of “Janus particles”, i.e. glass beads whose one hemisphere is naturally hydrophilic and the other one hydrophobic after a regioselective chemical surface modification. This well-chosen terminology was first employed by de Gennes<sup>[9]</sup> and refers to the god of the doors (literally janus in Latin) that is most commonly represented with a two-headed face, one looking at the past and the other one at the future and also considered as a representation of beginning and end (what explains that January is the first month of the year), war and peace, or life and death.

In the work of Casagrande and Veyssié, glass microspheres (around 50  $\mu\text{m}$  in diameter) were deposited on a solid support covered with a cellulose varnish film of controllable thickness protecting one part of the spheres whereas the other one was treated with octadecyltrichlorosilane, which is commonly used to make a surface hydrophobic. After removal of the varnish that let the protected surface hydrophilic, amphiphilic particles were obtained. Indeed, optical microscopy experiments showed a discriminatory behavior of adsorbed water with the formation of small droplets onto the hydrophobic part and a continuous film onto the hydrophilic one. Although

interesting for large particles, the technique is unsuitable for nanoparticles, because the control of the varnish layer thickness below 1  $\mu\text{m}$  would be rather difficult.

More recently, Fujimoto et al. have exploited techniques using air–liquid and liquid–solid interfaces to make polymer microspheres<sup>[10]</sup> and nanoparticles<sup>[11]</sup> dissymmetrical. In the latter case, after spreading and compression at the air–water interface of a Langmuir trough, a fluorine-containing (and consequently hydrophobic) terpolymer monolayer was transferred onto polymer particles (around 200 nm in diameter) previously deposited onto a glass substrate. Initially, the particles were hydrophilic owing to the presence of amine groups at their surface and became amphiphilic after the transfer. To give evidence of the fact, contact angle measurement were carried out as well as X-ray Photoelectron Spectroscopy analyses showing that fluorine atoms were only present onto one hemisphere, the one being covered with the terpolymer.

During the same period, a similar route was investigated for silica particles whose diameter was less than 100 nm.<sup>[12,13]</sup> Taking advantage of both Langmuir technique and chemical affinity between gold colloids and amine functions, silica nanoparticles were dissymmetrically decorated by gold clusters (diameter close to 8–10 nm). Transmission electron microscopy (TEM) observations show that adsorption of metallic colloids occurred only onto the immersed surface of the initial silica particle. More precisely, statistical calculations from TEM micrographs showed that about 40% of the final silica particles were obviously dissymmetrical, i.e. with a gold coverage onto one single hemisphere. Nevertheless, about 30% extra appeared to be homogeneously covered and were in fact probably badly positioned onto the TEM grid.

“Janus” gold nanoparticles with an average diameter of 2 nm were very recently prepared by ligand exchange reactions, using an air–water interface as dissymmetrization tool.<sup>[14]</sup> Hydrophilic thiol derivatives were injected into the water subphase after compression of a Langmuir film of hydrophobic alkanethiolate-passivated gold nanoparticles. The ligand place-exchange reactions only occurred on the side of the nanoparticles facing the aqueous phase, leading to the formation of nanoparticles that exhibit hydrophobic character on the one side and hydrophilic one on the other. This amphiphilic character was confirmed by contact angle measurements, FTIR, UV–visible, and NMR spectroscopies.

By using the so-called particle lithography technique, Yake and co-workers<sup>[15]</sup> have produced dissymmetrical nanoparticles. The essence of the method is to adhere particles to a surface and then to use the surface to mask one or more regions on the particle surface as the particle is coated by smaller nanoparticles (Fig. 3A). The diameter of the lithographed region ( $D$ ) is a function

**Fig. 3** (A) Schematic of patterning colloidal particles with particle lithography. Positively charged colloidal particles are electrostatically adhered to a negatively charged glass surface. The result is a monolayer of positively charged particles adhered to the surface. Negatively charged nanoparticles of the same or different material are placed in solution and allowed to electrostatically adhere to the positively charged, adhered larger particles. The nanoparticles adhere in all areas except where the larger particles are masked off by being adhered to the glass surface. (B) Field emission scanning electron microscope image of 520-nm amidine-functionalized polystyrene latex patterned with particle lithography using smaller 170-nm silica nanoparticles. *Source:* Reprinted with permission from Ref.<sup>[15]</sup>.

of the core particles radius ( $a$ ) and the coating radius ( $R$ ). Simple geometry shows that:  $D = 4(aR)^{1/2}$ . Fig. 3B shows that amidine-functionalized polystyrene latex with size as small as 520 nm was dissymmetrically patterned with silica nanocolloids.

#### Directional fluxes and fields

Takei and Shimizu<sup>[16]</sup> have been the first to describe an easy method to prepare surface-dissymmetrical particles by evaporating gold on one side of latex microspheres (diameter of 20–50  $\mu\text{m}$ ). If this route could also be described as using a reactive interface (gas–solid interface), it seems more logical to consider this type of dissymmetrization process as the result of a surface modification in a directional flux, i.e. the direction from the gold target to the substrate-particles. This technique was applied recently to produce dissymmetrical sub-micrometer silica spheres.<sup>[17]</sup> Monolayers of 600 nm silica beads were prepared by drop-casting aqueous suspensions of particles onto glass slides. An adhesion layer of Ti/W alloy was deposited on the templates by electron-beam evaporation, followed by a thin film of gold. After the deposition of the metallic film, the thermal annealing of the coated particles led to a great increase in the mobility of gold atoms. Each gold half-shell beaded up by dewetting from its edge where it was the thinnest, inducing the transformation into a gold microcrystal sitting atop of the silica bead.

More recently, bimetallic silica nanospheres were synthesized by depositing gold and nickel on opposite hemispheres of the same particle.<sup>[18]</sup> Because of the magnetic functionality, these dissymmetrical colloids could be used as building blocks to fabricate one-dimensional assemblies, which are less accessible for traditional materials.

#### Towards larger interfaces

In all these previously described works, dissymmetry was brought to a symmetric pristine particle through oriented surface reactions. The low amount of produced particles is, however, the main limitation for further applications. In the current state of the art, a rough calculation allows to evaluate the production (in a reasonable duration) of dissymmetrical particles from few tens of particles in the case of laser-induced dissymmetry (which operates particle by particle) to few milligrams in the Langmuir film-inspired technique (assuming a trough surface of  $1\text{ m}^2$  and that every particle may be recovered).

So, the industrial future of these routes, in particular those involving a reactive interface, will mainly depend on the development of processes involving interfaces with very large surface areas. The most promising outcomes will mainly be the use of emulsions or microparticulate solid substrates. Indeed, for a perfect dissymmetry, the interface has to be theoretically infinitely flat. But, for the dissymmetrization of nanoparticles, it is reasonable to anticipate that closed interfaces, such as droplets or particles of few tens of micrometers in diameter and dispersed in a liquid medium, would be promising tools. Moreover, since the pioneering works of Pickering,<sup>[19]</sup> organic or inorganic particles are known for their ability to place themselves at liquid–liquid interfaces and therefore stabilize some emulsions.<sup>[20]</sup>

A French patent was initially published according to these goals.<sup>[21]</sup> The whole principle was to place initially symmetrical oxide nanoparticles at the surface of silicon oil droplets dispersed in water. Not taking into account the stabilization parameter, it was assumed that particles adsorbed at this interface, even during a short period of time, were able to react with molecules dissolved in the oil phase. When the reaction

**Fig. 4** (Left) Epifluorescence of Janus-modified particles in an aqueous suspension. They are positively charged around the sphere but fluorescent on one hemisphere only. The particle diameter was  $1.5\ \mu\text{m}$ . *Source:* Reprinted with permission from Ref.<sup>[24]</sup>. (Right) TEM image of “Janus” 110-nm silica particles whose amine grafted area is decorated by gold nanoparticles.

was supposed to be completed, the so-modified particles were recovered through several centrifugation cycles. Following a similar strategy, Gu and co-workers have fabricated heterodimers by exploiting the partial protection of  $\text{Fe}_3\text{O}_4$  nanoparticles, which were placed at a liquid–liquid interface during the growth of silver nanoparticles at their surface.<sup>[22]</sup>

To avoid any rotation of the nanoparticles adsorbed at the liquid/liquid interface, molten paraffin wax was chosen as the oil phase. The emulsion was prepared at a temperature where wax was molten, and then it was cooled to room temperature to “lock” particles at frozen wax-aqueous surfaces, preventing particle rotation and facilitating subsequent chemical modification and purification. “Janus” silica particles with size ranging from  $2\ \mu\text{m}$ ,<sup>[23]</sup>  $1.5\ \mu\text{m}$ , and  $800\ \text{nm}$ ,<sup>[24]</sup> to  $110\ \text{nm}$  were thus obtained in large quantity, as shown in Fig. 4

Concerning the use of microparticles as solid substrates for making nanoparticles dissymmetrical, pioneer experiments concerned the use of commercial trityl resins, formyl polystyrene, and poly(methylmethacrylate) (PMMA) beads.<sup>[25]</sup> The first step consisted in the covalent grafting of amino-functionalized silica nanoparticles ( $100\text{--}200\ \text{nm}$  in diameter) at their surface. After a thorough washing, these raspberry-like particles were stirred in a gold colloidal solution and washed again. The more delicate step concerned the cleavage reactions for removing the silica particles.

Since then, the same strategy was followed to create “Janus” 10-nm magnetite nanoparticles<sup>[26]</sup> and heterodimers.<sup>[27]</sup> Water-dispersible hybrid nanotubes composed of an inorganic nanotube surrounded by a hydrophobic polymer layer (HPL) with water-soluble polymer chains grafted on the outer surface of the

HPL was recently used as a dissymmetrization tool during a reaction of polymerization.<sup>[28]</sup> Figure 5 shows that this process led to the formation of amphiphilic “Janus” particles in which water-soluble polymer chains are grafted on one side of a hydrophobic sphere. The “Janus” particles were found to self-assemble in water into supermicelles with a narrow size distribution. Under suitable conditions, the supermicelles can dissociate into individual nanosized “Janus” particles.

### Bulk-dissymmetrical Particles through Batch Polymerization Reactions

#### Phase separation processes

Several authors have studied the formation of dissymmetrical morphologies as the consequence of phase

**Fig. 5** TEM image of amphiphilic polymeric Janus nanoparticles stained with  $\text{RuO}_4$ . *Source:* Reprinted with permission from Ref.<sup>[28]</sup>.

**Fig. 6** TEM images of: (Left) dumbbell-like and (Right) snowman-like hybrid nanoparticles synthesized through polystyrene growth onto silica seeds. *Source:* Reprinted with permission from Ref.<sup>[40]</sup>.

separation phenomena during some growth-seeded polymerization processes.<sup>[29–37]</sup> By varying the nature of the seeds and the monomer mixture, exotic structures were obtained as ovoid-like and red blood corpuscle-like,<sup>[29]</sup> golf ball-like,<sup>[30]</sup> raspberry-like and octopus-like.<sup>[32]</sup> Theoretical explanations taking into account geometrical as well as thermodynamical considerations have been proposed to predict the final particle morphology.<sup>[33,34]</sup>

Nevertheless, Cho and Lee<sup>[36]</sup> reported that in specific conditions, the styrene emulsion polymerization in the presence of PMMA-based seeds led to biphasic latex particles, such as half moon-like particles offering simultaneously bulk-related and surface-related dissymmetries or sandwich-like particles, which were in addition dissymmetrical from the viewpoint of their shape. What is also remarkable is the final particle size, around 500 nm in the larger dimension, this being interesting for some applications, as it is shown later.

Similarly, Pfau and co-workers<sup>[37]</sup> synthesized mushroom-like nanoparticles (around 200 nm in diameter) with a poly(*n*-butyl acrylate) (PnBA) core partially capped with PMMA through successive emulsion polymerization reactions. As it is often the case, SEM and TEM are privileged techniques to characterize the so-formed polymeric objects. More unusually, atomic force microscopy experiments in tapping mode (AFM-TM) were carried out. They gave evidence for a preferential organization of the dissymmetrical particles depending on the chemical nature of the substrate surface: When the substrate was hydrophilic muscovite mica, an orientational ordering of the hydrophilic PMMA caps toward the surface was observed.

#### Controlled surface nucleation

Dissymmetrical morphologies were also reported in some experiments initially dedicated to the micro-encapsulation of inorganic particles in polymer shells.

In general, such techniques derive from heterogeneous polymerization techniques, such as emulsion, dispersion, suspension, and miniemulsion techniques.<sup>[38]</sup>

Conventional emulsion polymerization involves the use of monomers insoluble or sparingly soluble in water, surfactant, and water-soluble initiator. Polymerization normally takes place in monomer-swollen micelles and surfactant-stabilized polymer particles formed by nucleation in aqueous medium. The encapsulation of non-swellable particles such as inorganic particles is successful if the nucleation step is favored at particle surface and it depends not only on interfacial properties of inorganic seeds, but also on details of nucleation and stabilization of newly formed polymer particles. If core-shell particles are generally obtained, raspberry-like,<sup>[39]</sup> dumbbell-like, and snowman-like<sup>[40]</sup> shapes based on silica and polystyrene particles were recently reported (see Fig. 6). Mushroom-like and swaddle-like nanocomposite particles<sup>[41]</sup> were also prepared via one-step miniemulsion polymerization of styrene in the presence of locally surface-modified silica particles<sup>[42,43]</sup> as seeds.

On the basis of the concept that a removable mask can temporarily protect a part of an object in a reactive medium, “Janus” silica nanoparticles were synthesized through the selective functionalization of the unprotected mineral part of the snowman-like particles and the subsequent removal of the protecting polymer mask.<sup>[44]</sup>

Dissymmetrical nanoparticles were also obtained by the controlled growth of metals or metal oxides on metallic seeds. For instance, the decomposition of iron pentacarbonyl over the surface of gold nanoparticles, followed by oxidation under air, led to dumbbell-like Au-Fe<sub>3</sub>O<sub>4</sub> nanoparticles of various sizes (Fig. 7).<sup>[45]</sup> The Au-Fe<sub>3</sub>O<sub>4</sub> structure is most likely derived from the epitaxial growth of Fe<sub>3</sub>O<sub>4</sub> on the Au seeds as Au has a face-centered-cubic structure with a lattice parameter *a* of 4.08 Å, while Fe<sub>3</sub>O<sub>4</sub> has a cubic structure with *a* = 8.35 Å, which is within 3% of being

**Fig. 7** TEM images of Au-Fe<sub>3</sub>O<sub>4</sub> particles of different sizes: (A) 3–14 nm; (B) 8–14 nm. *Source:* Reprinted with permission from Ref.<sup>[45]</sup>.

exactly double. Once the Fe<sub>3</sub>O<sub>4</sub> starts to nucleate on an Au seed, the free electrons from the Au particle must compensate for the charge induced by the polarized plane at the interface. As the Au particle has only a very limited source of electrons, this compensation makes all other facets of the Au nanoparticle electron deficient and unsuitable for multi-nucleation, giving only the dumbbell structure.

Co<sub>9</sub>S<sub>8</sub>/PdS<sub>x</sub> acorn- or peanut-shaped nanoparticles (Fig. 8) were also recently synthesized through the anisotropical growth of Co<sub>9</sub>S<sub>8</sub> phases from preformed PdS<sub>x</sub> seeds.<sup>[46,47]</sup> A thorough study of the growth process of the Pd–Co–Pd sulfide structures revealed that the “nanopeanuts” resulted from the fusion of the “nanoacorns” when the amount of passivating agent, C<sub>18</sub>SH, was small.

## POTENTIAL APPLICATIONS

When compared with symmetrical particles, the indisputable advantages of dissymmetrical ones are the additional degrees of freedom related to the anisotropy of the properties or the chemical bifunctionality confined on single particles. These non-conventional nanoparticles possess original properties and the aim of this part is to present those which have been already noticed and checked and those which are expected so far.

## Stabilization of Complex Media

The behavior of amphiphilic Janus particles at water/oil interfaces was first studied by Casagrande and Veyssié.<sup>[8]</sup> During the synthesis of these particles, the authors managed to control the surface coverage of hydrophilic and hydrophobic domains by adjusting the varnish layer thickness, giving evidence that a parallel with the Bankroft rule, well known for amphiphilic molecules that can lead to either direct or inverse emulsions, was possible.<sup>[48–50]</sup> Moreover, as shown successfully by Ondarçuhu et al.,<sup>[49]</sup> such Janus particles are very likely to stay at oil–water interfaces, provided that they are specifically functionalized with both hydrophilic and hydrophobic groups onto separate parts of their surface. These particles can be thus considered as colloidal surfactants.

## Electronic Displays

Dissymmetrical particles could also be of interest in the field of electronics, assuming that they have a dipolar moment and are able to react to an applied electric field. Typically, the gradient sensitive microscopic probes synthesized by Takei and Shimizu<sup>[16]</sup> are a good example of such an application. Whether an electric field can be applied specifically onto one dissymmetrical particle supporting a gold cap on one hemisphere (this generating the dipole moment) and bare on the other side, one can orientate the particle as desired.

## Biology and Medicine

Dissymmetrical nanoparticles with hemispheres coated with two different species may exhibit a behavior sensitive to the gradient of physico-chemical (pH, ionic strength...) or biological environments. Therefore, these objects can be used as nanoscopic probes and may find a wide ranging utility in biological studies. Furthermore, if the species grafted onto the two sides are an antibody and a drug, for instance, potential applications of these objects in biomedicine may include a powerful recognition of the targeted cell and an improved drug delivery.

## Bio-inspired Systems

In the last fields of application, the use of surface-dissymmetrical particles may require large quantities of material, involving consequently mass production processes. However, techniques of elaboration leading to small amounts of product, such as those previously described while discussing about surface-dissymmetrical particles, may be of interest for some specific studies and for instance in biochemistry.<sup>[51]</sup>

## CONCLUSION AND PROSPECTS

The current trend in materials science is to elaborate “smart” functional nanomaterials, which often requires the control of the organization and therefore of the assemblies of molecules or particles. Such a control may be gained by a careful choice of complementary chemical or biochemical functions and a well-defined localization of those groups. Dissymmetrization is a powerful tool to control such a preferential localization and can be easily used to induce one-dimensional assemblies from nanoparticles. Recent extension of this process to tetrapods with a size in the nanometer range<sup>[52]</sup> now opens a way toward multi-functional materials that could be organized in a two- or three-dimensional fashion, as desired.

## INTRODUCTION

The formation of protein–DNA complexes is a crucial step in many biological processes. Structural information on such complexes originates mainly from X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy. However, only few experimental techniques are available to deduce structural information on larger flexible protein–DNA complexes. We have designed DNA-based nanoinstruments that enable us to measure DNA deformation in solution.

Using bioinformatics and conformational search force field methods, we designed DNA molecules with one, two, and three  $dA_5$  bulges separated by double-stranded sections of DNA to be used as substrates for DNA–protein binding assays. The molecules were synthesized and 5'-end-labeled with 6-fluorescein (Fl) and 5-tetramethylrhodamine (TMRh) dyes. These large DNA molecules adopt a nearly planar conformation in aqueous solution with their helix ends being close in space. Fluorescence resonance energy transfer (FRET) between dyes was used to measure end-to-end distances and monitor the binding of proteins such as catabolite activator protein (CAP). The changes in the FRET efficiency of three-bulge DNA structures containing the specific binding sequence of CAP demonstrated significant deformation of the DNA upon binding of CAP.

In addition, the NMR solution structure of the  $dA_5$  bulge DNA fragment was solved.<sup>2</sup> This structure together with explicit positions of the dyes at the DNA helix ends allowed us to translate the measured FRET data into precise structural information.<sup>3</sup> This was demonstrated with two further DNA-binding proteins, high-mobility-group protein (HMG-D) and integration host factor (IHF). The concept of DNA-based nanoinstruments detecting DNA deformations can be used in solution, in gels, and at surfaces. It allows one to measure the influence of the DNA sequence itself, of proteins, and of environmental factors.

## BACKGROUND

Structure and function are key items in the world of biomolecules as well as in the world of physical techniques. Molecular biology and physical nanofabrication both essentially deal with nanostructures. During the last few years, biomolecular science and physics of microfabrication have come together in the geometrical dimensions of the considered objects: The world of single molecules and the world of lithographic patterning and physical manipulation are no longer separated by their size domains.

Over the last years, modern biotechnology has added fascinating new concepts and ideas for their application. By learning how nature performs wonders and how molecules can play tricks, we are discovering novel solutions to our scientific and daily problems. Since molecules are doing the work, the machinery consequently becomes very small—in the nanometer scale. Nanotechnology seems to be the ultimate domain, as atoms by themselves cannot perform complex working steps. Molecular biologists gain detailed insight into the structures of organization mechanisms of large biomolecules and functional molecular complexes. Confocal techniques and scanning probe instruments make the detection and manipulation of single molecules possible.

Advanced methods of physical nanopatterning and molecular biotechnology are fused to use the advantages of both method repertoires. Biomolecules such as nucleic acids and proteins (e.g., enzymes) seem to be particularly suitable candidates for such trials since they are defined in geometry and function and can be treated by enzymes that serve as biogenic tools. Molecular biology, genetic engineering, chemistry, and supramolecular construction contribute to the new development, as well as solid-state technology and nanolithography, surface sciences, and ultramicroscopy. The application of biomolecules in biomedical diagnostics, in the development of new drugs, and in other fields of molecular biotechnology reflects a pioneering function for the development of nanosystems.

The biomolecules and biomolecular systems used are optimized in natural evolution for their biological function within their natural environment and not for the solution of technical problems, such as physical signal transduction, mechanical motion, energy conversion, or data storage and transmission. We think that future molecular developments will supply new materials and artificial molecular tools—probably from organic chemistry—adapted to the physical and chemical problems of nanosystems that are optimally designed for their technical purposes and economical restrictions. Future molecularly based nanotechnical systems might have similarities with natural systems; in general, however, they will not be identical to them. Soon, further progress will guide nanofabrication by means of biomolecules from technically adapted biomolecules to a biomimetic molecular nanotechnology. This leads us to well-organized, completely artificial molecular nanosystems.

The nanometer-range molecular distances within biomolecular complexes are hardly measurable by biophysical techniques in solution. Three-dimensional information on nucleo- and multiprotein complexes originates mainly from X-ray crystallography and NMR spectroscopy; both techniques are labor-intensive and require large amounts of material. The resolution of light microscopy is limited to distances larger than about 200 nm, although new optical techniques reduce the resolution down to a few tenths of nanometers. Cryo electron microscopy allows us to deduce global structural features of large protein-DNA complexes,<sup>[1]</sup> but does not directly yield information of low Ångstrom resolution. Atomic force microscopy (AFM)<sup>[2]</sup> is generally limited to surfaces.

One technique yielding distance information in the low nanometer range is FRET. FRET provides

distance information for labeled macromolecules in the range 1 to 10 nm. Energy is transmitted from a donor dye to an acceptor dye that emits at a longer wavelength. The efficiency of this energy transfer is related to the distance between the dyes. If these dyes are specifically linked to known sites at macromolecules, molecular distances can be measured. The position of the dye cyanine-3 (Cy3) is known at the helical ends of DNA with atomic resolution, and evidence is accumulated on the position of fluorescein and rhodamine. This allows one to deduce absolute distance values with small errors. The measured FRET efficiency is transformed into distance values of particular precision when the dyes are separated in the range of the Förster distance  $R_0$ . This is not a general limitation since, as we have shown, by introducing structural elements such as bulges, nucleic acids can be constructed such that the helix ends come close in space. FRET efficiencies can also be quantitatively determined in polyacrylamide gels and by using fluorescent proteins in fusion. FRET is unique in its ability to provide accurate distance information (1–10 nm) in solution under physiological conditions. Recent advances make FRET a powerful tool for structural molecular biology and the construction of nanoinstruments.

In this entry we describe approaches and concepts of how FRET can be used in bionanotechnology to detect structural changes in DNA.

## MEASUREMENT PRINCIPLE

Compared to other particles such as electrons, photons are nice reporters because they have no charge. In a particular energy range, they can be easily distinguished by their color. However, in the nanometer

**Fig. 1** Change of FRET efficiency  $E$  due to DNA deformation. Gray cylinder: DNA, donor dye (D) Fl, and acceptor dye (A) TMRh.

range molecular distances cannot be measured because in a normal optical microscope the resolution is determined by the wavelength (>200 nm). Nevertheless, tricks exist that help to circumvent these physical principles. Fluorescence resonance energy transfer is one of them.

### Principles of Fluorescence Resonance Energy Transfer Measurements

FRET is a photophysical process by which energy is transferred from a fluorophore (the energy donor D) in an excited state to another chromophore (the energy acceptor A). The transfer of energy is a non-radiative, long-range (10 to 100 Å) dipole–dipole coupling process.<sup>[3]</sup> The particular advantage of FRET is the dependence (and thus sensitivity) of the energy transfer efficiency ( $E$ ) on the sixth power of the distance ( $R$ ) between the chromophores (Fig. 1).<sup>[4]</sup>

$$E = \frac{R_0^6}{R_0^6 + R^6}$$

The Förster distance ( $R_0$ ) is a dye pair-dependent parameter in the range up to 70 Å.<sup>[5]</sup>

### Multibulge DNA Constructs for Measuring Protein-Induced DNA Deformation

The distance sensitivity of the FRET efficiency is strongest when this distance is about  $R_0$  (i.e., about 5 nm). However, this is also the size domain of many biomolecules to be studied (e.g., the DNA binding domain of many proteins): The difference in the end-to-end distance of a straight 32-base-pair (bp) DNA before (10.8 nm) (Fig. 2A) and after (Fig. 2B) binding to the catabolite gene activator protein (CAP) is small and cannot be well detected with FRET.<sup>[6]</sup> In addition, undesirable dye–protein interactions could occur (Fig. 2B, \*). These problems can be circumvented by using (multi)bulge DNA molecules with helix ends close in space (Fig. 2C).<sup>[7]</sup> This molecular construction offers three advantages: 1) the FRET signal is measured in the distance range ( $R_0$ ) of highest sensitivity rather independent of the size of the biomolecule or complex, 2) dye–protein interactions can be avoided, and 3) the DNA after the framing bulges become “reporter arms” that amplify the sometimes small DNA deformation, further increasing the sensitivity enormously.<sup>[8]</sup>

### Labeling Biopolymers with Dyes

Often FRET is used to measure distances in protein structures and their assemblies in solution.<sup>[9]</sup> Proteins

**Fig. 2** Detection and characterization of DNA bending utilizing DNA molecules with helix ends close in space. Straight 32-bp DNA before (A) and after (B) binding to the catabolite gene activator protein (CAP), potential dye–protein interactions (\*). Use of three-bulge DNA molecules (C, D) for bound (D) and unbound (C) DNA. The DNA structural changes due to CAP binding are amplified using these constructs.

contain intrinsic fluorophores (tryptophan and tyrosine). In addition, they can be labeled with dyes at defined sites such as cysteine residues. However, multiple occurrence of intrinsic fluorophores and tethering sites for dyes reduce the interpretability of FRET data obtained with these chromophores.

The known helical structure of double-stranded DNA and RNA can be exploited for measuring the global structure of nucleic acids and nucleoprotein complexes. Well-defined sequences of DNA and RNA oligomers are now routinely synthesized and fluorescently labeled at the 3'- or 5'-termini as well as within the DNA sequence. Dyes binding to the minor groove of DNA have also been used in FRET studies.<sup>[10]</sup> The end labeling has three main advantages (if the shortest possible DNA is used): 1) the dyes can be spatially separated from the binding protein to avoid protein–dye interactions, 2) the DNA end sequence can be specifically designed to provide an identical chemical environment and thus, identical fluorescence properties of the dyes in a series of molecules, and 3) the exact location of Cy3 on the DNA is known<sup>[11]</sup> and evidence is accumulated on the position of fluorescein and rhodamine.<sup>[12]</sup> In most studies, fluorescein and rhodamine have been attached to the 5'-ends. Because of its improved absorption and fluorescence properties, Cy3 will largely replace rhodamine as acceptor in FRET studies. Additionally and in contrast to rhodamine, Cy3 can directly be attached to the oligonucleotides during synthesis.

### Positions of the Dye Molecules on DNA Helix Ends

In FRET experiments, the energy transfer efficiency is not only dependent on the distance between the two dyes, but also on the orientation of the transition dipoles of the dyes. For an easy quantitative representation, at least one of the dyes should have rotational freedom<sup>[13]</sup> so that all dipole orientations appear with equal probability. To achieve this flexibility, the dyes are chemically attached to biopolymers via linear alkyl chains (two to six carbon atoms). Because of the flexibility of the dyes and the associated uncertainty in the dye positions, so far it has not been possible to use dye-to-dye distances as exact restraints comparable to nuclear overhauser effect (NOE) restraints in NMR spectroscopy (Fig. 3).

Norman and coworkers solved this problem for the dye pair fluorescein/Cy3. They determined the NMR structure of Cy3 tethered to the 5'-end of a 10-bp DNA duplex.<sup>[11]</sup> The resulting geometry of the dye-DNA adduct shows Cy3 stacked on top of the DNA

**Fig. 3** Dyes Fl (D, green) and TMRh (A, red) attached to the DNA (gray cylinder) via linkers. The positional space available to the dyes is shown as colored spheres, the minimal (1.5 nm) and maximal (9.5 nm) distance is indicated.

helix end, similar to an additional base pair (Fig. 4). The location of fluorescein is given by a maximally extended linker conformation.

We calculated the distribution of fluorescein (Fl) and rhodamine (TMRh) conformations at the DNA duplex ends using conformational sampling and energy minimization.<sup>[12,14]</sup> Most of the fluorescein conformers are pointing away from the DNA with an extended linker conformation because of the electrostatic repulsion of the twofold negatively charged dye and the poly-anionic DNA. The calculated averaged position is located 10 Å from the 5'-termini in a virtual elongation of the DNA backbone. This result is in concord with anisotropy measurements,<sup>[15]</sup> indicating that fluorescein freely rotates in solution. However, most of the calculated TMRh conformers either interact with the DNA in the major groove or stack on top of the DNA helix<sup>[16]</sup> (Fig. 4). The interaction of TMRh with the DNA is confirmed by anisotropy measurements,<sup>[17]</sup> and burst-integrated fluorescence lifetime (BIFL) experiments show direct contacts of TMRh with only the last base pair of the DNA helix (C. Seidel, personal communication). For the stacked conformation we obtained further evidence from FRET measurements of a complex of 55-bp DNA with the protein IHF.<sup>[16]</sup> Thus, TMRh, like Cy3, seems to stack on top of the DNA helix end (Fig. 4).

### DNA DEFORMATION MEASURED IN SOLUTION

Here we describe nanosystems that allow the detection of the DNA deformation in solution, in gels, or at surfaces.

#### Deformation Due to Protein Binding

The DNA deformation monitored by FRET can be used as a detection tool for the presence of those DNA-binding proteins that deform the DNA on binding. We also describe DNA constructions, either by specific proteins or DNA bulges, which yield in long reporter arms amplifying small changes in DNA structure.

#### Bending and kinking

Several proteins are known to bend or kink DNA. Some of them (e.g., TATA binding protein [TBP], PAPI, HMGs, IHF, and CAP) have been studied using FRET techniques.

*TBP*: The conformational change of a 14-bp, dye-labeled DNA upon binding of TBP has been studied in solution with FRET.<sup>[18]</sup> A strong decrease in the dye-to-dye distances was observed in the complex

**Fig. 4** Position of the dyes TMRh (left) and Cy3 (right) on DNA helix ends. The molecular surface of the DNA is shown in gray; the dyes are represented as stick models in black. The location of Cy3 with respect to a 10-bp self-complementary DNA duplex was determined using two-dimensional homonuclear NMR experiments.<sup>[11]</sup> The position of TMRh attached with a six-carbon linker to the 5'-end of a DNA heptamer was modeled using systematic conformational search techniques. *Source:* From Ref.<sup>[12]</sup>.

compared to the naked DNA. The FRET data are in accord with a three-dimensional structure determined by X-ray crystallography.<sup>[19]</sup> A detailed kinetic study that used FRET revealed two intermediate complex species with similarly bent DNA. TBP binding and DNA bending were shown to occur simultaneously.<sup>[20]</sup>

**PAP1:** The conformational change of a 26-bp DNA upon binding of PAP1, a basic region leucine zipper motif containing transcription factor homologous to human c-Jun, has been studied in solution.<sup>[21]</sup> The authors conclude that the DNA adopts a bent conformation characterized by a bending angle of about 26°.

**HMG:** The HMG box is an 80-amino-acid domain found in many DNA-binding proteins and transcription factors. For reviews, see Refs.<sup>[22,23]</sup> In several studies the interaction of HMG proteins with DNA was analyzed using FRET.<sup>[24–28]</sup> The transcription factors, sex-determining region Y (SRY) and lymphoid enhancer-binding factor 1 (LEF-1), bind sequence specifically to DNA and induce a bend of 80–120°, as shown by NMR.<sup>[29,30]</sup> However, other HMG proteins bind less sequence specifically. These show elevated affinity to DNA distorted by cisplatinum,<sup>[31]</sup> to bulged DNA,<sup>[32]</sup> or to four-way junctions.<sup>[33]</sup>

Heyduk et al.<sup>[24]</sup> studied the interaction of the *Chironomus* HMG1a to a 30-bp double-stranded DNA using FRET between a europium chelate complex as donor and terminally attached cyanine-5 (Cy5). They estimated a DNA bending angle of 150° in the complex. We studied the binding of the *Drosophila* HMG-D and protein homologues to a dA<sub>2</sub> bulge containing 18-bp DNA 5'-labeled with fluorescein and rhodamine.<sup>[25]</sup> Molecular modeling was used to interpret the FRET data and to deduce a bending angle of 95°.<sup>[34]</sup> This value compares well with a bending

angle of 110° in the X-ray structure of HMG-D binding to a 12-bp DNA.<sup>[35]</sup> Further structural details predicted by our model (which were based on NMR data, footprinting results, and FRET) (Fig. 5) were confirmed by the subsequently published X-ray structure.

**IHF:** The interaction of DNA with the protein IHF was studied in solution with FRET. The crystal structure of this protein<sup>[36]</sup> complexed with a 35-bp DNA fragment containing a nick shows that IHF induces a U-shaped DNA conformation. To check if the DNA in the “physiological” complex (with intact DNA) adopts a similar conformation as revealed by the X-ray structure, the end-to-end distances of nicked and intact 55-bp DNA oligomers in the presence of IHF were measured using FRET.<sup>[16]</sup> For nicked

**Fig. 5** HMG-D binding (right) to dye-labeled, 18-bp, dA<sub>2</sub>-bulged DNA (naked DNA: left). Upon binding the protein increases the bend angle and reduces the dye distance from 6.4 to 5.6 nm.

DNA, the experimental dye-to-dye distance agrees, within 1–2 Å, with the distance between the dyes in a model based on the X-ray. The measured dye-to-dye distance of intact DNA is 4 Å larger than that of nicked DNA, suggesting a slightly different conformation of the IHF complex in solution for intact compared to nicked DNA (Fig. 6).

**CAP:** Catabolite activator protein binding to straight DNA (see Figs. 2 and 7) leads to a significant bending of the nucleic acid molecule.<sup>[37]</sup> Using an iterative approach of molecular modeling, DNA synthesis, and FRET measurements, we designed 22- to 65-bp-long DNA molecules with two or three dA<sub>5</sub> bulges each separated by double-stranded sections of B-DNA.<sup>[7]</sup> A molecular model of a two-bulge DNA molecule with close helix ends is shown in Fig. 8. Double-helical B-DNA regions can be used as substrates for protein binding. DNA molecules 65 bp long and containing three dA<sub>5</sub> bulges (and the CAP binding site in between) were constructed, 5'-end labeled, and used to monitor the binding of CAP by measuring FRET.

**Fig. 6** FRET analysis of IHF in complex with an intact 55-bp DNA.<sup>[16]</sup> The model building was based on the X-ray structure of IHF with a nicked 35-bp DNA oligomer.<sup>[36]</sup> Explicit positions for 5'-labeled dyes F1 (green) and TMRh (red) are shown. DNA strands are colored according to the covalently attached dyes, the protein is depicted in blue. Large spheres indicate the hypothetical range of locations for the dyes. Without knowledge of the exact dye positions, the end-to-end distance of the DNA could in principle be interpreted to range between 10 and 90 Å. FRET measurements show a distance of 55 Å, which is in agreement with a dye-to-dye distance of 56 Å (black arrow) in this model.

A decrease of Förster transfer efficiencies from 21% with CAP to 8% without CAP was observed (Fig. 7 and 2).<sup>[7]</sup> To be able to interpret the FRET data on a high-resolution level, we determined the NMR structure of a dA<sub>5</sub> bulge containing DNA fragment<sup>[38]</sup> and modeled the multiple bulge molecules (Fig. 8).

We constructed a series of double- and triple-bulged DNA molecules with different linker and reporter arm lengths to select those molecules that are (close to) planar and show maximal FRET efficiency<sup>[7]</sup> (Fig. 9). Because of handling reasons, the large triple-bulge DNA constructs (Fig. 9E and F) contain a nick.

### DNA twist

We constructed large triple-bulged DNA molecules not only to study the effects of CAP (see Figs. 2, 7, and 9) but also those of *EcoRI* binding (Fig. 10). Upon binding, *EcoRI* induces a twist into the DNA helix.<sup>[39]</sup> This subtle change can in principle be detected by labeled reporter arms (Fig. 10). Larger triple-bulge constructs are required to guarantee a sufficiently long and undistorted DNA binding site. The planar molecule (Fig. 10, left) is predicted to be twisted out of plane (Fig. 10, right) by *EcoRI*, increasing the dye distance and reducing FRET efficiency.<sup>[12]</sup>

### Influence of the Environment on DNA Deformation: Electrostatic Interaction of Double-Stranded DNA Strands

In the U-shaped DNA molecule, the two double-stranded arms are parallelly oriented<sup>[12]</sup> and the dyes are close to one another. The bulge–turn–bulge “linker” fixes the distance of the two helices at the “bottom” of the U. Thus, at this end the distance of the two strands is known (Fig. 3). The distance at the open end of the U-shaped molecule is measured by FRET in solution. This construction allows one, e.g., to measure the electrostatic interaction between the two negatively charged DNA double-stranded arms.

Because of the negatively charged phosphate backbones, the two roughly parallel helices repel each other. The electrostatic interaction between the two DNA arms was changed in two alternative ways: 1) the charge of the DNA arms was reduced by introducing methylphosphonates replacing backbone phosphates and 2) the salt concentration was increased. In the first case, the electrostatic repulsion is reduced because of the lower charge of the DNA backbone. Here, the FRET measurements can be performed under identical buffer conditions so that buffer influences on the properties of the dyes can be excluded. With increasing salt concentration, the additional mono- (Na<sup>+</sup>) and divalent (Mg<sup>2+</sup>) cations shield the DNA phosphate

**Fig. 7** CAP binding to three-bulged DNA (left: naked DNA, right: CAP–DNA complex). Upon binding, CAP bends the DNA. Because of the reporter arms, the increase in end-to-end distance is large.

charges and reduce the electrostatic repulsion between the arms. Because of the increased salt concentration, buffer conditions change, and the influence of the buffer on the properties of the dyes has to be taken into account. Both procedures result in a shortened end-to-end distance between the DNA helix ends and thus in an increased FRET efficiency.

Such U-shaped DNA molecules with two nearly parallel DNA helices were constructed by introducing two  $dA_5$  bulges into the DNA helix that are separated by 9 bp of double-stranded DNA. The U-shaped structure and sequence is shown in Fig. 11. Four DNA

molecules were synthesized using increasing amounts of methylphosphonates. We compared the FRET efficiencies of a native, fully charged DNA with three partially uncharged DNA structures with 2, 4, or 6 methylphosphonate groups in the DNA backbone. The positions of the substituted nucleotides are shown in Fig. 11. The electrostatic effect of these methyl groups was maximized by placing them inside the U-turn facing each other at closest distances.

The fully charged U-shaped DNA molecule and its three less charged variants containing 2, 4, and 6 methylphosphonates were analyzed by measuring the

**Fig. 8** Atomic model of a DNA molecule containing two  $dA_5$  bulges. The molecule consists of three double-helical stems (16-, 9-, and 17-bp length). The longer FI-labeled strand is composed of 52 bases and colored green in the model; the shorter 42-base strand is labeled with TMRH and is depicted in red. The model is based on the NMR structure<sup>[38]</sup> of the  $dA_5$  bulge and FRET measurements.<sup>[7]</sup> Combining local (NMR) and global (FRET) structure information with the use of molecular modeling allows one to deduce this detailed model of a large DNA molecule in solution.

**Fig. 9** DNA constructs including two or three  $A_5$  bulges leading to close helix ends and thus a high FRET efficiency between end-labeled dyes. Fl-labeled strands are colored green and TMRh labeled are shown in red. A and B contain two  $A_5$  bulges and double-helical sections with different lengths flanking the bulges. The length of the double-helical section between the two bulges was varied between 7 and 11 bp. C, D, E, and F contain three  $A_5$  bulges. In addition, E and F have a CAP and *EcoRI* binding site in the longest stem and contain a nick.

FRET efficiency in the presence of 50 mM Tris-borate, pH 7.9, with increasing NaCl and  $MgCl_2$  concentrations. We found the FRET efficiency  $E$  strongly increasing with salt concentration (Fig. 12).

The strong increase of  $E$  levels off above about 200 mM NaCl or, alternatively, 10 mM  $MgCl_2$ , and shows only a moderate increase of  $E$  above these concentrations.

**Fig. 10** *EcoRI* binding to a triple-bulged DNA construct. *EcoRI* twists the DNA out of plane. This deformation can in principle be measured by these DNA nanoinstruments.

**Fig. 11** Sequence and global structure of the double-bulge DNA molecules. The positions of the methylphosphonates are shown in bold with an asterisk (left side) and shown in green and red for fluorescein and TMRh-labeled oligonucleotide, respectively, and pointed at by arrowheads (right side). The methylphosphonates are placed inside the U-turn facing each other. The dyes fluorescein (FI) and tetramethylrhodamine (TMRh) are shown in green and red, respectively.

The control experiments indicate that the increase of the FRET efficiencies of the double-bulge and the single-bulge molecules is due to structural changes of the DNA and not to changes of the dye properties or

positions. The strong increase at low salt concentrations is due to structural changes in the bulge (see single-bulge control, Fig. 12). The slightly increased FRET efficiency from 0.30 to 0.36 of the double-bulge molecules above 130 mM NaCl or 5 mM MgCl<sub>2</sub> is induced by reduced electrostatic repulsion of the two nearly parallel DNA helices.

**Fig. 12** FRET efficiency dependence of the double-bulge constructs and, as control, a single bulge molecule on NaCl (A) and MgCl<sub>2</sub> (A) concentration. The roman numbers indicate the different DNA oligomers that were annealed for double-strand formation.

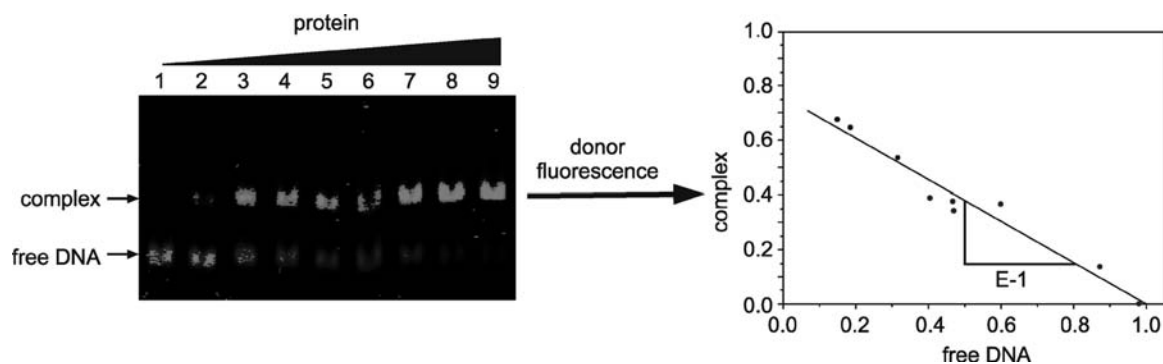

### Influence of the DNA Sequence on DNA Deformation

Dye-labeled, U-shaped DNA molecules can also be used for the very sensitive study of structural details of particular DNA sequences. When different sequences are placed between the two bulges, structural differences of these sequence stretches are strongly amplified and thus sensitively reported by the two helix arms. FRET between dyes attached to the helix arm ends can be used to measure twist and curvature changes.

### DETECTION OF DNA DEFORMATION IN POLYACRYLAMIDE GELS

The FRET efficiency can also be determined quantitatively in polyacrylamide gels<sup>[40]</sup> (Fig. 13). We labeled the two 5'-ends of the double-stranded substrate DNA with fluorescein and tetramethylrhodamine and measured the increase of FRET by binding of two proteins, either the HMG protein NHP6a or IHF; both proteins bend the DNA. In the gel, fluorescein retains its free rotational flexibility. However, the quantum yield is reduced, which can be taken into account by a different Förster distance  $R_0$  in the gel compared to solution. From the FRET increase, we determined the dye-to-dye distances in the protein-DNA complexes from polyacrylamide gel data<sup>[40]</sup> (Fig. 13),

**Fig. 13** Determination of FRET efficiency  $E$  by the gel-based fluorescence assay “FRET in polyacrylamide gel electrophoresis (PAGE).”<sup>[40]</sup> Constant amounts of double-labeled DNA are incubated with increasing amounts of protein. The free DNA is separated from the complex in a polyacrylamide gel. In the complex, the DNA is bent and, thus, the dyes attached to the DNA helix ends are close to one another in space allowing for energy transfer. The donor fluorescence is quenched compared to free DNA. By plotting the donor fluorescence intensity of the complex vs. free DNA, a straight line is obtained with a slope ( $E - 1$ ) yielding the energy transfer efficiency  $E$ .

yielding global structural information on the complexes such as DNA bending angles.

#### DETECTION OF DNA DEFORMATION AT SURFACES

Often it is of advantage when molecular detection systems are bound to surfaces. For example, immobilized constructions allow for washing procedures. Such a

requirement does not exclude our detection concept. If one or two of the  $90^\circ$  bends in the DNA structure are due to protein binding by TBP or IHF, respectively (e.g., replacing one or two of the DNA bulges), and these proteins are linked to a surface by classical protein immobilization techniques, the detection principles and systems described above are applicable. For example, when a one-bulge DNA molecule including a TATA-box sequence in the longer stem (Fig. 14, left) binds to TBP (being immobilized to a surface) FRET

**Fig. 14** One-bulge DNA with TATA box sequence without (left) and with bound TBP (right). TBP is immobilized to a surface. Upon binding, TBP induces a DNA bend of approximately  $90^\circ$  leading to a strong FRET signal.

occurs due to the bending of the longer stem, resulting in a close dye distance (Fig. 14, right).

## CONCLUSION

We have shown that DNA-based nanoinstruments, designed by molecular modeling and realized by linear chemical synthesis, can be valuable tools for detecting and quantifying DNA bending and kinking, e.g., by proteins binding to DNA. Since those constructs allow one to bring dyes in a certain distance to each other, a new measurement principle was generated. For future work, these DNA molecules may not only carry dyes, but other molecules (enzymes, small organic compounds, catalysts, etc.) that work only in defined distances from each other. Such constructs could be switched on and off by modifying the structure of the DNA resulting in controllable nanomachines.

# DNA-Conjugated Metal Nanoparticles: Chip Detection Applications

Wolfgang Fritzsche

Department of Biotechnical Microsystems, Institute for Physical High Technology (IPHT),  
Jena, Germany

## INTRODUCTION

Metal nanoparticles exhibit interesting optical, electronic, and catalytic properties, which are primarily based on their small size and their high surface-to-bulk ratio. By the application of standard processes of chemical synthesis, large numbers of particles with a narrow size distribution can be prepared in a size range between 1 and 100 nm. The properties of these nanoparticles are often different from bulk materials of the same kind and are usually influenced by the particle size. A typical example is the color of gold nanoparticles, as apparent in colored glass from the middle ages or in the labeling solutions used in light and electron microscopy. Other examples are the quantized behavior of electrons tunneling onto gold nanoparticles under low-temperature conditions, and the surface enhancement of Raman spectroscopy for molecules adsorbed onto the surface of metal particles.

To access these interesting properties, an integration of the nanoparticles in technological systems is needed. This integration could be based on the long tradition of bioconjugated nanoparticles in biological microscopy, which is explained in details in this entry. Thus DNA-modified nanoparticles could play an important part in DNA chip detection and, furthermore, establish a novel, multidisciplinary approach in molecular nanotechnology (Fig. 1).

## PREPARATION OF BIOCONJUGATED METAL NANOPARTICLES

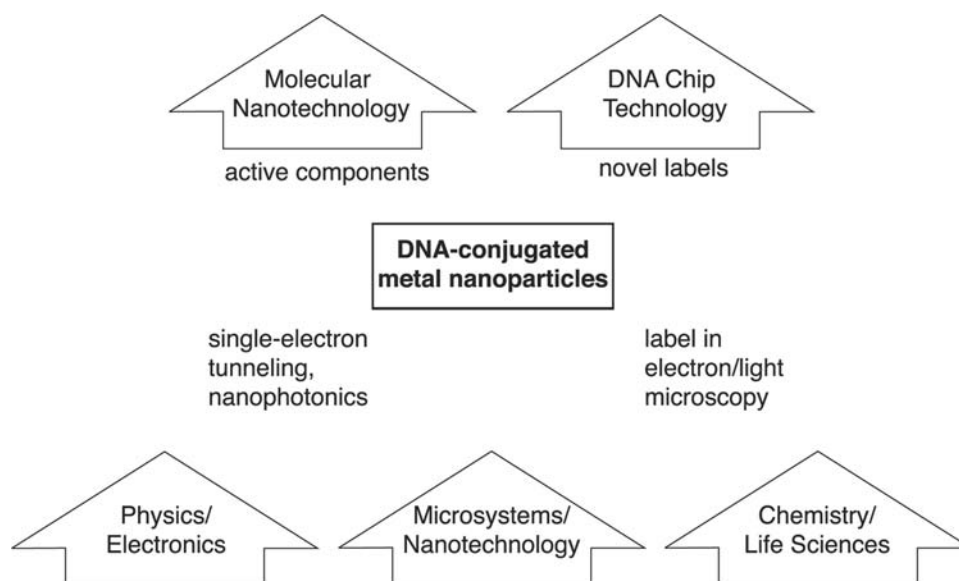

The need for electron-dense labels for nanometer structures in electron microscopy leads to the development of bioconjugated particles. Monodisperse colloidal gold can be produced by several methods in a size range of less than 2 nm up to 150 nm and more.<sup>[1]</sup> Therefore proteins were adsorbed onto gold particles, induced by hydrophobic interactions and/or the binding of thiol groups (present in the protein) to the gold surface. This thiol-gold binding is an important principle for the connection to gold surfaces in fields as diverse as molecular labeling or molecular

nanotechnology.<sup>[2]</sup> The interaction of thiol-containing molecules with gold surfaces was extensively studied in the case of self-assembly monolayers (SAMs). It is based on the high affinity between sulfur and gold, and results in a covalent bond. The experiences of these fields regarding gold binding of proteins were also extended to DNA. The stability of an unmodified gold solution is based on intercolloidal electrostatic repulsion and is sensitive against higher salt concentrations. This sensitivity increases with larger particle diameter. By modification of the gold with DNA, a significant stabilization of the colloid because of increased charging of the surface (induced by the negatively charged DNA backbone) is observed, which is a prerequisite for further (bio)chemical or molecular-biological manipulations.

## NETWORKS IN SOLUTION BASED ON SPECIFIC DNA BINDING

Material sciences are driven by the search for new materials with preferably customized properties. One approach is the synthesis of such materials starting from elemental building blocks. By adjusting the parameters of the building blocks, the properties of the resulting bulk material should be determined. Because of their size and their adjustable parameters (size, composition), nanoparticles present ideal candidates for these building blocks. As demonstrated in electron and light microscopy, metal nanoparticles can be positioned because of specific molecular interactions of conjugated biomolecules. This principle can also be used for the fabrication of nanoparticle-based materials utilizing bioconjugated particles. It applies a binding pair of biomolecules, so that each of two batches of nanoparticles is conjugated to one of these partners. After mixing both batches, specific bonds are established. This process results in a network of particles interconnected because of specific binding of the molecules.<sup>[3,4]</sup>

These networks exhibit an interesting optical behavior. Solutions of statistically distributed gold nanoparticles (with or without attached biomolecules)

**Fig. 1** Nanoparticles exhibit interesting properties as, for example, regarding single-electron tunneling and nanophotonics. This potential is complemented by decades of experiences with bioconjugated nanoparticles in microscopy, and will result in active components for molecular nanotechnology (with the potential for integration) as well as in novel labels for DNA chip detection.

show at a certain concentration a visible color, ranging from yellow for small particles (<5 nm diameter) over reddish (about 20–40 nm) to increasingly violet (>60 nm). However, if these solutions aggregate, as it is the case after increasing the salt concentration (because of higher screening of the electrostatic repulsion as stabilizing factor), a dark fallout can be observed. The colors are induced by surface plasmon effects, a result of the interactions of photons with the highly localized electrons in the nanoparticles. This effect is influenced by the average distance of neighboring particles, and can be used for macroscopical detection of DNA-based nanoparticle networks. Therefore two batches of nanoparticles were modified with each DNA molecule with a sequence A' or B' (A' is non-complementary to B'). If these two batches are mixed, the purple color of the solution remains unchanged. However, after the addition of DNA linker molecules that exhibit sequences A and B (complementary to A' and B', respectively), the solution changes its color to blue. This color change is indicative of the creation of networks of nanoparticles connected

by the linker DNA, as shown in the scheme in Fig. 2. For better visibility, the reaction solution can be transferred to a solid substrate (e.g., to a reverse-phase silica plate).<sup>[5]</sup>

The constructions with nanoparticles of the same size (homogeneous systems) were extended toward systems combining particles of different sizes.<sup>[6]</sup> Therefore two batches with gold particles of 8 and 31 nm diameter, respectively, were modified with thiolated oligonucleotides in a way that each of both batches had a different sequence. A nanoparticle satellite structure was created after the addition of a DNA linker (which bridges the sequences on the particles, comparable to the scheme in Fig. 2). Transmission electron microscopy (TEM) images of such structures show extended aggregates of two different-sized particles with (large particle/small particle) periodicity. The demonstrated use of the recognition properties of oligonucleotides to direct the placement of two different particle types within extended particle assemblies should be expandable beyond size differences (e.g., to building blocks that differ in chemical composition).

**Fig. 2** A network of DNA-interconnected particles results when a connecting linker DNA molecule AB is added to a mixture of nanoparticles with sequences A' or B' (A and B are complementary to A' and B', respectively).

## IMMOBILIZATION ONTO SOLID SUBSTRATES

### Microscopical Marker Applications

The localization of specific molecules (antigens) in microscopical preparations using labeled molecules, which bind specifically to the molecule of interest, is a basic technique in numerous microscopical techniques. Typically, antibodies against the molecule of interest are labeled with a marker molecule or substance, and after the binding of the antibody, the conjugated marker is detected. Thus the position of the antibody and of the molecule of interest is identified. Gold colloids are an example for such a label. They have a long tradition as markers in electron and light microscopy (e.g., by using their high electron contrast for tissue<sup>[7]</sup> or single-particle<sup>[8]</sup> identification). Large numbers of particles are detectable by optical microscopy (e.g., for cell labeling).<sup>[1]</sup> An interesting extension of gold labeling is the silver enhancement method, which amplifies the signal for better detection.<sup>[9]</sup> Therefore a stabilized silver solution is used, which leads to a specific silver deposition on gold surfaces. Thus the gold nanoparticles increase in size because of silver deposition, resulting in a stronger signal in the optical or electron contrast.

### Applications in Molecular Nanotechnology

Immobilized DNA–nanoparticle construction exhibits several advantages over the complexes created in solution. For nanotechnology, the integration of the fabricated molecular structures into materials or devices is seriously hampered by the difficult access to the individual structures floating in solution. Technology is only possible with structures integrated into technical systems, allowing for defined access. For example, the envisioned use of electronically active molecules needs techniques for the inclusion of such molecules in a defined manner into electrical circuits. Because of the small size, conventional microstructuring techniques are not applicable. Thus self-assembly principles have been proposed to provide an answer to these problems. These techniques rely on the specific interactions of binding pairs, comparable to the antibody–antigen pairing. DNA is of special interest for such approaches because it provides an easily accessible and well-studied system with a large variety of different binding pairs because of its sequence variability. Thus DNA–nanoparticle complexes coupled to DNA-modified surfaces present an interesting model system for the demonstration of the feasibility of DNA-based connection and/or positioning of inorganic structures for molecular nanotechnology.

### Chemical immobilization strategies for DNA

The binding of DNA-conjugated nanoparticles to surfaces via specific DNA–DNA interactions requires the immobilization of single-stranded (ss) DNA on the surface, which acts as a capture molecule (Fig. 3D). This procedure is comparable to the techniques used in the preparation of DNA microarrays and DNA chips. In principle, there are two approaches regarding the kind of binding, namely, a non-specific adsorption and a defined terminal covalent binding. The so-called non-specific adsorption is usually based on electrostatic interactions between the rather positively charged surfaces and the negative charges in the phosphate backbone of the DNA. Another less defined interaction is the binding of DNA to surfaces with an affinity to amino groups, resulting in covalent bonds to such groups inside the DNA molecule. However, defined terminal bonds with much higher efficiency are possible using similar amino-binding surfaces and terminal amino-modified DNA, or utilizing the beforementioned affinity between gold surfaces and thiol-modified DNA (Fig. 3A). The latter binding pair is well studied and highly efficient,<sup>[10]</sup> but it shows some serious disadvantages. First, thiol modification of DNA is difficult and expensive. Moreover, especially the interesting optical or electronic properties of gold nanoparticles are hardly, or not, accessible after immobilization onto gold substrates. Thus other substrates are required, which allow optical transmission or which are electrical isolators. Glass provides ideal optical properties and can be used for DNA immobilization. Controlled DNA immobilization onto glass can be achieved by the modification of the activated glass surface (inducing OH groups) with substituted silanes, which bind to the glass and provide a coupling group for modified DNA (Fig. 3B). A standard system is the application of amino-modified DNA and 3'-aminopropyltrimethoxy-silane (APTES) or 3'-glycidoxy-propyltrimethoxy-silane (GOPS) as described elsewhere.<sup>[11]</sup> Because of the similar chemical composition, silicon oxide surfaces as found on oxidized silicon wafers are accessible by the same techniques (Fig. 3C).

### Immobilization techniques

A straightforward method for DNA immobilization is the incubation of the whole substrate (e.g., glass) with the required solutions. As a result, the substrate is covered by immobilized DNA (Fig. 4A). For instance, this approach was used for the fabrication of glass substrates for the immobilization of nanoparticle-labeled DNA prior to silver enhancement and optical readout.<sup>[12]</sup> Although simple and robust, this technique

**Fig. 3** Strategies for surface immobilization of DNA. (A) The high affinity of thiols to gold surfaces is used by the utilization of thiolated DNA. (B,C) The standard chemistry for the modification of glass or silicon oxide surfaces to bind DNA is based on silanization. Silanes with functional groups able to bind, for example, amino-modified DNA directly or via a linker molecule are used. (D) Scheme for binding of DNA-conjugated nanoparticles onto surfaces modified with complementary DNA.

does not meet the requirements of either molecular nanotechnology or chip detection for a variety of different sequences on one substrate. For molecular construction, the DNA has to be further aligned in binding spots and should not cover the whole surface. On the other side, DNA chips exhibit an array of different sequences for detection purposes; this quantity is a key advantage of DNA chip technology. These requirements for multiple-sequence substrates are realizable using spotting techniques. Therefore, applying similar chemical strategies as described above, substrates are usually modified and/or activated before small quantities (droplets) of a solution of modified DNA are applied to this surface for immobilization (Fig. 4B). Typical dimensions of an area modified with DNA according to such an approach are 100  $\mu\text{m}$ .

Although this is quite sufficient for today's DNA chips, it blocks both further integration of DNA detection schemes and nanotechnological applications. Another shortcoming is the low reproducibility and homogeneity of the DNA layers realized by this method. A highly efficient way to achieve immobilization is the on-chip synthesis in a DNA synthesizer.<sup>[13]</sup> This technique results in a homogeneous, high-density coverage of the surface, and is compatible with microstructuring techniques. Thus a predefined pattern of DNA-modified regions with a resolution in the lower micrometer range is possible (Fig. 4C). However, only one sequence of DNA is synthesized on each substrate, which prevents the inclusion of on-chip control sequences or the high integration regarding DNA chip applications.

**Fig. 4** Immobilization techniques. (A) Whole substrate incubation. (B) Spotting of DNA. (C) microstructured surfaces for DNA immobilization.

A hybrid approach combining microstructuring and manual spotting provides  $1 \times 1$  mm windows in a hydrophobic passivation layer for the manual deposition of DNA solution for immobilization.<sup>[14]</sup> Thus different DNA sequences can be arranged on the same substrate without the need for spotting equipment. Moreover, the typical problems with the inhomogeneous signal of spotted DNA (because of drying artifacts and insufficient binding of the DNA) are minimized in this approach because the microstructured windows serve as a reservoir for the incubated droplets and minimize drying and the associated artifacts. Another advantage is the defined geometry and position of the signal, so that the required readout algorithms are streamlined and the image processing is simplified by standard masking procedures.

### MARKER APPLICATION FOR DNA CHIP READOUT

The previous paragraphs introduced typical setups for a chip-based DNA detection: DNA molecules immobilized on a substrate, with a sequence complementary to DNA of interests. When the latter molecules are present in a solution, which is applied onto the chip surface, specific binding occurs and the molecules of interest are bound to the surface. To detect this binding event, the surface-bound molecule of interest has to be labeled. Typical labels (beside the extremely sensitive but complicate radioactive substances) are fluorescence dyes. They exhibit a high sensitivity and allow a fast and spatially resolved readout as needed for highly integrated DNA arrays and chips. However, they require a sophisticated scanner with a high price tag and need expert knowledge to measure/process/interpret the results. Moreover, the fluorescence signal depends on the local chemical environment, so that chip-to-chip comparisons or calibrations are hampered. Another problem is bleaching, an irreversible process resulting in a decay of the fluorescence signal. Gold nanoparticles are a possible complement to, or even replacement for, the fluorescent readout mainly because of their signal stability. In the optical contrast (both transmission and reflection), an ensemble of

nanoparticles induces a detectable signal, which does not depend on the chemical environment and which will not significantly decrease over time. For medium surface densities of particles and microstructured binding areas in the medium micrometer range, this signal is already detectable by the naked eye.<sup>[13]</sup> Microscopical images demonstrate the excellent contrast in plain optical contrasts as transmission and reflection. However, the dynamic range is limited. There seems to be a saturation limit before a monolayer of particles can be achieved,<sup>[15]</sup> which is probably based on electrostatic interactions between the particles. On the other side, lower surface concentrations of nanoparticles are hardly detectable by optical means. The detection limit of nanoparticle labeling was significantly enhanced by the introduction of metal enhancement procedures (Fig. 5), as known from optical and electron microscopical applications of gold nanoparticles.<sup>[9]</sup> Thus the signal is enhanced and allows detection in a standard flatbed scanner, without the requirement for a microscope.<sup>[12]</sup> But the metal layer induced by the metal enhancement results not only in a much stronger optical signal, it also allows for a quite different detection principle: an electrical detection based on the resistivity change between two electrodes, which are connected by this layer.<sup>[16,17]</sup> Such an electrical detection represents a significant development regarding future point-of-care applications of DNA analytics and their requirements of easy and stable assays in connection with low equipment costs (Fig. 6).<sup>[18]</sup>

### NANOPARTICLES IN MOLECULAR NANOTECHNOLOGY

Molecular nanotechnology describes a field, which uses a molecular approach for the fabrication of novel materials and devices. Molecular units are utilized, so that the addressable dimensions reach the molecular scale. This potential makes molecular nanotechnology a promising candidate for complementing, or maybe even replacing, the traditional, silicon-based microelectronics. However, there is still a long way to go until realistic concepts for this revolutionary new field

**Fig. 5** Metal enhancement of immobilized nanoparticles. Nanoparticles specifically bound to substrates by DNA–DNA interactions (A) can be enhanced by a chemical metal enhancement step, resulting in the deposition of, for example, silver on the gold nanoparticles (B). This effect can be applied to create a conductive layer between prestructured microelectrodes (C).

**Fig. 6** System for electrical readout of DNA hybridization.<sup>[18]</sup> Top row: An array of micrometer-sized gaps (left, center) of microstructured gold electrodes for DNA detection (cf. Fig. 5C) is arranged on a half-inch chip (right). Bottom row: A chip holder (left) is part of the reader (right) that contains measurement electronics controlled by an embedded PC. © 2003 American Institute of Physics.

of electronics are worked out. One problem is the missing technology for interconnections, which is needed for the integration of molecular devices into an electronic setup. To develop first demonstrators, hybrid approaches are needed, which use molecular parts in a still conventional (macroscopical/microscopical) technological environment. But what are the active parts in such hybrid setups, as long as molecules with interesting electronic or optical properties are not directly accessible? Thus nanometer-sized structures are needed, which represent active parts but are already addressable today. Metal nanoparticles are an optimal candidate for such structures because they combine small size with interesting physical properties. Nanoparticles are promising replacements for the electron confinements in single-electron tunneling structures in quantum electronics,<sup>[19,20]</sup> and they show potential as nanoconverters of photonic energy to thermal energy.<sup>[21]</sup> Moreover, complexes of bioconjugated

metal nanoparticles with biomolecules based on specific molecular binding used for decades in microcopy demonstrated the use of nanoparticles in biomolecular assemblies. This points to a possibility to overcoming the interconnectivity problem, namely, using specific molecular binding. In microscopical applications, antibody-conjugated nanoparticles attach in a highly specific manner onto complementary surface regions of the specimen. This process can be reversed; instead of detecting the location of complementary regions, predefined complementary regions can be utilized to direct the nanoparticles to the selected location. Although such molecularly modified surface regions can be created, the anchored molecular structure is still not accessible by two contacts, as needed for a variety of applications (e.g., the molecular-based electronic switch,<sup>[22]</sup> lasers,<sup>[23]</sup> etc.). One approach for a two-sided terminal binding is based on very small (lower nanometer range) electrode gaps, and applies electrostatic

trapping<sup>[24]</sup> or specific binding<sup>[25]</sup> of molecular structures. Because the fabrication of such structures is complicated, other ways for the integration of molecules were proposed. One possibility is the use of a long DNA molecule, with each end specifically connected to an electrode modified with complementary DNA.<sup>[26]</sup> This structure can be used as base for further assemblies by relying on specific attachment of short ssDNA to a location along the long immobilized DNA,<sup>[27]</sup> following the standard technique used for in situ hybridization in cytogenetics. Additionally, the short DNA can be coupled to an interesting molecular structure, such as a nanoparticle. A single-electron tunneling structure utilizing this scheme to position a DNA-conjugated nanoparticle along a micrometer-long DNA molecule that is stretched between pre-structured microelectrodes on a chip surface was proposed.<sup>[28]</sup> Key steps in this project, as the attachment of the nanoparticle to DNA including microscopical characterization as well as the positioning of individual DNA molecules in a microstructured gap, could already be demonstrated.<sup>[29]</sup>

## CONCLUSION

DNA-conjugated metal nanoparticles represent a unique class of nanomaterials with applications both in molecular diagnostics (DNA chip detection technology) and molecular nanotechnology. In both fields, these complexes of nanoparticles with DNA combine many advantages and could demonstrate the large potential of nanotechnology by the realization of a demonstrator system. Thus molecular diagnostics could reach high sensitivity combined with highly stable and low-cost equipment. On the other side, because of their DNA handles, nanoparticles have a realistic chance of serving as active elements in nanotechnological setups, which are assembled by self-assembly principles.

## ACKNOWLEDGMENTS

## INTRODUCTION

Nature has created a multitude of biological molecules that perform tasks with remarkable efficiency, accuracy, and precision. Increasingly these systems are being viewed more and more as machines because of the complexity of their function. In an effort to harness the engineering of Nature, many scientists and engineers are going beyond characterizing biological systems by investigating methods for direct manipulation. This effort has been promoted by the enormous progress in understanding the complex mechanisms and structures of biological systems. This knowledge, largely fueled by the advances in biological and biochemical tools and characterization techniques such as X-ray crystallography and NMR, has reached a point where one can describe the structure and mechanisms of large biological molecules in molecular detail. Consequently, direct manipulation of biomolecular activity is an attractive avenue for the development of new types of systems that utilize the engineering of Nature. Deoxyribonucleic acid (DNA) hybridization is a simple process that has been investigated as an interface for control, assembly, and computation. The ideal method for controlling hybridization in many of these applications would display a high degree of specificity (to control target DNA strands and leave others unaffected) and reversibility, and allow for control *in vivo*. Many novel methods of controlling hybridization have been developed, such as by electric field direction of DNA hybridization on a chip and optical triggering, yet each of them has limitations concerning these criterion. Here we describe a form of electronic control that directly interfaces to a DNA molecule in solution.<sup>[1]</sup> The DNA is covalently linked to a metal nanoparticle, which can be inductively heated by a radiofrequency magnetic field (RFMF). The nanoparticle transfers heat to the DNA, denaturing it and thus switching on or off its activity. Heat dissipation into solution is rapid so once the field is turned off, the DNA can renature. This technique has been demonstrated to be both reversible and specific.

## BACKGROUND

DNA is the universal carrier of hereditary information for all cellular life. It is the molecule responsible for

transmission and conservation of genetic information. Its sequence of nucleotides contains the program for life for an organism. DNA also contains information for gene regulation, which permits organisms to respond to various environmental conditions such as stress.<sup>[2]</sup> In addition, Nature has created a system that can self-replicate so that the genetic information can be passed on to the next generation. By an ingenious construct, replication is semiconservative, in that DNA serves as a template for itself. The machinery of replication does so with high efficiency and speed (3000 bases/min in eukaryotes). Because the fidelity of the message is crucial for organisms, mechanisms for error correction exist, resulting in an overall error rate of 1 per  $10^5$  bases. This efficiency, speed, and reliability is what makes DNA and the machinery that interact with it attractive systems to control.

These properties have been determined by DNA's unique structure and chemical composition. The structure of DNA was determined to be double helical in which two strands align in an antiparallel configuration such that the bases along the backbone pair with one another by hydrogen bonds.<sup>[3-5]</sup> Its structure confirmed its function as a carrier of hereditary information. The double helix is stabilized by the stacking energy of the base pairs. Hydrogen bonds between bases provide specificity (G pairing with C, A pairing with T).<sup>[5]</sup> Remarkably, the combinations of four different bases are all that is needed to encode life.

## MANIPULATION OF DEOXYRIBONUCLEIC ACID

Enormous progress has been made in developing the tools for DNA manipulation and characterization such as cloning, synthesis, and sequencing. Many of these processes are now fully automated, permitting exploration into the genetic analysis of complex cellular systems and organisms. Structural characterization and analytical techniques for separation, purification, cloning, etc. are now widespread and often commercially available. DNA sequencing has made enormous progress in terms of efficiency and speed, thus enabling full characterization of the human genome<sup>[6]</sup> and of other organisms. Automated chemical synthesis of artificial nucleic acid oligos is now commercially available and

can be done with high accuracy for short pieces. Chemical modifications of the backbone or bases with a variety of functional groups can also be incorporated, which allow oligos to be linked to other molecules in inorganic systems such as bulk macroscopic surfaces and also nanoparticles. This has greatly furthered research and the development of pharmaceutical applications and permitted exploration of interdisciplinary studies with biology.

In addition to these analytical and synthetic techniques, there has been recent interest in manipulating and utilizing DNA as an information medium or a machine. DNA is an attractive system for this purpose as it has exquisite recognition properties in base pairing. In addition, DNA is involved in many information transfer processes in a cell such as self-replication. All the processes necessary for life are contained in DNA, as this is what is passed on from parent to offspring. Engineered into the DNA are complex information components such as promoter and repressor elements that can turn on or off expression of a particular gene, allowing the cell or organism to react to DNA environment. As a result, controlling its hybridization is one simple way to access the machinery of biology. In addition, with the sequencing of the human genome, the formidable task of gene profiling has generated interest in developing rapid, inexpensive, and high-throughput characterization and manipulation tools. Described below are just a few examples of the tools developed for studying and manipulating DNA.

### Microarray Chips

Recently, there has been tremendous interest in using gene chips to study genes for analysis of behavior of an organism. In order to study the presence of genes, multiple probe strands complementary to a given target strand are chemically tethered to a substrate. The slide is incubated with the set of target DNA strands, which hybridize to the corresponding probe strands. A reporter strand complementary to the overhang of the target strand is added.<sup>[7]</sup> The reporter strand has fluorophore chemically attached to it, so when the target is present fluorescence increases. Because of the multitude of groups and companies using this technology, the generation of DNA microarrays by automated spotters and their analysis of large numbers of them has been standardized. As a result, thousands of genes can be probed simultaneously, enabling high-throughput analysis of an entire genome on a single chip.

Some groups have taken this further by developing methods for spatially controlling hybridization on an array by using an electric field.<sup>[8,9]</sup> A DNA probe is chemically tethered to a site above an electrode on a surface. A voltage applied to the electrode attracts

negatively charged DNA complement, thereby directing where the DNA is hybridized with single nucleotide resolution. Electric field interfacing to DNA on a surface has the advantages of multiplex control of hybridization events. Other electronic interfaces to DNA molecules for the purposes of control include orientation of DNA helices on metal surfaces by an applied electric field.<sup>[10]</sup>

### Assembly of Nanoscale Structures in Solution or on Surfaces

Manipulation of DNA is attractive for purposes of assembly on the nanometer scale because of its dimension and high degree of specificity in base pairing. It is a unique structure for interfacing to nanoscale systems because DNA is in the same size range as nanoparticles in one dimension ( $\sim 2$  nm in width) but can be very long in the other (micrometers to millimeters)<sup>[11]</sup> so macroscopic and microscopic systems can be interfaced to it electronically. Many have explored the possibility of utilizing it not only as a nanoscale wire but also as a recognition medium for assembling patterns of inorganic nanoparticles and wires. In this case, the DNA serves as a chemical linker to a nanoparticle and also a tether that can recognize a specific set of electrodes that interface to the nanoparticle.<sup>[12,13]</sup>

In addition, DNA has great potential for assembling programmed structures.<sup>[14-17]</sup> The assembly is “programmed” in that one designs a structure by choosing appropriate sequences of the DNA and allowing them to self-assemble in solution. By harnessing biology’s use of self-assembly, which has the potential to create something as complex as an organism, one can construct complex biological/inorganic hybrid structures by supramolecular assembly. Consequently, DNA is being used to design and assemble in two and three dimensions,<sup>[15,17]</sup> also with nanometer-scale inorganic materials such as gold nanocrystals<sup>[18]</sup> that can act as colorimetric sensors for the hybridization event.<sup>[14,19,20]</sup> Eventually this will result in new classes of materials that possess properties unique from the corresponding bulk inorganic materials. Inorganic-biological composites that occur in nature such as abalone shell have remarkable properties such as strength and toughness. Combining nanometer inorganic structures with organization via DNA programmed assembly will result in new materials with designable properties that are unique from each component alone.

### DNA as a Computational Medium

Within the past decade, DNA has been recognized as a computing medium. DNA hybridization is a process in which a strand recognizes its complement according to

the code programmed in the strands, often with a resolution of a single base pair. Considerable effort has gone into investigating how to take advantage of the attractive properties of DNA and the machinery that edits and creates it such as self-replication, error correction, and recognition. Other factors that make DNA attractive as a computing mechanism emerge directly from comparison to silicon. Its size is smaller than current silicon design rules, which would result in an information density and potential processing power several orders of magnitude higher than traditional computers.

Many approaches to DNA computing involve exploiting the exquisite accuracy in which a strand of DNA can recognize its complement. To date, DNA has been used successfully to solve a model problem that is intractable for traditional computers. The answer to a simple version of the traveling salesman problem has been experimentally determined for DNA in solution.<sup>[21]</sup> In addition, other problems have been explored using DNA hybridization.<sup>[16,17,22–25]</sup> From these experiments, it has been determined that DNA computational operations are several orders of magnitude higher in efficiency than standard computers, close to thermodynamic limit. In addition, DNA is an attractive computational medium as the process of finding the answer is the oligos finding their respective complements in solution. This process is massively parallel because each type of molecule in solution can sample a large number of complements simultaneously. This results in a processing speed many times that of current computers. Other forms for DNA computers have examined systems on a surface<sup>[23]</sup> and also utilized transcriptional machinery to create binary logic elements such as a ring oscillator and toggle switches.<sup>[26,27]</sup>

### DNA as a Nanoscale Machine

Other work has used the hybridization properties of DNA to create a nanoscale machine.<sup>[28]</sup> Oligos in solution have been designed to be DNA “tweezers” that can be mechanically opened or closed depending on the presence of a third “fuel” strand. The fuel strand has a sequence such that it is complementary to the tweezers in such a way that when it hybridizes with it, the tweezers are forced to the closed position. Addition of a strand complementary to the fuel strand removes it from the tweezers, allowing the tweezers to revert to the open position. Readout of the motion was done by fluorophore–quencher pairs linked directly to the DNA strands. The opening and closing of the DNA tweezers has been shown to be completely reversible. This system represents a type of molecular tweezers or motor that requires only DNA for fuel.

This would be entirely specific as only a strand complementary to tweezers can open/close the tweezers. Similar work involves the construction of a nanomechanical device of DNA that undergoes a chemically induced structural transition between the B and Z forms.<sup>[29]</sup>

In addition, optical control of DNA hybridization has been investigated. Typically, these approaches use a chromophore such as azobenzene, which can isomerize between the cis and trans forms depending on the excitation wavelength. Higher-energy light ( $\lambda < 300$  nm) converts the molecule to the cis state, whereas lower-energy light ( $\lambda > 300$  nm) or heating converts it back to the trans state. This isomerization results in a dramatic structural change in the molecule. Azobenzene can be chemically incorporated into nucleotide sites and thus sterically destabilize hybridization. This isomerization has been utilized to control triplex formation of DNA. When the azobenzene is switched to the cis configuration, the triplex is destabilized and the observed melting temperature is decreased by as much as 13°C.<sup>[30,31]</sup> Photoexcited denaturation via azobenzene has been used to control the hybridization of nucleic acid antisense strands that block parts of the message for transcription *in vitro*, which is the machinery that replicates DNA.<sup>[32]</sup> The azobenzene-containing oligonucleotide is hybridized to its message, preventing polymerase from reaching the end of the template. This forces transcription of an abbreviated message. When the system is exposed to light, the blocking oligonucleotide is dehybridized from the template, and the full message is transcribed. This strategy of phototriggering azobenzene to disrupt conformation in a biomolecule has been extended to ribonuclease S for control of enzymatic activity.<sup>[33–35]</sup>

## ELECTRONIC CONTROL OF DNA HYBRIDIZATION

### Background

The basic goal of this work is to develop a means of controlling hybridization of nucleic acids. In general, such a technique should utilize some form of an electronic interface but also be applicable to systems *in vivo* where more complex and interesting processes occur. In addition, the method of control should be selective, reversible, direct, and externally addressed. Finally, it should be universal so that it can be applied not just to nucleic acids but to any biomolecule.

In designing a technique for control, the question of the interface between the biological and inorganic systems arises. In general, it is difficult to interface electronically to biological systems. Typically, it has been achieved by putting the biomolecule onto a fabricated

**Fig. 1** Induction heating of a metal sample (A) and of nanometer-sized gold particles in solution (B) covalently linked to the DNA or biomolecule to be controlled.

two-dimensional surface, an unnatural environment. Issues such as denaturation and subsequent loss of function can often be overcome, but biological systems do not exist solely in two dimensions. As a result, extension to controlling individual biological molecules in a cell or organism faces many challenges. Here we describe how one can interface between the biological and inorganic systems by using a nanoparticle.<sup>[1,36]</sup>

Control of DNA hybridization involves disrupting the hydrogen bonds between complementary strands. Chemical means of disrupting these bonds is achieved by introducing a denaturant. In addition, lowering the salt concentration of the solution decreases charge screening and thus the negatively charged DNA strands tend to repel each other, prohibiting hybridization. As a result, melting temperatures in low salt content are lower than at physiological levels. Hydrogen bonds can also be disrupted by heat. In general, heat disrupts the noncovalent bonds that hold together proteins, and denaturation by heat is a general effect in biology. Control via nanoparticles exploits this property where the nanoparticle is used as a heat source to initiate dehybridization of DNA. Metal nanoparticles can be heated by induction heating, which utilizes an alternating magnetic field to heat conductors. A rapidly alternating magnetic field induces alternating eddy currents in the metal that generates heat by the joule effect. This is an industrial method of heating bulk metals in a rapid and noncontact manner (Fig. 1A).<sup>[37,38]</sup> Here its use is extended to metal nanoparticles that are covalently linked to DNA in solution (Figs. 1B and 2). The alternating magnetic field is used to heat the metal nanoparticle, which transfers its heat to the DNA, dehybridizing it. Once the alternating magnetic field is turned off, the DNA dissipates the heat into solution rapidly,<sup>[39]</sup> and thus can rehybridize, so the denaturation is reversible. In addition, because

the nanoparticle is small (nm), heat is fairly localized, so biomolecules can be heated selectively without affecting neighboring molecules. Because the phenomenon by which the biomolecule is controlled is heat, this technique can be applied to nearly any biomolecule as heat denaturation is universal. For example, it can be attached to a protein to denature it slightly, turning off its activity. If the temperature rise is kept within a certain range, the biological molecule can renature and recover its activity.

Induction heating of metal conductors is characterized by a skin depth effect that results from partial cancellation of the external magnetic field by the generated magnetic field. Consequently, most of the power absorbed by the conductor is concentrated in the surface of the conductor to a depth of  $d_0$ , where  $d_0$  is defined by

$$d_0 = \frac{1}{2\pi} \sqrt{\frac{\rho \times 10^7}{\mu_r \mu_0 f}} \quad (1)$$

where  $\mu_r$  = magnetic permeability,  $\mu_0$  = permeability of free space,  $\rho$  = material resistivity, and  $f$  = frequency of the applied alternating magnetic

**Fig. 2** Basic mechanism for controlling the hybridization state of a DNA loop/hairpin molecule by a covalently linked 1.4-nm gold nanoparticle.

field. The power density  $P$ , which is a measure of how much heat can be generated in the sample, depends on the skin depth

$$P = 4\pi H_c^2 \mu_0 \mu_r f F \frac{d_0}{d} \quad (2)$$

where  $d$  = sample diameter,  $H_c$  = magnetic field strength, and  $F$  a transmission factor that has a sigmoidal dependence on  $(d/d_0)$ . As a result, it has been determined that optimal power absorption and heating occur when  $d/d_0 = 3.5$ . To inductively heat a gold nanoparticle with  $d = 1.4$  nm optimally, higher frequencies in the radio frequency to microwave range are required (1–10<sup>2</sup> GHz). However, because of experimental limitations the highest frequency achievable was 1 GHz. It should be of note that the inductively heating nanometer particles have not been explored extensively and will be the subject of future investigations.

### Nanoparticle Incorporation into Biological Systems

Nanoparticles are particles that are nanometers in diameter (1–100 nm) that contain about 10<sup>2</sup>–10<sup>4</sup> atoms (Fig. 3). Nanoparticles can be synthesized in a variety of inorganic materials, and have been predominantly semiconductors (group II–VI, III–V, and IV) such as CdS, CdSe, InP, InAs, GaN, Si, Ge, etc. They can also be made of metals such as Au, Ag, Cu, Pt, Pd, etc. In addition, they can be made of organic materials (polymers, dendrimers are nanoparticles) and often used as drug delivery agents. Materials in the nanometer size range can be synthesized by several different methods. The wet chemical route has been quite successful in producing high-quality particles that are tunable in size, monodisperse, crystalline, and soluble.<sup>[40–42]</sup> They typically have an organic capping ligand passivating the surface; Fig. 3 shows the coordinating ligand of R = trioctylphosphine oxide. Other methods for creating soluble nanoparticles include gas phase laser ablation followed by capping with solvent, or by crystallization on Langmuir–Blodgett surfaces.<sup>[43]</sup>

Nanocrystals are typically spherical although a variety of other shapes can be achieved through control of the wet-chemical synthesis yielding nanorods, core-shell structures, pyramids, dodecahedrons, “inorganic dendrimers.”<sup>[44]</sup> They also display physical properties (optical, magnetic, structural, chemical) that differ from bulk systems and vary with the size of the particle. This has fueled considerable interest in the study of the physical properties.<sup>[45,46]</sup> Furthermore, many applications of nanoparticles are being actively pursued as their size is of relevance to the electronic device industry, as transistors are now sub-100 nm in size. Device applications being explored that utilize nanoparticles include photovoltaics, LEDs,<sup>[47,48]</sup> photonic materials,<sup>[49]</sup> and sensors.<sup>[50]</sup>

In addition, nanoparticles have been utilized for biological applications.<sup>[51]</sup> They are ideally suited for incorporation into biological systems because their size approximates the lower range of proteins and DNA (nm). In addition, the chemistry to link nanoparticles to biological molecules has been explored.<sup>[18–20,52,53]</sup> Nanoparticle solubility permits ingestion into a cell/tissue for in vivo applications possible, and surface modification by ligand exchange or encapsulation has resulted in nanoparticles that are fully biocompatible. Besides the inherent compatibility with DNA, nanocrystals have unique properties, such as the scaling of physical properties by size. For example, the size-dependent fluorescent of nanoparticles has been exploited for use as fluorescent tags in biology.<sup>[52,54–57]</sup> Because of the broad absorption and narrow emission lines of semiconductor nanocrystals, one can excite multiple sizes of nanocrystals with a single laser line, facilitating a multicolor experiment. They also offer advantages over typical dyes as they can be made robust to photobleaching by careful choice of overcoats and capping groups, and exhibit enhanced lifetimes.

A nanocrystal can be covalently attached to DNA by chemical linkages synthesized onto the DNA backbone or on a base at a site not involved in base pairing. There has been extensive work on developing a chemical linkage to nanocrystals, some of which are shown in Fig. 4. This can be achieved by using a thiol on

Fig. 3 Schematic of a nanoparticle.

**Fig. 4** Three different schemes for covalently linking a nanoparticle to a biomolecule (R'). (A) The thiol group on the biomolecule reacts with the gold nanocrystal directly, gold-thiol, (B) NHS ester with a primary amine, (C) maleimide group-thiol.

the DNA to form a gold-thiol bond directly with the gold nanoparticle. In addition, the nanoparticle can be refunctionalized to have a different chemical identity on the surface such as a reactive group that can specifically react with a group on the DNA. A primary amine on the DNA can react with an *N*-hydroxysuccinimido ester (NHS ester) to form a peptide bond.<sup>[14,18,51,58]</sup> Alternatively, the nanoparticle can be functionalized with a maleimide group, which can react with a thiol on the DNA to form a thioether bond.<sup>[58]</sup>

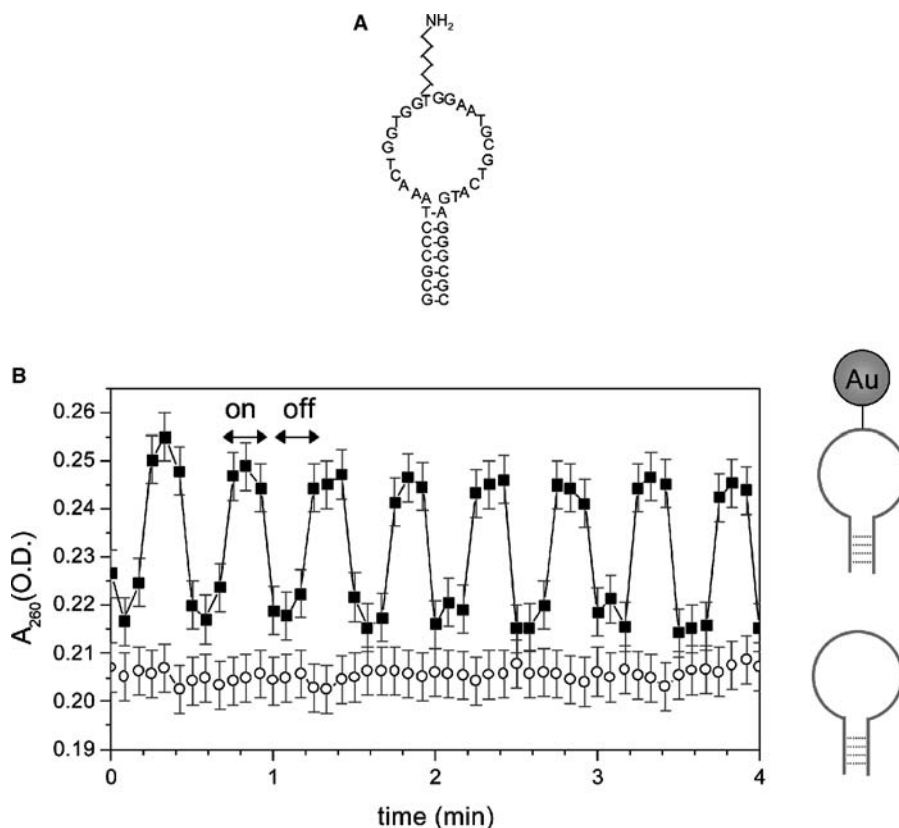

### Controlling DNA Hybridization via Nanoparticles: Experiments and Results

This section describes in detail the experiments using nanoparticles to control DNA hybridization. DNA oligonucleotides, purchased commercially, were synthesized via solid phase synthesis during which terminal groups (biotins, fluorophores) and internal amines were incorporated. Uncharged gold nanocrystals (1.4 nm) functionalized with a single sulfo NHS ester were purchased commercially (Nanoprobes). The nanoparticles were linked to the DNA oligos by incubation for 1 hr at room temperature in solution. Nanoparticles were used in large excess to ensure labeling of all of the DNA oligos. Excess nanoparticles were purified away by either ethanol precipitation or solid phase extraction of the desired product, with multiple washes with buffer (1 × phosphate-buffered solution, PBS).

Alternating magnetic fields were generated by applying an alternating current to coils that had 5–35 turns. Coils were wrapped around a plastic cuvette/

tube holder with open structures to maximize light passage and had a cross section of  $\sim 1 \text{ cm}^2$  so that microfuge tubes could fit inside. An RF signal generator (Hewlett Packard 8648C) generated currents at 1 GHz with an output of 1 mW, which were sent through an amplifier to result in an ultimate output power tunable from 0.4 to 4 W. This is an estimate as losses can occur from setup architecture. To eliminate effects from heating of the sample by the coil, the entire coil was placed in a large water bath at room temperature ( $T = 22^\circ\text{C}$ , volume  $\sim 1 \text{ L}$ ). Samples were heated in either quartz cuvettes or PCR tubes and had volumes of 180–200  $\mu\text{L}$ .

The first system used to demonstrate heating of the particle and transfer of the heat to the attached DNA was a molecular beacon, or a loop/hairpin,<sup>[59]</sup> which is single-stranded DNA with a sequence that is self-complementary on the ends for seven bases (see Fig. 5). Molecular beacons have become popular for applications of quantifying PCR products as they fluoresce when hybridized to its complement. The nanocrystal was attached to the DNA by a C6 primary amine off one of carbon 2 of a thymidine in the loop region. A 1- $\mu\text{M}$  solution of the DNA-nanoparticle conjugate in 1 × PBS was put in a cuvette in a coil that had an alternating current run through it. Using the hyperchromicity of DNA, its optical absorbance was simultaneously monitored to measure dehybridization of the hairpin structure. Fig. 5 shows the response in absorbance with the application of the RFMF. The RFMF was applied at 15-sec intervals, and each time the field was on the absorbance increased, suggesting dehybridization. When DNA alone was put into the solution at

**Fig. 5** Inductive coupling to nanoparticles linked to DNA (A) and evidence of dehybridization (B). *Source:* Reprinted by permission from Ref.<sup>[1]</sup>. © 2002, Macmillan Publishers Ltd.

a comparable concentration, the absorbance did not increase with the RFMF, indicating that the nanocrystals must be present for the absorbance to change. It is of note that the optical absorbance did increase in the presence of nanocrystals alone, which was probably a result of the perturbing of the plasmon resonance in the particles by the alternating magnetic field. However, the change in OD with the nanocrystals in the RFMF is much less than that of the DNA, and the plot in Fig. 5 has this contribution subtracted out.

Evidently the nanocrystals create a higher temperature that may be localized to the DNA oligo. To determine this effective temperature increase, samples that were exposed to the alternating magnetic field were compared to those exposed to fixed global temperatures. In this case, a two-phase system was utilized to avoid temperature-dependent effects on optical properties. Nanocrystals were linked to a 12mer of DNA that had the 5' end functionalized with a fluorophore, which served as a means to count the oligo. It was hybridized to a solid surface, which was done by using a complement that had a biotin on one end that could be captured onto streptavidin agarose bead. Because the beads were large (diameter  $\sim 100 \mu\text{m}$ ), they settled to the bottom of the tube, comprising the solid phase. The supernatant above it served as the solution phase. If the oligo was dehybridized by either heat or the RFMF, it can diffuse into the supernatant,

which can be removed and measured by fluorescence spectroscopy.

One sample of the two-phase system was prepared and aliquoted into separate tubes. Each tube was exposed to a fixed global temperature using a 1-L water bath, and one tube was placed in the coil with the RFMF at room temperature. Following heat or RFMF, the samples were spun down and the supernatant was removed. Each supernatant was then measured by fluorescence spectroscopy, which yielded a relative concentration of DNA present in the sample. Fig. 6 shows the spectra from the supernatants. The fluorophore, FAM, has an emission maximum at 515 nm. For samples exposed to higher temperatures, the fluorescence intensity increased as more DNA was dehybridized. The sample that was exposed to the RFMF (thick black line) had a fluorescence intensity between that of the 30° and 50°C samples. To quantify the effective temperature of the RFMF sample, the fluorescence intensity peaks were integrated and plotted as a function of incubation temperature (dots), shown in Fig. 6. The curve is fit to a sigmoidal (line) characteristic of DNA melting curves. The intensity for the RFMF sample was extrapolated (dotted line) to a temperature of 35°C, or 13°C above ambient temperature. This is the effective temperature increase the DNA oligo experiences from the RFMF. It is important to note that this temperature jump is

**Fig. 6** Determination of effective temperature from inductive coupling to a gold nanoparticle linked to DNA. (A) The two-phase system. (B) Supernatant fluorescence spectra. (C) Integrated peak intensity of the supernatant fluorescence spectra shown in (B) (squares) and a sigmoidal fit (solid line) and the intensity of the sample exposed to RFMF (dotted line). *Source:* Reprinted by permission from Ref.<sup>[1]</sup>. © 2002, Macmillan Publishers Ltd.

sufficient to partially denature many proteins in biology. However, using this technique to dehybridize longer strands of DNA that have elevated melting temperatures may be difficult using the parameters utilized in the experiments described here. One way to achieve denaturation of longer oligos would be to increase the delivered power to the coil, which would increase the heating of the nanoparticle. In addition, using multiple nanocrystals along the backbone can distribute heating along the DNA. However, functionalization becomes difficult as the only available points in the middle of the chain are off the bases themselves and nanoparticles attached to these sites may interfere with hybridization.

Next we tested if the heating of the nanoparticle could be localized to the strand to which it was linked. This property is crucial if nanoparticle antennas are to be utilized for specific control in real biological environments. The environment inside cells is crowded, with concentrations greater than 300 mg/mL. This results in very little space between proteins.<sup>[60]</sup> We used a mixture of oligos to test if the heating of the nanoparticle was localized using the two-phase system described above. The oligo to be dehybridized was mixed with another oligo. This second oligo was identical in sequence but had a fluorophore instead of a nanoparticle attached to the 3' end. The fluorophore for this second oligo was tetramethylrhodamine (TMR), which is spectroscopically distinct from FAM ( $\lambda_{\text{emission}} = 563 \text{ nm}$ ) and thus can be distinguished in fluorescence spectroscopy (Fig. 7). One sample was exposed to a 70°C water bath, and the other was exposed to the RFMF. Fluorescence spectra are shown in Fig. 7 where the ratio of the fluorescence intensity at 515 and 563 nm are compared. The globally heated sample had a higher ratio of TMR:FAM,

while the sample that was exposed to the RFMF had a lower ratio. Integration of the peaks to quantify the ratios showed that the sample exposed to the global heating has approximately 50:50 gold- vs. TMR-labeled oligos, while the RFMF sample has a ratio of 80:20. This signifies that dehybridization of the gold-labeled molecule was enhanced in the RFMF. One possible explanation for the dehybridization not to be completely specific is that streptavidin has the capacity to bind four biotins and thus four oligos, which on average would be a mixture of gold-labeled and TMR-labeled oligos. As a result, the TMR-labeled oligos were estimated to be about 10 nm or less away from a gold-labeled oligo. At these distances, it is expected that through-solution heating will occur, resulting in nonspecific dehybridization.

### Advantages and Weaknesses

Although the experiments described here are in vitro, the use of nanoparticle antennas to control molecules in highly disorganized environments in vivo shows promise. Because of the solubility properties of nanoparticles, they can be attached to proteins in solution or in cells. Incorporation of inorganic nanoparticles (CdSe, Au, Ag, Fe<sub>3</sub>O<sub>4</sub>, etc.) into cellular systems<sup>[61]</sup> and even living organisms have been successful.<sup>[57]</sup> Additionally, because the means of externally addressing the nanoparticles does not require light, it does not require transparent samples like optical techniques. Consequently, it avoids the problem of needing long-wavelength (>800 nm) excitable transducers so that the excitation can penetrate tissue. In addition, the nanoparticle antennas do not suffer short lifetimes or photobleaching that optical chromophores undergo.

**Fig. 7** (A) Two-phase system for testing selectivity. Another (B) difference fluorescence spectra (dots) (after dehybridization by heat/RFMF minus before dehybridization), individual fluorescence peak fits (dashes), and composite fit (lines). Sample exposed to RFMF (left) and to 70°C (right). *Source:* Reprinted by permission from Ref.<sup>[1]</sup>. © 2002, Macmillan Publishers Ltd.

However, there are considerable challenges that this technique faces. Because it is still being developed, it has not yet been fully explored, and limitations in sensitivity and resolution have not yet been quantified. In addition, it requires a coil placed around the sample to be addressed unlike lasers, which can address things from afar. Furthermore, unlike lasers, alternating magnetic fields cannot be focused to microscopic dimensions, although focusing to centimeters has been possible.<sup>[62]</sup> Finally, short- and long-term biological side effects of both the RFMF and the nanoparticles have yet to be tested.

### Future Work

To utilize nanoparticle antennas for controlling real biological systems, it is necessary to have a fundamental understanding of the electromagnetic heating mechanism of the nanoparticles and also the process of heat transfer to its surroundings. The degree of localization of the heating needs to be characterized. It is expected that the spatial extent of the heat from the nanoparticle is localized based on calculations for a sphere.<sup>[63,64]</sup> As a result, temperature drop-offs around the nanoparticle are expected to be rather sharp, as high as 95% by 10 nm, which is the approximate size of a protein. Therefore, spatial localization within complex environments such as a cell may be possible. In addition, the effect of localized heating on the structure of the DNA duplex can also be investigated.

Control by nanoparticle antennas can be easily extended to systems other than DNA such as proteins, since many proteins denature with heat. However, protein systems are much more challenging to control as placement of the nanoparticle is key to the switching of its activity. It must be linked to a section of the protein so that it does not normally affect the functioning of the protein. However, it should be at a site from which the heat can distort the shape of the active site. This relies on the enormous progress made in the molecular-level characterization of both the structures and mechanisms of proteins by X-ray crystallography or NMR combined with site-directed mutagenesis.

Magnetic particles have been used to heat tissues *in vivo*, in particular for tumor ablation, or hyperthermia. Because tumors are macroscopic objects (up to millimeters in diameter), the magnetic particles used to heat them are often much larger (up to 10  $\mu\text{m}$  in diameter), and are often used *en masse* to heat a large region of tissue rather than an individual molecule. The technique described here strives to have control of individual molecules so that selectivity is permitted, rather than heating a large bulk of molecules. This finer, molecular level of control imparts the potential to regulate more complex processes.

### CONCLUSION

The technique described above is just the beginning of only one way to control electronically biomolecular

activity. Other efforts in controlling biological systems show much promise in reaching goals of creating “biomolecular machines.” In the future, one would like to unite these methods to the myriad of biological phenomena that involve nucleic acids for applications in therapy and diagnostics. Control of DNA could lead to manipulation of the passage of the behavior of simple organisms and information transfer between them. Even control of the hybridization of a short oligonucleotide can have profound ramifications on the physical behavior of a cell or organism, as in antisense therapy or RNA interference. In addition, interfacing to biological systems is desirable for applications in computation and self-assembly. Direct manipulation of biological machinery would allow one to take advantage of the engineering inherent in the systems that Nature has built.

# DNA Interactions with Functionalized Emulsions

Thierry Delair

CNRS-bioMérieux, École Normale Supérieure de Lyon, Lyon, France

## INTRODUCTION

Synthetic colloidal DNA carriers have been under intense investigation lately as they represent one of the safer alternatives<sup>[1]</sup> to viral-mediated gene delivery. Moreover, in vaccination purposes, the group of Singh has demonstrated that DNA adsorbed onto particle surface could be a potent immunogene.<sup>[2]</sup> Colloidal carriers include particles, i.e., hard spherical objects made from polymers, and emulsions, dispersions of a liquid nonsoluble in the continuous phase, which most of the time are “soft objects.” Depending on the size of the droplets, the emulsions will be named macro-, micro-, or nanoemulsions. Emulsions are thermodynamically unstable, except for micro- or nanoemulsions, which can form spontaneously, upon mixing the appropriate amounts of components, in particular with a high concentration of surfactants. Emulsions are oil-in-water (O/W) dispersions or the reverse (water-in-oil, W/O) very often stabilized with phospholipids as surface active agent. They structurally differ from liposomes which consist in phospholipidic bilayers (ideally one) surrounding an aqueous core.

In clinics, emulsions have long been used for parenteral nutrition and later for drug delivery, as a means to reduce the toxicity of the active substance.<sup>[3]</sup> So, a solid technical background exists for the production at high scale and low cost of safe carriers for in vivo applications. Moreover, compared to related DNA particulate vectors, the manufacture of emulsions does not require the use of solvents, and components are well tolerated by the body, as for instance lipids such as triglycerides or olive oil, etc.

For DNA delivery, nanotechnologies are expected to develop formulations of nanocomposites capable of interactions with nucleic acids and transport to the targeted site. The nanometer-size range of these carriers allows a better uptake by cells and even offers the capability to cross the blood–brain barrier.<sup>[4]</sup> Moreover, nanoparticles can be administrated into the systemic circulation with no risk of aggregation and blockage of fine blood capillaries. In some applications, it may be essential to target not only a tissue, but as well a specific compartment of the cells.<sup>[4]</sup> Hence this chapter will be devoted to the elaboration of nanosized

emulsions, their interactions with DNA, and various applications of these composite objects.

## ELABORATION OF NANOEMULSIONS

### High-Pressure Homogenization

This technique has been developed for the emulsions for parenteral nutrition and thus much technical background is available and high-scale production lines exist. Both oils and solid lipids can be used, although the latter have to be processed under the molten form.<sup>[3]</sup> First, one preemulsion is obtained by mixing the oil and lipid containing surfactants such as lecithin, for instance, with the aqueous phase. Then, the homogenization step occurs by applying a pressure of up to 500 bars.<sup>[5]</sup> For sterilization purposes, the emulsions can be filtered through 0.22- $\mu\text{m}$  filters and eventually autoclaved (121°C, 15 min). This process can be applied to oil-based emulsions stabilized by cationic surfactants<sup>[6,7]</sup> or with a polysaccharide<sup>[8,9]</sup> and for solid lipids.<sup>[3]</sup>

### Emulsification-Based Methods

These methods rely on the emulsification of the oily phase in the aqueous phase using milder emulsification conditions than the process described above. Dissolved in an organic solvent, the oil containing phospholipid surfactants can be dried and then redispersed after hydration in an aqueous buffer. With this approach, cationic emulsions in the 170–250-nm range were obtained in the presence of a nonionic stabilizer for gene-transfer purposes.<sup>[10]</sup> In another approach, the phospholipids can be directly emulsified in the aqueous phase using ultrasounds or added as an alcoholic solution, subsequently added to the oil phase and sonicated—or microemulsified—to yield the emulsions.<sup>[11,12]</sup> The key parameters of the process are the interfacial properties of the emulsions which can be controlled by the nature and concentration of the phospholipid surfactants and the properties of the oil (surface tension, viscosity). It appears that for a high

colloidal stability, a high surface tension and a low viscosity were most favorable.<sup>[12]</sup>

### Solvent-Based Processes

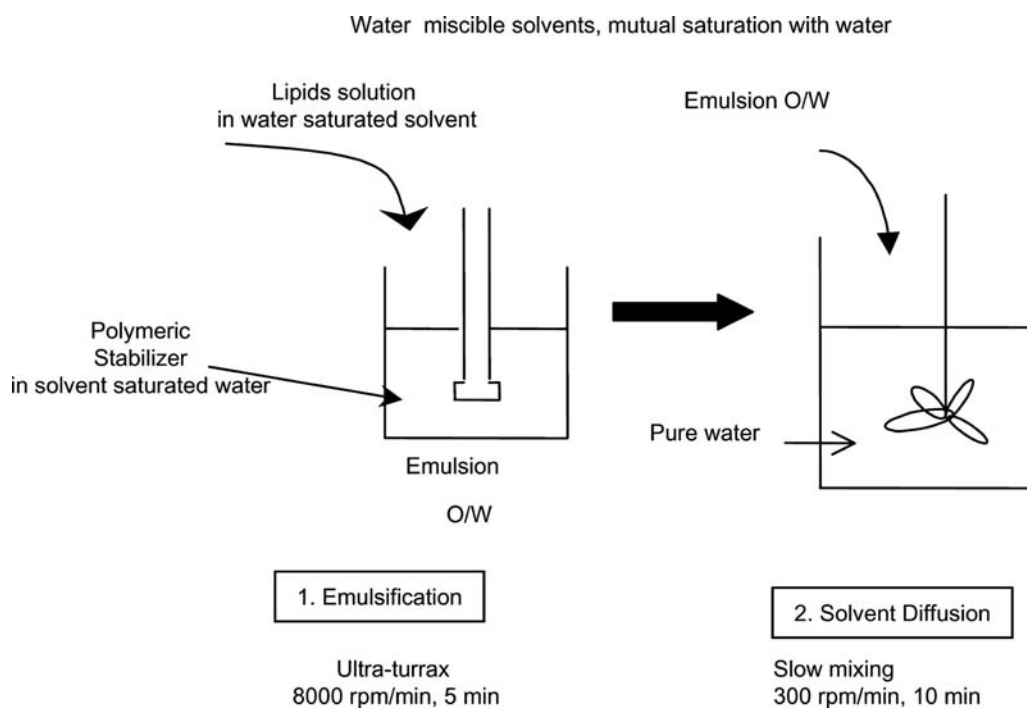

In order to avoid processes involving long and high shearing steps, the emulsification of two low viscosity nonmiscible phases has been investigated. Moreover, the following approaches can be performed at room temperature, even with solid lipids.

The lipid matrix, dissolved in a volatile water insoluble solvent, chloroform, or dichloromethane, can be emulsified in an aqueous phase often containing a stabilizer or a surfactant. In the last step, the solvent is removed under reduced pressure or by stirring overnight, yielding the final emulsion, whose average droplet diameter, in the 30–100-nm range,<sup>[13]</sup> depends on the fat load and emulsifier concentration. Solvents such as acetone, ethyl acetate benzyl alcohol, butyl lactate, etc., less toxic than the halogenated ones, can be used, but their water miscibilities have to be reduced. This is achieved by mutual saturation of both phases (organic by the aqueous and vice-versa). Thus the water saturated organic phase, containing the hydrophobic compounds, can be emulsified in the organic solvent-saturated aqueous phase. This emulsion is then added to a large amount of water under gentle stirring, as a result, the solvent can diffuse in the continuous phase (Fig. 1). Concentration by ultradialysis or under reduced pressure allows solvent

elimination. In this process, Trotta et al. showed that the natures of the emulsifiers were essential to obtain submicronic dispersions—160–320 nm depending on the solvent.<sup>[13]</sup>

Solvent displacement is a technically very simple process to obtain functionalized emulsions. In a water miscible solvent, the hydrophobic compounds are dissolved and slowly added to an aqueous solution containing a nonionic surfactant (Fig. 2). The diffusion of the solvent in the continuous phase allows the formation of emulsions (self-emulsification). This procedure was originally developed for the formation of nanocapsules<sup>[14]</sup> and was used by Trimaille et al. to obtain functionalized submicrometric particles by surface nanodeposition of amphiphilic functional copolymers.<sup>[15]</sup>

Nanocapsules made of a hydrophilic core and a solid lipid shell can be prepared by the water-in-oil-in-water (W/O/W) double emulsion technique. The primary W/O emulsion was obtained by emulsification of water, as the inner core of the capsules, in dichloromethane as the main continuous phase containing tripalmitin (10% w), and different amounts of lecithin. This emulsion was then emulsified in a 2% w of Poloxamer (nonionic surfactant) aqueous solution. Solvent evaporation allowed the formation of the solid lipid shell of the capsules, whose submicrometric diameter ranged from 200 to 395 nm.<sup>[16]</sup> In the hydrophilic core, water soluble active compounds could be incorporated.

**Fig. 1** Schematic representation of the emulsification diffusion process.

Fig. 2 Schematic representation of the solvent displacement process.

## Microemulsions

The development of the microemulsion procedures relied on the following advantages: 1) all ingredients can be potentially biocompatible and no solvent is needed; 2) the process can be adapted to include various excipients, as no damaging mechanical mixing, microfluidization, nor homogenization is required. Moreover, the method can be used with solid lipids to form particles. On a practical standpoint, a milky dispersion of the lipid is obtained in water, then, the appropriate amount of surfactant is added until a clear O/W microemulsion is formed. Cationic nanoparticles were obtained by this procedure using wax as the hydrophobic core and cetyltrimethylammonium bromide (CTAB) as a surfactant. The emulsion was formed with molten wax leading to droplets with a mean diameter of around 50 nm. On cooling, the wax solidified into particles of less than 100 nm in diameter. The main factors to control were the nature of the oily core and the CTAB concentration.<sup>[17,18]</sup> Applying a similar methodology, ethanol-in-fluorocarbon microemulsions containing DNA have been obtained in the presence of a fluorosurfactant.<sup>[19]</sup>

One of the major drawbacks of this procedure is the use of large amounts of surfactant to obtain the microemulsion. To remove the excess, gel filtration can be used.<sup>[17,18]</sup> Heydenreich et al. compared ultrafiltration, ultracentrifugation, and dialysis and found the latter method to be the best choice at yielding dispersions with reduced toxicity and improved physical stability.<sup>[20]</sup>

## Water-In-Oil Nanoemulsions

Water-in-oil nanoemulsions are stable liquid isotropic dispersions, which form spontaneously at defined stoichiometric ratios of ingredients. Thus, no shear and no toxic components need to be used, which makes this approach quite attractive for the encapsulation of DNA into nanoemulsions. To the oily phase constituted of olive oil containing a mixture of nonionic surfactants, a buffered solution of DNA was added. Gentle mixing leads to a DNA containing emulsion of droplet mean size of ca. 42 nm as compared to 32 nm in the absence of nucleic acid.<sup>[21]</sup>

## Interfacial Modification of Emulsions with Polymers

Nonionic polymers have been added to the formulation of emulsions in order to increase their colloidal stability in various media, in particular in the presence of serum. Castor oil-<sup>[10]</sup> or squalene-based<sup>[22]</sup> cationic dispersions have had their performances improved by the use of polyoxyethylene surfactants. Nonetheless, similar results were obtained when the polyoxyethylene chains were anchored in the bilayer via modified phospholipids.<sup>[6]</sup>

Chitosan,  $\alpha(1-4)$  2 amino 2-deoxy  $\beta$ -Dglucan, was used to obtain positively charged nanoemulsions. The polysaccharide was solubilized in an acidic aqueous phase to which was added the oily phase composed

**Fig. 3** Transmission electron microscopy after cryofracture. *Source:* From Ref.<sup>[15]</sup>.

of phospholipids and surfactants. After high-pressure homogenization, positively charged nanoemulsions of mean diameter of 150–200 nm were obtained (dispersities of 0.15–0.2), considered by the authors as monodisperse.<sup>[9]</sup>

Trimaille et al. used reactive polyanhydride copolymers<sup>[15]</sup> or poly *N*-hydroxysuccinimide macromolecules<sup>[23]</sup> as precursor backbones to obtain amphiphilic comb-like polymers, for the interfacial modification of nanoemulsions. The triglyceride nanoparticles were formed by the solvent displacement method using increasing amounts of amphiphilic polymers. The hydrophobic components of the emulsions were dissolved in acetone or ethanol, along with the modified copolymers. On addition of the organic phase to water, the spontaneous formation of the emulsions was observed, with a concomitant deposition of the amphiphilic structure at the interface. The presence of the polymer at the surface of the nanoemulsions was demonstrated by the alteration of the zeta-potentials of the functionalized emulsions compared to the bare ones and by <sup>1</sup>H NMR experiments.<sup>[23]</sup>

#### Nanoemulsion characterizations

Particle size and interfacial charge have to be measured to characterize nanoemulsions on a fundamental standpoint, but also for quality control in production.<sup>[8]</sup> The routine method used for diameter measurement is dynamic light scattering, or quasi-elastic light scattering known as well as photon correlation spectroscopy (PCS). The intensity of scattered light is measured at a 90° angle and the fluctuations of the intensity with time, due to the motion of the particles, lead to the hydrodynamic radius of the particles, i.e., the sum of the real

diameter of the object plus the strongly solvated molecules and ions.

Field flow fractionation (FFF) allows separation according to size, depending on the diffusion coefficient of the colloids. The fractionation is achieved with a field pressure, for instance, perpendicular to the direction of the flow of the mobile phase transporting the colloids. This method is rather well suited for solid lipid particles.<sup>[3]</sup>

Electron microscopy is a very powerful tool for the visualization of the colloids. In order to minimize the alterations of the samples due to experimental conditions, in particular because soft emulsions are fragile objects, cryofracture electron microscopy is an appropriate technique (Fig. 3).<sup>[8,15]</sup>

#### DNA–NANOEMULSION INTERACTIONS

DNA, as a hydrophilic, negatively charged macromolecule, is very water soluble, hence it is almost impossible to dissolve in any organic solvent, unless the organic phase has an elevated hydrophilic/lipophilic balance (HLB) as shown by Teixeira et al. for short oligonucleotides.<sup>[24]</sup> Thus a widely used strategy to tether DNA to emulsion droplets is to take advantage of the electrostatic interactions between positively charged nanoemulsions and polyanionic nucleic acids. Nonetheless, a few strategies have been described, based on the encapsulation of DNA within emulsions.

#### DNA Encapsulated Within Emulsions

To achieve an effective encapsulation, the use of W/O nanoemulsions has been reported fairly recently.<sup>[21]</sup>

The DNA solution was emulsified by spontaneous microemulsification using olive oil, polyoxyethylene 20 sorbitan monooleate (Tween® 80), sorbitan monooleate (Span® 80), and 1,2-Dioleoyl-3-trimethylammonium propane (DOTAP) as a cationic surfactant. The clear resulting nanoemulsion was sterilized by filtration for further in vivo transfection studies. A similar approach described for topical administration of DNA was reported. Ethanol-in-fluorocarbon microemulsions were obtained by gentle stirring of predefined mixtures of 40% w of pentadecafluorooctanoic acid and 60% w of perfluorooctyl bromide as the oily phase, and an 80% v of ethanol solution containing the DNA to be encapsulated, as a hydrophilic phase.<sup>[19]</sup> As these formulations were established to form stable dispersions, all the DNA is therefore within the emulsified aqueous phase.

Encapsulation of DNA within an O/W nanoemulsion requires either to use high HLB oils or to hydrophobize the nucleic acid to increase its solubility in apolar media. In the first approach, not so many oils are capable of dissolving DNA apart from octanol as reported in Ref.<sup>[24]</sup>. But the toxicity of this solvent is such that no in vivo application can be expected from this strategy. Hydrophobization of DNA and its incorporation in an O/W nanoemulsion was reported as an approach toward virus-mimicking nonviral vectors. Cationic derivatives of cholesterol were used to interact with the nucleic acid to form hydrophobic complexes in a chloroform/methanol/water (1:2.1:1)

mixture. The complex was extracted in the organic phase and subsequently added to the oily phase as a solution in chloroform. The emulsion was obtained by a rehydration/emulsification process, with 65% efficacy of DNA incorporation.<sup>[25]</sup>

## DNA Adsorption onto Emulsions

The strategy that consists in adsorbing DNA onto the surface of emulsion droplets is widely investigated and can be related to the approach using cationic liposomes. One advantage foreseen of emulsions vs. liposomes was the greater physical stability of the former over the latter. It has been shown that most liposomal preparations aggregate on interaction with DNA, which can cause embolism if administered systemically.<sup>[6]</sup> Moreover, in vitro, liposomal preparations suffer from a lack of stability in the presence of serum.<sup>[10]</sup>

Emulsion–DNA interactions have to be investigated in terms of droplet size, surface charge or zeta potential, loading capacity and efficiency, stability of the interactions, and release from the carrier. Finally, the overall cell activity of the DNA–emulsion complexes will have to be assessed in vitro or in vivo. As seen in Table 1, various formulations are capable of binding DNA with a fair level of colloidal stability (the particle mean size should not dramatically increase on immobilizing the nucleic acid). In some formulations, the global charge is inverted, which is a prerequisite as in

**Table 1** An overview of various formulations used for DNA binding

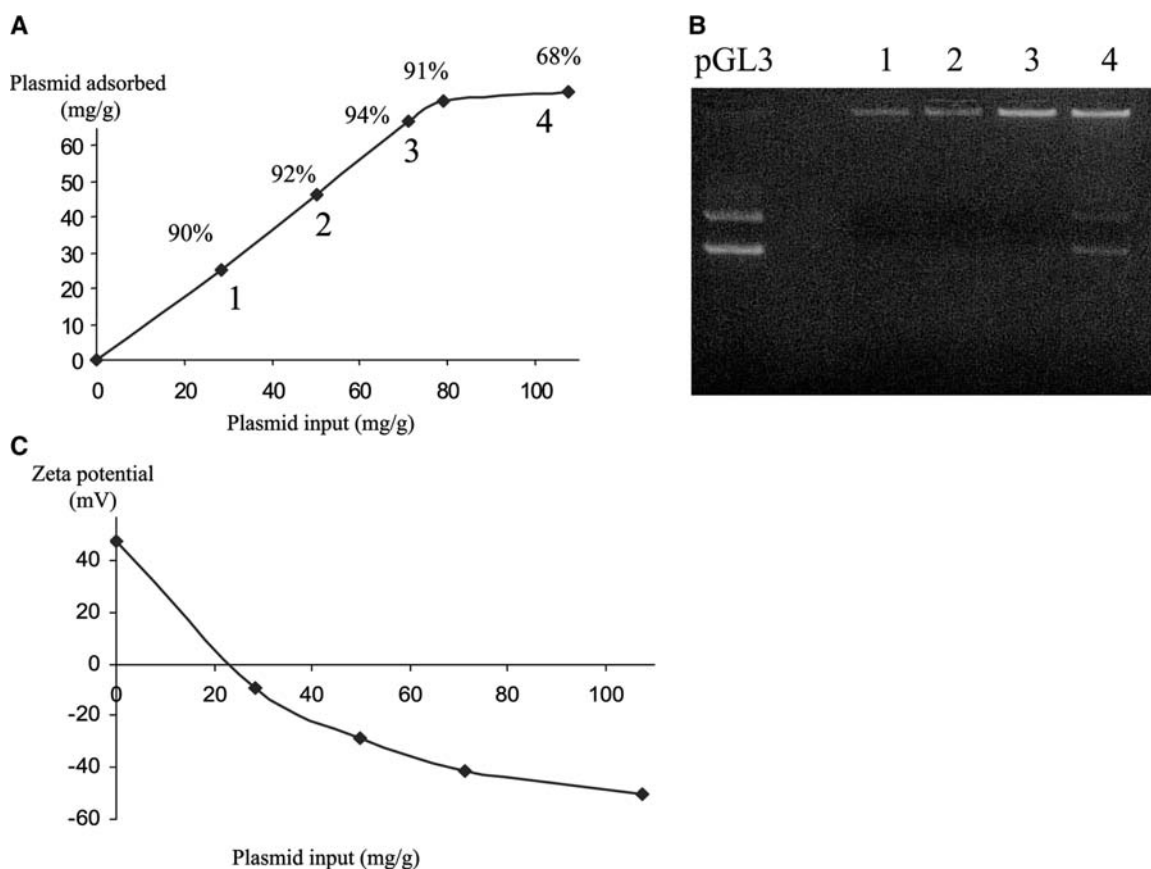

Emulsion composition	Emulsion mean diameter (nm)	Emulsion zeta potential (mV)	Emulsion/DNA complex mean diameter (nm)	Emulsion/DNA complex zeta potential (mV)	DNA loading (mg DNA/g oily phase)	References
Wax/CTAB	90–140 depending on CTAB concentration	+60	280–300	–25/ +22 depending on formulation	Calculated as in the 50–75 mg/g range	[17,18]
Solid lipid/EQ1	101	+42	Bi population aggregates	–10/ –16	Calculated as 50 mg/g	[5]
Castor oil/DOPE:DC-CHOL	187–194	NR	384–410	NR	Calculated as 30 mg/g	[10]
Soy bean oil/DOPE:DOTAP	180	+50	175–180	+40	Calculated as 27 mg/g	[6]
MCT/SA	183	+28	202–311	+33	Calculated as 16 mg/g	[26]
MCT/SA:polymer	185	+60	185	–30/ –40	70 mg/g at saturation	[23]
Squalene/DOTAP	180	+54	180	+32	ND	[34]

DOTAP: 1,2 dioleoyl-*sn*-glycero-3-trimethylammonium propane; DOPE: 1,2 dioleoyl-*sn*-glycero-3-phosphoethanolamine; EQ1: *N,N*-di-( $\beta$ -stearoyl-ethyl)-*N,N*-diethylammonium; DC-Chol: 3 $\beta$ -[*N,N,N'*-dimethylaminoethane] carbamoyl cholesterol; MCT: medium chain triglycerides; SA: stearylamine; NR: not reported; ND: not determined.

Ref.<sup>[23]</sup> to maintain the colloidal stability, but it may remain positive as in Ref.<sup>[26]</sup>. Surprisingly, not all positively charged emulsions bind DNA. Olbrich's group investigated four different formulations leading to cationic dispersions and only one could immobilize DNA, as visualized by agarose gel electrophoresis, although all emulsions had similar size and zeta potential. To obtain the most efficient formulation, the nature of the oily core and of the cationic surfactant had to be optimized.<sup>[5]</sup> The interfacial properties of emulsions can be modulated by varying the nature of the surface active compound and the concentration of cationic surfactants<sup>[18,26]</sup> or of functionalized polymers.<sup>[23]</sup> Even negatively charged emulsions can interact with short-chain, single-stranded oligonucleotides, but, in that case, interactions are too weak and a massive release was observed in phosphate buffer saline (PBS) pH 7.1.<sup>[24]</sup> Adsorption isotherms, which relate the amount of adsorbed DNA to the input, can provide further information on DNA–emulsion interactions. The adsorption process can be monitored using agarose gel electrophoresis<sup>[5,6,23]</sup> or by quantifying the amount of free DNA in the continuous phase

by UV adsorption, which, by difference with the input, gives access to the amount of complexed nucleic acid. In Fig. 4, a complete set of data obtained for polymer functionalized emulsions is reported,<sup>[23]</sup> the isotherm was established by UV (Fig. 4A), confirmed by agarose gel electrophoresis (Fig. 4B), and the charge inversion was controlled by zeta potential measurements (Fig. 4C).

The conformation of the plasmid at the surface of the emulsion droplets can be assessed by the experiment named ethidium bromide (EB) displacement (Fig. 5). EB is an intercalant which becomes fluorescent on binding with double-stranded DNA. As a result of complexation with a polycation, DNA is compacted and EB is expelled into the aqueous phase provoking a drop in the fluorescence signal. At maximal compaction, only 10% of the original fluorescence remains. Fig. 5 gives the results for emulsion functionalized with an amphiphilic copolymer bearing spermine pendant groups (polymer T2). With the free polymer, a drastic loss in fluorescence was observed revealing a high compaction of the DNA; for emulsions functionalized with the same polymer, the loss in signal was far

**Fig. 4** Complexation isotherm and associated zeta potential measurement for the complexation of DNA onto cationic emulsions. A) isotherm obtained by UV and the subtraction method; B) agarose gel electrophoresis and EB staining; C) zeta potential measurements. *Source:* From Ref.<sup>[36]</sup>.

less, although, at the plateau, all the DNA had been complexed as checked by agarose gel electrophoresis. Thus the DNA adsorbed onto emulsions was rather expanded toward the aqueous phase. Another way to study the accessibility of immobilized DNA is to measure the amount of intercalating EB after the complexation of the DNA had occurred on the colloidal carriers. The authors showed that on increasing the emulsion content, the DNA was less and less accessible, to a plateau value that corresponded to the plateau determined by agarose gel.<sup>[5]</sup>

The stability of the complexation of DNA onto cationic emulsions was investigated by Teixeira et al. for the particular case of synthetic single-stranded oligonucleotide (ODN) in an antisense strategy. The authors used fluorescence energy transfer (FRET), surface tension measurements, cryomicroscopy to elucidate the fast oligonucleotide release from the carrier. It appeared that the ODN was released under the form of a complex with the cationic lipids, which ensured a protection against DNAs,<sup>[24,27]</sup> even in solution.

## APPLICATIONS OF DNA-NANOEMULSIONS COMPLEXES

DNA carriers have been designed for gene transfer applications aiming at delivering an exogenous gene either in vitro or in vivo. For biotechnologies, in vitro cell transfection is a means to produce recombinant proteins and highly performing transfection agents are required. Clinical applications of gene transfer are gene therapy and DNA vaccine. For gene therapy, expression of the foreign gene should take place in the right organ, for a prolonged period of time, in order to

substitute a defective one. In DNA vaccine, the expression of the gene will allow the production of the antigen, for which an immune response is looked for. Hence the endogenously expressed antigenic protein will be able to elicit both protective and cytotoxic immunity, which is a key advantage over conventional protein or attenuated virus-based vaccines.<sup>[18]</sup> Related to gene transfer is the delivery of oligonucleotides in an antisense strategy for the correction of genetic diseases, suppression of oncogenes, and eradication of viral infections.<sup>[28]</sup>

## In Vitro Cell Transfection

The production of papers dealing with in vitro cell transfection is very intense but because of lack of standards and normalized references, it is not easy to compare interexperiment performances. Apparently, the stability of the emulsion is an important factor in gene transfer and this can be achieved also by choosing the appropriate oil. With squalene, stable dispersions were obtained whose transfection properties were 30 times better than liposomes.<sup>[12]</sup> Solid lipid nanoparticles (120 nm in diameter) coated with plasmid DNA (220 nm after coating) were more powerful at transfecting cell lines than naked DNA, although they ranked average in comparison with some commercially available transfer agents. No toxicity was observed with these emulsions which was far to be the case with other carriers.<sup>[5]</sup> Cationic emulsions stabilized with nonionic surfactant are efficient transfer agents.<sup>[10,29]</sup> According to the authors, it seems that Tween<sup>®</sup> 80 seems the most efficient nonionic compound both for transfection efficiencies, which was confirmed later,<sup>[22]</sup> and for stability toward serum.<sup>[6]</sup>

## In Vivo Transfections

In vivo transfection in mice is the first step in preclinical evaluations. Emulsions elaborated according to Ref.<sup>[6]</sup> were tested as mucosal gene carriers and proved to be better performing than liposomes, thanks probably to a better stability of emulsions in contact with the nasal cavity mucosa.<sup>[30]</sup>

## Topical Transfection

Noninvasive delivery of active substances through the skin is quite attractive, as no needle is needed, the administration protocol is simple and safe. However, in order to efficiently deliver genes via the skin, it is necessary to circumvent its inherent barrier function. The presence of hair follicles and associated structures may allow local delivery to skin cells. With W/O nanoemulsions, the deposition of plasmid DNA was found to be primarily in follicular keratinocytes. Transgene expression was optimal at 24 hr following a single-dose application. No toxicity nor irritation was observed on the treated skins.<sup>[21]</sup>

## Emulsions as Adjuvants in DNA Immunization

It has been shown that naked plasmid DNA could induce strong T-helper type 1 (Th1) immune responses as proved by the production of interleukin-2 (IL-2) and interferon- $\gamma$  (IFN- $\gamma$ )<sup>[31,32]</sup> leading to a cytotoxic response. Protein-based vaccine tends to induce a Th2-type response with production of IL-4 and IL-10, associated to antibody production. The main limitation of the naked DNA approach is the large doses of plasmid required to obtain potent response in humans,<sup>[33]</sup> hence the need for powerful delivery systems.

Cationic emulsions based on squalene, Tween<sup>®</sup> 80, and DOTAP, prepared by microfluidization, could efficiently complex DNA on surface, up to 95%. After immunization, both mice and rabbits showed strong antibody titers in serum, 14- to 18 folds higher than with naked DNA, with a fair Th1 polarization of the response in mice. A similar orientation of the response was observed with particles engineered from warm O/W microemulsions using wax and CTAB.<sup>[18]</sup>

Skin is the body's front line for immunosurveillance as the viable epidermis contains Langerhans and dendritic cells which are effective antigen presenting cells. Moreover, these cells cover over 25% of the total skin area, making topical immunization very attractive.<sup>[35]</sup> Using either wax particles from microemulsions<sup>[17]</sup> or ethanol-in-fluorocarbon nanoemulsions,<sup>[19]</sup> the authors observed a 45-fold

enhancement of the total antibody titer as compared to naked DNA, with a strong Th1-type response. This result is also interesting in the sense that objects in the 100–200-nm size range can efficiently convey adsorbed DNA through the skin to the antigen presenting cells (although more work seems to be needed as mice were shaved prior to application. Shaving can generate microalterations of the skin integrity). When compared with intramuscular injection of DNA, which is the established route for naked pDNA, the overall response remains greater for the i.m. route, but the Th1 character was more important for the topical administration.

## CONCLUSION

Nanoengineered emulsion-based DNA vectors have been obtained by interaction of functionalized emulsions and DNA. Some manufacturing processes are already available for high-scale production using cheap and generally regarded as safe (GRAS) materials. Other elaboration methods are presently under investigation in order to improve the performances of the carriers, by increasing their colloidal stabilities and modulating their physico-chemical properties. Surface functionalization is an essential means for improving emulsion-based vectors and investigators use surfactants (cationic, nonionic) or polymers, for which the choice seems only limited by the researchers' imagination. The interactions of DNA with emulsions need more thorough investigations; fundamental knowledge on this aspect would be quite profitable for further applications.

Nanoemulsion–DNA complexes can serve as synthetic vectors for in vitro and in vivo purposes. In vitro cell transfection with DNA either coated on or adsorbed within emulsions has been well established, although performances are still modest. In vivo transfections were observed but gene expression was transient. More impressive were the results obtained by immunization. A strong immune response, including antibodies and cytotoxicity, was obtained in mice and rabbits. Moreover, nanoemulsion–DNA complexes could be either injected or applied onto the skin for topical administration. These appear to be sound results for the development of a fully synthetic DNA vaccine.

*Department of Chemical Engineering, Carnegie Mellon University,  
Pittsburgh, Pennsylvania, U.S.A.*

## INTRODUCTION

Since the development of the atomic force microscope (AFM) in 1986,<sup>[1]</sup> it has become a widely used and versatile tool in both the nanoscale imaging of surfaces<sup>[2–7]</sup> and in the measurement of many intermolecular and surface forces.<sup>[8–15]</sup> In AFM, forces between a probe and the relevant surface are measured through changes in the deflection of a flexible cantilever attached to the probe. For image collection, it is assumed that changes in sample topography affect the probe–sample interaction profile and therefore affect the response of the cantilever. The feedback control required to maintain a constant deflection of the cantilever is then used to reconstruct a three-dimensional image of the surface. In force measurements, the feedback control is disabled, and the deflections of the cantilever are measured as a function of normal probe–sample separation. Often, the interpretation of AFM images is assisted through force measurement results.

While there are currently numerous modes of AFM operation, they can be separated into two major categories—the dc or static method and the dynamic methods. In the dc mode of operation (also known as contact-mode AFM), the static deflection of the cantilever is the measured and controlled signal. The cantilever can be treated as a simple Hookian spring with its deflection proportional to the force acting on the probe. This was the first established AFM mode and is still the most commonly used one for force measurements. Dynamic AFM methods are more recent expansions of the technique and involve forced oscillation of the cantilever and the measurement and control of the dynamic response through quantities such as the cantilever's amplitude of oscillation, its resonance frequency, and its phase lag from the driving signal. Commonly used dynamic methods include noncontact mode (NC) AFM,<sup>[16]</sup> tapping mode (TM) or intermittent-contact (IC) AFM,<sup>[17]</sup> frequency modulation (FM) AFM,<sup>[18]</sup> and force modulation AFM.<sup>[19]</sup> With the exception of force modulation that uses small-amplitude oscillation of a tip or sample<sup>[20]</sup> in contact to measure local variations in material viscoelasticity, the other dynamic methods are less-invasive

methods of force measurement and imaging. In these methods, the cantilever is oscillated at large amplitudes and at frequencies close to or at its resonance frequency ( $\sim$  kHz). The NC and FM modes are operated out of contact with the sample (in the attractive regime). Frequency modulation measures the resonance frequency shift at constant amplitude operation, while NC measures changes in the oscillation amplitude at a fixed driving frequency. In both techniques, probe–sample interactions can be obtained from the frequency shift or from the change in the amplitude of oscillation. Tapping mode operation is similar to NC; however, the cantilever is forced to oscillate at larger amplitudes resulting in intermittent contact with the sample. As a result, the probe–sample interaction potential changes nonlinearly during each oscillation cycle. Because the dynamic quantities measured are averages over the whole oscillation cycle, it is non-trivial to directly relate the observed changes to the probe–sample interaction in TM. This makes the interpretation of both TM images and force measurement results more difficult. A recent review by García and Pérez<sup>[21]</sup> contains detailed information about the interpretation and application of these dynamic methods in air and vacuum.

Regardless of the complexities, TM is a valuable tool in the gentle and non-destructive imaging of soft and easily deformable surfaces such as biologically relevant surfaces<sup>[6,22,23]</sup> and soft polymer interfaces.<sup>[24,25]</sup> Contact loads in TM can be comparable to those in the conventional dc mode; however, it is the reduction of lateral shear of the sample, the brief probe–sample contact time, and the small contact area that enable it to be a less-destructive technique.<sup>[26,27]</sup> Some researchers have also hypothesized that soft biological materials undergo hardening under high frequency, making them less susceptible to deformation and damage upon impact.<sup>[28]</sup> Although TM is now used fairly extensively as an imaging tool, its force measurement capabilities have not been thoroughly exploited especially in nonambient environments appropriate for many surfaces of interest. Potentially, the gentle properties of the TM image process are shared in TM force measurements. Additionally, a

dynamic mode of measurement would offer increased sensitivity with the retention of lateral resolution and early detection of the sample before significant indentation takes place. It is these capabilities of TM AFM that we believe will make it a unique tool in the force measurement of heterogeneous biomaterial surfaces. We thus present a review of the common method of modeling TM force measurements in air and extend this method toward TM force measurement in liquid. We will report on the few studies aimed at understanding and improving TM in liquid and will focus on the importance of hydrodynamics in the system. Additionally, we will discuss the application of TM in liquid to the measurement of interactions occurring on biomaterial surfaces.

### TAPPING MODE ATOMIC FORCE MICROSCOPE: OBTAINING THE PROBE-SAMPLE INTERACTION

Unlike its dc counterpart, there is no direct method of obtaining the probe-sample interaction from TM force curves. Instead, an equation of motion that includes all the factors that affect the dynamics of the oscillator must be solved to obtain the full oscillatory behavior of the cantilever as a function of the equilibrium probe-sample separation,  $D$ . In air, the dynamics of the tapping cantilever can be suitably modeled using the forced damped harmonic oscillator (FDHO) model.<sup>[29–32]</sup> The cantilever is thus treated as a Hookian spring with some overall effective mass. Upon displacement from its equilibrium position, its inertia causes acceleration in the direction of the displacement, while its restoring force opposes the acceleration to return it to its equilibrium position. In the absence of external forces, the spring will oscillate for an infinitely long period of time with an amplitude,  $A$ , determined from its mass,  $m$ , and spring constant,  $k_c$  (harmonic oscillation). In real environments, a drag force caused by the viscous medium dampens the oscillations. Therefore to sustain oscillation, an external continuous energy supply is provided to the spring, and in most commercial AFMs, this is achieved with an external sinusoidal drive. All these contributions appear in the classical FDHO model. In TM experiments, however, probe-sample interactions exist that perturb the harmonic oscillation and, henceforth, we will refer to this as the *perturbed oscillator* [Eq. (1)]. In air, this probe-sample interaction is typically modeled as a long-range attractive van der Waals force and short-range contact mechanics that may include surface adhesion, and the contact mechanics usually dominate the cantilever response. Capillary-based attractive forces can also arise, but instabilities in cantilever motion caused by

this force are usually overcome through the use of very stiff cantilevers ( $k_c \sim 40$  N/m). The governing equation of motion that describes the cantilever motion is:

$$m \frac{d^2x}{dt^2} + \gamma \frac{dx}{dt} + k_c(x - D) = F_{\text{drive}} + F_{\text{P-S}}(x) \quad (1)$$

where  $\gamma$  is the viscous damping coefficient,  $F_{\text{drive}}$  is the external driving force, and  $F_{\text{P-S}}$  is the probe-sample interaction. The relevant positions of the oscillator are its instantaneous distance from the sample,  $x$ , and its equilibrium separation,  $D$  (Fig. 1). The FDHO model was derived for oscillations of a point mass; however, the distributed mass of the cantilever can still be lumped and approximated as a single vibrating mass because the vibration amplitude at the fundamental frequency is consistently at least an order of magnitude larger than the vibration amplitudes of higher harmonics.<sup>[33,34]</sup>

The mass of the cantilever is not a directly accessible parameter, so it is more convenient to write Eq. (1) in terms of the parameters that are usually measured:

$$\frac{d^2x}{dt^2} + \frac{\omega_o}{Q} \frac{dx}{dt} + \omega_o^2(x - D) = \omega_o^2 a_d \sin(\omega t) + \frac{\omega_o^2 F_{\text{P-S}}(x)}{k_c} \quad (2)$$

In the above equation, the relationships 1)  $\omega_o = (k_c/m)^{1/2}$  and 2)  $\gamma = m\omega_o/Q$ <sup>[35]</sup> were used to eliminate  $m$  and to replace  $\gamma$  with the term  $Q$  (quality factor) that is a descriptor of the viscous damping in the system and is obtained from the shape of the resonance curve.  $\omega_o$  is the resonance frequency of the cantilever for *free* oscillation (separations when the probe-sample interaction is negligible),  $\omega$  is the drive frequency, and  $a_d$

**Fig. 1** Schematic of the oscillating cantilever in TM AFM.  $x(t)$  is the instantaneous tip separation and  $D(t)$  is the equilibrium cantilever separation from the sample (grey box).

is the drive amplitude. In TM operation in air,  $Q$  is commonly on the order of 200–400 and  $f_o = \omega_o/2\pi \sim 400$  kHz.  $k_c$  can be calibrated experimentally with a variety of methods.<sup>[36–38]</sup> In most instances, the cantilever maintains approximately sinusoidal oscillation even when probe–sample interactions are significant. This oscillation is of the form  $A \sin(\omega t + \phi)$ , where  $\phi$  is the phase lag between the drive and the cantilever response.

The effect of probe–sample interactions on  $A(D)$  can be partially understood from frequency modulation studies.<sup>[39,40]</sup> In these studies, it has been shown that probe–sample interactions alter the overall spring constant of the system,  $k_o$ , thereby shifting the oscillator's resonance frequency. The frequency shift,  $\Delta\omega_r$ , arising from the interaction can be determined from the force gradient ( $\partial F_{p-s}/\partial x$ ) as long as this gradient is constant over the whole range of tip motion.<sup>[41]</sup>

$$\Delta\omega_r(D) = \frac{\omega_o}{2k_c} \frac{-\partial F_{p-s}}{\partial x} \quad (3)$$

Although this assumption is not strictly valid for TM operation, the general relationship derived is useful in understanding the cantilever response in TM force measurements. To illustrate this more clearly, Fig. 2 plots the total energy profile of the unperturbed harmonic oscillator and the perturbed oscillator. An attractive force (positive force gradient) lowers the potential energy of the oscillator ( $1/2 k_o x^2$ ) and corresponds to a decrease in  $k_o$ , while a repulsive force (negative force gradient) has the opposite effect. Because the oscillator's resonance frequency is proportional to the spring constant:  $\omega_p = (k_o/m)^{1/2}$ ,

**Fig. 2** Theoretical energy profile of the oscillator. Dotted line is the probe–sample interaction energy profile; dashed line is the unperturbed oscillator and solid line is the perturbed oscillator.  $A$ , at a specific energy, is defined as  $(D - x)$ , where  $x$  can be  $a$ ,  $a'$ ,  $b$ , or  $b'$ .

**Fig. 3** Theoretical resonance curve [ $A(\omega)$ ] of an unperturbed oscillator (thick solid line) and of the perturbed oscillator affected by an attractive probe–sample interaction (I), a repulsive probe–sample interaction (II), and additional damping (III). The driving frequency is the dashed line.

where  $\omega_p$  is now the resonance frequency of the perturbed system, decreasing  $k_o$  will result in a decrease in  $\omega_p$  or  $\Delta\omega_r = (\omega_p - \omega_o) < 0$ , while increasing  $k_o$  yields  $\Delta\omega_r > 0$ . In TM force measurements, where the drive frequency is fixed, frequency shifts cause an increase in  $A$  with attractive interactions or a decrease with repulsive ones (Fig. 3). Bielefeldt and Giessibl<sup>[42]</sup> have shown that the above analysis can be used to generate the linear decay in amplitude with separation that is observed experimentally on non-deformable samples such as silicon. On these samples, the contact stiffness is large and is the dominant interaction. Because the cantilever cannot penetrate the sample and is approximately symmetric in its oscillation, the amplitude decreases linearly with a linear decrease in the probe–sample separation.

In many TM experiments in air, the  $A(D)$  curves contain stepwise discontinuities that cannot be explained using the analysis presented earlier.<sup>[43,44]</sup> Using a variational principle approach to analytically solve Eq. (2) (assuming a van der Waals interaction), Nony, Boisgard, and Aime<sup>[45]</sup> and Aime et al.<sup>[46]</sup> have directly related these discontinuities to two possible stable oscillation states for the cantilever caused by the strong attractive potential. This bistability is observed as a jump in the  $A(D)$  curve that occurs because of the transition from one oscillation state to the other<sup>[32]</sup> (Fig. 4). The concept of bistability is perhaps more easily understood by examining the dependence of amplitude on frequency [ $A(\omega)$ ]. For perfectly harmonic systems, only one possible amplitude exists for each oscillation frequency (Fig. 3); however, with strong attractive potentials, the  $A(\omega)$  curve becomes distorted leading to two possible amplitudes at certain frequencies<sup>[45]</sup> (Fig. 5). Analytical solutions to Eq. (2) prove useful in elucidating the origins of specific

**Fig. 4** Bistable oscillation (manifested as a jump in the amplitude–displacement curve) observed experimentally in measurements involving a silicon tip tapping on a semiconductor surface. *Source:* From Ref.<sup>[48]</sup>.

features in the amplitude vs. distance,  $A(D)$ , and phase vs. distance,  $\phi(D)$ , force curves.<sup>[42,47,48]</sup> However, this method of solution is only valid if the probe–sample interaction is linear and if one assumes that the cantilever motion remains sinusoidal at all probe–sample separations. In most cases, the interaction is nonlinear in TM and deviations from sinusoidal motion can arise because of the stiffness of the impact. Therefore quantitative modeling is not possible using analytical approaches, and a numerical solution to Eq. (2) must be undertaken.

In the numerical solution, the probe–sample interactions are obtained by solving the inverse problem. This requires a fairly good understanding of the relevant interactions on the sample being studied. Fortunately, many intermolecular/intersurface interactions have been studied using dc AFM, and good agreement has

**Fig. 5** Distorted theoretical resonance curve when strong attractive interactions are incorporated into the probe–sample interaction. *Source:* From Ref.<sup>[49]</sup>.

been obtained between experiment and theory. Therefore the general force laws for many interactions are well described theoretically.<sup>[49]</sup> Anczykowski et al.<sup>[30]</sup> simulated tapping on silicon in air using the MYD/BHW (Muller-Yushenko-Derjaguin/Burgess-Hughnes White) model that combines a long-range attractive interaction with a short-range elastic repulsion at contact separations and observed fair agreement between the experiment and simulation results. They did note that quantitative agreement was highly sensitive to the exact form of surface potential applied and discouraged the use of linearized models to describe the surface potential. Bar et al.<sup>[50]</sup> reproduced experimental force curves on elastomers using contact forces that accounted for surface adhesion. They showed that bistability was not present during tapping on compliant samples and that sinusoidal oscillation was maintained even at small probe–sample separations, thereby validating the harmonic approximation. The work of Dubourg and Aime,<sup>[51]</sup> however, has shown that bistability can occur on elastomers when both elastic and glassy domains are present, but reproduction of experimental data was achievable with the correct form of surface adhesion in the interaction. Through analytical and numerical efforts by these and other groups, there is now a good understanding of how probe–sample interactions affect the dynamics of the cantilever in air and how to extract these interactions from  $A(D)$  curves. In principle, much of the analysis that is relevant to TM in air should be applicable to TM force measurement in liquid; however, we will discuss in the next section the added complexities associated with this form of measurement.

Although not yet discussed, another useful quantity that can be measured is the phase lag  $\phi$ . This is often used to determine the amount of energy dissipated by the cantilever during tapping<sup>[52]</sup> and can be a good measure of local material viscoelasticity or anisotropy.<sup>[27,53,54]</sup> Energy dissipation causes an increase in  $\phi$ ; however,  $\phi$  can also be affected by conservative tip–sample interactions<sup>[55]</sup> (Fig. 6). The phase lag is particularly useful in TM imaging where  $A$  is maintained at a constant value. As such, changes in  $\phi$  can be attributed solely to changes in the material-induced dissipation in the system.<sup>[56]</sup> If  $A$  is not constant, then the energy dissipated cannot be obtained from the phase information alone.<sup>[27]</sup> An additional advantage in collecting the phase signal is to identify whether the cantilever is operating in a primarily attractive (non-contact) or repulsive (intermittent contact) regime when the cantilever is driven at its resonance frequency.<sup>[27]</sup> Unfortunately, in TM in liquid, the phase signal is difficult to interpret as it is affected by the presence of other resonances in the system. The origin of these spurious resonances will be discussed in the next section.

**Fig. 6** Theoretical phase lag,  $\phi$ , of an unperturbed oscillator (thick solid line), the oscillator perturbed by an attractive probe–sample interaction (||), and the oscillator affected by additional damping (|||).

### EXTENSION OF THE FORCED DAMPED HARMONIC OSCILLATOR MODEL TO TAPPING IN LIQUID

Tapping mode in liquid<sup>[28,57]</sup> is not an extensively studied technique, although it is practical for the imaging of biofunctionalized surfaces.<sup>[22,58,59]</sup> In liquid, images of molecules in their physiological state can be obtained and the intermolecular interactions that occur in these conditions can be measured. Here cantilevers with spring constants that are comparable to those used in dc force measurements ( $k_c \sim 0.1\text{--}1\text{ N/m}$ ) are used, as stiff cantilevers are no longer needed because of the absence of capillary forces.

There are several intrinsic complications that arise from TM operation in liquid. The first is dependent on the mode of cantilever excitation. The most common method of forcing cantilever oscillation is through acoustic excitation. Here the cantilever oscillation is promoted through the vibration of the fluid cell at high frequencies. This gives rise to spurious resonances from the coupled oscillations of various parts of the cell that cloud the identification of the fundamental resonance of the cantilever<sup>[60]</sup> (Fig. 7). As mentioned previously, these spurious resonances complicate the measured phase signal in TM in liquid. It is no longer sigmoidal but can have multiple maxima and minima because of neighboring resonances (Fig. 7). If the form of cantilever excitation is changed to one that is more direct, such as directly oscillating a magnetized cantilever using an oscillating magnetic field (MAC-mode AFM),<sup>[61]</sup> the presence of these spurious resonances can be attenuated.

Because most commercial AFMs utilize acoustic excitation to drive the cantilever, we will only discuss operation with this mode of excitation. The thermal

**Fig. 7** Resonance behavior obtained by an acoustically excited silicon nitride ( $\text{Si}_3\text{N}_4$ ) cantilever ( $k_c \sim 0.5\text{ N/m}$ ) in water. Thick dotted line is the  $A(\omega)$  data and the solid line is the  $\phi(\omega)$  data.

noise spectrum of the cantilever<sup>[59,62]</sup> can be used to assist in the identification of the resonance of the cantilever. Additionally, it is common that the resonance of the cantilever exhibits the highest vibrational amplitude in the frequency sweep. However, further verification can be obtained from the initial phase lag when probe–sample interactions are negligible. Fig. 8 shows  $\phi$  for a cantilever oscillated at a frequency close to its resonance frequency and at a frequency off a neighboring spurious resonance. In the latter case,  $\phi \sim 90^\circ$ , whereas  $\phi > 90^\circ$  when the oscillating frequency is on the true cantilever resonance. When the cantilever is driven on or close to its resonance, we expect  $\phi$  to be sensitive to the damping environment of the cantilever, and a value  $>90^\circ$  indicating increased damping/energy dissipation closer to the surface is expected because of the presence of hydrodynamic forces. Some authors have also observed that

**Fig. 8**  $\phi(D)$  of the  $\text{Si}_3\text{N}_4$  cantilever ( $k_c \sim 0.5\text{ N/m}$ ) driven close to its fundamental resonance (solid line) and driven off a spurious resonance (dotted line) in water.

**Fig. 9**  $A(D)$  of a magnetically excited silicon nitride cantilever ( $k_c \sim 0.6$  N/m) with a silicon tip tapping against a mica surface. Additionally plotted is the instantaneous position of the cantilever (deflection signal). The drive frequency used (1 kHz) was much smaller than the resonance frequency of the cantilever (14.8 kHz). *Source:* From Ref. [67].

if the cantilever is driven at a frequency that is not close to its fundamental resonance, the oscillations do not decay symmetrically with tapping.<sup>[28,31,63]</sup> Instead, the lower turning point of oscillation varies, while the upper turning point remains constant (Fig. 9). The perturbed FDHO model does not describe this type of oscillatory response as Burnham et al. have shown.<sup>[31]</sup>

With the true resonance of the cantilever appropriately selected, a more significant complication with regards to modeling TM in liquid is the large hydrodynamic damping of cantilever oscillation. Resonance frequencies are now 3–4 times lower than those in air because of the added mass of liquid that moves with the oscillating cantilever<sup>[64–66]</sup> and  $Q$  is of order 1. These low-quality factors compromise the sensitivity of TM force measurements as they result in broader resonance curves and smaller  $\Delta A/\Delta D$  changes with probe–sample interaction (Fig. 3). Additionally, sample-induced dissipation becomes difficult to measure because of the dominance of hydrodynamic damping. To circumvent these problems caused by low-quality factors, Humphris, Tamayo, and Miles<sup>[67]</sup> have developed a positive feedback control loop system, known as active  $Q$  control, that increases the effective quality factor of the system to values that are more comparable with those obtained in air operation ( $>100$ ).  $Q$  control can also assist in the identification of the fundamental cantilever resonance in acoustically excited systems.

Hydrodynamic damping not only affects the free oscillation of the cantilever, but can also be distance-dependent through squeeze damping.<sup>[64]</sup> Squeeze damping can occur between the cantilever or probe and surface and is caused by an increase in hydrostatic pressure that develops because of the film of liquid that must be squeezed out of the gap between the relevant approaching surfaces.<sup>[68]</sup> Its onset scales with the size of the approaching object. Hosaka, Ito, and

**Fig. 10** Resonance behavior of an oscillating  $\text{Si}_3\text{N}_4$  cantilever ( $k_c \sim 0.5$  N/m) in water at  $D \sim 50$   $\mu\text{m}$  (thick solid line),  $D \sim 0.5$   $\mu\text{m}$  (solid line), and  $D \sim 0.05$   $\mu\text{m}$  (dashed line).

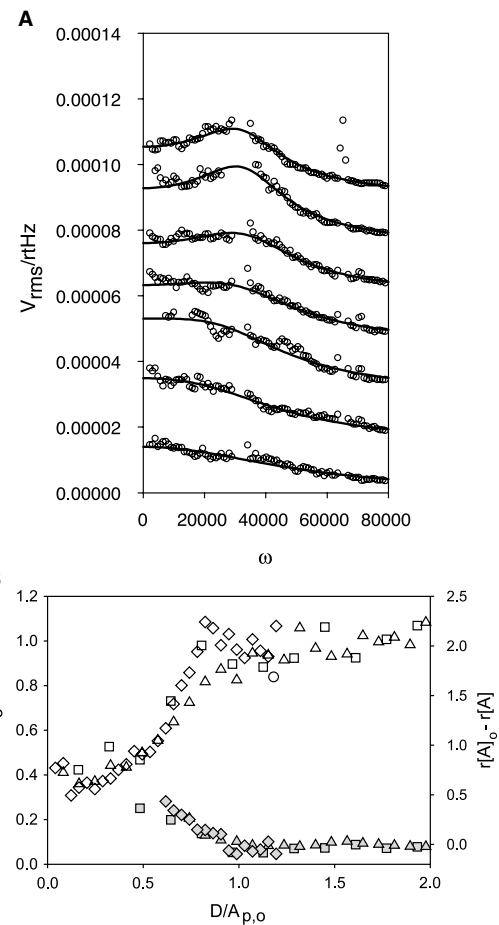

Kuroda<sup>[69]</sup> have derived the squeeze force for beam-shaped cantilevers by modeling the cantilever as a string of spheres and have shown that it varies with  $D^{-3}$ . However, Alcaraz et al.<sup>[70]</sup> have shown experimentally that the squeeze force varies more as  $D^{-1}$  for both rectangular and V-shaped cantilevers. For the probe (assuming a spherical geometry), the squeeze force is proportional to  $D^{-1}$  (Reynolds equation).<sup>[64,71]</sup> The theoretical models for the squeeze force are only valid for laminar flow within the squeeze film, i.e.,  $Re \ll 1$  in the film, for ideal geometries, for oscillation amplitudes that are very small relative to the gap distance, and for constant velocity approach of the object to the surface. Because many AFM cantilevers and probes (usually conical tips) have complex geometry and are inclined at a small angle, deviations from these models are not unreasonable. Additionally, in TM,  $A$  is comparable to the gap distance, making the analysis of the squeeze force more difficult.

In their study of solvation forces near a graphite surface, O'Shea and Welland<sup>[64]</sup> observed squeeze damping at tip–sample separations on the order of tens of microns for all the cantilevers used. This damping has also been observed in the aqueous solutions used in our work (Fig. 10). At smaller separations ( $<1$   $\mu\text{m}$ ) (while maintaining noncontact with the substrate), they observe no significant additional damping and conclude that squeeze effects between the tip apex and the surface are negligible in their experiments. This conclusion is consistent with the Reynolds model that predicts a tip squeeze-drag coefficient that is about 3 orders of magnitude smaller than the cantilever squeeze-drag coefficient, making the cantilever the dominant contributor to distance-dependent damping. O'Shea and Welland do observe a huge increase in damping at  $D < 2.5$  nm that they ascribe to the solvation layer becoming more viscoelastic because of confinement.

O'Shea and Welland's characterization of hydrodynamic damping was conducted at noncontact separations, and their separation calibration was affected by drift of the piezo and other experimental limitations. For TM force measurements, the form of damping must be known accurately for separation changes on the order of the resolution of the force measurement acquisition ( $\Delta D \leq 1$  nm). Additionally, it is possible that the tip-squeeze contribution is much larger in TM than in NC because of the very small squeeze gaps ( $< 1$  nm) created during oscillation. We therefore investigate how  $Q$  varies with  $D$  using *Fourier spectroscopy*.<sup>[72]</sup> This involves high-speed collection of the cantilever deflection signal during force measurement and discrete Fourier transformation of subsets of the signal (Hanning window) to obtain the resonance curve of the cantilever,  $A(\omega)$ , at various  $D$ . This method allows us to overcome effects such as piezo-drift because of the continuous acquisition involved, allowing accurate separation calibration. From the  $A(\omega)$  curves, we can obtain  $Q$  from the steady-state analytical solution of Eq. (2), in which the probe-sample interaction is accounted for through an average value,  $r[A]$ .<sup>[48]</sup>

$$A = \frac{a_d}{\sqrt{(1 - \omega^2/\omega_0^2 - r[A])^2 + \frac{\omega^2/\omega_0^2}{Q^2}}} \quad (4)$$

Several authors have shown that the cantilever oscillation is anharmonic in TM in liquid.<sup>[28,31,73]</sup> Indeed, the cantilever deflection has been observed to deviate fairly significantly from sinusoidal oscillation during intermittent contact that Chen et al.<sup>[65]</sup> attribute to cantilever buckling caused by motion of the fluid. Despite the anharmonicity, Eq. (4) still adequately fits the resonance curves of our tapping cantilever even up to small separations (Fig. 11A). Fig. 11B shows how  $Q$  varies with  $D$  for various drive amplitudes in tapping on silicon in water using a tip as the probe. The distance axis has been normalized using the free peak amplitude,  $A_{p,o}$ . All the curves collapse on top of each other, indicating that additional dissipation only ensues when the probe starts to intermittently contact the surface (onset of strong repulsive interaction observed through a more negative  $r[A]$ ). Because oscillation amplitude is a key factor in determining both the onset and extent of additional damping, we can only obtain  $Q$  averaged over the whole oscillation cycle,  $Q(D)$ , instead of  $Q(x)$ . In this analysis,  $D = 0$  is defined as the onset of constant oscillation amplitude in the approach curve after intermittent contact occurs. It is important to note that the point of zero separation is always ambiguous with AFM force measurements, as only the deflection of the cantilever is monitored in the technique. In dc operation, the point of zero

**Fig. 11** (A) Theoretical fit of  $A(\omega)$  curves [Eq. (2)] obtained using Fourier spectroscopy at various  $D$  for a free peak amplitude,  $A_{p,o}$  of 6.1 nm. The bottom curve is for  $D = 0$ , and each subsequent curve is +1.6 nm away from the previous curve. (B) Fitted  $Q$  (unfilled symbols) and  $r[A]$  (shaded symbols) as a function of normalized separation,  $D/A_{p,o}$  for different  $A_{p,o}$ .  $Q$  and  $r[A]$  have also been normalized by their free values (for negligible probe-sample interactions).  $A_{p,o}$  was 0.4 nm (circles), 3.1 nm (squares), 6.1 nm (triangles), and 12.2 nm (diamonds).

separation/contact is usually calibrated from the onset of linearity in the cantilever deflection. Equivalently in TM, one can define an equilibrium zero probe-sample separation,  $D = 0$ .

The results and discussion presented show that hydrodynamic forces are a key component of force measurements in liquid. Experiments using solutions of different viscosities<sup>[72]</sup> have illuminated that the origin of the  $Q$  decay that occurs in our TM force measurements with intermittent contact is not a result of squeeze damping. Instead, we hypothesize that the origin of the dissipation is a result of frictional losses associated with both cantilever buckling<sup>[73]</sup> and lateral sliding of the tip upon contact.<sup>[54]</sup> If we allow for the occurrence of this intermittent contact-induced

dissipation, introduced in the FDHO model through a decaying  $Q(D)$ , a more accurate simulation of TM force measurements in liquid is achieved.<sup>[72]</sup>

## DYNAMIC MEASUREMENTS OF STERIC FORCES FROM DIFFUSE POLYMER LAYERS

Physically and chemically adsorbed polymer layers are used to modify surface properties, such as charge and wettability, as well as to prevent adsorption of molecules onto the surfaces. On biomaterials, such polymer layers are commonly used as antifouling coatings as they exert repulsive steric forces that prevent contaminant adsorption. The polymer steric interactions arise from the osmotic penalties associated with confining the polymer segments.<sup>[74]</sup>

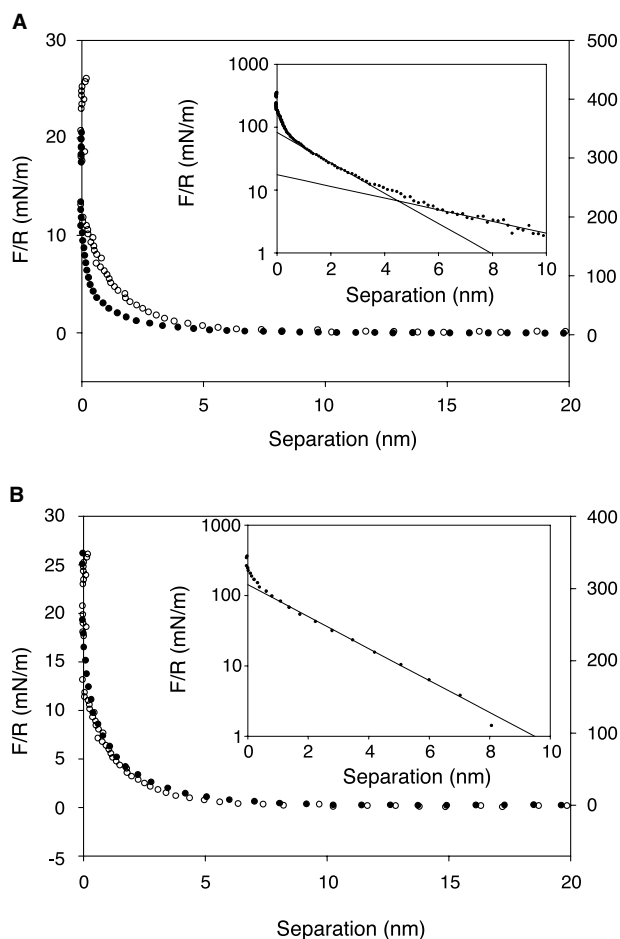

There have been a number of dynamic studies<sup>[75,76]</sup> focused on characterizing the viscoelastic properties of adsorbed or constrained polymer layers on surfaces using AFM. Traditionally, these studies were conducted using the surface forces apparatus (SFA),<sup>[77–79]</sup> where the interaction area of the approaching surface is many orders of magnitude larger than the probes used in AFM. Both techniques involve oscillating the sample at frequencies in the 10–1000 Hz range and looking at changes in the phase lag and the amplitude to obtain both the storage and loss moduli of the system through the Voigt model. A slightly different approach that has been taken to study the properties of swollen grafted polymer layers is to observe changes in the dynamic properties from the thermal noise fluctuations of the cantilever. This technique has been exploited by Gelbert et al.<sup>[80,81]</sup> to study the viscoelastic properties of various tethered polymer layers and offers advantages to forced oscillation because of the small oscillation amplitudes that ensure the dynamic responses are linear.

One of the few AFM studies involving high-frequency, large amplitude probing of polymer layers is Overney et al.'s<sup>[82]</sup> compliance measurement of a grafted polystyrene brush. In their work, oscillation was mediated through modulation of the cantilever at a free oscillation amplitude of 5.5 nm and a modulation frequency of 3 kHz. From storage modulus vs. distance profiles for both a bare silicon substrate and the polystyrene brush, a brush layer height was calculated that compared favorably to neutron reflectivity experiments and dc force measurements. The storage modulus is the elastic contribution from the compression of the polymer segments and is analogous to the steric repulsion exerted by the brush. Overney et al.'s polystyrene brush system is an ideal one in that the layer is dense enough to resist compression before significant penetration into the layer occurs, making escape transitions unlikely.<sup>[83,84]</sup>

Simulations<sup>[83,85]</sup> have shown that when sparsely grafted polymer layers undergo continuous compression from sharp tips, the polymer chains splay or escape away from the tip to minimize their energy of confinement. These events are frequently observed in dc force measurements<sup>[13]</sup> and result in an underestimation of the magnitude of the steric repulsion that would be experienced between the layer and an adsorbing molecule. It would be interesting to compare the sensitivities of dynamic and dc force measurements for sparsely grafted systems using a modulation frequency close to the cantilever's resonance to enhance sensitivity. Grafted polymer systems are ideal to study because they display an exponential resistance to compression that is well described theoretically<sup>[74]</sup> and they are commonly used in biotechnical applications because of the covalent form of attachment that increases stability.

We have explored the sensitivity of TM AFM force measurements on grafted poly(ethylene glycol), PEG, layers on silicon at two grafting densities using the integrated tips on the cantilevers as probes. Fig. 12A and B shows the results of dc force measurements on the two PEG layers for cantilevers of differing spring constant ( $k_{c1} \sim 0.01$  N/m and  $k_{c2} \sim 0.5$  N/m). For the sparsely grafted layer, the onset of deflection of the stiffer cantilever ( $k_{c2}$ ) is more short-ranged than that observed with the more flexible cantilever ( $k_{c1}$ ). This suggests that polymer chains are splaying/escaping from the tip of the stiffer cantilever (because of the high compression load), resulting in significant penetration of the tip through the layer before a detectable resistance to compression is measured. After a certain amount of compression, escape transitions become less favorable because the polymer is constrained at one end and the stretching penalty associated with the chain completely escaping from under the tip is too great.<sup>[85]</sup> Therefore segments will start to resist compression. Confirming this, we observe two compression regimes in the force profiles on this layer. Only one compression regime is observed on the densely grafted layer because the osmotic penalty for chain escape as a result of the proximity of neighboring chains is large enough to prevent escape despite the large compression loads.

Tapping mode force measurements on the same surfaces described earlier are shown in Fig. 13. These force measurements were conducted with the stiff cantilevers, but the onset of deflection is comparable to the onset obtained from dc measurements with cantilevers of  $k_{c1}$  (Table 1). Therefore we can conclude that TM force measurements are more sensitive than their dc counterparts. This increased sensitivity is attributed to the large oscillation amplitude that allows the polymer layer to be sensed before significant compression occurs and the high frequency of oscillation

**Fig. 12** Interaction energy profiles measured on (A) a sparsely grafted PEG layer and (B) a densely grafted PEG layer using d.c. force measurements with  $\text{Si}_3\text{N}_4$  cantilevers of  $k_{c1}$  (unfilled symbols) and  $k_{c2}$  (filled symbols) (insets are the energy profiles for  $k_{c2}$  plotted on a semilog scale).

**Fig. 13** TM  $A(D)$  curves obtained on the sparsely grafted PEG layer (unfilled symbols) and the densely grafted PEG layer (filled symbols) using a  $\text{Si}_3\text{N}_4$  cantilever of  $k_{c2}$ .

**Table 1** Values indicate 5% deviation from the overall measured change

Experiment	Detection of change ( $D$ ) (nm)
dc: sparse PEG layer, $k_{c1}$	4.3
dc: sparse PEG layer, $k_{c2}$	2.85
dc: dense PEG layer, $k_{c1}$	3.5
dc: dense PEG layer, $k_{c2}$	4
TM: sparse PEG layer, $k_{c2}$	14
TM: dense PEG layer, $k_{c2}$	14.8

that possibly prevents slower events such as polymer escape from occurring.

## DYNAMIC MEASUREMENTS OF RECEPTOR-LIGAND INTERACTIONS

Much of biological activity and cellular response is mediated through specific interactions termed receptor-ligand interactions. These interactions are short-ranged ( $\sim 1-2$  nm) and occur because of a combination of hydrogen bonding, van der Waals interactions, and hydrophobic attractions between complementary sites on molecules.<sup>[86]</sup> Dc force measurements have been used extensively to measure the binding strength between receptor-ligand pairs.<sup>[14,15,87,88]</sup> In these measurements, the force of unbinding is determined by the amount the cantilever deflects because of the receptor-ligand attraction during retraction from the surface. Because biological interactions are, by nature, dynamic, many researchers have also investigated the dependence of the receptor-ligand binding strengths on the loading and unloading rate.<sup>[89-91]</sup> To our knowledge, only a few authors have investigated the feasibility of high-frequency dynamic probing of these interactions.

In particular, Raab et al.<sup>[92]</sup> have used MAC-mode AFM to conduct successful antibody recognition imaging using a functionalized AFM tip. In their work, they attached the antibody to a flexible polymer tether and carefully controlled both oscillation amplitude and driving frequency to optimize the contact time such that binding between the antibody and antigen was feasible. Liu Leuba, and Lindsay<sup>[93]</sup> have also examined single molecule stretching behavior with both dynamic and static AFM measurements. Additionally, a new tool named molecular recognition force microscopy (MRFM) that uses magnetic excitation of the cantilever has emerged in recent years. Here the tip is functionalized with a flexible cross-linker carrying a ligand that will complex to its complementary receptor on the surface. The oscillation responses of the cantilever and tip are then recorded as a function of frequency. Pastushenko et al.<sup>[94]</sup> and Schindler et al.<sup>[95]</sup> used a

theoretical analysis of the damped oscillator model to investigate the conditions necessary for the most sensitive detection of the receptor–ligand complexation (maximizing  $\Delta A$ ) with the lowest possible compressive load. They determined that if  $Q > 1$ , MRFM experiments are more sensitive than dc experiments and that driving below  $\omega_0$  offers greater sensitivity than driving above  $\omega_0$ . Their analysis, as they duly noted, did not rigorously account for the viscous interactions that affect the cantilever response in liquid; however, it is still a useful guide in optimizing dynamic MRFM experiments.

There is a lower limit to the flexibility of the cantilevers that can be used for these studies to increase the sensitivity of the measurement. With very flexible cantilevers (usually of larger dimension), hydrodynamic forces become too great<sup>[96]</sup> and result in  $\omega_0$  in liquid that occur within the noise frequencies of the instrument. Huge drive amplitudes are also needed to sustain oscillation, thereby increasing the impact force on the sample. In our experiments, stable tapping could only be achieved using cantilevers with  $k_c \geq 0.1$  N/m. However, it may be possible to drive the cantilever at frequencies off its higher eigenmodes of vibration that arise from its secondary bending and twisting states.<sup>[97]</sup>

## CONCLUSION

The interactions that we have discussed are relevant to many biomaterial surfaces<sup>[98–102]</sup> on which receptor–ligand interactions are used for the specific recruitment of biomolecules/analytes to the surface and polymer steric forces are used to prevent fouling of the surface by noncomplementary contaminants. In nature, carbohydrates that protrude out of the plasma membrane on the cell surface are responsible for imparting steric repulsion.<sup>[103]</sup> Understanding the interplay between these interactions will aid in the comprehension of important cellular processes such as cell adhesion and in the design of various biomaterials. The potential of TM AFM as a tool in the gentle, simultaneous probing of these interactions in physiological conditions is promising.

We have shown that hydrodynamics and other forms of energy dissipation that are independent of the probe–sample interactions play a very important role in TM in liquid. Full characterization of this dissipation is necessary before accurate quantitative extraction of the relevant probe–sample interactions is possible. This can be achieved for each force measurement using the Fourier spectroscopy technique that we proposed.

As with all AFM methods, the ambiguity associated with the knowledge of absolute zero separation is a

major limitation to the technique. This uncertainty affects quantitative reproduction of experimental data and accurate knowledge of the acting probe–sample interaction. Additionally, the dynamic signal measured is not specific to the motion of the probe, but reflects the overall motion of the cantilever. In TM in liquid, where the fluid can cause secondary bending and rotation of the cantilever, this complicates interpretation of the measured signal and limits the applicability of the FDHO model that treats the cantilever as a unified mass. We hope that with growing utility of this mode of measurement, these problems will be addressed in the future.

## ACKNOWLEDGMENTS

We would like to thank Dr. Tomasz Kowalewski for useful discussions on the physics behind AFM operation, and we would also like to thank all the scientists cited for their contributions toward the advancement of knowledge about AFM operation. Our personal work has been supported by the ACS Petroleum Research Fund and NSF-CTS-0210205.

## INTRODUCTION

When a surface is immersed or created in an aqueous solution, a discontinuity is formed at the interface where such physicochemical variables as electrical potential and electrolyte concentration change significantly from the aqueous phase to another phase. Because of the different chemical potentials between the two phases, charge separation often occurs at the interfacial region.<sup>[1]</sup> This interfacial region, together with the charged surface, is usually known as the electrical double layer (EDL). This layer, which can extend as far as 100 nm in a very dilute solution to only a few angstroms in a concentrated solution,<sup>[2]</sup> plays an important role in electrochemistry,<sup>[3,4]</sup> colloid science, and surface chemistry. Applications of the electrical double layer can be found in energy-storing devices in the form of capacitors, electrosorption of metal ions, purification of drinking water, nanomaterial processing, and sensor assembly.

The importance of the EDL has led to numerous studies, and many models were proposed in the past. The best known is the Gouy–Chapman model,<sup>[2]</sup> in which ions are considered as point charges and water is considered as a continuum. The electrical potential distribution and the concentration profiles can be predicted simply by using the Poisson–Boltzmann (P–B) equation. This theory, which has been proven very successful at low electrolyte concentrations and low surface charge densities,<sup>[5–7]</sup> has been applied to many EDL problems, such as heavy metal adsorption<sup>[8]</sup> and ion transport through membrane channels.<sup>[9,10]</sup> For higher concentrations of ions and higher surface charge densities, a better description of the EDL can be obtained by using primitive models,<sup>[5,7,11,12]</sup> in which water is still considered as a continuum but ions are considered as hard spheres with a point charge embedded at their centers. Various theoretical approaches such as molecular dynamics,<sup>[13]</sup> modified P–B equations,<sup>[14]</sup> integral equation theories,<sup>[15–19]</sup>

and Monte Carlo simulations<sup>[6,7]</sup> have been employed to study the primitive model. These studies confirm that the primitive model and the Gouy–Chapman model provide similar results for dilute solutions and low surface charge densities. However, the agreement between these two models becomes worse when a high ion concentration or a high surface charge density is encountered, especially if an asymmetric electrolyte is present in the solution.<sup>[7]</sup> A more realistic EDL model would be the non-primitive model,<sup>[13,20–27]</sup> in which water is considered as individual molecules instead of a continuum. For example, in the solvent primitive model (the simplest form of a non-primitive model),<sup>[23,24]</sup> water molecules are considered as neutral hard spheres. Because of the steric effect caused by water molecules, the ion concentration profile in the EDL shows strong oscillations, which cannot be observed in the primitive model. In this study, the results of Monte Carlo simulations used to compare the primitive and nonprimitive EDL models with the classical Gouy–Chapman model in 10- and 20-Å slit-type nanopores are reported.

## EDL AND SURFACE PROPERTIES

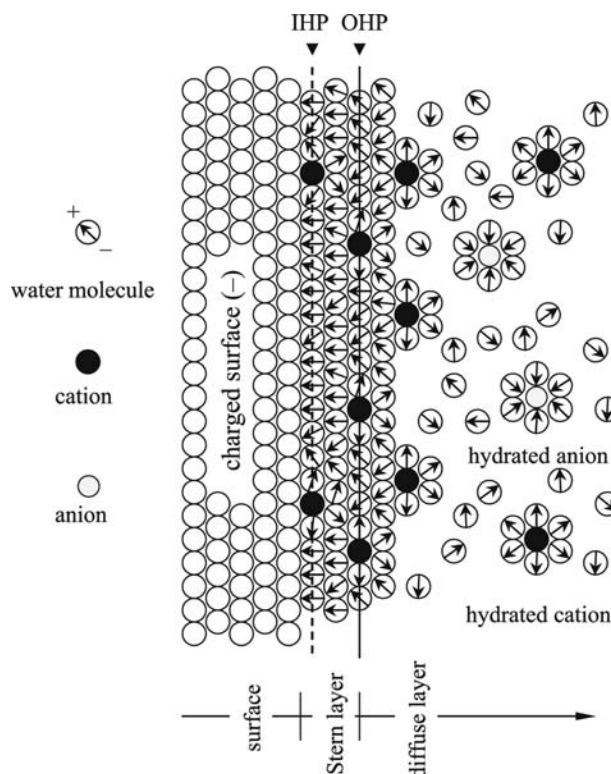

Because not all of interfaces are of the same kind, the characteristic behavior of the EDL depends on the properties of the particular interface. Ideally, such interfaces can be characterized either as polarizable or non-polarizable, depending on the interfacial resistance.<sup>[1]</sup> This idea can be better explained by the concept of an equivalent circuit. As shown in Fig. 1, the entire interfacial region can be represented by an equivalent circuit composed of an electrical double-layer capacitor (EDLC), an interfacial resistance, and a solution resistance, where  $C_{dl}$ ,  $R_f$ , and  $R_s$  represent the double-layer capacitance, the faradaic resistance, and the solution resistance, respectively. If  $R_f$  is very large (such as in metal–solution interfaces), the

**Fig. 1** Equivalent circuit of the interface and two ideal cases: ideally polarizable and nonpolarizable interfaces.

equivalent circuit can be simplified as a double-layer capacitor in series with a solution resistance. Therefore any increase in electrical potential on the surface will cause counterions to accumulate in the EDLC, preventing electric current from passing through the interface. In this case, the interface is characterized as ideally polarizable. On the other hand, if  $R_f$  is very small, such as in the case of a Ag/AgCl surface in contact with NaCl solution, the equivalent circuit can be simplified as solution and faradaic resistances in series. In this situation, any slight change in the electrical potential on the surface results in the flow of electric current across the interface. Therefore such an interface is characterized as ideally non-polarizable. Although the non-polarizable interface has its own importance in areas such as reference electrodes, only the polarizable interface is a good EDLC.<sup>[1]</sup> Accordingly, the following discussion focuses on the polarizable interface and all of the interfaces investigated in the study are assumed to be ideally polarizable.

A schematic diagram of an ideally polarizable interface is shown in Fig. 2, in which the interface can be further divided by the inner Helmholtz plane (IHP) and outer Helmholtz plane (OHP). By definition, the IHP is the locus of the centers of specifically adsorbed dehydrated ions, while the OHP is the plane of closest approach of hydrated counterions.<sup>[2]</sup> The ions in the layer outside the OHP are mobile, and their distribution depends on the balance between the electrostatic interaction and the thermal diffusion; therefore, this layer is called the diffuse layer, or Gouy–Chapman layer. On the other hand, ions inside the OHP are immobilized because they are strongly bound with the charged surface (specific adsorption). The immobile ions constitute the Stern layer, or the Helmholtz layer.

**Fig. 2** Schematic model of the EDL, showing the specifically adsorbed cations and the fully hydrated anions and cations on a negatively charged surface.

The EDL behaves like an electrical capacitor. When the surface potential is increased, the surface charge density increases as well. Because the Stern layer is very different from the diffuse layer, it is better to separate the entire EDL capacitor into a series of diffuse-layer and Stern-layer capacitors. Therefore the relationship between the double-layer, Stern-layer, and diffuse-layer capacitances can be written in the form

$$\frac{1}{C_{dl}} = \frac{1}{C_s} + \frac{1}{C_d} \quad (1)$$

where  $C_s$  and  $C_d$  are the Stern-layer and diffuse-layer capacitances, respectively.

Results of the EDL experiment involving NaF on the mercury surface<sup>[28]</sup> indicate that  $C_s$  has only a minimal dependency on the surface charge density or electrolyte concentration; therefore, it is customary to assume that  $C_s$  is constant at low surface charge density and low electrolyte concentration. On the other hand,  $C_d$  shows strong dependency on the surface charge density and electrolyte concentration. This capacitance has a minimum value when the surface charge density is zero and increases exponentially with the surface charge density and electrolyte concentration. Therefore under high electrolyte

concentration, the value of  $C_d$  is much larger than that of  $C_s$ , making the Stern layer more important than the diffuse layer. Because the overall capacitance is always determined by the smaller of two capacitors in series,  $C_{dl}$  is determined solely by  $C_s$  under such conditions. On the other hand, the diffuse layer is more important than the Stern layer for low electrolyte concentration and low surface charge density, and  $C_{dl}$  is determined solely by  $C_d$  in this case. Accordingly, by measuring  $C_{dl}$  at two extreme conditions (very concentrated and very dilute solutions),  $C_s$  and  $C_d$  can be determined independently. The experimental value of  $C_d$  can be compared with the theoretical value of  $C_d$  that is determined by using the classical Gouy–Chapman theory, which is described in the following section.

### GOUY–CHAPMAN THEORY

In order to maintain the overall electroneutrality of the system, an excess of charge on the surface side of the interface must attract an equal amount of oppositely charged ions in the diffuse layer, in which the electrical potential distribution is given by the Poisson equation:

$$\nabla^2\psi = -\frac{\rho}{\varepsilon} \quad (2)$$

where  $\nabla^2$  is the Laplacian operator,  $\psi$  is the relative electrical potential between the diffuse layer and the bulk phase,  $\varepsilon$  is the dielectric constant of the medium, and  $\rho$  is the volume charge density given by

$$\rho = \sum_i N_i z_i e \quad (3)$$

In this expression,  $z_i$  is the valence of ions of type  $i$ ,  $e$  is the elementary charge, and  $N_i$  is the number of ions of type  $i$ . According to the Boltzmann distribution,  $N_i$  can be expressed as

$$N_i = N_{i0} \exp\left[-\frac{z_i e(\phi - \phi_b)}{kT}\right] \quad (4)$$

where  $k$  is the Boltzmann constant,  $T$  is the absolute temperature,  $N_{i0}$  is the bulk concentration of ions, and  $\phi$  and  $\phi_b$  are the absolute electrical potentials in the double-layer region and in the bulk phase, respectively. It is convenient to define the reference electrical potential located in the bulk phase; therefore,  $\phi_b = 0$  and  $\phi$  can be represented by  $\psi$ . When Eqs. (2), (3), and (4) are combined, the Poisson–Boltzmann equation is then obtained:

$$\nabla^2\psi = -\frac{e}{\varepsilon} \sum_i N_{i0} z_i e \exp\left(\frac{-z_i e\psi}{kT}\right) \quad (5)$$

If the solution contains only single  $z:z$ -type electrolyte, Eq. (5) can be further simplified for a one-dimensional EDL system:

$$\frac{d^2\psi}{dx^2} = \frac{2N_0 z e}{\varepsilon} \sinh\left(\frac{ze\psi}{kT}\right) \quad (6)$$

The second-order differential equation given by Eq. (6) can be integrated by multiplying both sides by  $2(d\psi/dx)$ , followed by an integration with respect to  $x$ :

$$\int \frac{d}{dx} \left(\frac{d\psi}{dx}\right)^2 dx = \int \frac{4N_0 z e}{\varepsilon} \sinh\left(\frac{ze\psi}{kT}\right) d\psi \quad (7)$$

Integrating from the bulk solution where  $\psi = 0$  and  $d\psi/dx = 0$  up to some point in the double layer yields the first-order differential equation of  $\psi$ .

$$\frac{d\psi}{dx} = \frac{-2\kappa kT}{ze} \sinh\left(\frac{ze\psi}{2kT}\right) \quad (8)$$

where  $\kappa = (2N_A I e^2 / \varepsilon kT)^{1/2}$  is the Debye–Hückel parameter for a symmetrical 1:1 electrolyte,  $I$  is the ionic strength, and  $N_A$  is Avogadro's number.

The charge density in the diffuse layer,  $\sigma_d$ , is related to the volume charge density,  $\rho$ , by

$$\sigma_d = \int_d^\infty \rho dx \quad (9)$$

From Eq. (2),  $\rho$  can also be expressed as a second-order derivative of the electrical potential for a one-dimensional system; therefore,

$$\sigma_d = \int_\infty^d \varepsilon \frac{d^2\psi}{dx^2} dx = \varepsilon \left[\frac{d\psi}{dx}\right]_\infty^d \quad (10)$$

Because  $\psi = 0$  as  $x \rightarrow \infty$ , the derivative  $(d\psi/dx)_{x \rightarrow \infty} = 0$  and  $\sigma_d = \varepsilon(d\psi/dx)_{x=d}$ . From Eq. (8), a useful relationship between  $\psi_d$  and  $\sigma_d$  can be obtained:

$$\sigma_d = \frac{-2\varepsilon\kappa kT}{ze} \sinh\left(\frac{ze\psi_d}{2kT}\right) \quad (11)$$

By definition, the differential capacitance of the diffuse double layer,  $C_d$ , can be expressed as

$$C_d = -\frac{d\sigma_d}{d\psi_d} \quad (12)$$

Taking the derivative of Eq. (11) with respect to  $\psi_d$ , the expression of  $C_d$  can therefore be obtained as

$$C_d = \varepsilon\kappa \cosh\left(\frac{ze\psi_d}{2kT}\right) \quad (13)$$

**Fig. 3** Diffuse-layer capacitance of the EDL as a function of diffuse-layer potential for several concentrations based on Eq. (13): solid line, 0.1 M; long-dashed line, 0.01 M; short-dashed line, 0.001 M; dot-dashed line, 0.0001 M.

Based on Eq. (13), Fig. 3 plots the values of  $C_d$  as a function of  $\psi_d$ . As shown in the figure,  $C_d$  is very small at very low electrolyte concentration; therefore, according to Eq. (1),  $C_{dl}$  is determined solely by  $C_d$  at low concentration. On the other hand,  $C_d$  is very large at high electrolyte concentration. In this case,  $1/C_d$  becomes insignificant and  $C_{dl}$  is solely determined by  $C_s$ .

## EDL IN NANOPORES

### Gouy–Chapman Model

In the discussion of EDL formation adjacent to a single charged surface, only one side of the interface is considered and the boundary condition,  $\psi = 0$  as  $x \rightarrow \infty$ , is always true. However, if the EDL is confined by two charged surfaces such as in a slit-type pore, this boundary condition is valid only when the separation distance between these two charged surfaces, or the diameter of the pore in case of a cylindrical pore, is large enough. When the separation distance is decreased, the EDLs of the two surfaces begin to overlap in the central region as shown in Fig. 4. In this case, Eq. (6) still applies to the system but with a new boundary condition:

$$\frac{d\psi}{dx} = 0 \text{ and } \psi = \psi_m \text{ at } x = \frac{D}{2} \quad (14)$$

where  $\psi_m$  is the electrical potential at the midplane and  $D$  is the separation distance between the two identical charged surfaces. Thus the diffuse-layer charge density can be written as

$$\sigma_d = -\sqrt{4\varepsilon RTI} \left[ \cosh\left(\frac{e\psi_0}{kT}\right) - \cosh\left(\frac{e\psi_m}{kT}\right) \right]^{1/2} \quad (15)$$

**Fig. 4** The overlap of two diffuse layers in a nanopore. The electrical potential distribution adjacent to a single double layer is represented by the dashed line; the solid line is the electrical potential distribution that results from the overlapping of two EDLs; and  $\psi_0$  and  $\psi_m$  are the surface and midplane potentials, respectively.

where  $R$  is the ideal gas constant. The second term inside the bracket is the contribution from the overlapping of EDLs. When the two charged surfaces are far away from one another,  $\psi_m$  approaches zero and the second term becomes unity. If this condition is satisfied, then Eq. (15) can be simplified to Eq. (11), and the two charged surfaces can be viewed as two independent charged surfaces. Therefore the overlapping effect becomes important as the distance between two charged interfaces decreases, as in the case for a nanopore. When the overlapping increases to the extent that make  $\psi_0 = \psi_m$ , the EDLs no longer exist in the nanopore and  $\sigma_d = 0$ . In practical applications, especially for nanoporous materials, it is doubtful that the microporosity ( $< 2$  nm) contributes to EDL capacitance, because the effect of overlapping is too strong.<sup>[29]</sup> Moreover, it is questionable whether the P–B equation and the Gouy–Chapman model are applicable at a very small length scale.

### Primitive Model and Grand Canonical Monte Carlo (GCMC) Simulations

As indicated in the ‘‘Introduction’’, a better approach to the EDL problem would be the primitive model combined with Monte Carlo simulations, especially the GCMC. The advantage of the GCMC method is that the chemical potential, rather than the total number of ions, is kept constant. This feature is very important for the EDL problem because the number of counterions increases and the number of coions decreases considerably in the EDL region. Therefore only GCMC can provide an unambiguous way to determine the total number of ions in the EDL. Generally, a GCMC step includes two types of options. The first is a move in the canonical

ensemble, in which a randomly selected ion is moved from an initial position  $r_i$  to a new position  $r_j$ , and the move is accepted with a probability of  $f_{ij}$ , which is given by

$$f_{ij} = \min\{1, Y \exp[-\beta(U_j - U_i)]\} \quad (16a)$$

where  $Y = 1$ ,  $\beta = (kT)^{-1}$ , and  $U_i$  and  $U_j$  are the configurational energies at positions  $i$  and  $j$ , respectively. The second option involves the addition or deletion of a pair of positive and negative ions (so that the electroneutrality is still maintained during the addition/deletion processes). If a pair of ions is inserted in configuration  $i$  to reach configuration  $j$ , then the number of positive ions and the number of negative ions in state  $j$  are  $N_j^+ = N_i^+ + 1$  and  $N_j^- = N_i^- + 1$ , respectively. The transition probability from configuration  $i$  to  $j$  is given by Eq. (16a), with a different value assigned to  $Y$ :

$$Y = \frac{N_+ N_-}{N_j^+ N_j^-} \gamma_{\pm}^2 \quad (16b)$$

where  $N_+$  and  $N_-$  are the original numbers of positive and negative ions in the bulk phase of the same volume, respectively, and  $\gamma_{\pm}$  is the mean ionic activity coefficient in the McMillan–Mayer system at solution concentration  $C_0$ . In the primitive model, the activity coefficient,  $\gamma_{\pm}$ , was found to be  $-0.127$  for 1.0 M electrolyte concentration.<sup>[30]</sup>

The total potential energy,  $U_T$ , of an electrolyte system is the sum of the single-ion energy  $U_1$ , and the two-ion energy,  $U_2$ :

$$U_T = U_1 + U_2 \quad (17)$$

The only single-ion energy term,  $U_1$ , is the electrostatic interaction between an ion and the two charged surfaces. Thus  $U_1$  can be expressed as<sup>[20]</sup>

$$U_1 = \infty, \quad z_1, z_2 < d/2 \quad (18a)$$

$$U_1 = \frac{1}{4\pi\epsilon_0\epsilon_r} \sum_{i=1}^N q_i [\sigma_1 u(z_1, W) + \sigma_2 u(z_2, W)], \quad z_1, z_2 \geq d/2 \quad (18b)$$

$$u(z, W) = \left\{ 4W \ln\left(\frac{0.5 + r_1}{r_2}\right) - |z| \left[ 2\pi - 4 \tan^{-1} \frac{4|z|r_1}{W} \right] \right\} \quad (18c)$$

where  $W$  is the width and height of the square charged surfaces, and  $z_1$  and  $z_2$  are the distances between an ion carrying charge  $q_i$  and the first and second charged surfaces, respectively. The charge densities of these two charged surfaces are  $\sigma_1$  and  $\sigma_2$ , respectively. The

parameters  $r_1$  and  $r_2$  are given by

$$r_1 = \sqrt{0.5 + \left(\frac{z}{W}\right)^2} \quad (18d)$$

and

$$r_2 = \sqrt{0.25 + \left(\frac{z}{W}\right)^2} \quad (18e)$$

The two-ion energy,  $U_2$ , is basically the pair interaction between two ions. However, because the long-range electrostatic interaction is extended far beyond the small simulation box, an additional term needs to be used to properly account for the long-range effect. Therefore periodic boundary conditions are imposed in the dimensions  $x$  and  $y$ , and the traditional minimum image method is used.<sup>[31]</sup> In the  $z$  dimension, the long-range interaction is handled by a modified charged-sheet (CS) method proposed by Boda and Chan,<sup>[20]</sup> in which each ion forms an infinite CS minus the central square hole occupied by the simulation box. Therefore the two-particle energy is the sum of Coulombic interaction between two ions inside the simulation box and the interaction between one ion and the CS formed by another ion. The term  $U_2$  can be expressed as

$$U_2 = \infty, \quad r_{ij} < d \quad (19a)$$

and

$$U_2 = \frac{1}{4\pi\epsilon_0\epsilon_r} \left\{ \sum_{i=1}^{N-1} \sum_{j=i+1}^N \frac{q_i q_j}{r_{ij}} + \frac{q_i q_j}{W^2} \sum_{i=1}^N \sum_{j=1}^N [u(z_{ij}, \infty) - u(z_{ij}, W)] \right\}, \quad r_{ij} \geq d \quad (19b)$$

In this expression,  $r_{ij}$  is the magnitude of the vector  $\mathbf{r}_{ij}$  between the  $i$ -th and  $j$ -th ions, and  $z_{ij}$  is the  $z$  component of  $\mathbf{r}_{ij}$ .

Without loss of generality, both surfaces were assumed to be negatively charged, and an equal amount of excessive counterions in the solution phase was used to balance the charge on the surfaces. Moreover, the water is considered as a continuum with a dielectric constant  $\epsilon_r = 78.5$ , and the ions are considered as hard spheres with diameter  $d = 4.25$  Å as in the case for other primitive models found in the literature.<sup>[30]</sup> In the GCMC simulations, an equal probability of 1/3:1/3:1/3 was used to insert, delete, or move an ion. The maximum traveling distance between  $(-\eta_{\max}, \eta_{\max})$  was adjusted every 10 passes to maintain an acceptance ratio of 0.5. More details of the GCMC

simulation procedure for electrolyte systems can be found elsewhere.<sup>[6,7]</sup>

### Nonprimitive Model and Canonical Monte Carlo (CMC) Simulations

In the non-primitive model of the EDL, the water is considered as individual molecules instead of a continuum. To better describe the properties of water, the TIP4P-FQ water model,<sup>[32–34]</sup> in which the charge on each atomic site is allowed to fluctuate in response to its surrounding environment, is employed. A single water molecule has four atomic sites: one O, two H, and one M, representing oxygen, hydrogen, and an imaginary charged site, respectively. The oxygen atomic site, O, is the only Lennard–Jones (LJ) center for the water molecule and carries no charge. The negative charge of  $-1.04 e$  is carried by the imaginary site M, which is located  $0.15 \text{ \AA}$  away from the oxygen atom, along the bisector of the angle of the H–O–H bond. Two hydrogen atomic sites carry charges of  $+0.52e$  to balance the negative charge on the M site. The angle of the H–O–H bond is  $104.52^\circ$ , and its length is  $0.9572 \text{ \AA}$ .

The interaction energy between ion and ion, and ion and water can be divided into LJ and electrostatic energy. The total LJ energy,  $U_{LJ}$ , between any two water molecules, any two ions, or between one water molecule and one ion can be expressed as

$$U_{LJ} = \sum_{i=1}^{N-1} \sum_{j=i+1}^N \left( \frac{LJA}{r_{ij}^{12}} - \frac{LJC}{r_{ij}^6} \right) \quad (20)$$

where  $N$  is the number of water molecules plus the number of ions and LJA and LJC are the LJ parameters. In the current study, sodium and chloride ions are selected as representative cations and anions, respectively. LJ parameters between the same species are found in the literature for water,<sup>[35]</sup> sodium ion, and chloride ion,<sup>[36]</sup> otherwise, they can be obtained by the Lorentz–Berthelot mixing rule. All LJ parameters used in the simulations are listed in Table 1.

The electrostatic energy includes single-atom and two-atom interaction energies. The interaction energy between charged surfaces and atoms or ions constitutes the single-atom term in the system, and its value can be calculated by using Eqs. (18a) and (18b) with the dielectric constant,  $\epsilon_r$ , as unity and  $N$  becoming the total number of charged atomic sites of water molecules and ions. Similarly,  $d$  is the equivalent hard-sphere diameter of water molecule or ions, which is assumed to be  $2.5 \text{ \AA}$  for water and  $2.0 \text{ \AA}$  for ions. The use of Eqs. (18a) and (18b) implies that the CS method is used to calculate the long-range electrostatic

**Table 1** Lennard–Jones parameters used in eq. (20) for pair interactions

Type	LJC (kcal $\text{\AA}^6/\text{mol}$ )	LJA $\times 10^{-3}$ (kcal $\text{\AA}^{12}/\text{mol}$ )
O ... O	1138.0	1131.0
Na <sup>+</sup> ... Na <sup>+</sup>	300.0	14.0
Cl <sup>-</sup> ... Cl <sup>-</sup>	3500.0	26,000.0
O ... Na <sup>+</sup>	584.3	125.8
O ... Cl <sup>-</sup>	1995.7	5422.0
Na <sup>+</sup> ... Cl <sup>-</sup>	1024.7	603.3

interaction. Traditionally, the use of Ewald sum<sup>[31]</sup> has proven to be more accurate in the non-primitive model; however, the computational cost is very high. On the other hand, although the CS technique is easy to implement and the computational cost is relatively low, it shows strong size dependency when the box size is too small<sup>[37]</sup>. In the current study, the CS method is preferred because only the EDL in a slit-type nanopore is of interest; therefore, the width of the simulation box can be chosen to be large enough ( $W = 100 \text{ \AA}$ ) to avoid the problem of size dependency. More importantly, using CS allows a simulation to be performed more effectively. Therefore a larger simulation box can be used and the artificial periodicity can be reduced.

The two-atom term includes the intermolecular (ion–ion and ion–water) and the intramolecular interaction within the same water molecule. The former can be calculated by Eq. (19b), with  $N$  becoming the total number of charged atomic sites of water and ions, and the latter,  $U_3$ , can be calculated by

$$U_3 = \sum_{i=1}^N \sum_{\alpha} \sum_{\beta} (J_{\alpha\beta} q_{i\alpha} q_{i\beta}) \quad (21)$$

where  $q_{i\alpha}$  and  $q_{i\beta}$  are the charges of atoms  $\alpha$  and  $\beta$  on the same water molecule  $i$  and  $J_{\alpha\beta}$  is a constant that is derived elsewhere.<sup>[32]</sup> In this study,  $J_{OH}$  and  $J_{HH}$  are  $286.4$  and  $203.6 \text{ kcal}/(\text{mol } e^2)$ , respectively.

Because charge fluctuation occurs among different atomic sites within a water molecule, the asymmetric distribution of partial charge at different atomic sites has to be accounted for by an additional energy term,  $U_{FQ}$ :

$$U_{FQ} = \sum_{i=1}^N \sum_{\alpha} \left( \bar{\chi}_{\alpha}^0 q_{i\alpha} + \frac{1}{2} J_{\alpha\alpha}^0 q_{i\alpha}^2 \right) \quad (22)$$

where  $\bar{\chi}_{\alpha}^0$  is the Mulliken electronegativity parameter of the isolated atom  $\alpha$  and  $J_{\alpha\alpha}^0$  is twice the hardness of the electronegativity of an atom. The parameters used in this study are  $(\bar{\chi}_{O}^0 - \bar{\chi}_{H}^0) = 68.49 \text{ kcal}/(\text{mol } e)$ ,  $J_{OO}^0 = 371.6 \text{ kcal}/(\text{mol } e^2)$ , and  $J_{HH}^0 = 353.0 \text{ kcal}/(\text{mol } e^2)$ .

More detailed discussion of the TIP4P-FQ model can be found elsewhere.<sup>[32]</sup>

The total number of ions in the simulation box is obtained from the GCMC simulations. Water molecules are then added to achieve a bulk water density of  $1.0 \text{ g/cm}^3$ . However, partial volume in the simulation is occupied by hydrated ions; therefore, the total volume available to water molecules is the volume of the simulation box minus the volume occupied by the ions in their hydrated form. The radii of hydrated sodium and chloride ions are found to be 2.3 and 3.2 Å, respectively, which correspond to an excluded volume of 51.0 and  $137.3 \text{ Å}^3$  for a single hydrated sodium and chloride ion, respectively.

Metropolis Monte Carlo simulations based on the canonical ensemble ( $N, V, T$ ), that is, CMC simulations, were then carried out for an electrolyte system including TIP4P-FQ water molecules and ions between two charged surfaces. The dimensions of the simulation box in the  $x, y, z$  directions ( $W \times W \times L$ ) were  $100 \times 100 \times 10 \text{ Å}$  (for a 10-Å nanopore) and  $100 \times 100 \times 20 \text{ Å}$  (for a 20-Å nanopore), respectively, and periodic boundary conditions similar to those employed in GCMC simulations were also used here. For each step, a water molecule or a single ion was allowed to move a random distance between  $(-\eta_{\max}, \eta_{\max})$ . Water molecules were also rotated at an angle between  $(-\phi_{\max}, \phi_{\max})$  around three randomly chosen axes and each charge was randomly fluctuated between  $(-\delta_{\max}, \delta_{\max})$ , while intramolecular electroneutrality was maintained. The maximum degree of rotation,  $\phi_{\max}$ , and the maximum amount of charge allowed to fluctuate,  $\delta_{\max}$ , were also adjusted every 10 passes in the program to reach an average acceptance ratio of 0.5.

## RESULTS AND DISCUSSION

All simulations were carried out on either an IBM SP with a total of 18 nodes and 72 CPUs or on SGI-Origin 3400 supercomputer with 16 CPUs. The original computer code was written in FORTRAN 95 and parallelized by OPEN-MP.<sup>[38]</sup> In the Monte Carlo simulations, every single simulation started from an initial configuration with randomly distributed ions and water molecules (only in the non-primitive model). Initial configurations were preequilibrated until fluctuations of the total energy were stabilized. In the GCMC simulations, 2 million passes were performed. The final 500 K passes were used to calculate the ensemble average of the total number of ions and the ion concentration profiles. For the final ion configuration, CMC simulations were performed for another 500 K (for a 10-Å pore) or 100 K passes (for a 20-Å pore). The final 20% of the passes were then used to calculate the ensemble average.

## Grand Canonical Monte Carlo (GCMC) Simulations of the Primitive Model

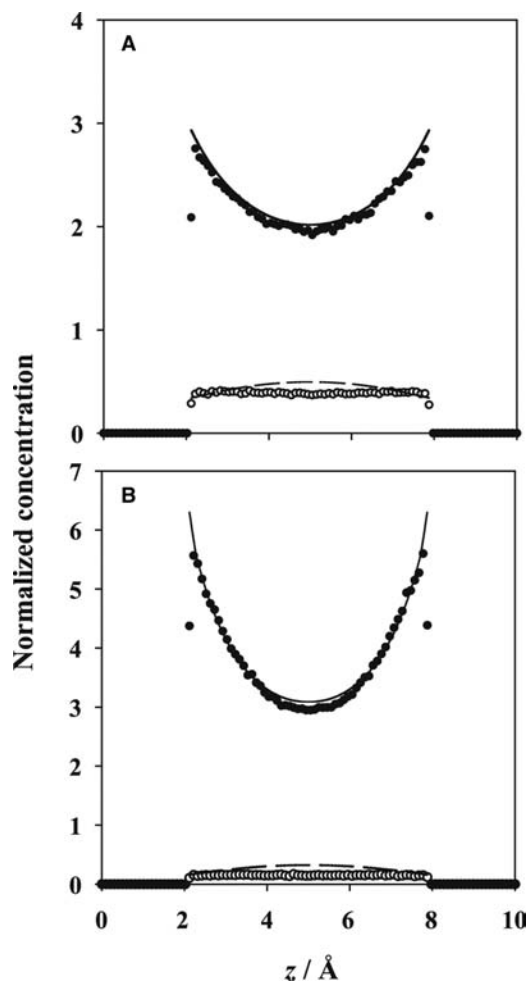

Two simulation boxes were used in the GCMC simulations. A smaller box ( $W \times W \times L = 200 \times 200 \times 10 \text{ Å}$ ) was used to simulate the EDL in a 10-Å slit-type nanopore, while a larger one ( $200 \times 200 \times 20 \text{ Å}$ ) was used to simulate a 20-Å nanopore. Four different initial conditions used in the simulations are summarized in Table 2. Comparisons of the ion concentration profiles for the Gouy–Chapman and primitive models in the nanopore at  $-0.05$  and  $-0.1 \text{ C/m}^2$  are presented in Fig. 5A and B, respectively. As shown in Fig. 5A, the maximum concentration adjacent to the charged surfaces is slightly overestimated by the Gouy–Chapman model because the steric effect is neglected. Moreover, because more counterions accumulate at the surface and a stronger shielding effect occurs as a result, the coion concentration at the central region predicted by the Gouy–Chapman model is also higher than that predicted by the primitive model. Nevertheless, the Gouy–Chapman model still gives a fairly good approximation of the ion concentration profile in the entire range. For a higher surface charge density ( $-0.1 \text{ C/cm}^2$ ), as shown in Fig. 5B, the counterion concentration is higher than that shown in Fig. 5A and the coion concentration is lower. This feature implies an ion-exclusion effect in nanopores—most coions are pushed out of the pores by strong electrostatic force and, therefore, only counterions can exist.

In the case of a larger pore, 20 Å for example, the counterion concentration is still higher than the coion concentration throughout the entire pore space, as shown in Fig. 6A and B. However, their values are closer in the central region, meaning that equal numbers of both ions exist in this region and the bulk phase can be reproduced. Again, the Gouy–Chapman model gives a very good approximation for a larger-size pore as well, and no significant difference can be observed between the primitive and the Gouy–Chapman models. Because the effect of pore size is more pronounced than that of the surface charge density,

the effect of pore size and ion species on EDL, a non-primitive model together with CMC simulations was used to study this problem for several initial conditions (Table 3). An illustration of a single CMC simulation of both electrolyte (NaCl) and water molecules in a 20-Å negatively charged nanopore (Run 3) is shown in Fig. 7. A brief look at this figure reveals that the charged surface is covered by water molecules rather than counterions, as suggested in the classical Gouy–Chapman model. This observation is further confirmed in the following discussion.

Results in Fig. 8A show the comparison of ion concentration profiles for the Gouy–Chapman and the nonprimitive models in a 10-Å pore, with a surface

**Table 3** Initial conditions used in the CMC simulations of the non-primitive model

charge density of  $-0.05$  C/m<sup>2</sup> on both surfaces (Run 1). The Gouy–Chapman model predicts that an excess number of positive ions (i.e., sodium ions) accumulate adjacent to the negatively charged surfaces and then decay exponentially toward the center. However, it is surprising to see that this is not the case predicted by the nonprimitive model. In fact, in the latter case, the maximum counterion concentration is located at the center and then decays toward the surfaces. This unique feature can be explained by a strongly adsorbed water layer at the charged surfaces. Because water molecules are polar, they tend to compete with other charged species and cause the approaching ions to remain in the diffuse layer rather than be adsorbed on the charged surfaces.<sup>[26,39]</sup> When compared with the water distribution shown in Fig. 8B, distinct water peaks are shown in the region adjacent to the charged surfaces. Thus it is sufficiently clear that water molecules are more favored at the charged surfaces than ionic species are.

A similar argument that ions accumulate at the center of a nanopore was also made by Williams et al.,<sup>[40]</sup> who conducted a neutron diffraction experiment involving vermiculite clay. Williams et al. observed that the negatively charged clay surfaces were covered by two layers of partially ordered water molecules and that the concentration of counterion ( $C_3H_7NH_3^+$ ) reached a maximum at the center of the interlayer

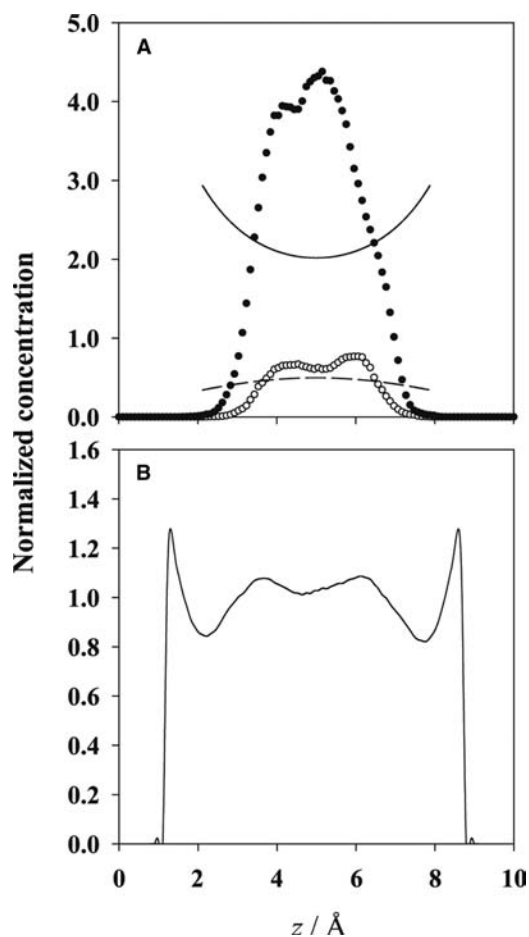

region. This observation was supported by theoretical analysis of a one-dimensional adsorption model and the competition between water and counterions.<sup>[41]</sup> The results showed that fewer than 15% of the sites are bound with counterions. This feature may have important implications for ion transport through a charged nanochannel, an issue that has relevance for many physical, chemical, and biological problems. If water molecules keep ions from being adsorbed on the charged surface of a nanochannel, the ion transport should be faster than expected because ions are not constrained by the charged surface. As a result, higher ionic mobility can be expected.

Another discrepancy between the non-primitive and Gouy–Chapman models is that the ion concentration predicted by the non-primitive model is much higher than that predicted by the Gouy–Chapman model. This discrepancy can be explained by the strongly adsorbed water layer as well. Because water molecules cover the negatively charged surfaces, the effective volume of the nanopores to accommodate ions is reduced. The initial number of ions in the nonprimitive model is estimated from the primitive model, which does not take this layer of water into account; therefore, the initial number of counterions is overestimated. This effect may not be critical in a mesopore or macropore, but is considerably larger in a 10-Å nanopore. If a water molecule is considered as a hard sphere with a 2.5-Å diameter, 50% of the pore volume is occupied by a compact layer of strongly adsorbed water molecules and the number of ions should be decreased at least 50%.

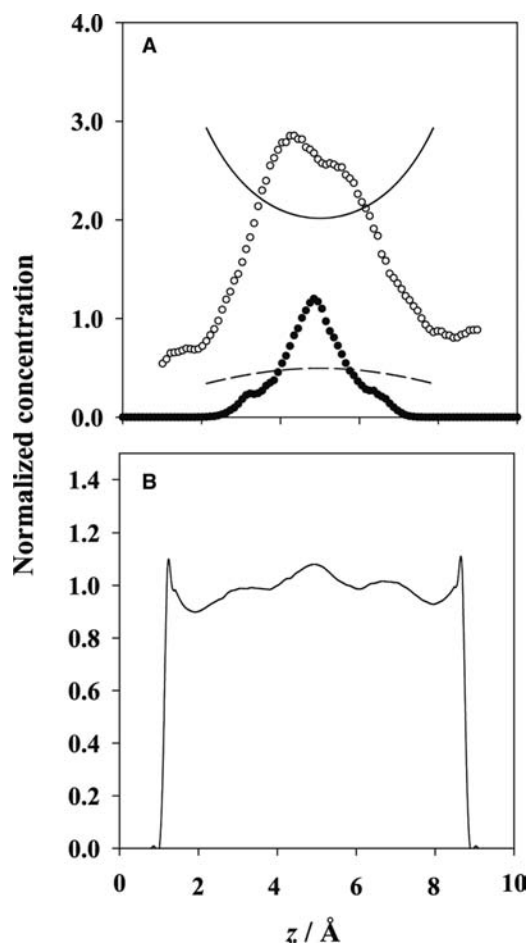

When both surfaces are switched from negatively charged to positively charged, more anions (chloride ions in this case) will be present in the solution phase (Table 3, Run 2). In the primitive or Gouy–Chapman model, cations and anions are treated as similar hard spheres, except for the fact that the charges are of opposite sign. Therefore changing the sign of the surface charge does not change the counterion

**Fig. 7** A Monte Carlo simulation of a 1.0 M NaCl electrolyte solution in a 20-Å charged nanopore. The surface charge density on each surface is  $-0.05$  C/m<sup>2</sup>, and the numbers of chloride, sodium, and water molecules are 69, 133, and 5333, respectively.

concentration profile; as a result, the solid and dashed lines in Figs. 8A and 9A are identical. However, in the non-primitive model, each species is unique. As shown in Table 1, the LJ parameters for the chloride ion differ greatly from those of the sodium ion. Consequently, the concentration profile of chloride ions in Fig. 9A is also considerably different from that of sodium ions in Fig. 8A. Because of the larger volume of the chloride ion and the lower hydration energy, a small amount of chloride ion is specifically adsorbed on the charged surfaces, which can be observed from the non-zero concentration at 2 and 8 Å in Fig. 9A. This point can be further demonstrated by observing the water density profile in Fig. 9B. In this figure, the water peaks near

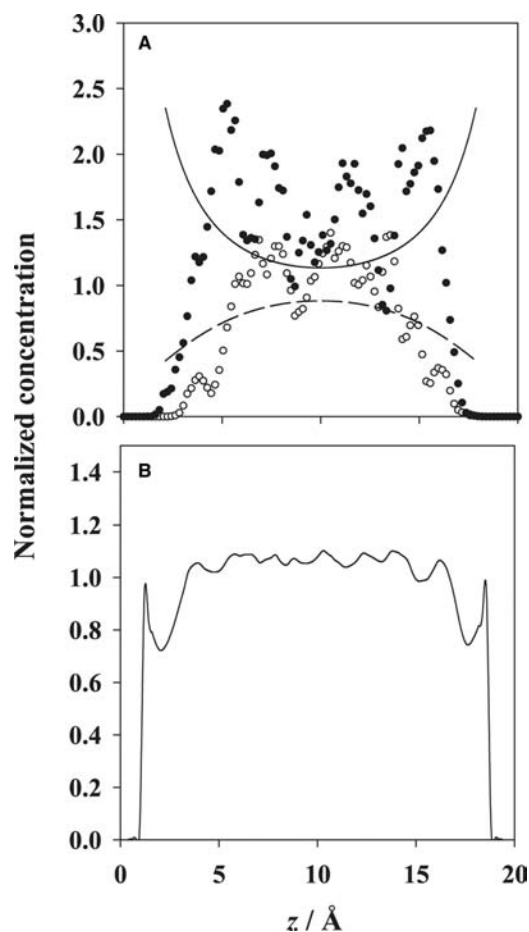

the charged surfaces are less obvious than those shown in Fig. 8B. This feature implies that the chloride ions tend to compete with water molecules for adsorption and that contact adsorption of chloride is also energetically favorable.

Different adsorption behaviors of sodium and chloride ions can be explained by their hydration radii and the pair-distribution functions with water molecules. The ion–oxygen pair-distribution function and the accumulated number of water molecules are shown in Fig. 10A and B, respectively. As shown in Fig. 10A, the sodium ions are smaller (hydrated radius: 2.3 Å) than the chloride ions (hydrated radius: 3.2 Å). Water molecules are associated with the sodium ion in a very

**Fig. 10** Comparison of the hydration radius and the hydration number of sodium and chloride ions. (A) Ion–water pair-distribution function,  $g(r)$ : the solid line represents sodium ion, and the dashed line represents chloride ion. The hydration radius for sodium ions is estimated to be 2.3 Å, while that for chloride ions is 3.2 Å. compact hydrated shell (sharp peak) when compared with the loose hydrated shell (broad peak) surrounding the chloride ion. The number of hydrated water molecules can be estimated from Fig. 10B, in which the number of hydrated water molecules around a sodium ion is approximately 6, while that of a chloride ion is about 7. Because water molecules are loosely bound with chloride ions, chloride ions are more likely than sodium ions to lose their hydration water when both approach a charged surface. This phenomenon explains the contact adsorption of chloride ions at the charged surfaces. However, the bulky hydrated chloride ions prevent other chloride ions from forming a dense layer at the charged surfaces. Thus only a small

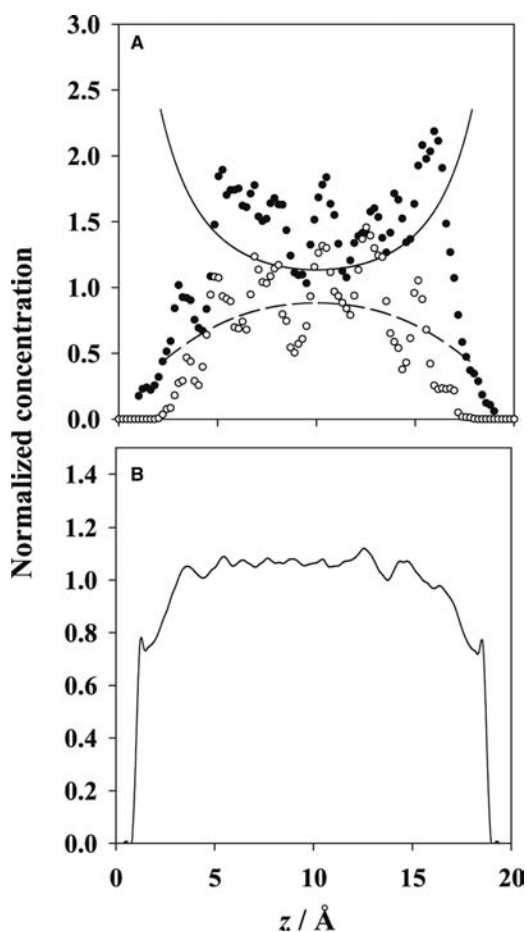

**Fig. 11** Ion and water concentration profiles in a 20-Å slit-type nanopore with a surface charge density of  $-0.05 \text{ C/m}^2$ . (A) Ion profiles: The solid and open circles are the normalized concentrations of sodium ion (counterion) and chloride ion (coion), respectively, based on the non-primitive model and CMC simulations. number of chloride ions are adsorbed on the charged surfaces, and the maximum concentration in Fig. 9A is still located in the central region.

Simulation results of the EDL formation in a 20-Å pore with a surface charge density of  $-0.05 \text{ C/m}^2$  (Run 3) are shown in Fig. 11A for the ion concentration profiles and in Fig. 11B for the water concentration profile. The concentration profiles for both counterions and coions in Fig. 11A are oscillatory. For counterions, two major peaks at 5 and 15 Å are followed by smaller peaks at 7.5 and 12.5 Å, respectively. For coions, in addition to the two major peaks at 7.5 and 12.5 Å are two smaller adsorption peaks at 4 and 16 Å. These oscillatory patterns can be attributed to the steric effect caused by water molecules, which

can be seen in Fig. 11B. A similar pattern was also observed in other non-primitive models, such as in the solvent primitive model.<sup>[23]</sup> On the other hand, such an effect cannot be observed if water is treated as a continuum, such as in the Gouy–Chapman or primitive model. In both cases, smooth concentration profiles for counterions and coions were obtained. For a positively charged 20-Å pore, the concentration profiles of ions and water are shown in Fig. 12A and B, respectively. As shown in Fig. 12A, oscillatory ion concentration profiles similar to those shown in Fig. 11A are obtained; however, the peaks of counterion concentration are less apparent in Fig. 12A. This observation can be explained by the loose hydration shell and

**Fig. 12** Ion and water concentration profiles in a 20-Å slit-type nanopore with a surface charge density of  $+0.05 \text{ C/m}^2$ . (A) Ion profiles: The solid and open circles are the normalized concentrations of chloride ion (counterion) and sodium ion (coion), respectively, based on the non-primitive model and CMC simulations. less-pronounced steric effect for chloride ions. The first water peak also becomes much smaller, as shown in Fig. 12B, as a result of the competition on the surface site between water molecules and chloride ions.

The difference between the primitive and Gouy–Chapman models generally becomes smaller in a larger pore, and the characteristic behaviors caused by different counterions also become less significant because the space occupied by adsorbed water molecules accounts for a smaller percentage in the pore. Moreover, the prediction of the ion concentration profiles by the Gouy–Chapman and the primitive models becomes more satisfactory in a larger pore, as shown in Figs. 11A and 12A. Therefore, it is believed that when the separation distance between two charged surfaces is increased, the system behaves more and more like a classical EDL system, and it becomes reasonable to treat individual ions as indifferent ions, as in the primitive and Gouy–Chapman models. In these cases, ions are always in their hydrated form and remain in the diffuse double layer. However, this is not the case when the confined effect becomes dominant in a small nanopore. Adsorption of water molecules and ions downplays the importance of the diffuse double layer, and only the non-primitive model can provide a viable way to simulate these effects.

## CONCLUSION

In this study, Monte Carlo simulations are used to compare the primitive and non-primitive EDL models with the classical Gouy–Chapman model in 10- and 20-Å slit-type nanopores. The Gouy–Chapman and primitive models generally give similar results, except that the primitive model shows some steric effects at high surface charge density. However, the non-primitive model gives a very different view of the EDL in a 10-Å nanopore. Sodium ions tend to form a very compact hydration shell with 6 water molecules, and contact adsorption with the charged surfaces is prevented. Therefore the charged surfaces are covered by a strongly adsorbed water layer instead of sodium ions, which means that the maximum sodium ion concentration occurs at the center. This interesting phenomenon cannot be seen by using the classical Gouy–Chapman model or even the primitive model. On the other hand, the chloride ions are able to form a small portion of contact adsorption layer with the charged surfaces because their hydration energy with 7 water molecules is much lower than that of sodium ions. However, the maximum chloride ion concentration is still located at the center of the pore for the simulation conditions of this work.

For a 20-Å pore, the discrepancy between the non-primitive model and the primitive and Gouy–Chapman

models decreases, except that the concentration profile obtained in the non-primitive model has an oscillatory behavior. For larger pores or in an open space (e.g., one charged surface), the classical theories are still reliable. The agreement of all these models in open space explains why classical theories are still successful and viable for resolving many EDL problems.

## INTRODUCTION

The use of nanoparticles in advanced technological applications has surged because of their unusual properties, such as enormous surface-to-volume ratio, specific interactions, and confinement effects on the nanoscale. Most of the present practical applications use the nanoparticles as suspensions, material fillers, and in coatings. As knowledge and complexity in nanoscience and nanotechnology progress, nanoparticle assemblies are expected to find use in more complex photonic and electronic devices on the microscale. In this entry, we will focus on methods for the assembly of nanoparticles suspended in liquids into electrically functional devices and will present examples of such assemblies and their potential applications. First, nanoparticle assemblies can work as simple electrical conductors, transmitting currents on chips and in liquids to make microscopic circuits. More complex functions can be realized by utilizing the non-linear properties of such nanoparticle conductors in the fabrication of sensors, photocells, light-emitting diodes, electronic elements, and quantum electronics. Electrical functionality can also be imparted by modulating the properties of the nanoparticle assemblies via electrical fields and using the response for the manipulation of currents and light in displays and for transport and mechanical actuation on the microscale.

## ELECTRICAL FIELD-INDUCED FORCES IN COLLOIDAL SUSPENSIONS

Nanoparticle self-assembly can be effected by a variety of colloidal forces, including electrostatic repulsion and van der Waals attraction, capillary forces acting on fluid surfaces, hydrodynamic liquid drag, biospecific interactions, and others. One very convenient way to realize the electrical functionality of nanoparticle suspensions is to subject them to the action of electrical fields via external electrodes. External fields can easily

manipulate the particles in suspension and can be used for rapid and controllable assembly of structures. Suspended colloidal particles can be manipulated by applying constant (d.c.) or alternating (a.c.) voltage to electrodes in contact with the liquid.<sup>[1]</sup> Three general types of forces can be distinguished (Fig. 1):

1. The electrophoretic (EP) force,  $F_{EP}$ , operating on a particle in a d.c. electric field,  $E$ , is proportional to its charge  $q$

$$\vec{F}_{EP} = q\vec{E} \quad (1)$$

The particles move toward the electrode of opposite sign. A common problem in using d.c. fields in ionic media (such as water) is the electrophoretic mobility of the liquid adjacent to the walls. The moving liquid can drag the particles in arbitrary direction or distort the assembled structures. The assembly process can also be disrupted by electrolysis.

2. The dielectrophoretic (DEP) force is driven by the application of an a.c. field across the suspension. As the sign of the electrode polarization changes constantly, the particles are not attracted by direct charge-electrode electrostatic interactions (apart from oscillations at low frequencies on the order of tens of hertz). Instead, the DEP force arises via interaction of the induced dipoles with the gradient of the field. Its sign and magnitude are dependent on the effective polarizability of the particle, which is given by the real part of the Clausius-Mossotti function,  $K$

$$Re|K| = \frac{\epsilon_2 - \epsilon_1}{\epsilon_2 + 2\epsilon_1} + \frac{3(\epsilon_1\sigma_2 - \epsilon_2\sigma_1)}{\tau_{MW}(\sigma_2 + 2\sigma_1)^2(1 + w^2\tau_{MW}^2)} \quad (2)$$

**Fig. 1** Electrical forces exerted on a charged dielectric particle by a.c. or d.c. fields applied to two coplanar electrodes. The electrophoretic force,  $F_{EP}$ , in d.c. fields attracts the particle toward the electrode of opposite charge in the direction of the field  $E$ . The dielectrophoretic force,  $F_{DEP}$ , in a.c. fields moves the particle along the field gradient,  $\nabla E$ . In this configuration, the DEP and EP forces act in perpendicular directions. The chaining force,  $F_{chain}$ , brings the particles together along the field lines.

where  $\varepsilon_1$  and  $\sigma_1$  are the dielectric permittivity and conductivity of the media and  $\varepsilon_2$  and  $\sigma_2$  are the dielectric permittivity and conductivity of the particles, respectively. Metallic particles are always attracted to the regions of high-field gradient. For dielectric particles, this function changes sign (that is, the force changes from attractive to repulsive) at a crossover frequency of  $\omega_C = (\tau_{MW})^{-1}$ , where  $\tau_{MW}$  is the Maxwell-Wagner charge relaxation time.

$$\tau_{MW} = \frac{\varepsilon_2 + \varepsilon_1}{\sigma_2 + 2\sigma_1}$$

Such a frequency-dependent change of sign of the interactions is commonly observed with polymer microspheres in water<sup>[2-4]</sup> and allows a high degree of control.

The resultant force,  $F_{DEP}$ , is dependent on the gradient,  $\nabla E$ , caused by inhomogeneities in the field and the radius of the particle,  $r$ .<sup>[2-6]</sup>

$$\vec{F}_{DEP} = 2\pi\varepsilon_1 R e[\underline{K}(w)] |r^3 \nabla E_{rms}^2 \quad (3)$$

The use of alternating voltage allows manipulation of virtually any type of particle in any type of media and has the advantage of permitting high-field strengths without water electrolysis and electro-osmotic currents.

- The “chaining” force,  $F_{chain}$ , originates between the particles in the suspension when the dipoles induced in them by either a.c. or d.c. fields interact with each other. This force is dependent on the field strength,  $E$ . A generalized expression for the force between adjacent particles is

$$F_{chain} = -C\pi\varepsilon r^2 K^2 E^2 \quad (4)$$

where the coefficient  $C$  ranges from 3 to  $>10^3$  depending on the distance between the particles

and the length of the particle chain. This force can provide directional orientation during the colloidal assembly as the particle chains are always aligned along the field lines.

## FABRICATION OF ELECTRICAL CIRCUITS VIA COLLOIDAL ASSEMBLY

The mature electronics industry possesses a very well developed set of tools for fabrication of electrical circuits at almost any length scale, from wiring and soldering on millimeter scale to micropatterning and microfabrication of integrated circuits with features smaller than 100 nm. Yet the current lithographic techniques work poorly for applications where electrical circuits have to be fabricated in complex 3-D configurations. Another domain that is not accessible for conventional lithographic patterning and soldering is the fabrication of electrical circuits in liquids and specifically in water. In this section, we will first discuss how capillary forces can be used to assemble 3-D circuits and how electrical connections in liquid can be made via directed electrochemical deposition of metals. The main focus will then be placed on electrical-field-driven assembly of nanoparticles into microwires and their use in making in situ electrical connections in liquids.

### Assembly of Electrical Circuits by Capillary Forces

One of the major requirements for self-assembly of electrical circuits from prefabricated components is the use of forces that could bring together the elements of the circuit in predefined, directional patterns. Most of the colloidal forces, such as the electrostatic and van der Waals, do not provide directionality and may be too weak to align electronic components. However, the “capillary forces” generated by the action of interfacial tension on bodies wetted by liquid can provide the long-range attraction and alignment required to assemble objects of up to a millimeter scale.<sup>[7-11]</sup> This technique has been pioneered by the group of Bowden et al.<sup>[12]</sup> originally for the self-assembly of topologically complex, millimeter-sized objects. When these objects are suspended on a water-oil interface, they assemble into designed close-packed, or loose, ordered structures. Structures fabricated by this method include arrays and gratings with different symmetry, “host-guest” templated structures, or even analogs of bio-recognition and DNA doublets.<sup>[12-17]</sup>

This technique has enabled the fabrication of 3-D electrical circuits from self-assembling blocks in density-matched liquids.<sup>[18-25]</sup> The assembly blocks

in this method are prefabricated octagons or prisms of millimeter size. Some of the facets of these blocks are fabricated with a pattern of solder patches that match the pattern on the opposing units only in certain orientation(s). The assembly is carried out by capillary attraction of liquefied low-melting point solder wetting the connector patches. The process is carried out by tumbling the elements in heated liquid whose density matches the one of the blocks. Only configurations of complementary match of the patterns are held strongly enough by the capillary forces of the molten solder to stay together during the tumbling, and thus the elements self-assemble into the designed circuit rejecting wrong orientations during the process. The capillary assembly method has been used to fabricate arrays of small light-emitting diodes (LEDs) on the surfaces of cylindrical substrates with rows of addressable electrodes.<sup>[26]</sup> The complex cylindrical displays obtained in this way illustrate the potential of self-assembly in fabrication of 3-D circuits.

### Formation of Electrical Circuits by Chemical and Electrochemical Deposition

The engineering of self-assembled electrical circuits often requires particles with specific shape and electrical properties. A simple and elegant method for synthesis of rod-like metallic and semiconductor particles has been reported by Martin<sup>[27]</sup> and Alkawlawi, Liu, and Moskovits.<sup>[28]</sup> It is based on electrochemical reduction inside uniform cylindrical micropores of alumina membranes. The process begins by vapor deposition of a metal layer on the branched side of the membrane, which closes the pore openings on that side and serves as a substrate electrode for electrodeposition inside the pores. The diameters of the metallic rods formed are equal to the diameter of the membrane micropores and typically are in the range of 200–300 nm. The rods are released into suspension by dissolving the templating alumina membrane in basic aqueous solution. A variety of precisely structured rods from different metals, semiconductors, and polymers have been fabricated.<sup>[29–35]</sup>

These suspensions of complex microscopic rods can be assembled in specific patterns and interfaced with electrical circuits. Chemical functionalization of the tips of the microrods during the process can be used to bind them to surfaces or to each other. The molecular layer can be attached by using agents with a terminal cyanide group (binding to Au and Pt) or thiol group (very strong binding to Au);<sup>[29,32]</sup> either the whole surface or only the tips of the rods can be functionalized.<sup>[34]</sup> The attachment of DNA and biomolecules is of specific importance,<sup>[34]</sup> as it allows the assembly of rod-particle structures or the application of the barcode

rods in highly selective bioassays.<sup>[30]</sup> The rods can be oriented and manipulated by external electric and magnetic fields to interface electrodes on surfaces.<sup>[35,36]</sup> Once the rods are positioned onto the electrode pads, they can be electrically connected to the probe by metal evaporation on top, allowing precise measurement of their current–voltage characteristics.<sup>[35]</sup>

Direct metal reduction and deposition, either by chemical or electrochemical reduction, is one of the simplest techniques for making electrical connections in liquids and can be used in template-directed growth of electrically conductive wires. Direct electrical connections between electrodes have been created via electrodeposition<sup>[37]</sup> and electropolymerization.<sup>[38,39]</sup> Electrochemical reduction of metal has been utilized for the fabrication of direct electrical connections between metallic beads in electrolyte solutions.<sup>[40]</sup> Such controllably deposited wires can be used to make connections on circuit boards and electrical circuits.<sup>[41–43]</sup> The bipolar electrochemistry method, however, is relatively slow and has limitations in terms of the voltages and distances between the connected particles.

Another electrodeposition method used for electrochemical fabrication of metallic nanowires is the selective reduction of molybdenum and palladium upon natural 2-D templates provided by the step edges of materials such as graphite.<sup>[44,45]</sup> The Mo wires are created by a two-step chemical process. At first, molybdenum oxides ( $\text{MoO}_x$ ) are electrodeposited on the step edges of cleaved molecularly smooth graphite. In the second step, the oxides are reduced to metal by hydrogen reduction at 500°C. The Pd mesowires are directly reduced on the graphite steps from a solution containing  $\text{Pd}^{2+}$  ions. The thickness of these hemicylindrical metallic nanowires and mesowires ranges from tens to hundreds of nanometers; their length can be larger than hundreds of micrometers. These metallic structures can be embedded in polymers such as polystyrene and cyanoacrylate, lifted off the graphite substrate, and their resistance and electrical response can be measured after metallic electrodes are deposited on the two sides of the plastic substrate spanned by the wires (Fig. 2). The conductivity and mechanical resiliency of the Mo wires are similar to those of bulk molybdenum. The Pd nanoparticle wires can be used as sensors and will be discussed in the corresponding section below. The simple fabrication principle may be extended to other metals and devices. The major disadvantage is the inability to create the structures directly in the desired conformations in electrical circuits.

The complementarity of DNA pairing has been one of the most efficient tools for the designed assembly of nanoparticles into microstructures and prototype nanomechanical devices.<sup>[46–51]</sup> Designed DNA strands have also been used as templates for metal deposition

**Fig. 2** Scanning electron micrographs (SEMs) of Pd mesowires prepared by electrodeposition (A) from aqueous 2.0 mM PdCl<sub>2</sub> and 0.1 M HCl and (B) from aqueous 2.0 mM Pd(NO<sub>3</sub>)<sub>2</sub> and 0.1 M HClO<sub>4</sub>.<sup>[45]</sup> Note that the wires are composed of multiple metallic grains. Such mesowires can act as sensitive hydrogen sensors and switches. *Source:* From Ref.<sup>[45]</sup>. © American Association for the Advancement of Science, 2001.

and creation of microscopic electrical connectors.<sup>[52]</sup> The connection is achieved by chemical reduction of silver nanocrystals on top of the DNA chain. In the first step, a DNA bridge is assembled in the 12–16 μm gap between two gold electrodes from three complementary strands. The two terminal oligonucleotides are attached to the gold surface by thiol chemistry. The third DNA segment has “sticky” ends that are complementary to the two immobilized segments and attaches to them to complete the bridge. The metallic silver is deposited on the DNA surface via electroless reduction of a silver salt. The Ag<sup>+</sup> ions attracted to the surface of the DNA molecule nucleate the metallic nanocrystals, so the polynucleotide bridge becomes encrusted into a dense shell of 30–50 nm large nanoparticles. The electrical current through the nanoparticle shell is originally a nonlinear function of the voltage, but the structure can be “annealed” by

applying a higher voltage, resulting in wires of ohmic properties and of resistance in the megaohm region. The technique has been used for making DNA-guided metallic microwires from palladium<sup>[53]</sup> and platinum,<sup>[54]</sup> and the properties of these structures have been characterized in detail.<sup>[55–57]</sup> It is expected that DNA pairing could be used in the creation of more complex electrically functional nanodevices.

### Assembly of Electrical Circuits from Nanoparticles

Fabrication of electrical wires by metal ion reduction in solution can be problematic because of the chemical reactivity of the reagents or the relatively slow speed of deposition. An alternative technique for making such connectors is to assemble the wires from metallic particles. The directional chaining of particles in an external electric field [Eq. (4)], similar to that found in electrorheological fluids, can be used to make simple electrical connections. When the particles in such fluids are conductive, the chain will form a kind of conductive wire between the electrodes. Dueweke, Dierker, and Hubler<sup>[58]</sup> have studied the assembly of millimeter-sized steel spheres in castor oil under the action of d.c. voltages on the order of 20 kV. The spheres organize into a chain in a few tens of seconds, bridging the gap between the electrodes submerged in the oil. Average growth times are proportional to the distance between the electrodes. The authors also noted that these connections are self-repairing with new spheres assembling at the ends of open chains and have discussed the “Hebbian learning” in such systems, i.e., the easier restoration of previously built chains because of the presence of agglomerated particles in the gaps.<sup>[59]</sup>

Chaining and column formation of conductive particles has also been studied experimentally by Wen, Lu, and Zheng<sup>[60,61]</sup> for system of 65-μm copper particles suspended in silicone oil. The chains are grown between planar and coaxial electrodes and between vertical plates. The particles form fractal agglomerates of dimension between 1.2 and 2, increasing with the volume fraction of the Cu particles. In analogy to the diffusion-limited aggregation (DLA), responsible for the formation of fractal aggregates in colloidal suspensions, the concept of electric-field-induced diffusion-limited aggregation (EDLA) has been extended. This concept, however, has been indirectly questioned by a theoretical study by Kun and Pál,<sup>[62]</sup> who have performed lattice simulations of the growth of aggregates under similar conditions and have found out that the Brownian diffusion of the particles does not play a crucial role in structure formation. This work confirms the power law dependence of the fractal dimensions on the sphere concentration and points out the importance

of particle–particle interactions for structure growth. The assembly of electrical circuits is not specifically discussed, but the potential to use the structures as electrically conductive wires is obvious. One major disadvantage of these structures is the disassembly of the chains when the electric field is removed, which limits their potential to be used in microscopic circuits or as permanent connectors inside liquid environments.

To overcome the above restrictions, a truly versatile technique for direct wire assembly should be based on dispersion of conductive nanoparticles in water. We have recently described a new class of electrically functional microwires assembled by dielectrophoresis from suspensions of metallic nanoparticles in water.<sup>[63]</sup> Microwires are assembled from a suspension of 15–30 nm gold nanoparticles enclosed within a thin chamber above planar metallic electrodes on a glass surface. An alternating voltage of 50–250 V and frequency of 50–200 Hz is applied to the planar electrodes (resulting in a field intensity of ca. 250 V/cm), causing thin metallic fibers to grow on the electrode edge facing the gap (Fig. 3A). The wires are of diameter on the order of a micrometer and can grow longer than a centimeter with a speed that is typically  $\approx 50 \mu\text{m}/\text{sec}$ , but, in some cases, can be up to an order of magnitude

**Fig. 3** (A) Optical micrograph of a DEP assembly process of a microwire from suspension of metallic nanoparticles. The wire is growing from the edge of a planar electrode. Note the high concentration of particles at the tip of the wire and the depleted region behind. higher. When the wire is completely assembled, the electrodes become effectively short-circuited (Fig. 3B).

The finding that dielectrophoretic forces can readily assemble nanometer-sized metallic particles from aqueous suspensions into long, electrically conductive microwires is not directly predicted by theory. The dipole–dipole interaction energy between 15 and 30 nm particles separated by a gap of a few nanometers is smaller than  $10^{-2}kT$  ( $kT$  being the thermal energy) and therefore insignificant. Instead of direct chaining, the assembly is driven by the DEP force arising from the interaction of the particle dipoles with the non-uniform a.c. field. The tip of a growing microwire creates local fields of high intensity and gradient, attracting and concentrating the particles at the end. Purple coronas of highly concentrated areas in front of the tips of the growing wire and depletion zones behind them are clearly observed at low nanoparticle concentrations (Fig. 3A). The concentrated particles aggregate at the tip of the fibers, sustaining the growth toward the opposite electrode. Thus the microwire formation is a collective effect whereby the nanoparticles are highly concentrated at the tip and subsequently aggregate to extend the wire in the direction of the field gradient.

The microwire growth direction can be steered via inhomogeneities in the electric field by introducing objects of high dielectric permittivity in the gap between the electrodes. For example, when small islands of (conductive) carbon paint are deposited in the gap, the wires grow in their direction and spontaneously connect these islands to both electrodes (Fig. 3B and C). More complex structures involving multiple connections between multiple conductive pads can be formed. The field strength and particle concentration are also key variables, as they must exceed a threshold value in order for the wire to start growing. This threshold behavior emphasizes the collective nature of the assembly, as it shows that aggregation occurs only at sufficiently high concentration of particles accumulated near the end of the wire.

The porous nature of the wires was confirmed by scanning electron microscopy (SEM). When the field is removed, the wires remain intact, which enables SEM analysis of the dried structures. Fig. 4A shows a wire formed from 25-nm diameter gold particles in low electrolyte solution ( $5 \times 10^{-4} \text{ M NaCl}$ ). The wire has a high surface area and an even growth pattern under these conditions. In higher electrolyte concentration ( $1 \times 10^{-3} \text{ M NaCl}$ , Fig. 4B), the wire structure is more uneven consisting of large particle aggregates that form because of the suppressed electrostatic interactions between the particles in the bulk liquid.

The resistivity of the microwires was measured by adding a second pair of electrodes to the cell, which allows for compensation of the electrolyte conductance

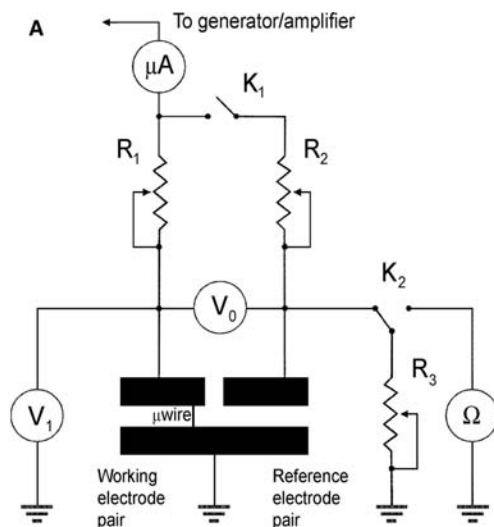

**Fig. 4** (A) Scanning electron micrograph of the tip of a wire grown in low electrolyte solution ( $5 \times 10^{-4}$  M NaCl) that highlights the uniform growth and high surface area of the structure. (B) Scanning electron micrograph of a wire grown in high electrolyte solution ( $1 \times 10^{-3}$  M NaCl) containing large particle aggregates that form because of the suppressed electrostatic interactions. *Source:* © American Association for the Advancement of Science, 2001.

in the surrounding medium (Fig. 5A). The wires have linear (ohmic) current-to-voltage response for both a.c. and d.c. voltages, with specific resistances that depend on the conditions of assembly and ranges from  $3 \times 10^{-6}$  to  $20 \times 10^{-6} \Omega\text{m}$  (Fig. 5B). This resistivity is 2 to 3 orders of magnitude higher than that of bulk solid gold because of the porosity and small interparticle contact areas in the microwires, yet it is comparable to that of good electrical conductors. Wires formed under identical conditions have highly reproducible resistivities, and despite being highly porous, they also possess good mechanical stability.

The self-assembling conductive wires can quickly and simply connect electrical circuits in water. In Fig. 6A, a light-emitting diode is attached to one of the planar electrodes and the aqueous gold suspension is placed in the gap between them. When voltage is applied, a single wire grows and energizes the LED (Fig. 6B). As mentioned previously for the large particle chains, these self-assembling electrical connections are also self-repairing. When the current applied to the single microwire is increased, the structure will

**Fig. 5** (A) Schematic of the bridge mode circuit that enables accurate measurement of the wire resistivity in situ by compensating for the conductivity of the surrounding medium. (B) Plot of the current ( $I$ ) to voltage ( $V$ ) response of a selection of microwires assembled under various experimental conditions. eventually break and snap open. It is immediately restored, however, by the build up of particles from the surrounding medium in the region of high-field intensity between the broken wire ends. This often results in the assembly of a second wire, which allows more current to flow through the circuit so that the LED shines with brighter intensity (Fig. 6C).

A further example of how the wires can form, break, and re-form electrical connections on chips is shown in Fig. 7. Wires are grown in the 18- $\mu\text{m}$  gaps between three pairs of electrodes in Fig. 7A. These connectors are burned open in Fig. 7B by substituting the gold

**Fig. 6** Example of assembling rudimentary electrical circuits in liquid. (A) Before the voltage is applied, the colloidal gold suspension is placed in the gap between a planar electrode and one of the electrodes of a commercial LED. (B) After the a.c. field is applied, a single wire connects between the electrodes and the LED starts to glow. suspension with pure water and applying a high voltage. Four pairs of wires are then reassembled in Fig. 7C by applying a voltage across a fresh gold suspension. Such wiring and rewiring could, in principle, be used to store bits of information on a chip and post-production reconfiguring of electrical microcircuits.

Dielectrophoresis is also capable of assembling more complex core-shell metallo-dielectric microwires from mixtures of metallic particles and submicrometer polystyrene latex spheres (Fig. 8). In this case, both types of particles are attracted to the tip of the growing wire resulting in a core of metallic particles that are surrounded by a shell of polymer spheres. The resistivity of this structure is comparable to a metallic wire grown under identical conditions in the absence of the

**Fig. 7** Example of using microwires as reconfigurable on-chip connections and memory storage. Wires grown in an 18- $\mu\text{m}$  gap between electrodes deposited on a microchip (A) are burnt open at high voltage (B) and reassembled in a different configuration (C). *Source:* © American Association for the Advancement of Science, 2001.

polymer beads. A variety of similar structures can potentially be assembled by this method, possibly enlarging the scope of applications for this technology. An illustration of the use of the microwires in chemical sensors is presented in the next section.

## ELECTRICALLY FUNCTIONAL MICROSTRUCTURES FROM COLLOIDAL PARTICLES

In this section, we will present a few examples that demonstrate the potential of the nanoparticle assemblies as microscopic electrically functional devices modulating electrical currents. The most obvious and important application of nanoparticle structures interfacing liquid flows and electrical circuits is as chemical and biological sensors.

### Chemical Sensors

One of the characteristic properties of nanoparticles and nanowires is their enormous surface area. This

**Fig. 8** (A) Optical micrograph of a composite wire consisting of a fractal gold structure surrounded by a half-shell of micron-sized latex particles. (B) Scanning electron micrograph of the latex-coated wire; the gold core in the middle is resolved by its higher intensity. *Source:* © American Association for the Advancement of Science, 2001.

property makes the nanowires very sensitive to changes in the environment that might affect their surface composition and properties. Any modification would be easily detected by a shift in the electrical characteristics of the wire. Similar “chemiresistance” effects can be observed in both gaseous and liquid media. The phenomenon has been extensively studied theoretically and experimentally for the cases of ultrathin metallic films and wires.<sup>[64–68]</sup> For example, the conductance of nanoscopic gold films and wire junctions has been shown to be sensitive to adsorbates ranging from  $N_2$  to ethanol, to pyridine, mercaptans, and thiols.<sup>[64,65]</sup> Chemiresistance substrates for sensors can also be made from metallic nanoparticles.<sup>[69–71]</sup> The particles are capped with a thiolated ligand and are deposited by drying or spraying of suspension on top of interdigitated electrodes. The resistance of such nanoparticle films changes two times or more in the presence of vapors of organic compound such as aliphatic and aromatic hydrocarbons, alcohols, and even water. The response of this type of sensor to organic

vapors is roughly proportional to the partial vapor pressure and depends on the core size of the nanoparticles and the chemical nature of the linking molecules in the shells. The response is fast (less than a second), reversible, and selective to vapor molecules that have strong interaction and sorption on the nanoparticle film. Detection limits below 1 ppmv have been reported.<sup>[71]</sup>

Electrically conductive nanowires and microwires can also serve as active elements in chemical sensors. The method of Zach, Ng, and Penner<sup>[44]</sup> and Favier et al.<sup>[45]</sup> for electrochemical reduction of palladium mesowires on graphite step edges has allowed the formation of a novel type of hydrogen sensor. The Pd wires consist of polycrystalline metallic grains of sizes from 10 to 300 nm (Fig. 2). Arrays of these mesowires have shown remarkable sensitivity to gaseous  $H_2$ , acting as switches that short-circuit the gap in the presence of hydrogen and disconnect the current in its absence. The hydrogen-sensing effect is based on the swelling and shrinking of the grains making or breaking the electrical contacts between them. Hydrogen sensors with characteristics comparable, or superior, to the ones based on alternative principles have been made.<sup>[45]</sup>

The technique for DEP microwire assembly described above<sup>[63]</sup> also presents a simple and efficient way to make electrically interfaced nanoparticle sensors. The properties of microwires formed between planar electrodes in a 170- $\mu$ l flow cell have been measured in bridge mode (Fig. 4A) as a function of organic solutes added to the liquid. The ionic conductivity of all samples of the analytes has been adjusted constantly. An easily resolvable and concentration-dependent increase of the resistivity of the microwires has been observed after exposure to analytes that adsorb and modify the gold surface such as 2-(dimethylamino)ethanethiol hydrochloride and sodium cyanide (Table 1). The percentage shift of the response in the table denotes the difference between the initial voltage and the voltage measured after 10 min of flushing with the sample. The residual response is the compensated resistance of the wire, measured after the bridge has been balanced. The resistivity is shown to increase by  $\approx 2$ –12% after treatment with thiol solutions at increasing concentrations and  $\approx 5\%$  after treatment with NaCN at pH 11.<sup>[63]</sup> This signal possibly results from a decrease in the surface conductivity of the gold nanoparticles in the wire structure as they become covered by an organic layer. No signal was measured from solutions containing the protein lysozyme, which adsorbs on the gold surface without significantly affecting its surface conductivity. This demonstrates that the signal is specific to analytes that intimately modify the counterionic layer around the gold nanoparticles. In comparison to conventional gold nanoparticle assemblies on surfaces, the microwires can

**Table 1** Example of the response of the nanoparticle microwires as chemiresistance sensors

Analyte	Concentration	Response (% shift)	Residual response after refluxing (%)
Dimethylamino ethanethiol	$0.5 \times 10^{-4}$ M	+1.6	+1.6
	$2.5 \times 10^{-4}$ M	+9.0	+8.4
	$6.25 \times 10^{-4}$ M	+12.1	+11.3
Cyanide at pH 11	500 ppb	+4.7	+4.7
Protein lysozyme	1 mg/ml	0	0

The changes in resistance result in voltage drop changes on the order of a few volts, and thus the response is easily and reliably detectable. For additional details, see the supplementary material to Ref.<sup>[63]</sup>.

provide a quick response by virtue of their very high surface-to-volume ratio and easy analyte adsorption from the bulk of the surrounding solution. These sensors can potentially be tailored to specific analytes by surface functionalization with self-assembled monolayers (SAMs), which may specifically bind ions and small molecules. The conductivity response of the wires is sensitive to the presence and state of adsorption monolayers, so it is likely that it will also be sensitive to the presence of small charged molecules that specifically bind to the surface of such monolayers.

## Biological Sensors

Biosensors and bioarrays with direct electrical interfacing between electronic chips and particle assemblies have a number of potential advantages compared with the present technologies based on optical detection. The particle assemblies are the essential element that interfaces the wet 3-D biological environment with the dry 2-D electronic circuits. A pioneering example of how microscopic electrically readable sensors can be assembled by DEP in situ from microparticles and nanoparticles has been presented by Velev and Kaler.<sup>[72]</sup> The method is schematically shown in Fig. 9. The sensors are assembled on glass substrates with four pairs of photolithographically fabricated gold electrodes separated by gaps of  $30 \times 12 \mu\text{m}$ . Micron-sized latex particles, of the type used in agglutination assays, are assembled between the electrodes by positive dielectrophoresis at relatively low frequencies (1–5 kHz). The latexes are stabilized by electrostatic or steric interactions, so they immediately disassemble when the field is removed. A particle immobilization step is therefore necessary to decrease the repulsive interactions. Addition of an oppositely charged surfactant causes the charged particles to coagulate by neutralizing the charge on their surface. Particles stabilized by non-ionic surfactant are easily bound together by washing away the adsorbed steric protective layer. The assembly procedure can be repeated many times by exchanging the particle suspension and addressing

different gaps so that different microscopic sensors can be assembled on the same “chip.”

The model target molecule for these sensors has been human immunoglobulin (IgG). Immunoglobulin binds specifically to the protein A on the latex and is detected by tagging the molecules with colloidal gold conjugated to a secondary antibody, antihuman IgG. To ensure that the binding of IgG is specific, the immobilized latex particles are washed with a saline solution containing serum protein and a nonionic surfactant, which restore the steric coating to the particles. The gold particles in the shells are enlarged and fused together by a silver layer deposited from a metastable solution of silver salts (Fig. 9). This short-circuits the electrodes (Fig. 10), and the electronic readout is obtained by simply measuring the resistance. The size of these sensors has been a state of the art in miniaturization, and the experimentally estimated lower limit of detection (LOD) is on the order of the better IgG agglutination assays and immunosensors available. Further miniaturization of the sensor would increase the sensitivity of the active elements, possibly as low as a few tens of hundreds of molecules. This method could potentially be optimized by using easily assembled latexes with customized interactions, increasing the speed and sensitivity by generating an electro-osmotic flux over the sensor area, and by micromachining a microscopic sample chamber.

The electrical detection method utilizing nanoparticle short-circuiting of electrodes has recently been extended to miniaturized DNA assays by Möller et al.<sup>[73]</sup> and Park, Taton, and Mirkin.<sup>[74]</sup> In both of these studies, oligonucleotide strands are chemically immobilized on the surface between the electrodes. Gold nanoparticles become bound only if a complementary match between the DNA fragments is found; the complementary strands were either bound to the gold particles<sup>[73]</sup> or bridge the strands on the surface and the ones on the gold particles.<sup>[74]</sup> Some degree of quantification of the DNA concentration in the sample has been made possible by measuring the time required to short-circuit the electrodes after the enhancer is introduced. The ability to fabricate parallel microscopic

**Fig. 9** Schematics of formation of microscopic biosensor patches via DEP assembly of latex particles and direct electric readout of the results via gold tagging and silver enhancement.<sup>[72]</sup> The procedure is illustrated on the basis of IgG detection. *Source:* © American Chemical Society, 1999.

arrays of detectors for specific genetic markers is promising for the biotechnology and medical diagnostics industries.

### Quantum Electronics Nanoparticle Devices

Very interesting effects are observed when the nanoparticles assembled on chips are less than a few nanometers in diameter and insulated from the electrodes (and each other) by a layer of surfactant. The tunneling current increases in discrete steps as a function of the number of electrons injected inside the nanoparticle.<sup>[75–81]</sup> The incremental electron tunneling manifests itself in the so-called “coulomb staircase” current–voltage dependence. These quantum-based effects can, in principle, be used to store bits of information within a single nanoparticle and to make miniature lasers.<sup>[79–83]</sup> The assembly of such quantum dots in larger-scale structures is likely to produce devices

bridging the domains of molecular electronics and semiconductor technologies. This very promising area occupies a large research domain of its own, so we will not go into detailed overview and discussion here.

### ELECTRICAL FUNCTIONALITY VIA FIELD-DRIVEN ASSEMBLY OF PHOTONIC AND OPTICALLY ACTIVE STRUCTURES

The electrical functionality of nanoparticle and micro-particle assemblies can also be realized in areas beyond conducting and modulating electrical currents. Very active research is focused on the formation of colloidal crystals via the use of electric fields. As long as the products of the assembly process, 2-D and 3-D periodic structures, can act as photonic crystals, the process itself is an example of electrically imparted functionality in nanoparticle structures. The reversible assembly

**Fig. 10** Scanning electron micrograph of a 10- $\mu\text{m}$  patch from functionalized latex spheres in the miniature immunosensors with direct electronic readout.<sup>[72]</sup> (A) Functionalized latexes heavily coated by deposited metal that short-circuits the electrodes. (B) The nonfunctionalized particles in the negative control patches are only marginally tagged by deposited metal. *Source:* © American Chemical Society, 1999.

can eventually be used in switchable electro-optical devices. Another broadly similar application of enormous practical importance is the use of nanoparticle structures in displays and “electronic paper.” Nanoparticles can also find application in active elements of light-emitting diodes. A brief overview of these research areas will be given in this section (Fig. 11).

### Assembly of Colloidal Crystals by Electrophoretic Forces

Dielectric particles in water such as latex and silica microspheres always possess some degree of surface charge, which prevents them from coagulating. Electrophoretic (d.c.) attraction toward electrodes can be

**Fig. 11** Schematics of four different devices where photonic or optical function of particle assemblies is imparted by electric field. (A) Two-dimensional colloidal crystals assembled by d.c. field in thin cells with opposing electrodes. (B) Oriented two-dimensional colloidal crystals assembled by DEP between coplanar electrodes on a surface. (C) Electronic ink by electrophoretic segregation of colored particles in microcapsules. (D) Light-emitting diodes assembled from layers of oppositely charged semiconductor particles and polyelectrolyte.

used efficiently for concentrating the particles near the oppositely charged surface and for colloidal crystallization. The process can be viewed as speeding up the deposition of dense particle crystals that may otherwise be formed under gravity. The use of electrophoretic forces in the deposition of ordered arrays of gold and latex particles onto carbon-coated copper grid surfaces has been reported by Giersig and Mulvaney.<sup>[84]</sup> The process takes place in field intensities on the order of 1–5 V/cm. Holgado et al.<sup>[85]</sup> achieved direct electrophoretic control of the deposition speed of silica spheres for the fabrication of high-quality crystals. The d.c. field is applied in the vertical direction in cylinders with sedimenting spheres, controlling the speed at which the spheres deposit on the bottom. The electrophoretic deposition method has been used to prepare a variety of crystals and multilayered deposits.<sup>[86–90]</sup>

Functionality that is potentially usable in devices can be achieved when the particle suspensions are enclosed in thin films between electrodes a few micrometers to tens of micrometers apart (Fig. 11A). This configuration can be used for quick, potentially reversible, assembly of 2-D crystalline structures. The dynamics of electrophoretic particle deposition and ordering onto conductive surfaces has been observed microscopically by Trau, Saville, and Aksay<sup>[91,92]</sup> and Böhmer.<sup>[93]</sup> When the potential applied between the cell electrodes exceeds ca. 0.5 V d.c., the microspheres move toward the oppositely charged electrode, forming ordered 2-D clusters on its surface. The microspheres

also exhibit lateral attraction forces, which, at higher potentials (1–2 V), act at distances exceeding a few particle diameters. Because of that lateral attraction, the 2-D ordered aggregates can attract to, and merge with, other aggregates until the electrode is covered with a complete monolayer or multilayer of crystalline array. The ordered sphere arrays formed, however, are multicrystalline and made up of domains with different orientation, which may restrict their application in photonic structures.

Electrophoretic 2-D colloidal crystallization has been observed with latex, silica, and gold particles, suspended in deionized water or in moderate electrolyte, in both d.c. and a.c. fields. The high-field intensity in the thin gap leads to the appearance of electrohydrodynamic currents around the particles and lateral dipole–dipole interactions. The electrohydrodynamic flows are generated because the counterionic atmosphere around the colloidal particles disturbs the concentration polarization layer onto the electrode, leading to emergence of local flow streams perpendicular to the cell wall. The hydrodynamic interaction of the flows around the microspheres leads to attraction between the particles and their aggregation into ordered patterns. Electrohydrodynamic models have been developed that explain the reversibility of the process and the “softness” of the incurred attractive forces that allow the lateral rearrangement of the particles into ordered arrays.<sup>[92,94–97]</sup>

The electrophoretic method, concurrently with the photosensitivity of indium tin oxide (ITO) layers, has been used to make optically tunable micropatterns from colloidal crystals.<sup>[98]</sup> The microspheres slowly migrate to the regions illuminated through a mask to form patterns from ordered arrays. The particles diffuse back to an unordered state when the voltage is turned off. If the particles in the illuminated patterns are pushed beyond the coagulation threshold by increased current, the assembled patterned arrays are permanently immobilized onto the electrode. Electrophoretic patterning has also been used to deposit live cells on surfaces.<sup>[99]</sup>

### Assembly of Colloidal Crystals by Alternating Current Chaining and Dielectrophoretic Forces

Particle chaining as a result of interaction between dipoles directed along the electric field [Eq. (4)] can be used for reversible assembly and alignment of ordered colloidal structures. Dipolar chaining has been used for a long time in electrorheological and magnetorheological fluids, which drastically increase their viscosity and become rigid when the particles stick together in the field.<sup>[100,101]</sup> It has been found that particles in

electrorheological fluids commonly arrange into 3-D body-centered tetragonal (bct) crystals.<sup>[101–104]</sup> This field-driven structure formation can be used to assemble and align colloidal crystals. Various stable and metastable crystalline phases formed in electrorheological suspensions of silica spheres have been reported by Dassanayake, Fraden, and van Blaaderen.<sup>[104]</sup> The chaining effect can also be used to induce annealing and large-scale orientation of colloidal crystals formed by conventional sedimentation.<sup>[105]</sup> Structures other than colloidal crystals can be fabricated by modifications of the method.<sup>[106]</sup>

The confinement of suspensions in thin closed cells can make use of chaining and DEP effects in colloidal crystallization. The first observation of particle clustering in thin cells was described by Richetti, Prost, and Barois<sup>[107]</sup> who reported that above a certain threshold magnitude of the a.c. voltage, the spheres are attracted to the surfaces of the electrodes and exhibit lateral attraction, forming ordered 2-D aggregates. The ordered structure “melts” at frequencies higher than  $\approx 5$  kHz. The electrophoretic mobility at frequencies below 100 Hz can cause particle compression and long-range crystallization in highly deionized systems.<sup>[108,109]</sup> The a.c. field-induced particle interactions in thin films can also be repulsive for certain combinations of cell thickness and particle sizes. Gong and Marr<sup>[110]</sup> have studied the “strictly confined” system where the thin gap between the electrodes is just ca. 20% larger than the particle size. The high-intensity fields induce strong dipoles in the microspheres, and as these dipoles are parallel, they repel each other (in contrast to the case of chaining, where the dipoles are colinear). The strongly repelling microspheres organize into 2-D crystals with long-range separation between the particles. The lack of friction, the relatively high mobility, and the long-range repulsion lead to rapid formation of relatively large crystal domains.

Combinations between DEP and chaining forces can be used for controlled colloidal crystallization above planar electrodes on a surface. Lumsdon et al.<sup>[111]</sup> have recently studied the reversible formation of crystals in suspensions of latex or silica microspheres subjected to an a.c. field in a gap above two coplanar electrodes (Fig. 11B). In this geometry, positive DEP forces attract the particles to the gap as predicted by Eq. (3). The chaining forces assemble the particles in the direction of the field as explained above. Formation of specifically oriented 2-D hexagonal crystals with areas above  $25 \text{ mm}^2$  has been observed. The transitions between ordered and disordered states take place within seconds and can be repeated tens of times. The laser diffraction patterns of all consecutively formed crystals are identical, which can be used to make rudimentary optical switches (Fig. 12). Various combinations of DEP, EP, and

**Fig. 12** Diffraction pattern of a laser beam directed through a 2-D crystallization cell with planar electrodes similar to the one in Fig. 11B.<sup>[111]</sup> (A) Diffuse scattering from a suspension of 0.7- $\mu\text{m}$  latex particles before the electric field is applied; (B) 1 sec after a.c. voltage is applied, the particles align in chains diffracting in parallel lines; (C) 3 sec after voltage is applied, the particles crystallize into hexagonal close packed array. The process is fully reversible and can be used in beam splitters. *Source:* © American Institute of Physics, 2003.

chaining forces are likely to find more elaborate applications in the reversible assembly of ordered structures inside electrically controlled devices.

### Electrical Displays Based on Nanoparticle Manipulation

The optical properties of colloidal structures can be modulated even more simply by using microparticles of different color and moving them to face the observer or backward. This principle could be used in display

technologies based on colloidal particles that are a competitive alternative to the common liquid crystal displays. One very promising research area is the development of microencapsulated electrophoretic inks for electronic “paper.”<sup>[112,113]</sup> This “ink” is made from thousands of capsules 30–300  $\mu\text{m}$  in diameter, incorporating a suspension of white and black microparticles in the size range of 1–5  $\mu\text{m}$ . The white and black particles carry opposite charges and are protected from heterocoagulation via a polymeric adsorption layer around their surfaces. Alternatively, only white particles suspended in dark liquid can be used.

The microcapsules are spread in a thin layer and addressable electrodes from ITO and silver-doped polymer are applied from top and bottom, respectively. To switch the color on and off, potential fields of a few volts per micrometer are applied across the electrodes. The particles move to oppositely charged electrodes, separating into black mass on one side of the capsule and white on the other side (Fig. 11C). If the electrode potential is reversed, the position of the black and white particles changes, reversing the color of the capsule. Such displays exhibit high optical reflectance and contrast and wide viewing angle.<sup>[114]</sup> Potential for achieving resolutions as high as 1200 dots per inch has been suggested. The displays may be made flexible and can retain the displayed information after the electric field is turned off. Recent commercial development of this technology has led to the fabrication of color displays of relatively low cost and low energy consumption. The commercialization of such displays is intertwined with the development of technologies for fabrication of inexpensive organic transistors and electronic circuits by printing on flexible plastic films.<sup>[115,116]</sup>

### Photovoltaic Cells and Light-Emitting Diodes

Conductor and semiconductor nanoparticles have found application in light-emitting diodes and photovoltaic cells, the active junctions of which are created by self-assembly instead of vacuum evaporation and ion implantation. Ultrathin structures of semiconductor nanoparticles can form electronic elements similar to the heterojunctions of doped semiconductors used in solid-state electronics. One convenient method for the assembly of thin layer-by-layer structures is nanoparticle adsorption onto oppositely charged polyelectrolytes.<sup>[117–120]</sup> The delicate balance of the forces in layers of alternating charge allows sequential deposition of particle layers of various types. The particles/polyelectrolyte layers are assembled on a metallic surface acting as the first electrode, and a layer of another metal is coated on top of the structure to form the second electrode (Fig. 11D). This technique has been used in the fabrication of prototypes of

nanoparticle-based rectifying and Zenner diodes.<sup>[121,122]</sup> Optically active elements such as LEDs<sup>[123–131]</sup> and photovoltaic cells can also be fabricated.<sup>[132,133]</sup> The size and the chemical composition of the nanoparticles can be used as a means to tune the emission wavelength of the electroluminescence. Additional advantages offered by the nanoparticle layering technique are simple processing, precise control of the layer thickness, choice of a wide range of semiconductor nanoparticle types (e.g., CdSe, CdS, Si, TiO<sub>2</sub>, ZnO, etc.), and the ability to tune and improve the electrical characteristics of the devices via polyelectrolytes and self-assembled monolayers.<sup>[120,128,129]</sup>

## CONCLUSION

We show in this entry how simple nanoparticles and microparticles suspended in water can be assembled in a variety of structures, which can act as electrical connectors in liquid and as active elements in biological and chemical sensors or in optical devices. The assembly of the nanoparticles can be driven by a variety of colloidal forces; however, among the most convenient tools for controlled assembly are external a.c. and d.c. electrical fields applied to on-chip electrodes. The diverse scientific results reviewed here are by no means inclusive of all exciting developments in related research areas. Carbon nanotubes and semiconductor nanowires form a large research topic not reviewed in detail here because of the higher complexity of these “nanoparticles,” which are rarely used in aqueous environments. We have also not reviewed the exciting field of quantum and molecular electronics, which deals with electrical structures smaller than the nanoparticle scale.

The field of creating electrically functional nanoparticle structures is still in its infancy, and exciting and important developments can be expected in the near future by bringing together new techniques and interdisciplinary research. For example, the combination of electrically functional nanostructures with microfluidics is likely to bring forward novel sensors and bio-electronic devices. The combination of the techniques and structures presented here with biomolecules, molecular electronics, and carbon and semiconductor nanotubes is almost unexplored yet and holds enormous possibilities for nanotechnology applications. Novel electrically functional nanostructures are likely to find practical applications in the near future.

# Electrochemical Langmuir Trough

Natalia Varaksa  
Thomas F. Magnera  
Josef Michl

*University of Colorado, Boulder, Colorado, U.S.A.*

## INTRODUCTION

The term electrochemical Langmuir trough is used to describe a modification of the original Langmuir trough in which compression isotherms and thus surface areas per molecule can be measured at the interface between two conducting liquids at a controlled electrical potential. The instrument has been used to investigate molecular surface areas as a function of applied potential and to examine insoluble monolayers on mercury surface. These include films built from trigonal connectors and believed to have an open grid structure.

## THE LANGMUIR TROUGH

The Langmuir trough<sup>[1–3]</sup> was introduced by Irving Langmuir<sup>[4]</sup> and co-worker Katherine Blodgett<sup>[5]</sup> for the investigation of the behavior of amphiphilic molecules on a water–air interface. Such molecules contain hydrophilic and hydrophobic parts and tend to organize on the surface with their hydrophilic groups directed toward the aqueous phase. In a typical experiment, a solution of an amphiphile in a volatile solvent is spread on water, and the solvent is allowed to evaporate, leaving the water-insoluble molecules broadly dispersed on the water surface. A moving compression barrier is then used to reduce the surface area, until a closely packed and organized monolayer is formed in favorable cases. During the compression the two-dimensional interfacial material often goes through several phase transformations: from a dilute gas-like phase to a liquid-like phase, and finally to a condensed, solid-like phase. Those transitions are clearly reflected in the surface pressure ( $\pi$ ), which can be measured as a resistance to further compression. It is conveniently determined using a platinum plate attached to an electrobalance and partly immersed in a liquid (Wilhelmy plate). The net force acting on a Wilhelmy plate is composed of gravity, surface tension, and buoyancy. In surface pressure measurements the gravity and buoyancy components, invariant with surface areas, are subtracted out, leaving the surface tension as the

only surface-area-dependent variable. If the plate is completely wetted by a liquid (i.e., contact angle is zero), the resulting surface pressure depends only on the surface tension changes normalized to the perimeter of the plate in contact with a liquid.

The plot of  $\pi$  against the surface area  $A$  is known as the Langmuir isotherm (Fig. 1). To deduce the area per molecule at the interface, several compression isotherms are measured with different numbers  $N$  of amphiphile molecules on the surface. The steeply rising part of each isotherm is extrapolated to zero surface pressure, giving the compressed monolayer area  $A$ . The plot of areas  $A$  against  $N$  is linear and its slope corresponds to the area per molecule  $\sigma$ .

The compressed film can often be transferred to a solid substrate by passing the substrate through the water surface. Depending on the direction of the passage and the nature of the solid surface, the hydrophilic or the hydrophobic end of the molecules can face the solid. Multilayers can be deposited upon multiple passage. The transfer technique was worked out by Blodgett,<sup>[5]</sup> and the resulting thin films are known as Langmuir–Blodgett monolayers or multilayers. A horizontal transfer is also possible (Schaefer transfer).<sup>[6]</sup>

Traditionally, the liquid phase is pure water or aqueous electrolyte solutions, but mercury has also been used.<sup>[7–9]</sup>

## ELECTROCHEMICAL LANGMUIR TROUGH

This is a modification of the Langmuir trough in which the water–air interface is replaced by a mercury–electrolyte interface, kept at a well-defined potential. Solid films on mercury drop electrodes have been studied for a long time,<sup>[10]</sup> and electrochemical measurements permit a determination of  $\sigma$ , the surface area per redox center. The electrochemical Langmuir trough provides a complementary capability for such studies, the determination of surface area per molecule.

As mercury is easily oxidized in the presence of atmospheric oxygen and moisture, the electrochemical

**Fig. 1** Schematic plot of monolayer transformations from the “gaseous” (G) to the expanded (E) and to the condensed phase (C), and their effect on surface pressure changes.

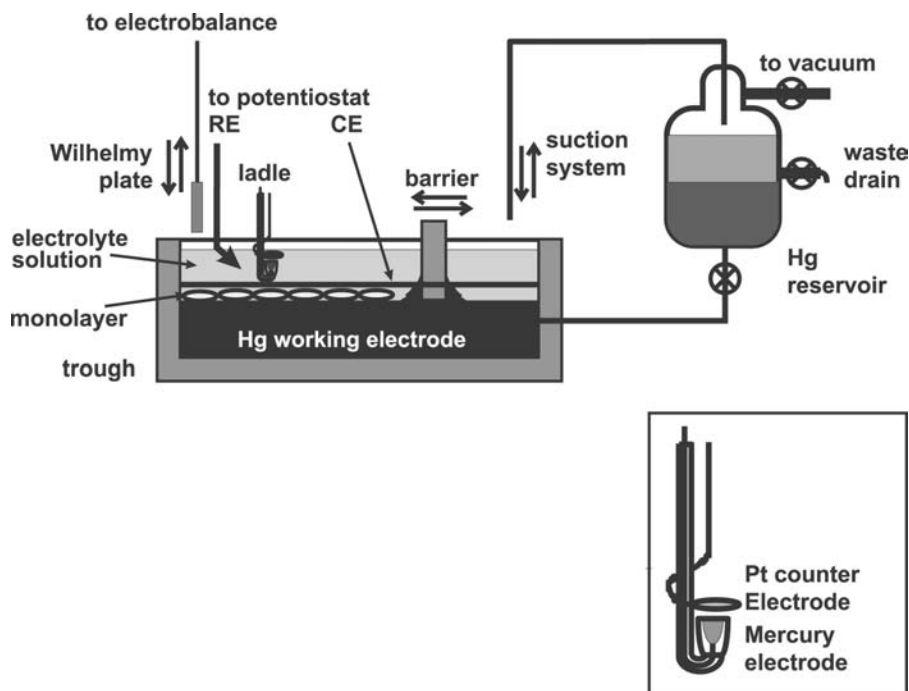

Langmuir trough must be used under an inert atmosphere, which is usual in most electrochemical studies. As mercury reflects electromagnetic radiation, it is relatively easy to perform grazing incidence spectroscopy of the interfacial material during compression. It is also possible to make standard electrochemical measurements such as cyclic voltammetry at various stages of compression, but special precautions are necessary because of the large area of the working electrode.

A schematic design of our latest version of the electrochemical Langmuir trough is shown in Fig. 2.

A rectangular Teflon trough has inside dimensions of 40 cm × 5 cm × 1 cm and a deeper well on one side, intended for the transfer of an interfacial film onto a solid substrate. A platinum barrier slides along the trough edges, and it is operated via a gearing system coupled to an electric motor. Once amalgamated, the surface of platinum is wetted by mercury, which forms a convex meniscus, preventing leakage of surface layers under the barrier and assuring proper monolayer compression.

Before each experiment, the mercury surface is swept with the barrier, and any contaminants present are compressed at one end of the trough and aspirated with a pipette into a mercury reservoir attached to the trough. The reservoir is designed to separate waste products from clean mercury by gravity, as the impurities concentrate in the upper layer in the reservoir. Fresh mercury from the bottom of reservoir is delivered to the trough, allowing circulation of mercury within the apparatus and the automatic adjustment of the mercury level in the trough.

During electrochemical experiments an electrolyte layer is added above the mercury pool and is provided with a counterelectrode (CE) (a platinum wire running along the inner perimeter of the mercury trough) and a reference electrode (RE). A common electrolyte is CH<sub>3</sub>CN/Bu<sub>4</sub>NPF<sub>6</sub>, with Ag/0.01 M AgNO<sub>3</sub>/0.1 M Bu<sub>4</sub>NPF<sub>6</sub> in CH<sub>3</sub>CN as the reference electrode. However, all potentials reported below are referred to the aqueous Ag/AgCl/1 M LiCl electrode via the intermediacy of the ferrocene/ferricinium couple. The electrical potential of the mercury pool is controlled with a

**Fig. 2** Schematic drawing of the electrochemical Langmuir trough. Inset: the ladle electrode.

Fig. 3 Cross section of the electrochemical Langmuir trough with extended wings for spectroscopy of compressed monolayers.

potentiostat, connected to the trough through sealed leads. The trough along with the barrier driving system and the electrobalance with an attached Wilhelmy plate are enclosed in a purgeable airtight stainless steel box. For IR spectroscopy an IR beam enters in a direction perpendicular to the long axis of the trough at grazing incidence and exits through a pair of wedged ZnSe windows (Fig. 3). The instrument also has a removable transparent glass top, used for viewing and for Raman spectroscopic measurements. The communication between the trough and a potentiostat, as well as the control of the barrier movements and the electrobalance readings (interface unit/software), is accomplished via sealed electrical connectors installed in the body of the steel box. The glass top accommodates several airtight ports. Three ports with replaceable septum pads (inserts) are used for the introduction of solutions and solvents into the system from a syringe. Another port is used for a reference electrode and yet another for a ladle working electrode (See Fig. 2, inset). The box also has inlet and outlet ports for purging with inert gas.

In a typical experiment, a solution of a compound of interest is spread on the mercury and the solvent is allowed to evaporate on a cleaned mercury surface. Electrolyte solution is then added, and the desired potential is applied simultaneously to enable electrochemical control. After a short pause, the surface pressure-area isotherm is recorded by moving the barrier toward the Wilhelmy plate position. Spectra are taken concurrently if desired. In the grazing incidence IR measurement, the beam is polarization modulated, removing all contributions to the spectrum from species not located at the interface.

Because of the large size of the working electrode, the mercury surface potential is not entirely uniform, but it appears that a small potential gradient can be tolerated in the isotherm measurement. For accurate electrochemical measurements on the monolayers, such as cyclic voltammetry, constant-potential coulometry,

or double-layer capacitance determination, a separate “ladle electrode” with a  $0.1\text{-cm}^2$  surface area is used. It consists of a long vertical glass handle carrying an insulating cup at the lower end, with a conductive contact at the bottom. Initially, the cup is fully immersed in the mercury pool. Before an electrochemical measurement, the handle is pulled up until the top of the cup emerges into the electrolyte and separates a small volume of mercury along with a portion of the surface carrying the partially or fully compressed film. After breaking the mercury surface, the ladle stays in the electrolyte solution, but the scooped portion of mercury with a monolayer is electrically insulated from the rest of the mercury pool electrode. The small amount of mercury in the ladle then serves as a separate working electrode. A circular platinum foil positioned above the top of the cup and parallel to it is used as a counter-electrode.

## EXAMPLES OF APPLICATION

### A Molecular Conformation [Ref.<sup>[11]</sup>]

Metal sandwich complexes provided with sulfur-containing substituents adsorb firmly on a mercury surface over a considerable range of potentials.<sup>[12]</sup> The compounds studied on the electrochemical Langmuir trough were tetraphenylcyclobutadienecyclopentadienylcobalt complexes with five “tentacles” attached to the cyclopentadienyl ring. In general, they form a chemisorbed layer at the least negative potentials, are merely physisorbed at intermediate potentials, and are not adsorbed at all at the most positive potentials, but there is considerable variation.

The compression isotherms (Fig. 4, right inset) for molecules with short tentacles containing a single sulfur atom (Fig. 5A) confirm that at potentials less negative than  $\sim -0.55\text{ V}$  a firmly chemisorbed surface layer is formed. The slope of the plot of extrapolated

**Fig. 4** Molecular surface areas of connectors of Fig. 5A as a function of applied potential. Insets: right, compression isotherms at  $-0.50$  to  $+0.15$  V (A) and at  $-1.15$  to  $-0.55$  V (B); left, extrapolated surface areas of connectors (A) vs. the number of molecules ( $N$ ) at the mercury/electrolyte solution interface (potential range  $-0.5$  to  $+0.55$  V).

monolayer areas for different numbers of molecules at the interface (Fig. 4, left inset) yields an area per molecule of  $\sim 2 \text{ nm}^2$ . At potentials more negative than  $\sim -0.55$  V the physisorbed molecules show no resistance to compression, and instead leave the surface and move into the supernatant solution. In a cyclic voltammogram,<sup>[12]</sup> a mercury redox peak occurs at  $-0.69$  V, and it seems that the formation of a firmly adsorbed layer is associated with the availability of mercury cations at the less negative potentials. Apparently, these bridge sulfur atoms that are located in different tentacles and produce an insoluble polymeric network.

When the substituents on the cyclopentadienyl ring are longer and each contains two sulfur atoms (Fig. 5B), the results are different. Now, the mercury redox peak appears at  $-1.14$  V in the cyclic voltammogram,<sup>[12]</sup> and

**Fig. 5** Molecular structures of tetraphenylcyclobutadienylcyclopentadienylcobalt complexes with a single (A) and with two (B) sulfur atoms per tentacle.

**Fig. 6** Molecular surface areas of connectors of Fig. 7B as a function of applied potential. Insets: right, compression isotherms of connectors at  $-1.6$  V (A) and at  $-1.0$  V (B); left, extrapolated surface areas of connectors (A) vs. the number of molecules ( $N$ ) at the mercury/electrolyte solution interface at  $-1.6$  to  $-1.2$  V (A) and at  $-1.1$  to  $-0.5$  V (B).

the compression isotherms show that the molecules are firmly adsorbed on the mercury surface both at potentials less negative and those more negative than  $\sim -1.15$  V, but the areas per molecule are different in the two regions (Fig. 6). At less negative potentials, the connectors seem to be adsorbed with both sulfur atoms in each tentacle, with the tentacles fully stretched on the surface and a surface area per molecule equal to  $\sim 4.5 \text{ nm}^2$ . At more negative potentials, the tentacles seem to contract and the surface area per molecule is only  $\sim 3.3 \text{ nm}^2$ . It is again likely that the conformation change is related to the availability of mercury cations.

Measurements of a doubled sandwich complex (Fig. 7) at  $-0.8$  V yield twice the surface area ( $8 \text{ nm}^2$ ), suggesting that the mode of absorption of these molecules on a mercury surface is analogous.

### Open Grids [Ref.<sup>[13]</sup>]

The fabrication of regular two-dimensional molecular grids<sup>[14–17]</sup> of desired structure, dimensions, and chemical functionalization is motivated by their potential use as molecular-scale separation membranes and selective barrier materials, and as organized surfaces for mounting molecular functionalities in a plane in a regular fashion. The building units of such grids are star-shaped monomers adhering to the surface with their arms. The arms can be tailored to control the lateral spacing and the nature of interactions between monomers. Given an ability to control the potential applied to the mercury/electrolyte interface, the grid structure can be governed and manipulated. Specifically, if mercury cations participate in grid formation by providing

**Fig. 7** Molecular structures and compression isotherms of tetraphenylcyclobutadienecyclopentadienylcobalt complexes of Fig. 7B (A) and of altitudinal rotor molecules (B) at  $-0.8$  V.

links between neighboring arms, the use of the electrode potential to control their presence offers opportunities for defect annealing.

The adsorption and self-assembly of the trigonal connector, 1,3,5-tris[10-(3-ethylthiopropyl)dimethylsilyl-1,10-dicarba-*closo*-decaboran-1-yl]benzene, on a mercury surface under controlled electrochemical conditions have been examined and are compatible with the formation of a two-dimensional hexagonal grid (Fig. 8).<sup>[13]</sup> No adsorption is observed at potentials more negative than  $\sim -0.85$  V, physisorption takes place between  $\sim -0.85$  and 0 V, and at positive potentials anodic dissolution of mercury promotes the

**Fig. 8** AM1 optimized structure of the proposed hexagonal grid (A) and the chemical structure of the trigonal connector (B).

**Fig. 9** Compression isotherms of trigonal connectors under potential control. Inset: extrapolated areas ( $A$ ) vs. the number of molecules ( $N$ ) at the mercury/electrolyte solution interface.

mutual binding of thioether-containing arms through surface mercury cations.

Langmuir compression isotherms (Fig. 9) show that at potentials more negative than the mercury reduction peak, trigonal connectors offer no significant resistance to compression. At potentials more positive than the mercury redox peak, the trigonal connectors form an insoluble adsorbed surface layer on mercury. The areas per molecule at various potentials are shown as dark circles in Fig. 10. The average number is  $6.20$  nm<sup>2</sup>, and this fits fairly well with the area expected from a semiempirical AM1 geometry optimization of a perfect hexagonal grid (Fig. 8). The benzene rings are at the vertices of a hexagon, and mercury cations are midway between each pair of benzene rings. The S–Hg–S or S–Hg–Hg–S line is roughly perpendicular to the edge of a planar hexagon. After unconstrained optimization, the structure is nearly planar and almost sixfold symmetric. Assuming the S–Hg–S structure, the edge length is  $1.89$  nm, which corresponds to an area of  $4.64$  nm<sup>2</sup> per connector molecule. This is less than the  $6.2$  nm<sup>2</sup> deduced from the electrochemical Langmuir isotherm, but the result agrees closely with the electrochemical data of Ref. <sup>[13]</sup> (area per molecule  $4.4$  nm<sup>2</sup>), suggesting that the number of electrons exchanged per redox center is 2, and the binding cations are Hg<sup>2+</sup> or Hg<sub>2</sub><sup>2+</sup> (not Hg<sup>+</sup>).

A noteworthy peculiarity of this hexagonal network on mercury is the existence of a bistable state up to the potential  $-0.85$  V. When the monolayer is formed at  $+0.1$  V, and then the potential is stepped to a more negative value, the surface layer remains on the mercury surface and resists the compression. The areas per molecule of trigonal connectors deduced from the corresponding compression isotherms

**Fig. 10** Bottom: Trigonal connector footprints ( $\sigma$ ) vs. potential ( $E$ ). Hollow circles represent an alternative long-term stable state of adsorbed molecules. Top: cyclic voltammograms of trigonal connectors on a static mercury drop electrode, scanned in both directions.

average  $\sim 6.20 \text{ nm}^2$ , the same as obtained at potentials more negative than the redox peak. It is not clear why the self-assembled layer remains ordered after the structure-defining mercury cations have been reduced. Although complexes of  $\text{Hg}(0)$  are known to exist,<sup>[18]</sup> it is unlikely that the mercury atoms stay in place, continuing to bridge the thioether arms. Perhaps  $\text{Li}^+$  ions from the supporting electrolyte perform the same function as the mercury cations do at more positive potentials.

## CONCLUSION

The electrochemical Langmuir trough combines two powerful methods to permit the manipulation of

molecules on the surface of liquid mercury through the simultaneous control of the electrochemical potential and surface density. The technique has been demonstrated to be useful for monitoring the molecular conformation of adsorbed molecules as a function of electrical potential and for the assembly and characterization of open and regular two-dimensional molecular grids. The ability to synthesize regular two-dimensional molecular grids with precise control represents progress in the development of new nanoporous ultrathin membrane materials.

## INTRODUCTION

Nanostructured materials allow the development of miniature sensing devices that are compact, low-cost, low-energy-consuming, and easily integrated into field-deployable units. This article reviews our recent successful development of electrochemical sensors that are solid-state and mercury-free by using nanostructured materials. Specifically, thiol- or acetamide phosphonic acid-functionalized nanoporous silica materials have been incorporated in carbon paste electrodes for the detection of uranium,<sup>[2]</sup> and the simultaneous detection of lead/mercury,<sup>[1]</sup> and copper/lead/cadmium.<sup>[3]</sup> Thiol-functionalized mesoporous silica thin film has been immobilized on gold electrode arrays for the detection of lead ions.<sup>[4]</sup> The electrochemical sensors based on functionalized nanoporous silica yield reproducible measurements with excellent detection limits (at a few ppb of metal ions) and require little or no regeneration of electrode materials. Other advantages of our approaches, compared to those of current sensor technology, will also be discussed.

## BACKGROUND

There is enormous current interest in exploiting nanostructured materials in the developments of electrochemical sensors of metal ions.<sup>[1-14]</sup> Nanostructured materials are defined as materials that have at least one dimension smaller than 100 nm. The unique properties (e.g., electrical, optical, magnetic properties) of the nanomaterials, obtained as the particle sizes approach molecular dimensions, make them very useful for specific applications.<sup>[14]</sup> Nanostructured materials allow the development of miniature sensing devices that are compact, low-cost, low-energy-consuming, and easily integrated into field-deployable units.

Currently, quantification of heavy metals at surface and subsurface hazardous waste sites relies upon the collection of liquid discrete samples for subsequent laboratory analysis using techniques such as inductively coupled plasma mass spectrometry (ICP-MS) and

atomic absorption spectroscopy (AAS). Sensors for obtaining real-time ppb-level heavy metal concentrations would reduce time and costs associated with the characterization and treatments of hazardous waste sites. Desirable characteristics of the metal ion sensors include specificity for targeted metal ions, enhanced measurement frequency and precision, robustness, inexpensiveness, and infrequent regeneration of sensor material. Electrochemical sensors based on stripping voltammetry appear to be a promising technique that meets these requirements.

Adsorptive stripping voltammetry (AdSV) is an extremely sensitive electrochemical technique for measuring trace species. Its remarkable sensitivity is attributed to the combination of a selective preconcentration step with advanced measurement procedures that generate an extremely favorable signal-to-background ratio. AdSV usually involves preconcentration of metal ions at an electrode surface, followed by quantification of the accumulated species by voltammetric methods. Preconcentration of metal ion species at an electrode surface prior to the detection step allows the sensitive detection of the metal species that may be present at extremely low levels (ppb) in contaminated groundwater or wastewater. Preconcentration of metal species at mercury drop or mercury film electrodes has been available for decades; however, mercury drop electrodes have the disadvantage of being mechanically unstable during various steps of the assay procedure, and thus, they are less desirable than solid-state sensors in routine field applications.<sup>[15,16]</sup> In addition, all mercury-based electrodes have issues related to the use and disposal of toxic mercury.

We have focused on developing mercury-free, solid-state electrochemical sensors, in which the preconcentration of metal species at the electrodes modified with functional ligands uses the specific binding properties of the ligand (toward the target metal ions) to accumulate the metal ions via coordination or chelation onto the electrode without applying any potential. These ligand-modified electrodes have several advantages: 1) they can preconcentrate metal ions that cannot be

reductively accumulated such as species that require excessively large negative reduction potentials; 2) electrolytes are not required in the preconcentration solution, thus reducing the risk of introduction of contaminants (i.e., trace metal impurity in chemical reagents) or competing ligands; and 3) with the appropriate ligand, the overall selectivity of the analysis for the targeted metal ions may increase.

Chemically (ligand) modified electrodes (CMEs) have been fashioned by immobilizing functional ligands on electrode surfaces using thin-polymeric films,<sup>[9,10]</sup> self-assembled monolayer (SAM) thin films,<sup>[11,12]</sup> or by immobilizing suitable functional ligands on an electrically conductive porous matrix.<sup>[17–24]</sup> One major limitation for CMEs based on polymeric films is slow diffusion across the films. CMEs based on SAM thin films can effectively remove this limitation. This approach has shown to provide a reproducible method for the sensitive and selective determination of trace cadmium<sup>[11]</sup> and chromium(VI).<sup>[12]</sup> The potential drawback of CMEs modified with SAM thin films is that the total number of binding sites in SAM thin films is limited, which may lead to a narrow linear range of the calibration curves.

Chemically modified carbon paste electrodes are often used in AdSV because they have low background currents, have a large potential domain, are low cost, and are easy to prepare and regenerate. Carbon paste electrodes modified with functional ligands have been employed to detect heavy metal ions.<sup>[17–24]</sup> However, the ligands in these sensors are in loose association with the conductive carbon matrix, thus the sensors may easily degrade over time from depletion of ligand-bearing material. In our work,<sup>[1–3]</sup> suitable ligands were first immobilized via covalent bonding through the self-assembly process onto a high surface area mesoporous silica substrate (MCM-41) prior to embedding the self-assembled monolayer on mesoporous silica (SAMMS) in a carbon graphite matrix. Thus the chemical functionality of the sensor is retained despite diffusion or abrasive wear.

The use of carbon paste electrodes modified with functional groups grafted on mesoporous silica supports for the detection of metal ions is a relatively new research area. Several unmodified silica materials were incorporated into carbon paste electrodes for copper(II)<sup>[5]</sup> and mercury(II)<sup>[6]</sup> detection by exploiting the silanol groups inherent in the MCM-41 silica materials. By using unmodified mesoporous silica materials, specificity for the targeted metal ions was limited to the silanol groups of the silica materials. In the pH range of 4–7, only metal hydroxides of mercury(II) are soluble enough to reach and react with silanol groups of the MCM-41 via a condensation process.<sup>[6]</sup> Metal species that are not hydroxylated can only bind with silanolate groups, which are formed in significant

amounts at above pH 7. Therefore ammoniacal medium was used as a preconcentration medium so that the silanolate groups could accumulate positively charged species such as  $\text{Cu}(\text{NH}_3)_4^{2+}$ .<sup>[5]</sup> Polysiloxane-immobilized amine ligands<sup>[7]</sup> and aminopropyl-grafted silica gel<sup>[8]</sup> were later used successfully by Walcarius and co-workers as electrode modifiers in order to study the uptake of copper(II) from an aqueous solution. Both functionalized MCM-41 materials show very promising results as electrode modifiers. Two factors believed to affect voltammetric detection responses of copper ions are the number of immobilized functional groups and the structure of the organically modified silicates, the latter of which governs the accessibility to the binding sites and the diffusivity of the copper ions.<sup>[5,7]</sup> However, amine functional groups are highly selective mainly for copper ions. Using this class of materials as the electrode modifiers for other toxic metal ions has therefore become our main research focus.

## FUNCTIONALIZED NANOPOROUS SILICA FOR SELECTIVE ADSORPTION OF METAL SPECIES

Self-assembled monolayer on mesoporous silica is a new class of nanostructured sorbent materials developed at the Pacific Northwest National Laboratory (PNNL) through the marriage of nanoporous ceramic science with self-assembly chemistry.<sup>[25–36]</sup> Self-assembled monolayers provide a simple and direct method of chemically derivatizing ceramic oxide surfaces. These nanoporous hybrid materials with particle sizes of 5–200  $\mu\text{m}$  and a nominal pore size of 5 nm<sup>[35]</sup> are highly efficient sorbents. The high surface area (up to 1000  $\text{m}^2/\text{g}$ ) of nanoporous ceramic backbone coupled with the dense monolayer coating promises a high loading capacity. The close proximity of the binding sites allows for multiligand chelation of the target ion in the monolayer interface, enhancing the binding affinity and stability. The open pore structure that allows facial diffusion into the nanoporous matrix and the rigid ceramic backbone that prevents pore closure due to solvent swelling result in fast sorption kinetics.<sup>[31]</sup> The interfacial chemistry of SAMMS has been fine-tuned to selectively sequester a specific target species, including lanthanides,<sup>[32]</sup> actinides,<sup>[34]</sup> heavy and transition metal ions,<sup>[25–28,35]</sup> and oxometallate anions.<sup>[29,33]</sup> Two SAMMS materials have been investigated in our laboratory, first as sorbent materials and further as modifiers for electrochemical sensors for metal ions including thiol-terminated self-assembled monolayer on mesoporous silica (SH-SAMMS) and self-assembled acetamide phosphonic acids on mesoporous silica (Ac-Phos SAMMS). The schematics of both materials are shown in Fig. 1.

**Fig. 1** Schematics of thiol (SH)-SAMMS and acetamide phosphonic acid (Ac-Phos) SAMMS.

The SH-SAMMS was designed to be an excellent sorbent for lead and mercury.<sup>[36]</sup> With thiol coverage of up to 82%, the SH-SAMMS has a loading capacity for Hg of 0.64 g Hg/g.<sup>[28]</sup> From batch competitive adsorption experiments previously performed at PNNL,<sup>[25]</sup> in the presence of Ag, Cr, Zn, Ba, and Na, the SH-SAMMS has demonstrated the mass-weighted distribution coefficients ( $K_d$ ) of Hg and Pb on the order of  $10^5$  at neutral pH. Background ions, such as Na, Ba, and Zn, although present at high concentrations (i.e., 350 times higher concentrations than Hg and Pb), did not bind to the SH-SAMMS. Other transition metals such as Cd, Cu, Ag, and Au may bind to the SH-SAMMS, but not as effectively as Hg and Pb. The  $K_d$  values of Cu and Cd, for instance, are about 25 times lower than those of Hg. The presence of other anions (i.e.,  $\text{CN}^-$ ,  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$ ,  $\text{PO}_4^{3-}$ ) did not significantly interfere either with the adsorption of lead and mercury ions onto the SH-SAMMS.<sup>[36]</sup> The high selectivity of SAMMS material toward Hg and Pb is a combined effect of the suitable stereochemistry of the ligand, size of the chelation cavity, and hardness/softness of the metal ion and ligand field.

Similarly, the Ac-Phos SAMMS material was designed to be highly selective for hard Lewis acids such as actinide ions<sup>[37]</sup> by pairing a “hard” anionic Lewis base with a suitable synergistic ligand. The Ac-Phos SAMMS material displays excellent selectivity for actinide ions with virtually no competition from a wide variety of transition metal and alkaline earth cations.<sup>[31]</sup> In the absence of actinides, the Ac-Phos SAMMS is a good sorbent material for heavy and transition metal ions such as Cu, Pb, and Cd.<sup>[35]</sup> With a functional group density of 2.0 mmol phosphonic acid/g, the Ac-Phos SAMMS has a loading capacity of 0.3 mmol Cd/g and is able to uptake 99% of 2 mg/L  $\text{Cd}^{2+}$  within 1 min at a solution-to-solids ratio of 200.<sup>[35]</sup>

## ELECTROCHEMICAL SENSORS BASED ON FUNCTIONALIZED NANOPOROUS SILICA

### Electrochemical Sensors Based on SAMMS-Modified Carbon Paste Electrodes

The high loading capacity and high selectivity of SAMMS materials are desirable for metal ion detection based on the AdSV technique because they minimize the competition for the binding sites of the nontarget species, thereby reducing the interferences and preserving the signal intensity of the target metal ions. In addition, as SAMMS particles are not conductive, the high surface of the material does not contribute to the charging current when the material is used as electrode modifiers, leading to the low background current for measurements. Self-assembled monolayer chemistry readily allows installation of a wide variety of chemical monolayers that can be tailored to specific metal ion detection needs when used as electrode modifiers. Our sensors that are based on different functionalized mesoporous silica materials are summarized as follows.

#### Thiol-terminated self-assembled monolayer on mesoporous silica

The anodic stripping voltammetry at a carbon paste electrode modified with a SH-SAMMS provides a new sensor for simultaneous detection of lead ( $\text{Pb}^{2+}$ ) and mercury ( $\text{Hg}^{2+}$ ) in aqueous solutions.<sup>[1]</sup> The overall analysis involved a two-step procedure: an accumulation step at an open circuit, followed by medium exchange to a pure electrolyte solution for the stripping analysis. For example, the reactions that occur between Pb(II) and an SH-SAMMS ( $\text{SiO}_2\text{-SH}$ )-modified electrode during each step in AdSV experiments can be summarized as follows.

Preconcentration of Pb(II) ions under an open circuit (Eq. (1)):

Because SAMMS is an electronic insulator, desorption of  $\text{Pb}^{2+}$  previously accumulated on the SH-SAMMS to the electrode/solution interface must occur for the voltammetric detection to be possible (Eq. (2)).

Then the desorbed  $\text{Pb}^{2+}$  may be detected directly by reduction from lead ions to elemental lead ( $\text{Pb(II)} \rightarrow \text{Pb(0)}$ ). However, it is more sensitive and quantitative to first perform a thorough electrolysis by applying a negative potential to deposit  $\text{Pb(0)}$  on the electrode surface (Eq. (3)),

followed by performing anodic stripping voltammetry to oxidize the previously reduced  $\text{Pb(0)}$  to  $\text{Pb(II)}$  (Eq. (4)).

Factors affecting the performance of the SH-SAMMS modified electrodes were investigated. The most sensitive and reliable electrode contained 20% SH-SAMMS and 80% carbon paste. The optimal operating conditions were a sequence with a 2-min preconcentration period, then a 60-sec electrolysis period of the preconcentrated species in 0.2 M nitric acid, followed by square

**Fig. 2** The voltammetric responses of  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$  (A) measured after 2 min of preconcentration in 30 ppb  $\text{Pb}^{2+}$ /160 ppb  $\text{Hg}^{2+}$  solution and (B) measured after 20 min of preconcentration in 1.5 ppb  $\text{Pb}^{2+}$ /3 ppb  $\text{Hg}^{2+}$  solution. *Source:* From Ref.<sup>[1]</sup>.

wave anodic stripping voltammetry from  $-1.0$  to  $0.6$  V in 0.2 M nitric acid. Fig. 2 shows that the  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$  anodic peaks appear at  $-0.5$  and  $0.4$  V, respectively; the large differential potential ( $\Delta E$ ) of 0.9 V enables  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$  to be detected simultaneously without interference with each other. Table 1 summarizes the detection limits and the parameters for the calibration curves of metal ions measured by various types of SAMMS-modified electrodes, including the SH-SAMMS-modified carbon paste electrode for simultaneous detection of  $\text{Hg}^{2+}$ / $\text{Pb}^{2+}$ . After 2 min of preconcentration, the area of each anodic peak of  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$  was proportional to their concentrations in the range of 10–1500 ppb  $\text{Pb}^{2+}$  and 20–1600 ppb  $\text{Hg}^{2+}$ , respectively. The experimental detection limit for  $\text{Pb}^{2+}$  was 10 ppb after a 2-min preconcentration period and improved significantly to 0.5 ppb after a 20-min preconcentration period. Similarly, the detection limit for  $\text{Hg}^{2+}$  was 20 ppb after a 2-min preconcentration period and improved to 3 ppb after a 20-min preconcentration period.

#### Self-assembled acetamide phosphonic acids on mesoporous silica

Because of its excellent selectivity for actinide ions, the Ac-Phos SAMMS was used to modify a carbon paste electrode for uranium detection.<sup>[2]</sup> One issue for stripping voltammetric detection of uranium is the potential interferences from heavy and transition metal ions existing at higher concentrations in most wastes. The superior selectivity for actinides over heavy and transition metal ions of the Ac-Phos SAMMS greatly improves the selectivity for uranium sensing. Compared to propyl gallate (PG)<sup>[16]</sup> and trioctylphosphine oxide (TOPO),<sup>[38]</sup> carbamoyl methyl phosphine oxide (CMPO) is a more notable class of ligands in which a carbonyl amide and a  $\text{P}=\text{O}$  double bond are arranged in a suitable fashion to chelate actinide cations.<sup>[34,39–41]</sup> The characteristic of the  $\text{C}=\text{O}$  methyl  $\text{P}=\text{O}$  moiety in the Ac-Phos SAMMS (Fig. 1) plays an important role just like the CMPO, which leads to high selectivity for actinide binding.

Uranium in aqueous solution will form complexes with ligands that may vary as a function of solution pH. Speciation can greatly affect the voltammetric responses of uranium (matrix effect). The type and concentration of anions, the concentration of uranium, and the pH of the solution are factors that determine which uranium complex will be preferentially formed in the solution. Sensors based on cathodic stripping voltammetry techniques rely on electrodeposition of metal–ligand complexes on electrode surfaces before detecting the metal within the same solution, hence the presence of ligands in the sample matrix can affect both deposition and detection steps. Using SAMMS-based electrodes with medium exchange in

**Table 1** Summary of the detection limits and calibration curve parameters of SAMMS-based electrodes

Modifier	Electrode	Metal ion	Detection Limit Detection limit (preconcentration time)	Calibration Curve		
				Linear range (preconcentration time)	Slope (area or current/concentration)	$R^2$
SH-SAMMS	Carbon paste	Hg/Pb	0.5 ppb Pb <sup>2+</sup> / 3 ppb Hg <sup>2+</sup> (20 min)	10–1500 ppb Pb <sup>2+</sup> (2 min)	0.0011 V $\mu$ A/ppb Pb <sup>2+</sup>	0.98
			10 ppb Pb <sup>2+</sup> / 20 ppb Hg <sup>2+</sup> (2 min)	20–1600 ppb Hg <sup>2+</sup> (2 min)	0.0006 V $\mu$ A/ppb Hg <sup>2+</sup>	0.98

			250 ppb Pb <sup>2+</sup> (5 min)			

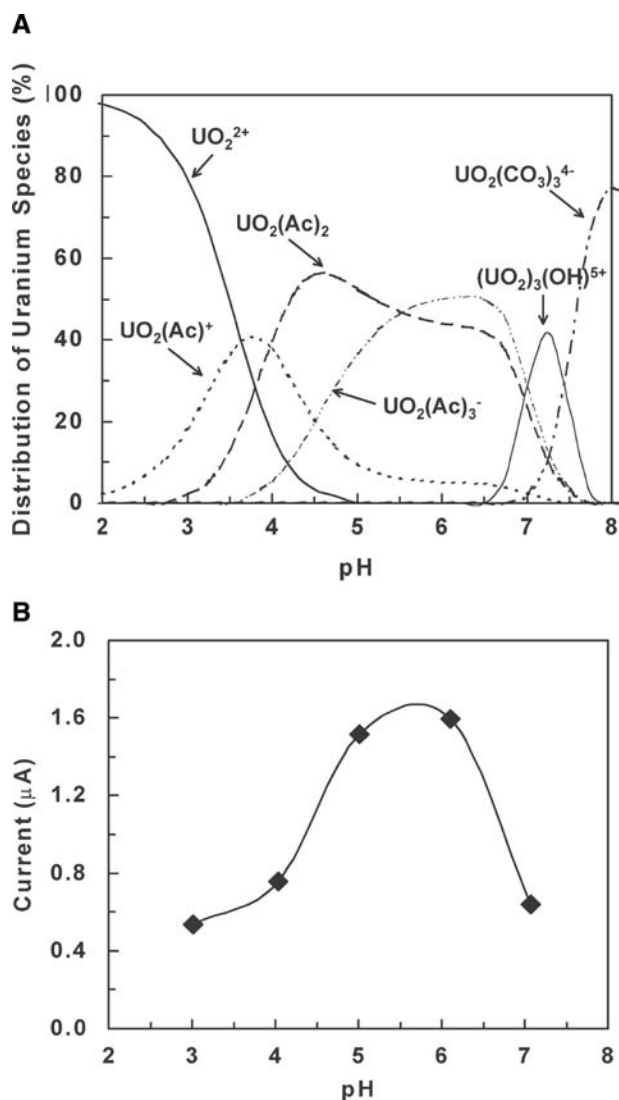

the detection step after uranium preconcentration can overcome the matrix effect and ligand interference.

The pH of the solution was predicted to affect the distribution of uranyl complexes with acetate, hydroxyl, and carbonate ligands as shown in Fig. 3A using 500 ppb U(VI) in 0.05 M CH<sub>3</sub>COONa open to atmosphere. Fig. 3B shows the effect of pH on the voltammetric responses of 500 ppb U(VI) in 0.05 M CH<sub>3</sub>COONa. In the pH range of 2–5, the dominant uranyl species is one with positive or neutral charge (e.g., UO<sub>2</sub><sup>2+</sup>, UO<sub>2</sub>(Ac)<sup>+</sup>), and its binding strength to phosphonic acid (on Ac-Phos SAMMS) increased with increasing pH, leading to an increasing amount of uranium being preconcentrated, and hence increasing voltammetric responses with increasing pH. Above pH 6, uranyl species with negative charge appear to cause repulsive forces, resulting in low uranium adsorption onto binding sites and correspondingly low voltammetric responses. A series of experiments at varied aqueous U(VI) concentrations in 0.05 M CH<sub>3</sub>COONa (pH 5) showed that, after a 5-min preconcentration period, the current of the anodic peak of uranium (appearing at –0.37 V) was proportional to the U(VI) concentration in the range of 25–500 ppb (Fig. 4). The uranium detection limit, obtained experimentally, improved significantly from 25 ppb, after a 5-min preconcentration period, to 1 ppb, after a 20-min preconcentration period (parameters are reported in Table 1).

Ac-Phos SAMMS has been used to modify a carbon paste electrode for simultaneous detection of cadmium

(Cd<sup>2+</sup>), copper (Cu<sup>2+</sup>), and lead (Pb<sup>2+</sup>) in the absence of actinides.<sup>[3]</sup> Most of the operating conditions (e.g., electrode compositions, electrolysis/stripping media conditions, electrolysis time) for heavy metal ion detection obtained by using SH-SAMMS-modified electrodes can be used effectively with the Ac-Phos SAMMS (and other SAMMS)-modified electrodes. The Cu, Pb, and Cd peaks appeared at –0.2, –0.5, and –0.75 V, respectively. The voltammetric responses of 50 ppb Pb<sup>2+</sup> increased linearly with the preconcentration time from 1 to 30 min. Fig. 5 shows that the voltammetric responses of Cu<sup>2+</sup>, Pb<sup>2+</sup>, and Cd<sup>2+</sup> after 2 min of preconcentration were linear with respect to metal ion concentrations ranging from 10 to 200 ppb (parameters are reported in Table 1). At any given concentration below 200 ppb, the copper peak response obtained from the multicomponent metal ion solution was not significantly different from that obtained from the single-component Cu<sup>2+</sup> solution (Fig. 6). Therefore one can infer that the electrochemical responses for copper ions were not affected by the presence of lead and cadmium in the concentration range studied, owing to the high loading capacity of the SAMMS materials. At 200 ppb Cu<sup>2+</sup>/Pb<sup>2+</sup>/Cd<sup>2+</sup>, the total moles of metal ions in the solution corresponded to approximately 0.0004% of the total number of binding sites (phosphonic acids).<sup>[3]</sup> Above 200 ppb, the detection of each Cu<sup>2+</sup>, Pb<sup>2+</sup>, and Cd<sup>2+</sup> started to interfere with each other because of the insufficient anodic potential difference between two adjacent metal peaks

**Fig. 3** The effects of pH on (A) uranium speciation, as predicted by MINEQL+ for conditions of 500 ppb U(VI) in 0.05 M  $\text{CH}_3\text{COONa}$  and open to atmosphere ( $\text{Ac} = -\text{COOCH}_3$ ), and (B) uranium voltammetric responses, measured after 5 min of preconcentration with 500 ppb U(VI) in 0.05 M  $\text{CH}_3\text{COONa}$ . (i.e.,  $\Delta E_{\text{Cu-Pb}} = 0.3 \text{ V}$ ,  $\Delta E_{\text{Pb-Cd}} = 0.25 \text{ V}$ ), and not because of their competition for the binding sites on SAMMS.

The binding between SAMMS and metal ions is reversible, therefore the SAMMS-modified carbon paste electrodes can be easily regenerated without damaging the ligand monolayer by desorption of the preconcentrated species in an acidic solution. By choosing an appropriate acid solution (i.e., 0.2 M  $\text{HNO}_3$ ) as a stripping medium, the electrodes usually are ready for reuse after the stripping voltammetric measurement. We found that SH-SAMMS electrodes were reliable even after 80 consecutive runs with no need for surface renewal.

**Fig. 4** Uranium voltammetric responses as a function of U(VI) concentration in 0.05 M  $\text{CH}_3\text{COONa}$  (pH 5), measured after 5 min of preconcentration. Inset shows the voltammograms with varied U(VI) concentration (in the ascending order) from 25, 50, 100, 200 to 500 ppb. Source: From Ref.<sup>[2]</sup>.

### Electrochemical Sensors Based on a Microelectrode Array Modified with a Functionalized Nanoporous Silica Thin Film

Most electrode modifications with mesoporous silica (MCM-41) have been accomplished via composite coating of the silica materials on electrode surfaces<sup>[42,43]</sup> or mixing of the silica materials with conductive materials such as graphite powder.<sup>[1-3,5-8]</sup> These techniques often rely on graphite powder as a

**Fig. 5** The voltammetric responses of  $\text{Cu}^{2+}$ ,  $\text{Pb}^{2+}$ , and  $\text{Cd}^{2+}$  measured after a 2-min preconcentration period in multicomponent  $\text{Cu}^{2+}/\text{Pb}^{2+}/\text{Cd}^{2+}$  solutions with concentrations ranging from 10 to 200 ppb of each metal ion. Inset shows representative voltammograms in the ascending order of 25, 50, and 100 ppb (each)  $\text{Cu}^{2+}/\text{Pb}^{2+}/\text{Cd}^{2+}$  solutions. Source: From Ref.<sup>[3]</sup>.

**Fig. 6** The voltammetric responses of  $\text{Cu}^{2+}$  measured after a 2-min preconcentration period in 10–500 ppb single-component  $\text{Cu}^{2+}$  solutions and in multicomponent  $\text{Cu}^{2+}/\text{Pb}^{2+}/\text{Cd}^{2+}$  solutions with concentrations ranging from 10 to 200 ppb of each metal ion. *Source:* From Ref.<sup>[3]</sup>.

conductive additive or polystyrene as a binder between the mesoporous silica materials and the electrode surfaces. Therefore we have focused on a method for preparation of mesoporous silica thin film-modified electrodes through an interfacial silica-surfactant self-assembly process that does not require additives or binders.<sup>[4]</sup> The self-assembly process allows surface layers to be constructed in a manner that is highly reproducible which is very important for any two-dimensional surface reaction to be successful.<sup>[44]</sup>

Mesoporous silica films with pore sizes of up to 100 Å have been synthesized from spin-coated silica sol-gels (normally consisting of silica precursor, acid solution, organic solvent, and water) by a surfactant-templating process in which the pores are formed upon removal of the surfactant by calcinations.<sup>[45–49]</sup> The precise design and control of pore structure, pore size/volume, and pore orientation of the silica films

can be achieved by using structure-directing agents, such as the nonionic surfactant Pluronic F-127 ( $\text{EO}_{106}\text{PO}_{70}\text{EO}_{106}$ ), as in our case. By controlling the film thickness (e.g., changing the composition of the precursor solution, spin rate, calcination conditions), a continuous, defect-free, mesoporous silica thin film is produced. However, spin-coated silica thin films have been found to be unstable in basic aqueous solutions but stable in pure water and acidic electrolyte solutions.<sup>[50]</sup> The instability is caused by the dissolution of the mesoporous framework, which increases with increasing pH. Because electrodes modified with these silica films cannot be used in basic solutions, the silanol groups, inherent to the nanoporous silica, are not useful in binding with metal ions in the preconcentration step of AdSV. Silanol groups must be ionized in a basic solution (e.g., ammoniacal medium) in order to accumulate positively charged ion species.<sup>[5]</sup> Therefore, without functional ligands attached, the spin-coated films of mesoporous silicas are often used as molecular sieves in electrodes by either blocking or improving the voltammetric responses of the analyte species.<sup>[50]</sup>

To remove this limitation, we have immobilized organic thiol ( $-\text{SH}$ ) functional groups onto the nanopore surfaces of the silica thin film through a self-assembly process, subsequently after the film was attached onto the surface of a gold microelectrode array by the spin-coating of the silica sol-gel.<sup>[4]</sup> Fig. 7 shows the schematics (top and side views) of the thiol functionalized mesoporous silica (SH-FMS) thin-film-modified gold microelectrode array. The modified microelectrode array was then used for detection of lead ions by employing the AdSV technique. To our knowledge, this is the first time that a microchip-based electrode modified with functionalized mesoporous silica thin film for metal ion detection based on AdSV has been investigated. With the SH-FMS thin film-modified electrode array, the preconcentration step can be performed in slightly acidic electrolyte solutions or neutral nonelectrolyte solutions as long as the thiol

**Fig. 7** A schematic of the gold electrode array with the SH-FMS thin film: (A) top-view of the array and (B) side-view of the three-layer sensor ( $\text{SiO}_2/\text{Au}/\text{SH-FMS}$ ). *Source:* From Ref.<sup>[4]</sup>.

ligands can adsorb the target analyte, based on a previous pH study using batch adsorption experiments.<sup>[25]</sup> In nonbasic solutions, the mesoporous silica films are more likely to remain stable for a long period of time.

Several surface characterization methods were performed on the mesoporous silica thin film before and after thiol functionalization. TEM measurement of the SH-FMS film shows short-range ordered mesopores. The nitrogen adsorption/desorption isotherms of the untreated SiO<sub>2</sub> thin film are of type IV with a clear H<sub>2</sub>-type hysteresis loop, which is consistent with the film's large ratio of pore size to pore spacing<sup>[51,52]</sup> and cubic arrangement of pores.<sup>[53]</sup> From BET analysis, the calcined film had a large primary pore diameter of 77 Å, a porosity of 60%, and a high BET surface area of 613 m<sup>2</sup>/g. The FTIR spectra indicate that organic thiol monolayers were successfully immobilized inside the nanopores of the mesoporous silica. After the thiol immobilization, the refractive index of the mesoporous silica film increased from 1.16 to 1.36, corresponding to the decrease in film porosity from 66% to 23%. However, both XRD patterns of the film before and after thiol functionalization were alike, indicating that the structure of mesoporous film remained unchanged after the thiols attachment.

When the SH-FMS thin film-modified electrode array was tested for Pb<sup>2+</sup> detection, the electrode behaved in a similar fashion with the powdered SH-SAMMS-modified carbon paste electrodes. For example, the optimum cathodic electrolysis, corresponding to optimum voltammetric response, was obtained at 60 sec; the lead voltammetric responses were poorer at lower than 60 sec due to the incomplete electrolysis process and at 120-sec electrolysis period, perhaps due to the generation of H<sub>2</sub> bubbles on electrode surface, which affected the stability of the signals. Fast electrolysis (60 sec) is evidence of a fast desorption rate and diffusion of Pb<sup>2+</sup> species out of the mesoporous silica to reach the conducting substrate, owing to the suitable surface chemistry (e.g., hydrophilicity) and pore geometry of SAMMS. The voltammetric responses for 1 ppm Pb<sup>2+</sup> increased linearly with the preconcentration time from 1 to 30 min. Fig. 8 shows that the responses also increased linearly with Pb<sup>2+</sup> concentrations ranging from 250 to 5000 ppb after 5 min of preconcentration and from 25 to 100 ppb after 30 min of preconcentration (parameters are reported in Table 1). The large dynamic range for lead ion sensing is a result of the functionalized mesoporous thin film having a high binding site density due to the high surface area of mesoporous silica. This solves a potential drawback of AdSV based on conventional chemically modified thin-film electrodes that the total number of binding sites in the thin films is limited, leading to a narrow linear range of the calibration (preconcentration time and concentration)

**Fig. 8** The calibration curve for Pb<sup>2+</sup>, measured after a 5-min preconcentration period, with inset (A) showing the representative voltammograms of Pb<sup>2+</sup> concentrations (in ascending order) of 0, 500, 2000, 3500, and 5000 ppb Pb<sup>2+</sup>, and inset (B) showing the low-concentration-range calibration curve measured after a 30-min preconcentration period. All experiments were performed with a 60-sec electrolysis period and 0.1 M HNO<sub>3</sub> as electrolysis/stripping media. Source: From Ref.<sup>[4]</sup>.

curves. In addition, high binding site density in FMS thin film is extremely important for miniaturized sensors because it provides sufficient sensitivity at the electrodes of limited size.

Similar to the powdered-SAMMS-modified carbon paste electrodes, the SH-FMS thin-film-modified gold microelectrode has many appealing aspects: it has excellent stability (i.e., data were collected for several weeks using the same electrode) because the ligands are immobilized via covalent bonding onto silica substrates, it has low maintenance requirements (no activation and regeneration were required during this testing). The advantages of SH-FMS thin-film-modified microelectrode array over powdered SAMMS-modified carbon paste electrodes are that the SH-FMS electrode arrays are easier to be mass-produced with highly reproducible surface properties and low costs as well as easier to be incorporated into portable sensing devices. Manipulating the pore structure and pore orientation as well as the thickness of the silica film to improve the detection limits of metal ions and reduce the detection time will require further investigation.

## CONCLUSION

Nanostructured self-assembled monolayers on mesoporous supports (SAMMS) materials reported here are highly effective as electrode modifiers in the forms

of powder and thin film. The interfacial chemistry of SAMMS can be fine-tuned to selectively sequester a specific target metal ion. The functional groups in SAMMS materials allowed the preconcentration of metal ions to be accomplished without the aid of mercury, adding supporting electrolytes, or applying an electrodeposition potential. The high loading capacity and high selectivity of SAMMS materials are desirable for metal ion detection based on the AdSV technique because they minimize the competition for the binding sites of the nontarget species, thereby reducing the interferences and preserving the signal intensity of the target metal ions. The covalent bonding between the functional groups and the surface of silica prevents sensors from degradation over time due to the depletion of ligand-bearing materials. The reversible binding between metal ions and ligands on SAMMS enables many successive uses of SAMMS-based electrodes with virtually no requirements for surface regeneration and renewal.

Our future work will be focused on using other class of SAMMS materials to construct electrochemical sensors for other ion detection needs. For example, SAMMS that is synthesized from installation of copper(II) ethylenediamine (Cu-EDA) on silica pore walls will be investigated for the detection of chromate and pertechnetate ions. Interfacial chemistry and electrochemistry of metal species on surfaces of SAMMS-based electrodes will also be studied: this fundamental knowledge is required for predicting how the sensors will perform in real wastes that consist of many interferences and ligands at a broad spectrum of pH levels. The best electrodes for each specific waste constituent will be integrated onto our patented portable microfluidic/electrochemical sensor systems<sup>[54]</sup> specifically designed for field-deployed detections.

## ACKNOWLEDGMENTS

This work was supported by the SERDP Program, U.S. Department of Defense; DOE-EMSP program, and NIH/NIEHS R01 (#1 R01 ES010976-01A2). Pacific Northwest National Laboratory (PNNL) is operated by Battelle Memorial Institute for the U.S. Department of Energy (DOE). The research was performed in part at the Environmental Molecular Sciences Laboratory (EMSL), a national scientific user facility sponsored by the DOE's Office of Biological and Environmental Research and located at PNNL.

The authors thank Dr. Mychailo Toloczko for reviewing this manuscript.

## INTRODUCTION

Medical abnormalities from exposure to toxic chemicals constitute a critical public health problem in our modern world. The use of toxic chemicals in agriculture, heavy industry, and other human endeavors throughout the past century has led to widespread pollution of our environment with potential disease-causing substances.<sup>[1]</sup> New drugs also have important toxicity issues. Twenty years ago, Singer and Grunberger<sup>[2]</sup> estimated that 65,000 chemicals were commonly used in modern society, and over 200,000 new chemicals were discovered each year. Since that time, advances in automated methods of chemical synthesis including combinatorial techniques<sup>[3]</sup> have led to an explosion into the millions of new chemicals produced each year for end-use applications including drugs, agriculture, personal care, and nutrition. While only a fraction of these new compounds will turn out to be acutely toxic, those that do may have long-term possibilities of causing cancer and reproductive damage.

A major mechanism of chemical toxicity involves activation of chemicals by catalytic oxidation mediated by cytochrome P450 (cyt P450) enzymes in the liver.<sup>[4–6]</sup> Lipophilic molecules bioactivated in this way often damage genetic material (i.e., DNA). They include styrene, benzo[a]pyrene, naphthylamines, and many others.<sup>[7–11]</sup> Covalent DNA adducts of these activated molecules with DNA bases are important biomarkers of cancer risk in humans exposed to toxic molecules.<sup>[12–14]</sup>

Conventional toxicity evaluation of new chemicals proceeds from microbiological testing to animal testing and is expensive and time consuming. While advances in speed and automation of microbiological test are on the horizon, simple, inexpensive chemical screening protocols that could be used at early stages of commercial consideration would be very useful. One such scheme could be based on enzyme bioactivation of the chemicals with detection of DNA damage from the resulting metabolites. Sensors built on this principle could be used to screen chemicals and metabolites that clearly damage DNA. These compounds could

then be eliminated from further commercial consideration and testing. Such a screening process could decrease the cost of bringing new drugs and agricultural chemicals to the marketplace by eliminating toxic candidates early in their commercial development and lightening the burden on toxicity bioassays. Of course, new commercially viable chemicals would still need to be subjected to microbiological and animal testing before final marketing.

## OVERVIEW

Nanoscience can be harnessed to make sensors featuring active metabolic enzymes and double-stranded DNA in films of nanometer-scale thickness<sup>[15]</sup> for toxicity screening. Early in the quest for such toxicity sensors, we evaluated a number of film formation strategies. (For an overview, see Ref.<sup>[16]</sup>.) We found that the excellent films for these applications could be made by a layer-by-layer construction method developed over the past decade.<sup>[17–20]</sup> The films are assembled by electrostatic adsorption of alternately charged layers of macromolecular ions and provide films with good stability, excellent enzyme activity, and control of thickness and architecture on the nanometer scale. Film construction relies on a series of steps in which the oppositely charged macromolecules (e.g., DNA, enzymes, and polyions) are adsorbed alternately from solutions onto an electrode. Iron heme enzymes in these films, such as cyt P450s, are easily activated for catalysis by addition of hydrogen peroxide along with substrate to a reaction solution.<sup>[15]</sup> The resulting DNA damage can be monitored by a variety of electroanalytical methods and by electrochemiluminescence, as will be seen below.

## CONSTRUCTING ENZYME–DNA FILMS

Preparation of enzyme–DNA films one layer at a time provides excellent control over the thickness of films designed to the specifications of the builder. Films containing two layers each of enzyme and DNA that

are 20–40 nm thick are easily made. Alternate adsorption of layers of biomolecules and polyions is a general method that has been developed over the past decade by Lvov et al.<sup>[17–20]</sup> The technique has been used to make ultrathin films of a wide variety of proteins and oppositely charged polyions including DNA. Some polyions that have been used to make such films are shown below.

SiO<sub>2</sub> Clay

A DNA/enzyme film grown on a rough pyrolytic graphite electrode is illustrated in Fig. 1. The pyrolytic graphite has a negative charge by virtue of oxygenic functional groups on its surface, and oxidizing the surface can enhance this negative charge. The films are made as follows. First, the negatively charged electrode is immersed into a 2 mg mL<sup>-1</sup> solution of positively charged PDDA. The polycations adsorb at roughly monolayer coverage in about 15–20 min,<sup>[18–20]</sup> effectively reversing the charge on the solid surface.

**Fig. 1** Conceptual representation of DNA/enzyme films used for toxicity sensing.

The electrode is rinsed with water, then immersed in a 2 mg mL<sup>-1</sup> solution of double-stranded (ds) DNA, and now the surface develops a negative charge. This surface is rinsed again, then immersed into a solution of enzyme (1–3 mg mL<sup>-1</sup>) in a buffer of pH lower than the enzyme's isoelectric point to assure a positive charge. An enzyme layer adsorbs, and the surface becomes positive. The latter two adsorption steps can be repeated as many times as desired to obtain a film of reproducible alternating layers of enzyme and DNA in a multilayer assembly. In practice, protein does not even have to be positively charged because charge patches on protein surfaces often enable good binding to oppositely charged polyions.<sup>[21]</sup> While there is extensive intermixing of neighboring layers,<sup>[17–20]</sup> this does not adversely affect the performance of most devices.

In the initial stages of developing new films, it is important to monitor layer growth during or after each adsorption step with quartz crystal microbalance (QCM) weighing, surface plasmon resonance (SPR), spectroscopy, or voltammetry. Fig. 2 illustrates QCM monitoring during the construction of DNA/enzyme films on gold-quartz resonators. The frequency of the QCM resonator decreases in direct proportion to the

**Fig. 2** Quartz crystal microbalance frequency shifts for cycles of alternate myoglobin/ds-DNA and cytochrome P450<sub>cam</sub>/ds-DNA adsorption on gold resonators coated with mixed monolayers of mercaptoproionic acid/mercaptopropanol as first layer and PDDA as second layer. DNA was from salmon testes (ST) and calf thymus (CT). Average values are shown for five replicates of [Mb/ST ds-DNA] (○) and four replicates of [cyt P450<sub>cam</sub>/ST ds-DNA] (●) films. Source: From Ref.<sup>[15]</sup> with permission. © American Chemical Society.

mass on its gold coating, provided the viscoelasticity of the interface does not change.<sup>[22]</sup> Estimates of the weight of each layer and of the repeatability of the multiple adsorption steps can be obtained from QCM of dry films. Drying minimizes bias from interfacial viscoelasticity changes and absorbed water. For 9-MHz quartz resonators, mass per unit area  $M/A$  ( $\text{g cm}^{-2}$ ) of the film is related to the QCM frequency shift  $\Delta F$  (Hz) by:

$$M/A = -\Delta F / (1.83 \times 10^8) \quad (1)$$

where the area is that of the metal disk on the resonator in  $\text{cm}^2$ . Direct scaling between  $\Delta F$  and nominal film thickness ( $d$ ) is given by:<sup>[18–20]</sup>

$$d(\text{nm}) \approx -(0.016 \pm 0.002)\Delta F \text{ (Hz)} \quad (2)$$

To mimic the PG electrode surface for QCM measurements of layers adsorbed on the gold-quartz resonators, we first chemisorb a mixed monolayer of mercaptopropionic acid/mercaptopropanol. This layer is represented by the first point in Fig. 2, labeled MPA. The second layer is PDDA. Quartz crystal microbalance frequency decreasing in a roughly linear fashion and at regular intervals for the multiple adsorption steps demonstrates repeatable adsorption for the two DNA/enzyme films. Relative precision of layer formation on multiple resonators within  $\pm 15\%$  can be achieved. Film thicknesses and component weights in Table 1 were obtained by analyzing the QCM data with Eqs. (1) and (2).

## ELECTROANALYTICAL METHODS FOR DETECTING DNA DAMAGE

### Electrochemistry of DNA

Fundamental studies of the electrochemistry of DNA have shown that single-stranded (ss) DNA is more easily oxidized at guanine and adenine base sites than double-stranded (ds) DNA.<sup>[23–25]</sup> The double helical ds-DNA structure does not allow ready access of the bases to the electrode or to catalytic oxidizing agents. However, unwinding of the double helix frees the bases for closer access by oxidants, leading to faster reaction rates. Voltammetry has been applied to detecting

DNA damage from strong acids,<sup>[26]</sup> strand cleavage agents,<sup>[27]</sup> and hydroxyl radicals<sup>[28]</sup> after adsorbing the DNA onto mercury electrodes. In a similar experimental approach, damage to DNA from ionizing radiation and detected by linear sweep voltammetry<sup>[29]</sup> and alkylation was monitored by a.c. voltammetry.<sup>[30]</sup> In these methods, the DNA in solution was damaged and then accumulated on the electrodes by adsorption prior to analysis. Guanine and adenine bases in ss-DNA can also be oxidized on *solid* electrodes,<sup>[31]</sup> such as glassy carbon and pyrolytic graphite. Damage from ionizing radiation to DNA adsorbed onto carbon electrodes was detected by chronopotentiometry.<sup>[32]</sup>

Guanine, with a formal potential at pH 7 of  $\sim 1.3$  V vs. normal hydrogen electrode (NHE) (1.06 V vs. saturated calomel electrode (SCE)), is the most easily oxidized of the four DNA bases.<sup>[33]</sup> The other bases have formal potentials up to 0.5 V more positive. Detecting nucleic acids by electrochemical oxidation depends on structure, with double-stranded (ds) DNA giving only trace oxidation peaks at best and single-stranded (ss) DNA giving irreversible oxidation peaks at about 1.0–1.2 V vs. SCE on carbon electrodes.

Enhanced electrochemical signals for DNA can be obtained by catalytic electrochemical oxidation using transition metal complexes.<sup>[34]</sup> Studies by Thorp et al.<sup>[35–40]</sup> showed that  $\text{Ru}(\text{bpy})_3^{2+}$  (bpy = 2,2'-bipyridine) is an efficient electrochemical catalyst that oxidizes only guanine bases in DNA and oligonucleotides. The reaction follows the catalytic pathway below:

$\text{DNA}(\text{guanine}_{\text{ox}})$  represents a guanine radical site<sup>[41,42]</sup> on DNA.  $\text{Ru}(\text{bpy})_3^{3+}$  formed by oxidation at the electrode is cycled back to  $\text{Ru}(\text{bpy})_3^{2+}$  by the fast chemical step in Eq. (4), which provides greatly enhanced voltammetric current over that of  $\text{Ru}(\text{bpy})_3^{2+}$  or DNA alone. The peak current depends on the rate of the chemical step in Eq. (4). In oversimplified terms, the faster the rate of the chemical step, the larger the peak. Guanine accessibility is important in these catalytic

**Table 1** Average characteristics of protein/DNA films from QCM results

Film	Total thickness (nm)	wt. DNA ( $\mu\text{g cm}^{-2}$ )	wt. Protein ( $\mu\text{g cm}^{-2}$ )
DNA(Mb/CT-ds-DNA) <sub>2</sub>	20	3.1	3.6
DNA(Mb/ST-ds-DNA) <sub>2</sub>	30	5.8	4.9
DNA(Cyt P450 <sub>cam</sub> /ST-ds-DNA) <sub>2</sub>	40	15	2.9

oxidations as in direct electrochemical oxidation; that is, guanine in ss-DNA reacts much more rapidly than in ds-DNA. In addition, the reaction rate at a given guanine site is dependent on the sequence of neighboring bases in the DNA.

### Electrochemical Methods for Toxicity Sensing

Against the backdrop of the electrochemical research on DNA summarized above, we set out to develop methods to detect chemical DNA damage as the basis for toxicity screening. Our first attempts involved derivative square wave voltammetric (SWV) analysis of films of double-stranded (ds) DNA and ionomers Eastman AQ38S or Nafion.<sup>[43,44]</sup> Square wave voltammetric analysis was used because of its inherent high sensitivity and resolution. DNA-ionomer films were incubated with styrene oxide, which reacts with guanine bases and disrupts the DNA double helix.<sup>[7,8]</sup> Damage to DNA in these films resulted in multiple oxidation peaks that developed during the reaction. This damage was confirmed by capillary electrophoresis detection of DNA base adducts in hydrolyzed DNA reacted with styrene oxide under these same conditions. Total integrals of the derivative SWV oxidation peaks increased with time of incubation with styrene oxide.

Unfortunately, direct electrochemical detection of DNA damage in films suffered from poor signal to noise ratios and data analysis that required derivative or other background corrections. Thus we explored catalytic methods of DNA oxidation (cf. Eqs. (3) and (4)) to improve signal to noise in SWV detection.<sup>[45]</sup> At the same time, we began to realize that layer-by-layer growth of films had clear advantages in versatility, stability, and thickness control and so was used to make films of DNA and the polycation PDDA. The best sensitivity was found with ds-DNA as the outer layer of the film and at low salt concentration. Quartz crystal microbalance of (PDDA/ds-DNA)<sub>2</sub> on gold resonators showed that the average thickness was 6 nm and that each film contained 0.23 μg of ds-DNA. [The (PDDA/ds-DNA)<sub>2</sub> terminology represents two bilayers of PDDA/DNA.]

(PDDA/ds-DNA)<sub>2</sub> films on oxidized PG electrodes were reacted with styrene oxide, then the electrodes were washed and transferred into pH 5.5 buffer containing 50 μM Ru(bpy)<sub>3</sub><sup>2+</sup> as the catalyst. The SWV oxidation peaks increased with incubation time with saturated styrene oxide (Fig. 3). Control (PDDA/ds-DNA)<sub>2</sub> electrodes incubated in buffer or saturated toluene showed much smaller peaks characteristic of intact ds-DNA layers in the films. Average peak current for catalytic SWV oxidation of the ds-DNA films increased with incubation time for 30 min, then

**Fig. 3** Square wave voltammetric of (PDDA/ds-DNA)<sub>2</sub> films on oxidized PG electrodes in pH 5.5 acetate buffer containing 50 mM NaCl, with 50 μM Ru(bpy)<sub>3</sub><sup>2+</sup> in buffer and after incubations at 37°C with saturated styrene oxide (SO) or unreactive toluene. *Source:* From Ref.<sup>[45]</sup> with permission. © American Chemical Society.

decreased slightly (Fig. 4). Each point represents a single electrode, and error bars reflect electrode-to-electrode variability. Incubation of films with toluene, for which no chemical reactions with DNA have been reported, gave catalytic oxidation peaks that showed no trends with reaction time. Catalytic SWV oxidation with Ru(bpy)<sub>3</sub><sup>2+</sup> provided more sensitive

**Fig. 4** The influence of incubation time with saturated styrene oxide and toluene in pH 5.5 buffer on the average catalytic peak current (less current for controls) for 5 to 15 trials per data point for (PDDA/ds-DNA)<sub>2</sub> films. Error bars represent standard deviations. *Source:* From Ref.<sup>[45]</sup> with permission. © American Chemical Society.

detection of DNA damage than direct SWV oxidation. Studies of DNA and polynucleotides in solutions and films suggested that oxidation of guanine and chemically damaged adenine in partly unraveled damaged DNA were the most likely contributors to the catalytic peaks.<sup>[45]</sup>

Another method to monitor DNA damage in films employed a cationic electroactive probe that binds better to ds-DNA than to damaged DNA.  $\text{Co}(\text{bpy})_3^{3+}$  was used to probe films of  $(\text{PDDA}/\text{ds-DNA})_2$  grown layer-by-layer on PG electrodes first coated with a layer of PSS.<sup>[46]</sup> After incubation of  $(\text{PDDA}/\text{ds-DNA})_2$  films with styrene oxide, electrodes were rinsed, placed into  $20\ \mu\text{M}$   $\text{Co}(\text{bpy})_3^{3+}$ , and the  $\text{Co}^{\text{III}}/\text{Co}^{\text{II}}$  reduction peak at  $0.04\ \text{V}$  vs. SCE from the DNA-bound complex was monitored by SWV. Peak current decreased with increasing time of reaction with styrene oxide because of the decreasing ability of the damaged outer layer of DNA to bind  $\text{Co}(\text{bpy})_3^{3+}$ . A single electrode can be used to measure the incubation time course. Denoting the initial SWV peak current as  $I_{\text{p,initial}}$  and the peak current after incubation as  $I_{\text{p,final}}$ , plots of the peak current ratio  $I_{\text{p,initial}}/I_{\text{p,final}}$  vs. incubation time (Fig. 5) were used to monitor DNA damage rates. This ratio helps correct for electrode-to-electrode variations.  $I_{\text{p,initial}}/I_{\text{p,final}}$  increased for ds-DNA electrodes with increasing incubation time with styrene oxide solutions. No significant variations were found for controls with or without toluene.

**Fig. 5** Influence of incubation time on average SWV peak current ratios for  $(\text{PDDA}/\text{ds-DNA})_2$  films in  $20\ \mu\text{M}$   $\text{Co}(\text{bpy})_3^{3+}$  at pH 5.5 after incubations with styrene oxide, toluene, or pure buffer.  $I_{\text{p,final}}$  corresponds to the peak current after each incubation;  $I_{\text{p,initial}}$  corresponds to peak current before incubation. Building films a layer at a time allowed us to incorporate catalytic metallopolyion catalysts for DNA oxidation into “reagentless” toxicity biosensors. Two polyions containing  $\text{Ru}(\text{bpy})_2^{2+}$  were used that are capable of catalytically oxidizing guanines in DNA. The one shown below, denoted Ru-PVP, has 6 Ru-N bonds and reversible oxidation at  $1.15\ \text{V}$  vs. SCE.

**Structure of catalytic metallopolymer  $[\text{Ru}(\text{bpy})_2(\text{PVP})_{10}](\text{ClO}_4)_2$**

A related polymer denoted RuCl-PVP has 5 Ru-N bonds with chloride as the sixth Ru ligand. It is reversibly oxidized at  $0.75\ \text{V}$  vs. SCE<sup>[47–49]</sup> and provided clearer peaks on a flatter background for the catalytic reaction at this lower voltage without sacrificing very much sensitivity. Use of this catalytic polymer is illustrated in Fig. 6A, showing an increase in catalytic SWV peaks of RuCl-PVP in PSS/RuCl-PVP/DNA/PDDA/DNA films after incubation with styrene oxide.

PSS/RuCl-PVP/DNA/PDDA/DNA films were also incubated with methylating agents dimethyl sulfate (DMS), a confirmed human carcinogen, and suspected carcinogen methyl methanesulfonate (MMS).<sup>[50]</sup> Films incubated with DMS or MMS gave increases in the peak current that suggested DNA damage. Fig. 6B shows changes with reaction time in the ratio of final SWV peak current of the films to the initial peak current for the PSS/RuCl-PVP layers alone. The increase in the ratio is a result of DNA unwinding caused by nucleobases that have been methylated by MMS and DMS.<sup>[51,52]</sup> Damage to DNA under these conditions was confirmed by capillary electrophoresis detection of methylated guanines and adenines in hydrolyzed DNA that had been reacted with MMS or DMS.

Ru-PVP, the more powerful oxidizing agent, was used to develop a new method of DNA detection, direct electrochemiluminescence (ECL). A SWV waveform oxidized the  $\text{Ru}^{\text{II}}$  sites in the metallopolymer to  $\text{Ru}^{\text{III}}$ . Electrochemiluminescence was measured simultaneously with catalytic SWV peaks in a simple apparatus employing an optical fiber to conduct light from the electrode to a photomultiplier detector. The

**Fig. 6** Examples of data obtained with catalytic RuCl-PVP layer in films: (A) SWV of PSS/RuCl-PVP/DNA/PDDA/DNA films after incubations at 37°C and pH 5.5 with saturated styrene oxide (SO) for 5, 10, 20, and 30 min, respectively. Incubations in toluene gave no changes in peak current. (B) Influence of reaction time (37°C, pH 6.5) of PSS/RuCl-PVP/DNA/PDDA/DNA films incubated in 2 mM dimethyl sulfate (●), 2 mM methyl methanesulfonate (○), and buffer control (△) on ratio of final SWV peak current to initial peak current of PSS/RuCl-PVP. *Source:* From Ref.<sup>[49]</sup> with permission. © American Chemical Society.

principle is illustrated in Fig. 7, showing the alternating layers of ds-DNA and the ruthenium metallopolymer  $[\text{Ru}(\text{bpy})_2(\text{PVP})_{10}]^{2+}$  used in the film. Direct electrochemiluminescence (ECL) involving DNA oxidation was observed in 10-nm films of Ru-PVP assembled layer-by-layer with DNA.<sup>[53]</sup> The electrode oxidized the  $\text{Ru}^{\text{II}}$  sites in the metallopolymer to  $\text{Ru}^{\text{III}}$  sites that reacted with guanines in the DNA. Electrochemiluminescence was measured simultaneously with catalytic voltammetric peaks at about 1.15 V vs. SCE (Fig. 8). Electrochemiluminescence was observed only when guanines were present on oligonucleotides in the films.

**Fig. 7** Conceptual cartoon of film of ds-DNA and the catalytic metallopolymer  $[\text{Ru}(\text{bpy})_2(\text{PVP})_{10}](\text{ClO}_4)_2$  designed for simultaneous electrochemiluminescent (610 nm) and voltammetric detection of DNA. *Source:* From Ref.<sup>[53]</sup> with permission. © American Chemical Society.

This result along with previously proposed ECL pathways suggests that guanine radicals initially formed by catalytic oxidation of guanines by  $\text{Ru}^{\text{III}}$  react with the metallopolymer to produce electronically excited  $\text{Ru}^{\text{II}*}$  in the film.  $\text{Ru}^{\text{II}*}$  spontaneously emits light at 610 nm and decays to ground-state  $\text{Ru}^{\text{II}}$ . Simultaneous linear

**Fig. 8** Simultaneous SWV (downward curves) and ECL (upward curves) responses for  $(\text{Ru-PVP/ds-CT DNA})_2$  films on PG electrodes in pH 5.5 buffer after incubations at 37°C with saturated styrene oxide. Curve labels are incubation times in min. *Source:* From Ref.<sup>[53]</sup> with permission. © American Chemical Society.

growth of ECL and SWV peaks occurred after incubation with styrene oxide over 20 min. The estimated detection limit was 1 damaged DNA base in 1000, or 0.1% damage. Control incubations of metallopolymer/ds-DNA films in buffer containing unreactive toluene resulted in no significant trends in ECL or SWV peaks with time.

### COMBINING BIOACTIVATION WITH DNA DETECTION

A practical approach for toxicity screening combines bioactivation and DNA damage detection into a single biosensor for toxicity screening. To make these types of sensors, ultrathin films (20–40 nm thick) containing myoglobin or cytochrome P450<sub>cam</sub> and DNA were grown layer-by-layer on electrodes. [Film composition is denoted by listing the components in their order of assembly, e.g., PDDA/ds-DNA/(enzyme/ds-DNA)<sub>2</sub>, where PDDA = polydiallyldimethylammonium ion.] Enzymes in the films were activated by hydrogen peroxide, generating test metabolite styrene oxide from styrene.<sup>[54]</sup> Styrene oxide formed in these nanometer-scale films reacted with double-stranded (ds) DNA in the same film, mimicking metabolism and DNA damage in the human liver. In the first demonstration of this concept, DNA damage was detected by SWV by using catalytic oxidation with dissolved Ru(bpy)<sub>3</sub><sup>2+</sup> or by monitoring the binding of Co(bpy)<sub>3</sub><sup>3+</sup> to the outer DNA layer in the film.<sup>[15]</sup> Later, we also detected DNA damage after enzyme-catalyzed bioactivation by using an inner RuCl-PVP layer in DNA/enzyme films.<sup>[49]</sup>

The SWV peak at 1.05 V vs. SCE for Ru(bpy)<sub>3</sub><sup>2+</sup> increased with time of the DNA damage reaction (Fig. 9). As in the case where enzyme-free films are incubated directly with DNA damage agents, ds-DNA in the film is damaged by styrene oxide. As a result of these reactions, guanines are released from the protection of the double helix, as are adducts of adenine.<sup>[45]</sup> These species are more easily oxidized than the original ds-DNA, and the catalytic oxidation current increases.

Control electrodes incubated in hydrogen peroxide without styrene showed catalytic oxidation peaks of similar heights to freshly prepared films (Fig. 9). Thus the low concentrations of hydrogen peroxide used had no measurable influence on ds-DNA. Only peaks for films that had been activated by hydrogen peroxide and styrene together increased with reaction time.

Similar results were obtained using cyt P450 as the enzyme. DNA/(Cyt P450<sub>cam</sub>/ST-ds-DNA)<sub>2</sub> films were incubated with styrene and hydrogen peroxide, and a rapid increase in SWV peak current in the first 5 min was followed by a slower increase from 5 to 30 min

**Fig. 9** Catalytic square wave voltammetry of PDDA/ds-DNA/(Mb/ds-DNA)<sub>2</sub> films on rough PG electrodes before and after incubations at 37°C with 2% styrene (no styrene in controls) and 0.2 mM H<sub>2</sub>O<sub>2</sub> in aerobic buffer (SWV amplitude: 25 mV; frequency: 15 Hz; step height: 4 mV; PDDA = polydiallyldimethylammonium ion). After incubation, electrodes were washed and placed into pH 5.5 buffer containing 50 μM Ru(bpy)<sub>3</sub><sup>2+</sup> for the SWV analysis. *Source:* From Ref.<sup>[15]</sup> with permission. © American Chemical Society.

(Fig. 10A). Capillary electrophoresis and HPLC-MS analyses of DNA in thin films that were reacted with styrene oxide, and then hydrolyzed, confirmed formation of known styrene oxide adducts of DNA bases under similar reaction conditions.

Average SWV peak currents for ds-DNA/Mb films also increased with incubation time with hydrogen peroxide and styrene at relatively larger rates for the first 5 min, then at smaller rates at longer times (Fig. 10B). Slightly larger initial rates of peak growth were found with Mb/ST ds-DNA films than with Mb/CT ds-DNA films (CT = calf thymus, ST = salmon testes). Error bars are mainly the result of film-to-film variability. No significant growth in peak current with reaction time was found for films incubated with toluene and hydrogen peroxide, styrene alone, benzaldehyde, or hydrogen peroxide alone (Fig. 10, controls).

In alternative assays, Co(bpy)<sub>3</sub><sup>3+</sup> was used as an electroactive probe. Co(bpy)<sub>3</sub><sup>3+</sup> reduction peaks at 0.04 V decreased as DNA was damaged by enzyme-generated styrene oxide. Little change in SWV signals was found for incubations of DNA/enzyme films with unreactive organic controls or hydrogen peroxide. The catalytic SWV method was more sensitive than the Co(bpy)<sub>3</sub><sup>3+</sup>

**Fig. 10** The influence of reaction time with 2% styrene + 0.2 mM  $\text{H}_2\text{O}_2$  on catalytic SWV peak in  $50 \mu\text{M Ru}(\text{bpy})_3^{2+}$ : (A) for PDDA/ds-ST-DNA/(cyt P450<sub>cam</sub>/ds-ST-DNA)<sub>2</sub> films (●) in  $50 \mu\text{M Ru}(\text{bpy})_3^{2+}$  solution. Control (○) is for incubation with 0.2 mM  $\text{H}_2\text{O}_2$ . (B) PDDA/ds-DNA/(Mb/ds-DNA)<sub>2</sub> films using CT-DNA (●) and ST-DNA (○) (5–15 trials per data point, CT = calf thymus, ST = salmon testes). Also shown are controls representing incubation of ST-DNA/Mb films with 2% styrene but no  $\text{H}_2\text{O}_2$  (□), 2% toluene + 0.2 mM  $\text{H}_2\text{O}_2$  (▼), and 0.2 mM benzaldehyde + 0.2 mM  $\text{H}_2\text{O}_2$  (△) (average peak current for unreacted DNA/enzyme electrodes was subtracted). binding assay, providing multiple measurements over a 5-min reaction time. However, the  $\text{Co}(\text{bpy})_3^{3+}$  binding assay may be more useful in the presence of potential interferences because of its low measurement voltage where few electroactive species are reduced or oxidized.

## CONCLUSION

This entry described how adsorption of layers or biomolecules and polyions onto electrodes can provide films of nanometer-scale thickness on electrodes for screening the toxicity of chemicals and their metabolites. Such films containing DNA and enzymes enable detection of structural damage to DNA as a basis for the toxicity screening. The most sophisticated versions of these sensors bioactivate chemicals to their metabolites, which may react with DNA. The approach mimics toxicity pathways in the human liver. DNA damage can presently be detected at levels of about 0.1% to 0.5% by methods including catalytic square wave voltammetry using soluble or polymeric catalysts, electrochemically active DNA binding probes, or electrochemiluminescence using a special metallo-polymer. Catalytic polyions can be incorporated into DNA/enzyme films leading to “reagentless” sensors for chemical toxicity. These sensors are suitable for detection of relative DNA damage rates in 5–10 min.

We expect good future progress in applications of enzyme/DNA films to toxicity biosensors. The analytical approaches discussed above may also be adaptable to monitoring DNA oxidation, which has been suggested as a clinical marker for oxidative stress.<sup>[55]</sup> Electrode arrays could be developed to provide many

tests simultaneously. Future sensor arrays could be configured to detect toxicity of metabolites generated by a range of human cyt P450s.

## Abstract

Transmission electron microscopy (TEM) is one of the most frequently used tools for the characterization of nanomaterials. Aberration-correction has revolutionized the field of electron microscopy and now equipment is commercially available providing sub-Ångström resolution and single atom sensitivity for atomic, electronic, and chemical structure analyses. In this entry, aberration-corrected scanning transmission electron microscopy and related techniques are reviewed in the framework of nanomaterials sciences. Three examples from the areas of catalysis, hydrogen storage, and nanoscale thin films, are used to demonstrate experimental capabilities and current resolution limits.

## INTRODUCTION

The characterization of structure and electronic properties of materials is a key issue in modern nanotechnology. Electron microscopy techniques, especially transmission electron microscopy (TEM), are probably the most important tools for the investigation of nanomaterials since many properties can be directly accessed with very high spatial resolution.<sup>[1,2]</sup> The Royal Swedish Academy of Sciences named the electron microscope as “*one of the most important inventions*” of the 20th century.<sup>[3]</sup> Ever since the invention of the electron microscope in 1932,<sup>[4]</sup> technical advances have brought higher and higher resolution limits all the way to the ultimate limit for materials sciences: the imaging and identification of a single isolated atom. This development in increasing the spatial resolution for materials sciences is illustrated in Fig. 1. Already in 1936, it was recognized by Scherzer that lens aberrations occur in electron optical round lenses as a result of physics rather than purely due to imperfections,<sup>[5]</sup> hence limiting the achievable resolution orders of magnitude apart from the electron’s wavelength. In his famous lecture entitled “*There’s Plenty of Room at the Bottom*,” Feynman directly addressed the development of electron microscopes by asking “*Is there no way to make the electron microscope more powerful?*”<sup>[6]</sup> He suggested to break axial symmetries to overcome spherical aberrations and, thus, improve the resolution limits so that one could “*see individual atoms distinctly*.” Even though first designs of aberration-correctors already existed,<sup>[7]</sup> it was not until the advance of fast computers that aberration-correction became suitable for the electron microscope.

Tuning and focusing correction elements for electron optics requires the alignment of many multipole lenses with accuracies of the order of  $10^{-7}$ , resulting in a parameter space with more than 40 dimensions.

Today, aberration-correction is successfully applied to both TEM and scanning transmission electron microscopy (STEM), and enables the discrimination of two objects separated by less than 1 Å with both techniques. In addition, the high spatial resolution can be combined with spectroscopy techniques to determine local chemical compositions and electronic structures. Therefore, TEM and STEM are invaluable tools for modern nanomaterials research and provide structural and chemical information with unprecedented detail and sensitivity.

In the following, basic concepts of TEM and different techniques for nanocharacterization will be reviewed. Emphasis will be laid on aberration-correction in STEM. Afterwards, different examples from nanomaterials research will be reviewed, which could only be obtained through the application of aberration-corrected STEM. Finally, an outlook to future developments in TEM/STEM in connection to nanomaterials sciences and technology will be offered.

## Transmission Electron Microscopy

The main focus of this entry lies on scanning transmission electron microscopy, in which a fine electron probe is scanned across the sample and signals provided by transmitted electrons are collected serially as a function of position on the sample. In contrast to STEM, conventional TEM uses a parallel illumination

**Fig. 1** The evolution of spatial resolution in microscopy since the early 1800s. Squares represent light microscopy, circles TEM, triangles STEM. Solid symbols refer to results obtained before aberration-correction, while open symbols denote studies after correction. Red, green, and blue lines, respectively, have been added to show overall trends. *Source:* Figure created from Ref.<sup>[8]</sup>.

of the electron transparent specimens. For the coherent electron beam conditions in TEM, contrast is mainly achieved through the use of apertures in the back focal plane of the objective lens to select or interfere diffracted beams, referred to respectively as diffraction contrast or phase contrast imaging.<sup>[1]</sup> Figure 2 shows

a sketch of the electron ray diagrams for STEM and TEM operation modes and compares the essential optical elements in both instruments for one picture element, i.e. image pixel. As can be inferred from Fig. 2, the bright field STEM and TEM ray diagrams are equivalent when read in opposite directions of electron propagation.<sup>[1]</sup> This equivalence is often referred to as the theory of reciprocity, which was formulated for light optics by Stokes, Lorentz, Helmholtz, and others in the 19<sup>th</sup> century.<sup>[9]</sup> The principle of reciprocity in the context of electron wave optics is based on time-reversal symmetry of the electron propagation process. The STEM collector aperture  $\beta_{\text{STEM}}$  is, therefore, equivalent to the TEM condenser aperture  $\alpha_{\text{TEM}}$  while the objective aperture  $\alpha_{\text{STEM}} = \beta_{\text{TEM}}$  remains the same. For clarification, apertures passed by the electron beam before interaction with the sample are denoted with angles  $\alpha$ , while post-specimen apertures are called  $\beta$ . Note, however, in a combined TEM/STEM instrument the STEM objective (i.e. probe-forming) aperture is usually the same aperture used as condenser aperture in the TEM mode. The difference in the two operating conditions is that in STEM, the image pixels are recorded serially while in TEM they are all acquired at once. It is important to recognize that when identical apertures  $\alpha_{\text{STEM}} = \beta_{\text{TEM}}$  and  $\beta_{\text{STEM}} = \alpha_{\text{TEM}}$  are used, and provided that  $\beta_{\text{STEM}}$  is coherently and  $\beta_{\text{TEM}}$  is incoherently illuminated, the principle of reciprocity results in identical image contrast for bright field STEM and TEM.<sup>[1]</sup>

In an STEM instrument, electrons are accelerated from a source and focused into a small probe onto the specimen by a set of condenser lenses and an objective lens. The objective aperture limits the maximum angle under which electrons contribute to the electron probe, which is scanned across the sample by a set of scan coils.

**Fig. 2** Theorem of reciprocity between (A) STEM and (B) TEM in terms of electron ray diagrams connecting the intermediate source and image. *Source:* From Ref.<sup>[1]</sup>.

Images are formed by recording electrons transmitted by the specimen as a function of probe position. Electrons scattered into high-angles are recorded with an annular detector. The cross-section for electrons scattered into high angles over a large angular range is roughly proportional to the squared atomic number of the scattering element.<sup>[1]</sup> For large enough scattering angles, coherent effects between, e.g., atomic columns average out. Hence, the scattering process itself can be considered purely incoherent, which bypasses the phase problem that complicates interpretation of conventional high-resolution TEM using phase contrast imaging. High-angle annular dark field (HAADF) imaging is often referred to as *Z*-contrast imaging because of the atomic number dependence of the scattering cross-section. Consequently, the HAADF technique is most sensitive to heavy elements, and images provide a high degree of chemical information in addition to structural details.<sup>[10]</sup>

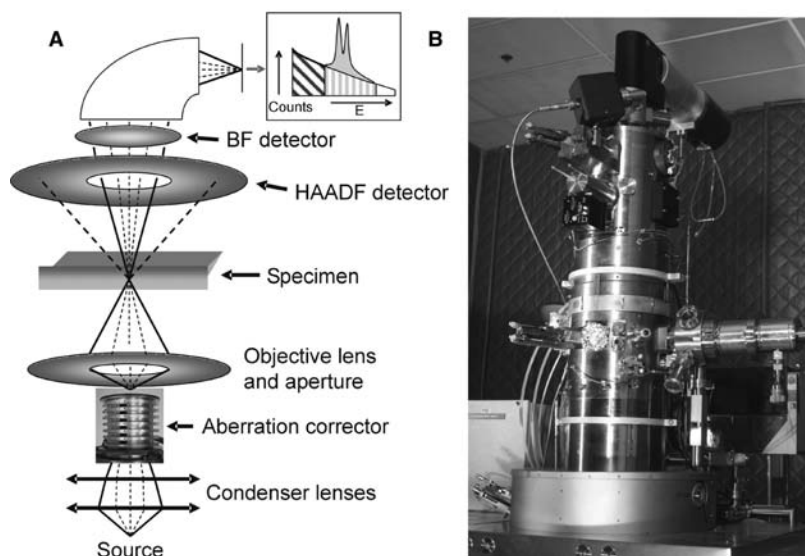

Those electrons scattered into small angles can be collected “*on-axis*” by a bright field detector, or they can be analyzed with respect to their kinetic energy to form electron energy-loss spectra to investigate inelastic scattering events. In addition, secondary electron detectors, energy-dispersive X-ray detectors, cathodoluminescence detectors, etc. can also be attached to the microscope. Consequently, STEM provides the simultaneous acquisition of multiple different image and spectroscopy signals while scanning the electron probe across the specimen or pointing it directly onto different defect structures, such as, for instance, point defects, grain boundaries, or heterophase interfaces.<sup>[10]</sup> Figure 3A shows a schematic drawing of the main components of a dedicated STEM instrument. As an example, Fig. 3B is a picture of the VG Microscopes HB603 U dedicated STEM operated at 300 keV accelerating voltage, which is located at Oak Ridge National Laboratory.

The spatial resolution of an STEM experiment is determined by the diameter of the electron probe. Therefore, the probe formation is the critical aspect determining interaction volumes inside the sample. To increase the spatial resolution, aberration-correctors have recently been developed to overcome limitations due to lens imperfections and aberrations. In the following section, some basics of the concepts for aberration-correction will be reviewed.

### Lens aberrations

Aberration-correction is most likely the most exciting recent development in electron optics and microscopy. Ideal lenses focus a point source to a single image point, as sketched in Fig. 4A. Scherzer, however, first recognized that every rotationally symmetric lens will always suffer from both spherical and chromatic aberrations.<sup>[5]</sup> Spherical aberrations cause electrons traveling at higher angles to the optical axis to be focused more strongly than those at smaller angles (cf. Fig. 4B). Chromatic aberrations describe the spread in focus of a lens dependent on the kinetic energy spread of the electron wave (Fig. 4B). Consequently, both types of lens aberrations lead to a blurring of the electron beam in the back focal plane and, hence, a degradation of the spatial resolution. The practical limit to the achievable spatial resolution in modern electron microscopes is determined by these lens aberrations and instrument instabilities to about 50 times the electron wavelength  $\lambda$ .

The aberration is an error in the optical path length between the actual wave front and the perfect sphere, and is commonly expressed as a Taylor expansion in angle  $\theta$ . When ignoring all non-rotationally symmetric

**Fig. 3** (A) Schematic drawing of the main components of an aberration-corrected scanning transmission electron microscope. The geometric setup allows simultaneous recording of different detector signals. (B) Picture of the Oak Ridge VG Microscopes HB603 U dedicated STEM.

**Fig. 4** Schematic drawing of main lens aberrations. (A) A perfect lens focuses a point source to a single image point. (B) Geometric aberrations such as the spherical aberration bring electron rays at different angles to different focus points. The chromatic aberration (C) focuses the electron beam at different positions as a function of energy blur. *Source:* Adapted and reprinted, with permission, from Ref.<sup>[10]</sup>.

aberrations, the aberration function  $X(\theta)$  becomes

$$X(\theta) = \frac{1}{2}\Delta f\theta^2 + \frac{1}{4}C_3\theta^4 + \frac{1}{6}C_5\theta^6 + \frac{1}{8}C_7\theta^8 + \dots, \quad (1)$$

where  $\Delta f$  is the defocus,  $C_3 = C_s$ ,  $C_5$ , and  $C_7$  are the coefficients of third-, fifth-, and seventh-order spherical aberrations, respectively. For round magnetic lenses, these coefficients are all positive and have dimensions of length. At first, the order of the aberration coefficients seems counter-intuitive to Eq. (1). However, geometric aberrations lead the electron rays at different angles towards the different focus points along the optical axis, causing a lateral displacement in the Gaussian focal plane. The lateral displacements are proportional to the gradient of the aberration function  $\text{grad}_\theta X(\theta)$ .<sup>[11]</sup> Therefore,  $C_s$  is often referred to as a third-order spherical aberration.

Similar notations as used in Eq. (1) can be used for non-round aberrations, such as astigmatism, by introducing the dependence on the azimuthal angle. The description of general lens imperfection to fifth order would need 25 aberration coefficients to be included in the expression of the aberration function.<sup>[12,13]</sup> Fortunately, most of these coefficients are small in round lenses and can be kept small by suitable lens designs and microscope column alignments.

### Aberration-correctors

In practice, every optical lens exhibits aberrations. The underlying principle used by aberration-correctors is to generate an identical but negative aberration coefficient, which cancels out with the one introduced by the actual lens itself. The fundamental strategy to achieve this has been laid out by Scherzer in 1947 when he proposed to break rotational symmetry to eliminate spherical and chromatic aberrations.<sup>[7]</sup> Consequently, non-round optical elements, so-called multipoles, have been used to facilitate aberration-correction for round lenses. At the time of writing, there are two main types

of aberration-correctors commercially available: the quadrupole–octupole corrector from Nion<sup>[12–14]</sup> and the round-lens-hexapole corrector from CEOS.<sup>[15,16]</sup> Both types of correctors consist of either octupoles or hexapoles as correction elements, and quadrupoles or round lenses as steering elements for the electron trajectories inside the corrector. The two different designs have certain advantages and disadvantages when compared with each other. A discussion of the two different strategies is well beyond the scope of this entry. However, it should be noted that the round-lens-hexapole design can not only be used for the probe-forming lenses in STEM, but also was initially introduced to the imaging optics of high-resolution TEM instruments to achieve sub-Ångström resolution.<sup>[17,18]</sup> In STEM, direct imaging of a crystal lattice with sub-Ångström resolution has been achieved initially with the quadrupole–octupole corrector design (see Fig. 5).<sup>[19,20]</sup> Similar results were reproduced shortly thereafter with the hexapole corrected STEM.<sup>[18]</sup>

### Effects of aberration-correction

The initial goal of all efforts to correct lens aberrations in electron microscopy was to increase the spatial resolution, i.e. to decrease the electron probe diameter in the case of STEM. That this goal has been achieved is demonstrated with today's sub-Ångström spatial resolution imaging conditions (see Figs. 1 and 5). However, in STEM aberration-correction provides two additional effects: single atom sensitivity<sup>[21]</sup> and drastically increased depth sensitivity.<sup>[20,22]</sup>

Figure 6 shows calculated electron probe profiles before and after aberration-correction. For both simulations, the number of electrons, i.e. the electron beam current, is conserved. It becomes immediately evident that not only the probe diameter becomes significantly smaller, but at the same time the intensity increases dramatically. In HAADF imaging, the signal scales with the square power of the reciprocal probe diameter, while the background scales with the square power of the diameter itself. Therefore, the strongly

**Fig. 5** HAADF image directly recorded from a silicon single crystal, which was oriented with its <112> direction parallel to the optical axis. Columns of Si atoms only 0.78 Å apart from each other were clearly resolved. The right panel shows a part of the Fourier transform of the same image revealing information transfer to 0.61 Å.<sup>[22]</sup> Source: Figure reproduced with permission from Ref.<sup>[19]</sup>.

increased beam current density after aberration-correction conveys higher sensitivity for annular dark field imaging, which enables single atom sensitivity in annular dark field images.<sup>[21]</sup>

The depth of field  $T$  in STEM can be expressed as the quotient of lateral spatial resolution  $\delta_s = 0.61 \cdot \lambda / \alpha$  and the probe-forming angle  $\alpha$ <sup>[11]</sup>

$$T = \frac{\delta_s}{\alpha} = 0.61 \frac{\lambda}{\alpha^2} \tag{2}$$

Equation (2) shows that the availability of larger illumination angles because aberration-correction decreases the depth of field much faster than it improves the lateral resolution. The major consequence of the smaller depth of field is that only very thin slices of the specimen come into focus at a time. Hence, a through-focal series acquisition of images can provide optical sectioning of the sample along the optical axis in a manner comparable to confocal optical microscopy.<sup>[22]</sup>

Such depth sectioning techniques have recently been established<sup>[20,23,24]</sup> and represent an additional avenue to tilt-series tomography<sup>[25,26]</sup> to deduce three-dimensional information from TEM samples.

The achievable three-dimensional spatial resolution, however, is highly anisotropic. As discussed above, aberration-corrected STEM has demonstrated sub-Ångström resolution in the lateral, i.e. in-plane directions. For the 300 keV VG HB603 U STEM at Oak Ridge, the depth of focus following Eq. (2) ranges around 3–4 nm.<sup>[22–24]</sup> Two atoms vertically displaced by the depth of focus  $T$  reveal total image intensity as shown in Fig. 7, which is, because of the incoherent nature of ADF imaging, a superposition of the contributions from each individual atom. Figure 7 demonstrates that in this case, the atoms cannot be discriminated using the depth-sectioning technique. For vertical distances equal to  $1.75T$ , the resulting image intensity plateaus, which is formally equivalent to a resolution criterion by Sparrow.<sup>[27,28]</sup> Both atoms can clearly be

**Fig. 6** Simulated images and intensity line profiles of the electron probe before and after aberration-correction. The number of electrons is identical in both cases. Source: Adapted with permission from Ref.<sup>[10]</sup>.

Dynamic –  
Electronic

**Fig. 7** Sketch of two isolated atoms vertically separated by  $1\times$ ,  $1.75\times$ , and  $2\times$  the depth of field  $T$ . At the position of each atom, a simulated vertical probe profile is plotted. The dotted line is a superposition of the two corresponding profiles and represents the resulting image intensity as a function of defocus. *Source:* Adapted from Ref.<sup>[24]</sup> with permission from Elsevier.

discriminated along the optical axis for vertical displacements of  $2T$ , for which the resulting image intensity reveals a contrast variation of about 20% between the atoms. Therefore, this condition has been chosen as a criterion for vertical resolution. It is equivalent to the lateral resolution criterion formulated by Lord Raleigh in that, in the absence of aberrations, one atom is placed at the first zero of the diffracted intensity of the other.<sup>[11,28,29]</sup>

Examples and applications of single atom sensitivity in STEM imaging and depth sectioning techniques, both of which are direct consequences of aberration-correction, will be discussed further.

## MICROSCOPY OF NANOMATERIALS

In the following sections, three applications of aberration-corrected STEM to functional nanomaterials, results obtained from activated carbon fibers, catalyst nanoparticles, and alternate gate dielectrics, will be reviewed.

### Activated Carbon Fibers for Hydrogen Storage

Nanostructured carbon materials, such as carbon fibers, are lightweight inexpensive materials, which exhibit hydrogen storage capabilities.<sup>[30–33]</sup> Physisorption of  $H_2$  on nanoporous carbon, although significant at cryogenic temperatures, is weak at room temperatures<sup>[30]</sup> and does not satisfy the current goals established by the US Department of Energy. However, on physical activation with  $CO_2$ <sup>[31]</sup> or doping with catalyst materials,<sup>[32]</sup> the hydrogen uptake can be enhanced when compared with unmodified carbons.

Recently, it was shown that significant enhancements of  $H_2$  adsorption can be achieved at room temperature and 20 bar for activated carbon fibers (ACF) modified with Pd catalyst particles.<sup>[33]</sup> To control such processes in greater detail, and to further enhance the hydrogen uptake capacity, it is necessary to understand the fundamental atomistic mechanisms of metal-assisted

hydrogen storage on nanostructured carbon fibers, and in particular, on how processing conditions affect the microstructure of Pd-doped activated carbon fibers.<sup>[34]</sup>

The following results were obtained from a sample processed at Clemson University.<sup>[35]</sup> An isotropic pitch precursor was mixed with about 1% Pd salt before melt-spinning. The traditional subsequent carbonization and activation processes were combined into a single-stage process of *direct carbonization and activation* in pure  $CO_2$ , and samples with various levels of burn-off were generated.<sup>[35]</sup> The particular material used for the results presented is characterized by a burn-off level of 40%. Further details of the materials processing and the effect on materials properties can be found in Refs.<sup>[34,35]</sup>. The hydrogen storage characteristics are not the subject of this entry and are reported elsewhere.<sup>[33]</sup> Details on the microscopy results reviewed in the following are the object of a separate publication.<sup>[36]</sup>

As described above, ADF images are very sensitive to heavy elements since the scattering cross-section is roughly proportional to the squared atomic number of the illuminated species. However, bright field (BF) images, which are very sensitive to light elements in the sample, can be recorded simultaneously (see Fig. 3). Aberration-correction in STEM leads to “slower” oscillations of the phase contrast transfer function so that larger BF detectors can be used.<sup>[37]</sup> This directly results into BF images with enhanced signal when compared with the uncorrected case, which, according to the theorem of reciprocity, are equivalent to phase-contrast images. The simultaneous acquisition of ADF and BF images with pixel-to-pixel correlation at very high resolution becomes a very powerful tool for the investigation of carbon microstructures in the presence of catalytic Pd particles.<sup>[36]</sup>

Figure 8 shows a pair of ADF and BF images, which were acquired with an aberration-corrected VG Microscopes HB603 U STEM operated at 300 keV. The microscope is equipped with a Nion third-order aberration-corrector (cf. Fig. 1). Bright spot-like contrasts in the ADF image represent small Pd clusters and, in many cases, even single isolated Pd atoms

**Fig. 8** Simultaneously acquired pair of ADF and BF images using the 300 keV aberration corrected dedicated STEM. The frames have pixel-to-pixel correlation, so that the location of single Pd atoms in the ADF images (encircled) can be superimposed on the BF image, which reveals the local carbon microstructure. *Source:* Image adapted from Ref.<sup>[36]</sup>.

distributed throughout the carbon microstructure. Through-focal series acquisition of ADF images was used to confirm that the observed bright regions are due to single Pd atoms.<sup>[37]</sup> Pd atoms became very mobile due to illumination with the electron beam and could in many cases not be imaged at the exact same location in a subsequently acquired frame but at a nearby position.

The simultaneously acquired BF image clearly reveals the carbon microstructure exhibiting graphene sheets in various different orientations. It is evident that the carbon fiber material is somewhat disordered on a larger length scale. However, some structural ordering with parallel but bent graphene layers can be observed. The overall contrast in the ADF image varies in steps from dark on the left to lighter gray on the right side, indicating different specimen thicknesses in the direction parallel to the electron beam. In the upper right corner, the ADF image shows a bright contrast region, which appears significantly dark in the BF image. This contrast is due to a larger Pd particle extending into the field of view when this set of images was acquired.

Figure 9 shows three magnified areas extracted from the BF image shown in Fig. 8. In Fig. 9A, one Pd atom is located within a highly disordered, probably amorphous region, while a second Pd atom

is terminating one graphene sheet located in between two others. Figure 9B shows a configuration in which a Pd atom is surrounded by concentric graphene sheets. A third configuration was observed in which Pd atoms are located in between two quasi-parallel sheets, which reveal slightly increased distances at and close to the Pd atom location. Such bending of atomic planes and the corresponding local straining reveals nanosized voids or pores inside the carbon microstructure correlated with the presence of single catalyst atoms. Previous investigations<sup>[38–40]</sup> indicate that nanosized pores are highly effective for hydrogen storage so that the configurations identified by STEM (Fig. 9) may represent local storage sites for atomic hydrogen after a spillover process,<sup>[41]</sup> encouraged by the presence of the metal catalyst. Such fundamental understanding of atomic-scale processes accessible by high-resolution STEM correlated with materials functionality, such as increased hydrogen gas uptake, can lead to more effective design of future storage materials.

### Catalyst Particles

In the previous section, it was shown that single isolated atoms can be detected and laterally localized

**Fig. 9** Three different areas extracted from the BF image in Fig. 8 with the positions of single Pd atoms transferred from the corresponding ADF images encircled. In the schematics underneath, the location of white BF contrasts is sketched as black lines, while the Pd atoms are marked by filled circles. *Source:* BF intensities are discussed in detail in Ref.<sup>[36]</sup>, from which this figure was adapted.

**Fig. 10** ADF (top row) and BF (lower row) images extracted from a through-focal series of Au nanoclusters supported by an amorphous carbon film. The defocus ( $df$ ) at which the images were taken is listed. *Source:* Figure reproduced from Ref.<sup>[42]</sup> with permission from Materials Research Society.

using aberration-corrected STEM. However, often times image quantification is desired to determine the absolute number of atoms forming, for instance, a catalyst particle. Since STEM typically provides a projection view of the investigated sample, the quantification of image contrast could in principle be used to determine specimen thickness.

Figure 10 shows a number of frames extracted from a through-focal series of simultaneously acquired ADF (upper row) and BF images (lower row) recorded from Au catalyst particles supported by an amorphous carbon film. The micrographs show four gold particles. The ADF image clearly exhibits lattice contrast for the crystalline particles while the carbon support film is almost invisible due to the Z-dependence of the scattering cross-section and, therefore, the large contrast differences. The corresponding bright-field images, however, clearly show the typical speckle pattern for amorphous carbon, whose contrast depends on the defocus value during image acquisition. Furthermore, the BF images also reveal lattice information of the Au clusters but with different contrast when compared with the ADF images.<sup>[1]</sup> The BF intensities change with defocus and even show contrast reversal, which is a typical feature of phase contrast imaging.<sup>[1]</sup> However, in this case the contrast inversion in the area of the amorphous carbon support film was used to calibrate the defocus scale.<sup>[42]</sup> Owing to the incoherent conditions for large inner detector angles, no reversal of contrast occurs for any defocus value in ADF imaging.

The ADF micrographs in Fig. 10 clearly exhibit regions with spot-like bright contrasts, which extend over multiple image pixels, and therefore represent single Au atoms in the vicinity of the larger Au clusters

(see, e.g., frames labeled  $df = 2$  nm and  $df = 3$  nm). In Fig. 11, two intensity line profiles A and B are plotted as a function of relative distance across one of the Au particles. The direction and exact location from which these profiles were extracted are marked in Fig. 10. Arrows in Fig. 11A highlight three different locations where minimal but identical image intensities of about 350 counts/pixel above the background level can be observed. These intensities represent single Au atoms.

Complimentary ADF image simulations were performed using parameters as determined by the aberration-corrector to calculate quantitative image intensities as a function of specimen thickness, i.e. number of Au atoms in a column. For the calculations an Au crystal was oriented with the  $\langle 111 \rangle$  zone-axis parallel to the incoming beam direction, resembling the experimental conditions as observed for the lower Au cluster in Fig. 10. It was found that the incoherent ADF signal is *linear* with the number of Au atoms for columns containing up to 6 atoms (see Fig. 12). Beyond 6 atoms, the ADF signal flattens out and channeling effects complicate the image quantification.

Based on the calculated calibration curve in Fig. 12, ADF image intensities were analyzed quantitatively. For each atomic column, the number of Au atoms along the electron beam direction was assigned. The results for line profile B are included in Fig. 11B. The anomalous background between the atomic columns could result from the so-called Stobbs factor.<sup>[43]</sup> Effects of chromatic aberrations or increased Debye–Waller factors due to a lower melting point of nanocrystalline Au clusters did not contribute to this background according to the image simulations.<sup>[42]</sup>

**Fig. 11** ADF intensity line profiles as extracted from the areas marked in Fig. 10. The net counts per single Au atoms were extracted from linescan labeled A, and the number of Au atoms in each column for the profile labeled B was assigned. *Source:* Original data are published in Ref.<sup>[42]</sup>. Figure reproduced from Ref.<sup>[42]</sup> with permission from Materials Research Society.

The number of atoms in each individual column of an atomically resolved catalyst particle can thus be determined with very high accuracy, which, in the case discussed here, is  $\pm 1$  atom for columns containing up

to 6 atoms, and  $\pm 2-4$  atoms for columns extending 2–4 nm along the beam direction. For the interpretation of catalytic activities, however, the true three-dimensional shape of the particle and its faceting is

**Fig. 12** Calculated fractional ADF intensities for different defocus values as a function of the number of Au atoms along the beam direction. The ADF intensity scales linearly with the number of atoms up to a thickness of 6–7 atoms.<sup>[42]</sup> *Source:* Figure reproduced from Ref.<sup>[42]</sup> with permission from Materials Research Society.

Dynamic –  
Electronic

of critical importance. Such aspects, though at smaller resolution, can be addressed by tilt-series electron tomography of single catalyst particles.<sup>[26]</sup> In a recent study, Huang et al. have combined ADF image quantification as described earlier with statistical data for crystal shapes to determine the true three-dimensional shape of Au nanoparticles<sup>[44]</sup> and how many Au atoms they contain. In the future, a combination of these techniques might reveal more detailed information about faceting and shaping of nanoparticles with single atom accuracy.

## Nanoscale Thin Films

It is well recognized that the macroscopic properties of polycrystalline or composite materials are determined to a large extent by their internal two-dimensional defect structures such as heterophase interfaces and grain boundaries.<sup>[45]</sup> Most structural and functional ceramics, for example, exhibit intergranular films with thicknesses around 1 nm (see, e.g., Ref.<sup>[46]</sup> and references therein). Composite materials provide their functionality through thin films with thicknesses in the nanometer regime. Very prominent examples are complex oxide structures exhibiting colossal magnetoresistance<sup>[47]</sup> or superconductivity properties.<sup>[48]</sup> Other examples include high-*k* dielectric films present in many semiconductor devices. Here, shrinking dimensions<sup>[49,50]</sup> demand material replacements to maintain device performance even though critical structures have dimensions of only a few atoms.<sup>[51,52]</sup> It is, therefore, of utmost importance to gain a fundamental understanding of interface structures and, hence, thin film properties.

HfO<sub>2</sub> is a prominent candidate as a replacement for SiO<sub>2</sub> as a high-*k* dielectric in semiconductor device structures. For the study reviewed in the following, 3 nm of HfO<sub>2</sub> were grown on the (100) surface of a silicon substrate using atomic layer deposition at 320°C. Afterwards, the thin film was capped with polycrystalline silicon by chemical vapor deposition techniques

and rapidly thermally annealed at 950°C in N<sub>2</sub> atmosphere for 30s. Cross-sectional TEM samples of the interface structure were prepared by mechanical wet-polishing<sup>[22]</sup> until electron transparency was reached. Figure 13 shows a pair of ADF and BF images simultaneously recorded from the interface structure. The TEM sample was oriented with the <110> direction in the silicon substrate parallel to the optical axis. Owing to the relatively high atomic number of Hf (*Z* = 72), the crystalline HfO<sub>2</sub> film appears with bright contrast in the ADF image. The typical silicon “dumbbell” spacing of 1.36 Å in this orientation is clearly observable in the ADF image. The BF image reveals an 8 Å wide amorphous interlayer between the HfO<sub>2</sub> thin film and the substrate. This interlayer was found to be a sub-stoichiometric silicon oxide.<sup>[53,54]</sup>

A through-focal series acquisition of ADF images revealed that within the SiO<sub>x</sub> interlayer, bright spot-like features come into focus in various different areas at different focus settings. Figure 14 shows nine frames extracted from a through-focal series. It was found that these contrast features are due to single isolated Hf atoms embedded inside the interlayer,<sup>[22]</sup> which can hence be located laterally with sub-Å precision and vertically with better than 0.5 nm accuracy owing to the focal increment of 0.5 nm/frame during the data acquisition.<sup>[22,24]</sup> According to the increased depth sensitivity discussed earlier, the recorded stack of images from the through-focal series acquisition contains three-dimensional information about the interface structure. A 3D representation of the imaging data was created by surface and volume rendering techniques<sup>[22]</sup> and is shown in Fig. 15. The HfO<sub>2</sub> film is represented by bold yellow color. Columns of Si atoms can be observed in addition to five representative Hf atoms located in the interlayer, which was not color-coded. Overall, a concentration of  $1.40 \pm 0.11$  atoms/nm<sup>3</sup> was found inside the interlayer.<sup>[22]</sup> A systematic investigation of the growth and annealing conditions during the interface formation revealed that the concentration of Hf atoms in the interlayer critically depends on the

**Fig. 13** Simultaneously acquired ADF (A) and BF (B) images of the alternate gate stack consisting of a HfO<sub>2</sub> layer deposited on a silicon substrate. The BF image reveals an amorphous interlayer formed between the alternate gate dielectric and the substrate. The ADF image exposes single Hf atoms within this interlayer. *Source:* Reprinted with permission from Ref.<sup>[42]</sup>.

quality, i.e. stoichiometry, of the silicon oxide before the annealing process<sup>[54]</sup> and the oxygen affinity of the alternative high-*k* material.<sup>[54,56]</sup> Hf atoms diffuse into the suboxide interlayer during the rapid thermal

**Fig. 15** 3D reconstruction of the HfO<sub>2</sub>/SiO<sub>x</sub>/Si interface structure. The HfO<sub>2</sub> film is represented by bold yellow on the left while columns of Si atoms can (gold color) can be observed on the right. annealing process owing to oxygen vacancy formation.<sup>[54,56]</sup> This ultimately creates states in the silicon band gap and can thus affect electron mobilities along or leakage across the gate channel.<sup>[56,57]</sup> The detection, identification and location of individual stray atoms and a fundamental understanding of their impact on the macroscopic materials properties is a critical aspect for the design and future application of functional nanomaterials.

## CONCLUSIONS AND FUTURE DIRECTIONS

In this entry, it was illustrated how aberration-corrected STEM can be applied for the characterization of a wide variety of nanostructured materials. The STEM represents an invaluable tool for the structural and chemical investigation of nanostructures using a variety of different imaging and spectroscopy tools. Aberration-correction has revolutionized electron microscopy by enabling the formation of electron probes with diameters well below 1 Å and enhanced depth sensitivity by reducing the depth of field. A resulting consequence is that STEM data can no longer be interpreted as a simple two-dimensional projection of a three-dimensional structure, but provides three-dimensional information with the ultimate sensitivity down to one single atom. Three different materials systems have been discussed here for which STEM techniques provided insights into atomic and electronic structures with heretofore unprecedented detail. Even

though many of the unanswered questions in the field of materials sciences can be addressed with lower resolution imaging capabilities than reported here, it is the sensitivity down to a single atom that is ultimately important and critical.

The availability of atomic resolution imaging and spectroscopy in combination with single atom sensitivities in all three dimensions stimulates a renewed interest in *in situ* capabilities. If it were possible to maintain the resolution limits on heating or cooling of the sample or changing the gas pressure and atmosphere during the experiments, new fundamental insights could be gained to understand critical processes in functional materials on the atomic length scale in their anticipated working environments. Such advances in electron microscopy will probably lead to an over-achievement of Feynman's request for a "better electron microscope."

## ACKNOWLEDGMENTS

## INTRODUCTION

The fundamental building block of modern electronic circuits is the switching element, typically a transistor, which can be used to perform computational operations when assembled into digital circuits. The number of devices on such circuits, or chips, has increased at a staggering rate, even exceeding the expectations of Moore's law, which predicts a doubling in areal density of devices about every 2 years. Devices are now routinely manufactured with submicron precision using the top-down approaches of photolithography, masking, and etching to produce complex circuits in silicon. A contemporary microprocessor produced by such methodology can have in excess of 40 million transistors, and this figure is likely to grow at least in accordance with Moore's law in the next 5 to 10 years. However, can this phenomenon continue beyond then? Beyond that horizon, the further downsizing of silicon devices throws up some seemingly insurmountable problems. The cost of manufacturing devices approaching nanoscale dimensions using top-down methodologies may well be prohibitive, but physical as well as financial constraints may prevail. Semiconductor junctions and oxide barriers may not have satisfactory performance when minimized to nanometer dimensions. For instance, ultrathin oxide barriers leak charge, or semiconductor junctions may not exhibit sufficiently developed band structure. In addition, thermal dissipation is already a problem for state-of-the-art chips and these problems will become more difficult to solve as the areal density of silicon-based devices is increased.

Given these problems on the horizon of the silicon industries road map for future miniaturization, many believe that there should be a paradigm shift in the architecture of devices.<sup>[1]</sup> Such an approach would be the use of bottom-up methodology, in which molecular wires, nanoparticles, nanotubes, and other molecular structures are organized into functional units, using the methods of synthetic chemistry and self-assembly. Richard P. Feynman, in his classic talk, "There Is Plenty of Room at the Bottom," envisaged the development of nanotechnologies, and these bottom-up

methodologies may help us in understanding how this "room at the bottom" may be exploited.<sup>[2]</sup> Needless to say, the wiring, addressing, and organization of large-scale arrays of nanodevices will provide immense challenges. As a result, nanotechnology is more likely to first appear in hybrid technologies that integrate elements of nanometer devices with conventional micrometer technologies. Indeed, magnetic nanoparticles are already working their way into magnetic storage technologies.

## OVERVIEW

Recent years have seen a variety of often highly imaginative ways of fabricating chemically designed nanoscale components. This has been coupled with the development of techniques and devices in which electronic transport measurements can be made on molecular wires and nanostructures. It should be noted that this quest for practical nanodevices also yields important fundamental science on the behavior of mesoscopic aggregates of molecules and nanoparticles. Indeed, such an understanding is a requisite if functional nanodevices are to be exploited.

The most commonly featured building blocks for nanoscale devices include nanoparticles, carbon nanotubes, molecular "wires" and bridges, and redox molecules. In the following section, some of the basic architectures in which these units have been used for the construction of nanodevices with an electronic function will be reviewed.

## Nanoparticles and Quantum Dots

Nanometer-sized metallic or semiconductor particles are fundamental building blocks for the construction of electronic devices of nanometer dimensions. They can be used as the basis of single-electron information processing, in the attachment of molecular wires in forming ohmic or tunneling junctions, or they can be used to measure charge down to tiny fractions of an electron charge. Monolayer-capped clusters (MPCs)

have proven to be particularly attractive building blocks, in that they can be assembled into 2- or even 3-dimensional superlattices using the techniques of chemical self-assembly.<sup>[3–9]</sup> Such a self-assembled superlattice of Au nanoparticles with a narrow size distribution between 3 and 5 nm is shown in Fig. 1.<sup>[10]</sup> One particularly attractive feature of nanoparticles is the possibility of forming individual particles or even superlattices whose properties can be tuned through chemical control of the particles size, composition, and, in the case of superlattices, spacing.

Sub-10-nm particles lie in the interesting mesoscopic size range where unusual electronic, structural, and optical properties can arise because of their small size.<sup>[11,12]</sup> One interesting property that can be exploited is their unusual charging behavior for sufficiently small sizes. When the electrostatic charging energy for adding an electron to a nanoparticle sufficiently exceeds  $k_B T$ , then single-electron charging phenomena can be observed. This behavior could form the basis of a nanodevice capable of processing single electrons.

The electrostatic energy ( $E_{es}$ ) required to charge a nanoparticle of capacitance  $C$  by one electron is given by

$$E_{es} = \frac{e^2}{C}$$

The condition for observing single-electron tunneling behavior at room temperature is  $e^2/C > k_B T = 26$  meV, where  $k_B$  is the Boltzmann constant. Single-electron tunneling phenomena have now been observed in a wide range of nanostructures at both low and room temperature. Examples include nanosized metal islands, nanoparticles and monolayer-capped

nanoparticles on supports,<sup>[13–15]</sup> single metal or semiconducting nanocrystals placed between closely spaced metallic or semiconducting leads<sup>[16,17]</sup> and even kinked carbon nanotubes placed between contacts.<sup>[18]</sup> Single-electron tunneling for these nanoscopic systems has been measured using a variety of methods. Nanocrystals, both metallic and semiconducting, have been anchored through molecular spacers.<sup>[19,20]</sup> Typically dithiol-based self-assembling monolayers have been used to anchor nanoparticles to well-defined surfaces, as illustrated in Fig. 2.<sup>[20]</sup> Tunneling through such devices has been monitored using a scanning tunneling microscope (STM). In one such configuration using  $\sim 1.8$ -nm Au clusters and aryl dithiol self-assembled monolayers (SAMs) ( $\alpha$ ,  $\alpha'$ -xylyldithiol and 4,4'-biphenyldithiol) single-electron tunneling phenomena were observed.<sup>[20,21]</sup> For these measurements, localized  $I$ - $V$  responses were recorded with the STM tip positioned above the nanoparticle. The observation of current steps as the voltage is swept is a clear indication of Coulomb staircase behavior. This system can be modeled as a double junction: The Au surface–nanoparticle and nanoparticle–tip junctions can then be simplified as a coupled parallel RC circuit 1 and 2, as illustrated in Fig. 2.<sup>[20]</sup> The parameters  $R_1$ ,  $R_2$ ,  $C_1$ ,  $C_2$ , and  $Q_0$  (the fractional charge on the cluster) may be obtained with the standard semiclassical model of the Coulomb blockade. Single-electron tunneling for such nanoparticle system can be tuned by adjusting the RC junctions that connect the nanoparticle to the external circuits or by adjusting the particle size.<sup>[22–24]</sup>

**Fig. 2** Schematic diagram illustrating the STM measurement of Coulomb blockade behavior of a nanoparticle adsorbed onto a self-assembled monolayer of alkane-dithiol. The equivalent electrical circuit is shown on the left. *Source:* From Ref.<sup>[20].)</sup>

Other device structures have been used to monitor single-electron phenomena in nanostructures. Individual nanoparticles have been placed between two metallic leads created by mechanically forming break junctions in one approach, shown in Fig. 3.<sup>[16]</sup> This enables the isolation of individual nanostructures between metallic contacts for analysis of their electrical properties. In another approach, ensembles of nanoparticles have been sandwiched between electrodes covered with insulating dielectric layers.<sup>[25]</sup> Both approaches have enabled determination of single-electron transistor (SET) behavior at low temperature.

Another approach to observing single-electron tunneling phenomena has been to create quantum dots (QDs), which are typically confined semiconducting islands.<sup>[11]</sup> Semiconducting QDs have been produced using modern semiconductor fabrication techniques. For example, it has been possible to sandwich 10-nm-thick GaAs films between AlGaAs barrier layers. Electrons can be confined in movement within and parallel to these GaAs “quantum wells.” By placing electrostatic gates above and below the structure, electrons are confined laterally as well to create “quantum dots.” Electron transport to and from these QDs is governed by quantum mechanical phenomena and can be probed by monitoring the gate voltages at which individual electrons can be added successively to the dot. Great sensitivity could be achieved by probing the admittance changes with a 100 kHz a.c. signal as the d.c. gate voltage is changed. Spikes in the a.c.

admittance represent individual electrons entering the quantum dot.<sup>[11]</sup> Another particularly interesting feature of semiconducting QDs is the ability to control their electronic structure by tuning their size. However, even clusters of metal atoms, when sufficiently small and at sufficiently low temperatures, start to lose the characteristic electronic band structure of the metallic state in the size range between 1 and 4 nm and start to form discrete energy levels, which are determined by quantum physical phenomena.

This sensitivity of either quantum dots or nanoparticle-based structures shows the ability of these devices to record single-electron events, opening the possibility of electronic devices for processing single electrons. The energy for single-electron events increases as the device size is shrunk, clearly emphasizing the importance of developing reliable nanofabrication methods if SETs are to be practically implemented.

### Molecular Wires and Switches

The use of molecules as components to assemble electrical devices is an idea that has attracted many researchers since the subject was conceptually broached by Aviram and Ratner in 1974.<sup>[26]</sup> More recently, methods have become available to connect individual molecules between contacts and measure their electrical behavior.<sup>[27–31]</sup> Molecules have been attached to metallic probes through a variety of end groups including sulfur, selenium, tellurium, and isonitrile.<sup>[32]</sup> Molecules assembled into structures in such a way have been termed “molecular wires.” This term, wire, may be appropriate to thin metallic rods or conductive carbon nanotubes that exhibit an ohmic behavior arising from an extended band structure. However, as pointed out by Whitesides, the term “molecular wire” is misleading when describing the electrical properties of molecular devices because it implies metallic or ohmic conductivity, whereas electron transport through molecules is often far from ohmic.<sup>[33]</sup> Indeed, it is the non-linear electrical behavior of molecules that is of interest if they are to take up the function of electrical components such as switches, diodes, transistors, or logic gates.

Measuring and theoretically understanding the non-linear electrical behavior of molecules is a central question in molecular electronics.<sup>[34–38]</sup> Although there is a very long and extensive history of both theoretically and experimentally studying electron transfer processes, it is only more recently that electron transport across defined molecular films has been realized and still more recently that single molecule contacts and electrical measurements have been established.<sup>[27–31]</sup> A detailed understanding of charge transport through molecular films and single molecules is mandatory if

**Fig. 3** (A) A field electron microscopy image of the two leads and gap before the nanoparticles are introduced. (B) A schematic illustration of the immobilization of nanoparticles through dithiol linker molecules to the leads. *Source:* From Ref.<sup>[16]</sup>.

molecules are to be integrated into devices. Pioneering work in molecular electronics was conducted by Mann and Kuhn, who studied transport through molecular films.<sup>[39]</sup> More recently, electron transport across well-defined SAMs with redox active species at a fixed distance from the metal electrode surfaces has been studied by electrochemical means.<sup>[40]</sup> In these experiments, the rate of electron transfer from the electrode surface for redox active species such as ferrocene has been measured as a function of length and nature of the bridge. For simple alkanethiol monolayers, this rate has been found to depend exponentially on the thickness of the molecular layer, following a simple tunneling relationship:

$$I = I_0 e^{-\beta d}$$

where  $\beta$  is the attenuation factor, which depends on the medium in the tunneling gap between the contacts.

More recently, solid-state junctions have been formed by sandwiching two self-assembled monolayers between metal electrodes to give a junction of the form:

By using this approach,  $\beta$  was found to be structure dependent, with values of  $0.87 \pm 0.1 \text{ \AA}^{-1}$  for alkanethiols and  $0.6 \pm 0.1 \text{ \AA}^{-1}$  for oligophenylene thiols. These values for the attenuation factor can be rationalized in terms of tunneling theories, which are well developed for molecules in solution of the kind D–B–A, where electrons can be shuttled across a molecular bridge (B) from donor (D) to acceptor (A). This is somewhat analogous to a molecular bridge between two metal leads in which the donor and acceptor states take the place of the leads. The rate of electron transfer is determined by the coupling between donor and acceptor wave functions, and one of the simplest models for describing the distance dependence is superexchange. In this scheme electronic coupling is through high energy states in the bridge groups, which cause the electronic wave functions to fall off more slowly than if D and A were separated by vacuum, hence lowering  $\beta$ . However, it is also well recognized that the tunneling electrons may interact and strongly couple with nuclear degrees of freedom of the bridge molecules.<sup>[41]</sup> In superexchange there is only weak coupling and the electron transport can be envisaged as a “wavelike” electronic flow. On the other hand, the electron transfer may be sequential, in which it is best described by two or more consecutive electronic transitions. It is clear then that nuclear relaxation and thermal dissipation in the molecular bridge can play a determining role in the charge transport.

Another factor of importance in determining charge transport through a molecular bridge between two

metal leads is the degree of coupling between the metal contacts and the molecule, which will depend in a sensitive manner on the bonding between the molecule and the junction, the position of the Fermi level of the contacts, and the molecular and electronic structure of the bridging molecule. The variation of the electrochemical potential across the molecular bridge is also of significance. For instance, if the complete potential drop occurs solely at the interface between the molecule and the metal contacts, the electronic structure of the molecule is expected to be only slightly perturbed by the voltage drop. On the other hand, if a significant fraction of the voltage drop occurs across the molecule then electron transport across the molecule can be very sensitive to the profile of local electrochemical potential along the length of the bridge.

The direct measurement of the electronic factor  $\beta$  and hence the “conductivity” of individual molecules recently has been made possible with the development of the scanning probe microscope.<sup>[27–31]</sup> In experiments conducted by the group of Lindsay, molecules have been embedded into an insulating layer of thiol molecules attached to a gold electrode.<sup>[27–30]</sup> The molecules were then connected to gold nanoparticles so that a molecular bridge was formed between the gold electrode and the nanoparticle. Tunneling currents were measured with a conducting AFM probe by making direct electrical contact between the tip and nanoparticle. Values of  $\beta$  for alkanethiol molecule of about  $0.8 \text{ \AA}^{-1}$  have been obtained, as compared to  $2 \text{ \AA}^{-1}$  for vacuum tunneling. Both these single-molecule measurements and the measurements of electron transport across alkanethiol SAMs show the reduction in the electronic factor for tunneling across the alkanethiol bridge.

However, reduction of  $\beta$  alone in a molecule bridging two contacts is not sufficient for the generation of non-linear devices such as nanoscale switches. The involvement of molecular levels, charge trapping, or asymmetric contact geometries can all promote a non-linear response. In 1974, Aviram and Ratner predicted that molecules could act as diodes based on their non-linear electrical response.<sup>[26]</sup> They theoretically predicted rectification for the molecular system shown in [Scheme 1](#) on the basis of electron tunneling mediated through acceptor lowest unoccupied molecular orbitals (LUMO) and donor highest occupied molecular orbital (HOMO) levels of the donor–acceptor system. Because substantially larger threshold voltage was expected for alignment of the levels under negative bias than positive bias, an asymmetric  $I$ – $V$  response and, hence, rectification was expected.

Metzger et al. have made Langmuir–Blodgett (LB) films of the donor–acceptor molecule shown in [Scheme 2](#).<sup>[42]</sup> The LB films were sandwiched between aluminum electrodes and electrical measurements

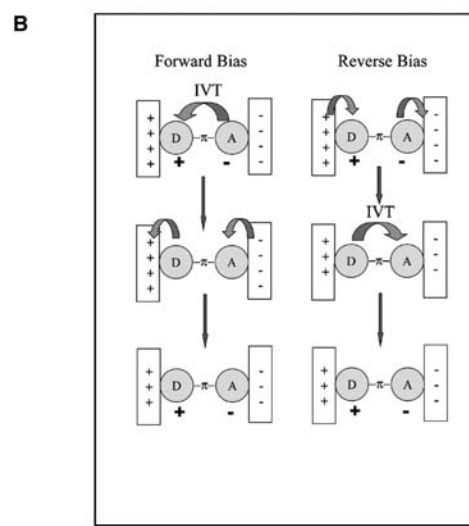

Scheme 1

demonstrated strong rectification, Fig. 4A. The rectification may be explained in the schematic model shown in Fig. 4B.<sup>[42,43]</sup> This model shows electron transfer under forward and reverse bias. The asymmetry in the  $I$ - $V$  behavior arises from the orientation of the donor-acceptor molecule in between the electrodes and intramolecular electron transfer within the molecule, as illustrated in Fig. 4B. Intervalence transfer (IVT) favors current flow in the forward bias direction, while it impedes it in the reverse bias direction. Although these experiments have been performed on extended LB films, they show the potential for the use of molecules in switching devices, where the rectifying behavior can be tuned by the electronic and molecular structure of orientated molecules.

More recently Chen et al. have shown that highly non-linear  $I$ - $V$  behavior can be achieved in molecular devices.<sup>[44,45]</sup> They self-assembled  $\sim 1000$  molecular wires containing nitroamine redox centers in a micro-fabricated device that could be used to measure conductivity of the monolayer.<sup>[45]</sup> A schematic representation of the nitroamine-based molecules used in the monolayers and their reduction is shown in Fig. 5A.  $I$ - $V$  responses of the device at 60 K shows negative differential resistance (NDR) with an on-off peak-to-valley ratio (PVR) of about 1000:1, as shown in Fig. 5B. This switching is attributed to the one-electron reduction of the molecule to the radical anion, which provides a conductive state for electron transfer across the molecular bridge.<sup>[45]</sup> A further increase in voltage leads to a second reduction to form the dianion, which is insulating, switching the device off. The authors note that the NDR switching could have

Scheme 2

numerous applications in either two- or three-terminal electronic devices.<sup>[45]</sup>

Redox active molecules can also be incorporated into nanoscale devices and “wired” to nanometer-sized metal particles. Gittins et al. noted that films consisting of 6-nm-sized Au nanoparticles and redox active viologen dithiol molecules can exhibit current rectification when assembled onto gold electrode surfaces.<sup>[46–48]</sup> This observation was noted when recording rates of electron transfer through such films using electrochemical methods. They have further shown that these redox active molecules can be wired to nanoparticles in individual nanostructures as illustrated in Fig. 6.<sup>[47]</sup> Recent measurements have shown that a double tunneling structure is formed between the redox active viologen center isolated in the middle of an insulating molecular wire and the gold contacts on either end of the molecule. This work shows the potential for incorporation of highly reversible redox couples into nanometer-sized tunneling devices.

**Fig. 5** (A) Schematic representation of the nitroamine-based molecules used in the monolayers of the molecular device showing NDR. (B)  $I$ - $V$  responses of the device at 60 K. *Source:* From Ref.<sup>[45]</sup>.

Although two-terminal connections to molecules can be used to create devices with rectifying or NDR behavior, the three-terminal transistor is the fundamental element of modern integrated circuit technology. Several studies have shown how nanometer-sized objects, such as CdSe nanocrystals<sup>[49]</sup> or carbon nanotubes,<sup>[18,50–52]</sup> can be functional elements in field-effect transistors, with these nanostructures being tethered between two contact leads and a third semiconductor gate underlying an insulating SiO<sub>2</sub> layer. However, reliable direct wiring of three or more metallic contacts to an individual molecule is certainly more tricky because it requires close proximity of at least three leads. Clearly, these contacts would have

to be of nanometer dimensions to accommodate the size of target molecules. Proposed multicontact-point molecules have been suggested that rely on thiol (or thioacetate)-based end groups, which form the relatively strong gold–thiolate bond. A three-terminal molecular device proposed by Wada is shown in Fig. 7.<sup>[43,53,54]</sup> Thiol groups attach the molecule to three gold electrodes that form the source, drain, and gate, respectively. These are individually linked by polythiophene-based molecular wires to an oligothiophene “dot,” which is isolated from the molecular wires by methylene spacers. However, the challenge exists to build, interconnect, and test junctions of this kind.

These selected examples show that great advances have been made in a relatively short period of time in the fabrication of molecular devices and in understanding electron transport across them. Great heterogeneity has been displayed in the electrical behavior ranging from ohmic to highly nonlinear responses. Molecular and electronic structure can be varied in a sensitive manner through organic synthesis and reactions can be scaled up to synthesize large quantities. However, some formidable challenges remain, including the need to arrange molecular devices in large, interconnected arrays that can be individually addressed.

### Carbon Nanotubes

Like metal or semiconducting nanoparticles, carbon nanotubes show promise as versatile components in the molecular electronics toolbox and in the construction of nanoscale switches.<sup>[18,51,55–60]</sup> Carbon nanotubes can be envisaged as sheets of graphite that have been rolled up into a seamless cylinder.<sup>[56,59]</sup> Both single-walled carbon nanotubes (SWCNTs) and

**Fig. 7** A nanoscale switching device proposed by Wada,<sup>[43,53,54]</sup> with thiol groups forming contacts to three gold pads that form the source, drain, and gate, respectively. Each arm of the molecular device is individually linked by polythiophene-based molecular wires to an oligothiophene “dot,” which is isolated from the molecular wires by methylene spacers. *Source:* From Ref.<sup>[53]</sup>.

multiwalled carbon nanotubes (MWCNT) can be produced, in the later case with diameters exceeding 50 layers.<sup>[60–62]</sup> SWCNTs are defined by a chirality vector whose indices  $(n, m)$  are given by the folding of the graphene sheet into a cylinder.<sup>[56,59,60]</sup> In an  $(n, m)$  nanotube the beginning and end of an  $(n, m)$  lattice vector in the graphene plane join together. An extended graphene sheet is metallic in six wave vector directions; however, for SWCNTs it is also necessary to consider the confinement of electrons around the tubes' circumference. On analysis, it is found that when  $n = m$  or  $n - m = 3i$  (where  $i$  is an integer) the tubes are metallic, whereas when  $n - m \neq 3i$ , the tubes are semiconducting. Thus, by tuning the diameter and the wrapping angle the conductivity can be altered in a sensitive manner. Another feature of the electronic structure of metallic SWCNTs is the confinement of electrons, which allows motion along only two directions of  $k$  space, making them model 1-D conductors. An important consequence of this is the reduced probability for carrier scattering. This combined with their high heat conductance and bond stability allows them to carry extremely high current densities ( $\sim 10^8$ – $10^9$  A/cm<sup>2</sup>), well above that of a metal, which would suffer severe electromigration at these current levels.<sup>[63]</sup>

Carbon nanotubes also have exceptional tensile strength and rigidity, making them good candidates for molecular wires and nanoscale electronic devices. Disadvantages include difficulty in selective synthesis of particular SWCNTs and formation of contacts and junctions with, for instance, nanoparticles or electrical leads. In the absence of scattering, ideally the resistance of a perfectly conductive ballistic nanotube connected to metal leads should be about  $h/4e^2 = 6.5$  k $\Omega$ .<sup>[59,63]</sup> This resistance is a quantum mechanical contact resistance caused by a mismatch in the number of conduction channels of the metallic SWCNT ( $N = 2$ ) and the relatively huge number of conduction channels in the metal leads.<sup>[59]</sup> However, other types of contact resistance can dominate the electrical transport of carbon nanotubes. Poor metal–nanotube contacts, in the form of interfacial barriers, or poor coupling between the CNTs and leads, led in some early transport measurements to high resistance values in the order of megaohms. However, these high contact resistances, much larger than the resistance quantum, when coupled with the sufficiently low capacitance of long SWCNTs provide good conditions for the observation of single-electron charging or Coulomb blockade behavior at sufficiently low

temperatures. Coulomb blockage behavior has been observed for micron-long nanotubes at liquid helium temperatures. Low-contact-resistance junctions between SWCNTs and metallic leads have also been achieved, approaching in some cases the quantum mechanical contact resistance. Resistances as low as  $12\text{ k}\Omega$  have been recorded for  $3\text{-}\mu\text{m}$ -long SWCNTs contacted by Ti electrodes evaporated onto the nanotubes.<sup>[60]</sup>

Three-terminal switching devices exhibiting transistor behavior have been fabricated in a number of ways from carbon nanotubes. Semiconducting carbon nanotubes have been incorporated into a device illustrated in the inset in Fig. 8.<sup>[60]</sup> The carbon nanotube is contacted at both ends by metal electrodes that form the source and drain. A highly doped and conducting silicon gate electrode is separated from the nanotube by a sufficiently thick insulating silicon oxide layer. The source–drain current across such a nanotube device as a function of gate voltages is shown in Fig. 8. This  $I\text{-}V_{\text{gate}}$  curve shows that by applying a sufficiently positive gate voltage the nanotube can be switched from a conducting to an insulating state.<sup>[60]</sup> The p-type behavior of these nanotubes results in hole depletion at positive gate voltages where the device is switched off.

Recently a novel approach has been adopted for fabricating single-electron devices from individual carbon nanotubes.<sup>[18]</sup> The concept used is to create a nanoscale “electron trap” within a double tunneling junction, similar to the approach used for QDs, but in this case individual metallic single-wall carbon

**Fig. 8** The inset shows a “transistor” based on semiconducting carbon nanotubes.<sup>[60]</sup> The carbon nanotube is contacted at both ends by metal electrodes that form the source and drain, respectively. A highly doped and conducting silicon gate electrode is separated from the nanotube by a sufficiently thick insulating silicon oxide layer. The graph shows the source–drain current across such a nanotube device as a function of gate voltage. This  $I\text{-}V_{\text{gate}}$  curve shows that by applying a sufficiently positive gate voltage the nanotube can be switched from a conducting to an insulating state. *Source:* From Ref.<sup>[60]</sup>.

nanotubes form the basis of the structure. An AFM image of the structure is shown in Fig. 9.<sup>[18]</sup> A double kink is introduced into the nanotube by mechanical manipulation with an atomic force microscope. The double kink induces two local barriers, leading to an “island” within the nanotube, which is connected at both ends to two metal terminals. This whole structure is assembled on top of a Si/SiO<sub>2</sub> substrate to provide a three-terminal device. Energy of 120 meV has been recorded for single-electron addition, rendering this a functional single-electron transistor device at room temperature with operation akin to a field-effect transistor.

In constructing complex logic systems it is necessary to create large arrays of devices and to interconnect them into a network. Rueckes et al. have indicated one possible way by which this might be achieved.<sup>[64]</sup> It is proposed that semiconducting SWCNTs are arranged into a parallel array with a set of perpendicular nanotubes suspended above them on a periodic array of supports, as illustrated in Fig. 10. The two sets of arrays consist of p- and n-doped carbon nanotubes, respectively. The nanotubes serve two functions; they form the wires as well as the individual devices. Device elements are at points where the wires cross. By applying a transient voltage between the respective CNTs the wires can be switched from being separated by a gap (“OFF”) to touching (“ON”) where the conductivity is higher.<sup>[64]</sup> The voltage pulse causes charging of the semiconducting nanotubes, resulting in attractive electrostatic forces and contact between the tubes. The OFF state with separation of the tubes can be regenerated by application of a restorative current transient. The operation of this electromechanical

**Fig. 9** An AFM image of a double kink introduced into a carbon nanotube by mechanical manipulation with the tip. This structure forms a nanoscale “electron trap” within the double tunneling junction created by the kink. This whole structure is assembled on top of a Si/SiO<sub>2</sub> substrate to provide a three-terminal device with single-electron transistor behavior at room temperature. *Source:* From Ref.<sup>[18]</sup>.

**Fig. 10** A schematic representation showing four junctions between two parallel pairs of carbon nanotubes. The bottom right junction is ON, with both nanotubes touching, while the other three junctions are OFF. The lower tubes lie directly on a thin dielectric layer (e.g.,  $\text{SiO}_2$ ), which is itself on top of a conducting layer (e.g., highly doped silicon). The upper nanotubes are suspended above the substrate by periodic supports (dark gray blocks). Each nanotube is contacted at the end (contacts not shown). *Source:* From Ref.<sup>[64]</sup>.

switch relies on the excellent mechanical properties of the SWCNT, which can withstand the high strain. Measurements demonstrating the principle of operation have been made on a single pair of crossed SWCNTs assembled into position through mechanical manipulation. This switching device showed a 10 times current difference between ON and OFF states for reversible operation and this was increased to  $10^5$  for irreversible operation. This shows how nanoscale switching elements can be interconnected through molecular scales wires, with operation of individual elements in an array of switches through the application of voltage pulses at the ends of respective wires. This integrated approach to nanoscale electronics shows a promising way forward, although great challenges still exist in the fabrication and addressing of reliable and sufficiently large arrays.

### Molecular Actuators

Another approach to electronic switching at the nanoscale level has been to exploit changes in the electronic structure of molecules that accompany major conformation or orientational changes. A molecular actuator

has been constructed around bistable catenane-based molecules.<sup>[65–67]</sup> Oxidation and subsequent reduction of this molecule induces the circumrotation of the molecule shown in Fig. 11, which forms the basis of the device. Fabrication is achieved by anchoring the catenane-based single monolayers with amphiphilic phospholipid counterions and sandwiching this between an n-type silicon electrode and a Ti/Al counter electrode. Oxidation of the molecular structure at +2.0 V opens the switch, while subsequent reduction at –2.0 V closes it. Reading was performed at between 0.1 and 0.3 V and the switch could be recycled many times. Although the solid-state devices used for examining the electrical properties were macroscopic, the bistable switching is, in theory, scalable to the nanoscale because it is based on defined molecular events.

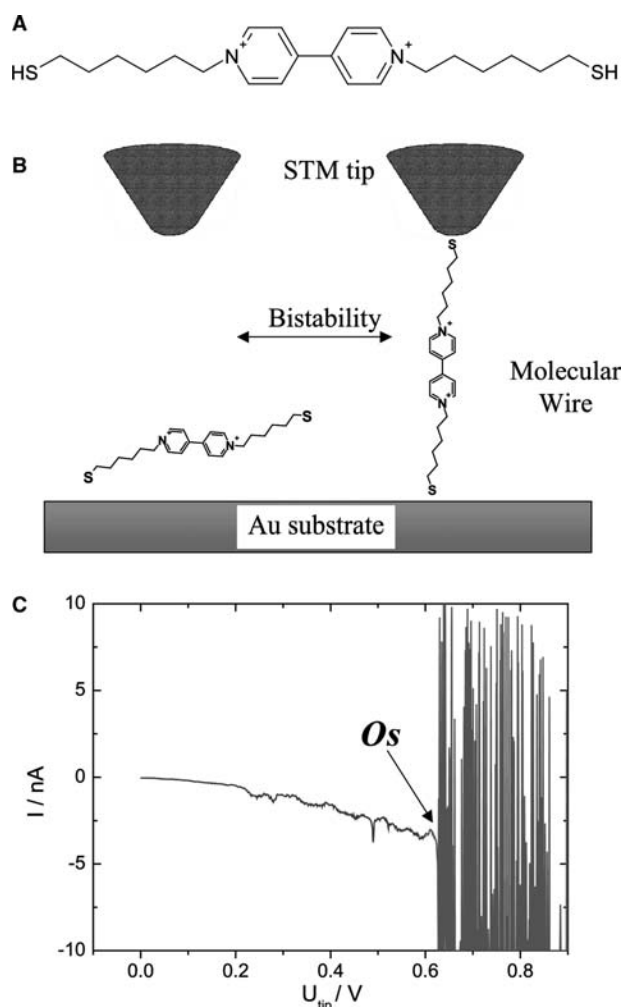

Joachim and Gimzewski have demonstrated another approach by which large and reversible changes in effective conductance of a single molecule could be achieved.<sup>[68,69]</sup> The active element of their device was a single  $\text{C}_{60}$  molecule, which was compressed between the tip and a Cu(111) surface. They found that the conductance of  $\text{C}_{60}$  molecule increased by more than two orders of magnitude with increasing tip pressure.<sup>[69]</sup> The origin of the increase is perturbation of the tails of the LUMO and HOMO of the  $\text{C}_{60}$  molecule resulting from structural deformation. They used this as a basis of a single-molecule “electromechanical amplifier” demonstrating an amplification factor of 5, and as such showing another method by which nanoscale structures might be used as switching elements.<sup>[69]</sup>

Changes in the orientation of molecules at surfaces could also be used for devices based on conductance switching. Donhauser et al. have observed with an STM the stochastic reorientation of single and bundled phenylene ethynylene oligomers isolated in matrices of relatively nonconducting alkanethiolate monolayers.<sup>[70]</sup> The inserted molecules were observed to undergo reorientation or reconfiguration from a state that exhibited low contrast to one with high contrast in the STM. This bistability between the ON and OFF states exhibited a stochastic behavior with persistence times ranging from seconds to tens of hours.

**Fig. 11** Molecular structures of the two conformers forming the basis of a bistable device. The switching is based on the voltage-actuated circumrotation of co-conformer  $[\text{A}^0]$  to co-conformer  $[\text{B}^+]$ . *Source:* From Ref.<sup>[66]</sup>.

Recently, Haiss et al. have demonstrated that molecular reorientation and accompanying large conductivity changes can be driven by an electric field between an STM tip and a gold surface.<sup>[71]</sup> This conductance switching was achieved for viologen dithiol molecules and is illustrated in Fig. 12. In their flat-lying state, molecular layers of viologen dithiol (Fig. 12A and B) have subnanometer thickness. However, reorientation can be used to bridge distances between conductors of over 3 nm and the molecular bridges formed provide the switch ON high-conduction state (the formation of one “molecular bridge” is shown in Fig. 12B). The reorientation is induced by

**Fig. 12** (A) Molecular structure of 6V6. (B) The bistability exhibited for 6V6 results from flipping between a flat-lying adsorbed phase and a vertically oriented phase in which the molecule bridges the gap between the Au substrate and the STM tip provide a higher conductivity path. (C) Current vs. tip voltage as measured in the STM configuration shown in (B). Oscillation occurs at  $U_{\text{tip}} > 0.6$  V and results from the formation and cleavage of molecular wires between the STM tip and substrate. *Source:* From Refs.<sup>[31,71]</sup>

the electric field between the STM tip and the substrate and results in oscillatory behavior at sufficiently high bias where a large number of molecules in the gap ( $\geq 20$ ) may partake.<sup>[31,71]</sup> It has been proposed that the oscillatory behavior results from thermal effects, where the molecular wires break following inelastic tunneling at a threshold voltage and subsequently reform after cooling in a cyclic process. This ON–OFF oscillatory switching behavior and the resulting a.c. signal measured at high fields could form the basis of a novel bistable device.

## CONCLUSION

A great deal has been learned in recent years about the manipulation, assembly, and properties of devices with nanoscale dimensions. In particular, there are a growing number of architectures in which molecular wires, nanotubes, nanoparticles, and quantum dots have been assembled into structures that can perform basic switching functions. The methods of chemical synthesis, self-organization, and self-assembly, as well as state-of-the-art microfabrication techniques have all played a role in the fabrication of such structures.

It is clear that substantial work lies ahead before nanofabricated devices could work their way into any practical electronic device. However, a great deal of new physics that underlies the behavior of mesoscopic structures has been learned from studying the properties of such systems and other nanofabricated devices. Notable examples include insights into the rich quantum mechanical behavior of electrons in quantum dots, quantification of thermal conductance in nanodevices, and a further understanding of charge transport through molecular wires. This demonstrates the contribution to the understanding of basic science that has been achieved in the quest for functional nanostructures.

# Enantioselectivity on Surfaces

David M. Rampulla

Andrew J. Gellman

Department of Chemical Engineering, Carnegie Mellon University,  
Pittsburgh, Pennsylvania, U.S.A.

## INTRODUCTION

Chirality is a critical property of amino acids that form proteins, the building blocks of life, and of DNA, which encodes the genetic traits passed from one generation to the next. Furthermore, chirality can be observed throughout nature in objects ranging from spiral seashells to the human hands. If an object and its mirror image are non-superimposable, then they have the property of chirality. This property is found in nearly every biological molecule and in many synthetic bioactive molecules such as pharmaceuticals and agrochemicals. From a practical perspective, the importance of molecular chirality arises from the fact that the two mirror images of a chiral molecule, known as enantiomers, can have vastly different physiological impacts when ingested by living organisms. As a result, it is necessary to produce many chiral compounds in enantiomerically pure form.<sup>[1]</sup> Understanding chirality and enantioselectivity is critical to the development of the separations and reactions used to achieve enantiopurity.

Many processes used in chemical production involve solid surfaces and can be made enantioselective by using chiral surfaces. There are three common types of chiral surfaces: surfaces modified by chiral organic adsorbates, surfaces of any naturally chiral bulk crystalline solid, and chiral surfaces prepared from achiral bulk crystals. A number of studies have shown that such chiral surfaces exhibit enantiospecific properties when exposed to chiral species in either the gas phase or in solution. Although chirality is simply a symmetry property of an object or an extended lattice, the enantiospecificity of surfaces is derived from the local structure of nanoscale features such as molecular adsorbates, or specific arrangements of atoms at a crystal surface. Experimental and theoretical work to elucidate the properties of these nanostructured surfaces is an active area of research in surface chemistry. Although a number of aspects of the enantioselectivity of chiral surfaces are now understood, many unanswered questions remain as topics of ongoing research in the field.

## CHIRALITY OF MOLECULES, SOLIDS, AND SURFACES

The simplest molecules exhibiting chirality are those containing a carbon atom tetrahedrally coordinated to four different substituents. Such molecules are not superimposable on their mirror images. Fig. 1 shows the tetrahedral arrangement of a simple, chiral carbon-centered molecule. The handedness of a chiral center or carbon atom is denoted *R* for rectus (right-handed) or *S* for sinister (left-handed) based on a convention conceived by Cahn, Ingold, and Prelog.<sup>[2]</sup> Biologically relevant molecules can be very complex and tend to have multiple chiral centers. Although possession of one or more tetrahedral carbon atoms having four different substituents is sufficient to render a molecule chiral, it is not a necessary condition. Chiral centers can also exist in molecular structures such as allenes ( $R'RC=CR'R$ ) and *trans*-cycloalkenes, which do not have tetrahedrally coordinated carbon atoms as their chiral centers.

Chirality can arise in crystalline solids because either the unit cell is chiral, or the basis of an achiral unit cell is chiral. Examples of the former case include all solids based on monoclinic unit cells. Examples of the latter case could be crystals of enantiomerically pure compounds. Of the 230 space groups into which all crystals can be classified, 65 are chiral.<sup>[3]</sup> Because mirror planes, inversion centers, and glide planes in crystal structures render them achiral, the chiral space groups can only contain screw axes and rotational axes as symmetry elements.

Surfaces can have structures that are chiral in the sense that they are non-superimposable on their mirror images. One of the most common and versatile approaches to preparing a chiral surface is to adsorb an enantiomerically pure chiral compound onto the surface of an otherwise achiral substrate (Fig. 2A). The mere presence of such a chiral modifier or template renders the surface chiral. The second obvious class of chiral surfaces is those produced by cleaving any solid having a chiral bulk structure. Many oxides have chiral bulk structures and thus expose chiral

**Fig. 1** The mirror images of chiral molecules are not superimposable on each other, thus simple molecules based on tetrahedrally coordinated carbon atoms with four different substituents are chiral.

surfaces (Fig. 2B). Although it is somewhat counterintuitive, it is also possible to create chiral surfaces from crystalline solids with achiral bulk structures. Metals have either face-centered cubic (fcc), body-centered cubic (bcc), or hexagonal close-packed (hcp) bulk structures, all of which are achiral. Nonetheless, many of their high Miller index surfaces have monoclinic lattices and thus are chiral. The fcc(643) surface shown in Fig. 2C is composed of terrace–step–kink features, which render it chiral. On all three types of chiral surfaces, the features that give rise to chirality have nanometer dimensions. This nanostructure is critical to their utility in enantioselective chemistry. In order for adsorbate–surface interactions to be enantiospecific, the length scale of the chiral structures on the surface must roughly match the length scale of the chiral features of the adsorbed molecule.

## IMPORTANCE OF CHIRAL SURFACES

The two enantiomers of a chiral compound are structurally related simply by mirror symmetry and, thus,

**Fig. 2** Chiral surfaces: (A) modification of an achiral surface with chiral organic molecules renders the surface chiral; (B) cleavage of bulk chiral solids exposes surfaces with chiral structures; and (C) cleavage of an achiral fcc metal along a high Miller index plane generates a surface with chiral kinks.

enantiomerically pure compounds have bulk properties such as density, melting point, heat of phase change, etc. that are truly identical. The properties of two enantiomers are only differentiated in a chiral environment and, in particular, in a chiral environment in which the length scale of the chiral features is on the nanoscale matching molecular dimensions. Living organisms constitute chiral environments because the proteins that perform most biochemical functions in living organisms are chiral and exist as single enantiomers. As a result, the physiological impact of the two enantiomers of a chiral compound will be different. Appreciation of this fact could have prevented one of the greatest tragedies in medical history. In the late 1950s, the chiral drug thalidomide was administered as a racemic mixture (equimolar concentrations of both enantiomers) to pregnant women to abate morning sickness and to act as a general sedative. Unfortunately, only the *R*-enantiomer has the desired therapeutic effect whereas the *S*-enantiomer is a teratogen and caused birth defects in thousands of infants born in that period of time.<sup>[4]</sup> As a consequence of this problem and related issues associated with the use of many chiral pharmaceuticals, the production of enantiomerically pure drugs has grown to be a large concern for the pharmaceutical industry. The current market for enantiomerically pure pharmaceuticals is estimated to be in excess of US\$100 billion per year.<sup>[5]</sup>

As a result of the fact that the physical properties of the two enantiomers of chiral compounds are identical, most chemical syntheses lead to the production of equimolar or racemic mixtures of both enantiomers. If one desires an enantiomerically pure product, the racemic mixture must be separated. The separation of mixed products of a chemical synthesis is commonplace and can be achieved by a number of means; however, the separation of racemic mixtures is very difficult. The most common separation methods exploit differences in physical properties such as boiling point, melting point, or density; however, in achiral environments, these properties are identical for two enantiomers. Separation of racemic mixtures must be performed in chiral environments that differentiate the properties of the two enantiomers. For example, mixing two enantiomers  $R_1$  and  $S_1$  with a single enantiomer of a second chiral compound ( $R_2$ ) can result in the formation of diastereomeric complexes  $R_1R_2$  and  $S_1R_2$  (molecules with more than one chiral center that are not mirror images). These complexes are not enantiomers of one another and thus can be separated by exploiting differences in their physical properties.<sup>[6]</sup> Once the two complexes are separated,  $R_2$  can be removed and separated to produce pure samples of  $R_1$  and  $S_1$ . The desired enantiomer can then be used, whereas the undesired enantiomer is either discarded or, if possible, racemized and subjected to further

**Fig. 3** The asymmetric hydrogenations of methyl acetoacetate on Ni (A) and methyl pyruvate on Pt (B) are the two most widely studied enantioselective reactions catalyzed by chirally templated surfaces.

enantioselective purification by complexation with  $R_2$ .<sup>[6]</sup> The point is that the addition of the pure enantiomer  $R_2$  to the racemic mixture constitutes the creation of a chiral environment in which  $R_1$  and  $S_1$  can be separated.

Most enantiomerically pure substances are formed by homogeneous syntheses and then separated using techniques such as the aforementioned creation of diastereomers. Direct enantiospecific syntheses or simpler separation methods would, of course, be preferable. Many such processes, including heterogeneous catalyses and chromatographic separations, are commonly performed using solid surfaces. The types of chiral surfaces that are the subject of this entry have many potential applications in enantiospecific chemical processing.

## TYPES OF CHIRAL SURFACES

Three types of nanostructured chiral surfaces will be described in this entry: those produced by chiral templating with an organic ligand, surfaces derived from chiral bulk structures, and those produced from achiral bulk structures such as metals. In all three cases, the length scale of the chiral features is that of nanometers and thus they can interact enantiospecifically with chiral adsorbates.

### Surfaces Templated with Chiral Organic Modifiers

The adsorption of enantiomerically pure chiral molecules on achiral surfaces yields surfaces that are chiral, provided that the adsorbed molecule retains its chirality. Such surfaces can be used for enantioselective heterogeneous catalysis<sup>[7,8]</sup> or enantioselective chromatography.<sup>[9,10]</sup> The most successful chirally templated, enantioselective heterogeneous catalyst has been Ni templated with tartaric acid, which is used for the asymmetric hydrogenation of  $\beta$ -ketoesters and Pt templated with cinchonidine used for hydrogenation of  $\alpha$ -ketoesters (see

Fig. 3). Many of the underlying issues encountered with these catalysts are common to other template/substrate systems, so this section will focus on these two examples.

### Hydrogenation of $\beta$ -ketoesters on nickel

The enantioselective hydrogenation of  $\beta$ -ketoesters on chirally templated Raney Ni catalysts has been reviewed extensively by Izumi.<sup>[11]</sup> Most works have used Raney Ni and nickel powder as catalysts; however, some have used Ni particles supported on high-surface-area materials such as silica and alumina.<sup>[12]</sup> These catalysts have demonstrated enantioselectivity for the hydrogenation of methyl acetoacetate to methyl-3-hydroxybutyrate, yielding enantiomeric excesses as high as  $ee = 95\%$ .<sup>[13]</sup>

The enantioselectivity of the catalytic hydrogenation of  $\beta$ -ketoesters is influenced by the nature of the Ni used as the catalyst, by the nature of the chiral modifier, and, in some cases, by the nature of a comodifier. In addition to tartaric acid, which has been shown to be the most promising modifier,  $\alpha$ -amino acids have been used. The superiority of tartaric acid is believed to arise from its ability to stereospecifically orient the reacting  $\beta$ -ketoesters on the surface via hydrogen bonding.<sup>[14]</sup> One model has been suggested to explain the enantioselectivity in which chiral five-member chelate rings are formed by the bonding of the tartaric acid to Ni through a carboxylate oxygen atom and the oxygen atom of the  $\beta$ -hydroxyl group.<sup>[15]</sup>

In addition to the nature of the chiral modifier, another factor that determines the enantioselectivity of Ni-based catalysts is the size of the Ni particles. During the modification process of the Ni particles, tartaric acid has been shown to selectively dissolve catalyst particles with diameters less than 2 nm. The tartaric acid creates the pores that contain the hydrogenation sites, and the longer a particle is leached, the more pores it will have. This supports earlier results showing that larger nickel particles yield higher enantioselectivity.<sup>[15–17]</sup>

Comodifiers can also influence the enantioselectivity of chirally templated surfaces. Typically, NaBr is used as the comodifier and is thought to poison the racemic sites, reaction sites that have no enantioselective bias for hydrogenation, thus increasing the net enantiomeric excess.<sup>[18]</sup> However, it has also been proposed that the NaBr modifies the stereochemistry of the product-determining surface complex between the reactant and the chiral template.<sup>[19]</sup>

### Hydrogenation of $\alpha$ -ketoesters on platinum

The most highly studied enantioselective reaction over a chirally modified heterogeneous catalyst is the

**Fig. 4** It has been proposed that the L-shaped structure of the cinchona alkaloid creates three possible reaction sites when adsorbed on a surface. Sites A and B allow the methyl pyruvate to interact with the adsorbed modifier and thus promote enantioselective hydrogenation. Site C is achiral and does not promote enantioselective hydrogenation.

hydrogenation of  $\alpha$ -ketoesters over Pt templated with cinchonidine. Studies of this reaction began in 1978 when Orito et al.<sup>[20]</sup> enantioselectively hydrogenated methyl pyruvate to *R*-(+)-methyl lactate in the presence of adsorbed cinchonidine. As in the case of the enantioselective hydrogenation on modified Ni catalysts, a variety of factors influence the enantioselectivity, including: temperature, the nature of the solvent, modifier concentration, and the size of the Pt particles.

One important aspect of the chirality of the cinchona-templated Pt surface is the structure and adsorption geometry of the cinchona alkaloid<sup>[21]</sup> illustrated in Figs. 4 and 5. There are three available sites for reaction. The first is the chiral cavity where the methyl pyruvate is bound to two or three cinchonidine molecules in an ordered array, the second is the 1:1 interaction between methyl pyruvate and a single cinchonidine molecule, and the third is a racemic site. One important characteristic of cinchonidine is its L-shaped configuration. Studies have shown that replacing the modifier with a chemically similar alkaloid that is not L-shaped, while increasing the reaction rate, eliminates enantioselectivity.<sup>[22]</sup>

Despite the large number of factors influencing the enantioselectivity of templated Pt catalysts, excellent results have been achieved by empirical tuning of pH, solvents, particle sizes, and comodifiers as was done with the Ni/tartaric acid system. Blaser, Jalett, and Wien<sup>[23]</sup> obtained an *ee* = 94% for the hydrogenation of methyl pyruvate. As in the case of the hydrogenation of  $\beta$ -ketoesters on Ni, the exact impact of

**Fig. 5** It has been suggested that three features of the cinchonidine structure are necessary to impart enantioselectivity. First, the quinoline ring system (1) is believed to anchor the modifier to the surface; second, the chirality of the reaction product is directed by the chiral region between the quinoline and the quinuclidine rings (2); and, third, the tertiary nitrogen in the quinuclidine ring (3) interacts with the C=O in the reacting ketoester.

these parameters must ultimately be elucidated to attain enantioselectivities approaching 100%.

### Other chiral templates

Three structural features of the cinchona modifier are thought to impart chirality to the Pt surface.<sup>[7]</sup> First,  $\pi$ -bonding through the quinoline ring system is believed to anchor the modifier to the surface; second, the chirality of the product is directed by the chiral region between the quinoline and quinuclidine rings; and, third, the tertiary nitrogen in the quinuclidine ring interacts with the C=O in the ketoester (Fig. 5). Based on this model for the origin of the enantioselectivity of catalysts templated with cinchonidine, new modifiers based on the cinchona alkaloid, such as dihydroapovincamic acid ethyl ester,<sup>[24]</sup> strychnine,<sup>[25]</sup> and others,<sup>[26,27]</sup> have been identified and have been shown to work with varying degrees of success.

Amino acids have also been identified as potentially useful chiral modifiers for catalytic surfaces.<sup>[25]</sup> In particular, the adsorption of glycine<sup>[28–30]</sup> and alanine<sup>[31,32]</sup> has been studied on Cu(110). These amino acids form well-ordered arrays whose structure is driven by hydrogen bonding. Alanine has been shown to be a promising modifier on Cu(110) because of the existence of a homochiral, two-dimensional phase that extends across the surface.<sup>[32]</sup>

### Surfaces Based on Bulk Chiral Materials

In addition to chiral surfaces that have been templated with chiral ligands, naturally chiral surfaces can be derived from inherently chiral bulk crystalline structures. This can be performed either by exposing a surface of a crystal of an enantiomerically pure organic compound, or by exposing a surface of a naturally chiral crystal. It has been postulated that the chirality of certain naturally occurring minerals may have been critical to the homochiral evolution of life on Earth. The homochirality of naturally occurring biomolecules (i.e., the preference for L-amino acids and D-sugars) may have arisen from enantioselective adsorption on naturally chiral crystal surfaces.<sup>[33]</sup>

#### Surfaces of bulk enantiomerically pure compounds

The crystallization of an enantiomerically pure sample of an organic compound will produce a crystal structure that must be chiral. Similarly, the surfaces of such a crystal must be chiral and should have enantiospecific properties. This ought to offer an excellent avenue for the study of enantiospecific interactions between chiral molecules; however, there do not seem to have been any significant attempts to study the surface chemistry of such materials.

#### Surfaces of bulk enantiomorphous crystals

Intrinsically chiral surfaces can be produced from crystalline materials with inherently chiral bulk structures. One of the most common chiral materials is quartz, whose bulk structure is formed by a helical arrangement of corner-sharing SiO<sub>4</sub> tetrahedra. This helical structure is chiral and renders quartz chiral. There have been some studies of the enantioselectivity of the surfaces of quartz crystals. However, much of this work has used powdered samples, which expose a variety of different crystallographic planes, each of which will have different adsorption characteristics for the same chiral species.<sup>[34,35]</sup> Bonner et al.<sup>[36,37]</sup> studied enantioselectivity on quartz powders prepared from enantiomerically pure crystals. By comparing the adsorbed concentrations of D-alanine and L-alanine on the same faces of quartz, a preferential enantioselective adsorption of approximately 1.4% was observed for D-alanine on right-handed quartz and for L-alanine on left-handed quartz. In another demonstration of enantiospecific surface chemistry, synthesis of pyramidal alkanols with an enantiomeric excess of *ee* > 90% was initiated using quartz and sodium chlorate crystals.<sup>[38]</sup>

Obviously, any material with a bulk chiral structure can expose chiral enantioselective surfaces; however, even achiral minerals can expose chiral surfaces. In an achiral environment, these would have equal surface energies and would be present in equal areas. However, it is possible to prepare achiral minerals, which expose surfaces with net chiral excess when grown in the presence of chiral molecules. When grown in the presence of chiral organic compounds, gypsum displayed an asymmetric growth.<sup>[39]</sup> Calcite, another achiral crystal, has also displayed asymmetric growth in the presence of chiral amino acids.<sup>[40]</sup>

The origin of homochirality in living systems is one of the most intriguing aspects of the development of life on Earth. It has been proposed that the enantioselective processes that must have led to this homochirality occurred on chiral surfaces. To study the origin of the homochirality of life on Earth, Hazen, Filley, and Goodfriend<sup>[41]</sup> have chosen to use calcite, an achiral mineral, which can expose chiral surfaces. Figure 6 shows the chiral facets of crystalline calcite. This mineral was abundant during the Archaean Era, a time in

**Fig. 6** On certain faces of calcite, the CaO<sub>6</sub> octahedra are arranged in a chiral structure.

the Earth's history when the homochirality of life is thought to have originated. Furthermore, amino acids have particularly high heats of adsorption on calcite. The naturally chiral  $(2\ 1\ \bar{3}\ 1)$  and  $(3\ \bar{1}\ \bar{2}\ 1)$  faces showed 10% enantioselective adsorption of D-aspartic acid and L-aspartic acid, respectively. A control experiment using the achiral  $(1\ 0\ \bar{1}\ 1)$  face displayed no preference for aspartic acid adsorption.

Most of the known crystalline materials with naturally chiral bulk structures are covalent inorganic solids such as oxides, which have surfaces with low chemical reactivity. One approach to enhancing their reactivity while maintaining enantioselectivity is through deposition of a transition metal film on their surfaces. Terent'ev, Klabunovskii, and Patrikeev<sup>[42]</sup> and Klabunovskii and Patrikeev<sup>[43]</sup> created a nickel-coated quartz catalyst that enantioselectively hydrogenated  $\alpha$ -phenyl cinnamic acid. The mechanism by which the chiral substrate imparts enantioselectivity to the metal is not clear. On one hand, it may induce chirality in the structure of the metal film. Alternatively, the quartz might orient the reactant enantiospecifically at the edges of Ni particles where they may be hydrogenated. In principle, metal deposition onto chiral substrates is widely applicable to chiral surfaces with low reactivity; however, few works have been done in this field.

### Chiral Surfaces from Achiral Bulk Crystal Structures

Although it may seem counterintuitive, chiral surfaces can be formed from crystalline materials with otherwise achiral bulk structures. This type of chiral surface is created by exposing a high Miller index plane with indices  $(hkl)$  such that  $h \neq k \neq l$  and  $h \cdot k \cdot l \neq 0$ . Most of such surfaces have structures formed of terraces, steps, and kinks, as shown in Fig. 2C. It is the kinks on such surfaces that impart chirality. Each kink is formed by the intersection of three low Miller index microfacets ( $\{111\}$ ,  $\{100\}$ , and  $\{110\}$ ) with different structures.<sup>[44]</sup> The chirality of the kink arises from the sense of rotational progression among the three microfacets when viewed from above the surface. Like chiral molecules, the handedness of chiral surfaces can be denoted by using a modified Cahn–Ingold–Prelog convention based on microfacet priority.<sup>[44]</sup> For fcc metals, the order of priority is  $\{111\} > \{100\} > \{110\}$  and surfaces with a counterclockwise progression of microfacets when viewed from above are denoted  $(hkl)^S$ , whereas surfaces with a clockwise progression are denoted  $(hkl)^R$ . The naming convention and microfacet structure are illustrated in Fig. 7.

If one considers the high Miller index surfaces with terrace–step–kink structures and recognizes that these

**Fig. 7** A kink on a high Miller index surface of an fcc structure is formed by the intersection of three dissimilar low Miller index microfacets ( $\{111\}$ ,  $\{100\}$ , and  $\{110\}$ ). Its handedness is dictated by the direction of rotational progression of the microfacets about the surface normal.

are formed by the intersection of three different low Miller index microfacets, it is clear that there are six types of chiral terrace–step–kink structures that can be formed on the surfaces of achiral bulk structures. The full set of surfaces that can be derived from an fcc bulk structure is usually represented by the stereographic projection shown in Fig. 8. The points on the perimeter of the stereographic projection represent surfaces that are achiral. The six types of chiral kinks divide the interior of the stereographic projection into six regions. The differences in the structures of the surfaces within each region are the lengths of the steps that separate the kinks and the widths of the terraces that separate the steps. The points along the dashed lines of Fig. 8 that separate the regions with different types of kinks represent surfaces with structures that have kinks formed of single unit cells of the low Miller index microfacets. They are also chiral but cannot be thought of as having structures with long step edges separating the kinks. Finally, at the center of the stereographic projection is the  $(531)$  surface with a structure that is formed of single unit cells of the  $(111)$ ,  $(100)$ , and  $(110)$  microfacets. It is also chiral but cannot be thought of as having a terrace–step–kink structure. In summary, the high Miller index surfaces of cubic lattices have structures that expose chiral kinks of a small number of types. These chiral kinks are based on the nanoscale arrangements of atoms at the intersections of microfacets.

### Roughening of naturally chiral surfaces

The ideal chiral surface structures that one obtains by simple cleavage of an fcc lattice along a high Miller index plane are formed of terrace–step–kink structures with nanoscale dimensions. The chiral kinks on the ideal surfaces are always single atom kinks along the step edge. These ideal structures will be destroyed by any amount of atomic motion or diffusion across the surface. A real chiral surface deviates from the ideal surface because of thermal roughening as seen in Fig. 9. Simulations by Sholl, Asthagiri, and Dower,<sup>[45]</sup> Asthagiri, Feibelman, and Sholl<sup>[46]</sup> and Power,

**Fig. 8** The stereographic projection allows a representation of all possible surfaces exposed by cleavage of an fcc structure. The points on the perimeter of the triangle represent achiral surfaces. The points contained within the triangle represent surfaces with kinked structures that are chiral. The dashed lines divide the triangle into six regions containing surfaces with six different kink structures represented by the examples shown in the ball diagrams. At the center of the triangle is the (531) surface, which is comprised of single unit cells of the (111), (100), and (110) microfacets and has the highest kink density of all the chiral surfaces.

Asthağiri, and Sholl<sup>[47]</sup> show that chiral surfaces roughen to form structures with nonideal kinks formed by the intersections of long step edges. Scanning tunneling microscopy of the Cu(5, 8, 90) surface has revealed such roughening of the step edges because of thermal diffusion of the kinks.<sup>[48]</sup> However, it is important to realize that the nonideal kinks generated by step roughening are still chiral because they are formed by the intersections of three different low Miller index microfacets. Equally important, the net chirality of the surface is preserved because the kinks present on the roughened surface are predominantly of the same chirality as the kinks on the ideal high Miller index surface from which it evolved.

**Fig. 9** A thermally roughened surface no longer exhibits the periodic kink structure seen in Fig. 2C. Because of kink coalescence, a thermally roughened surface has fewer kinks than an ideal surface, and these kinks are now formed by the intersection of longer step edges. Despite roughening, the surface maintains its chirality.

### Enantioselectivity of naturally chiral metal surfaces

McFadden, Cremer, and Gellman<sup>[49]</sup> first postulated that the naturally chiral, high Miller index planes of fcc metals ought to exhibit enantiospecific surface chemistry. Atomistic simulations by Sholl<sup>[50]</sup> of the interactions of small chiral hydrocarbons with chiral platinum surfaces demonstrated that such enantioselectivity should occur and that enantiospecific adsorption energies for chiral molecules on chiral surfaces should be observable. Recently, temperature-programmed desorption studies of *R*-propylene oxide and *S*-propylene oxide<sup>[51,52]</sup> and *R*-3-methyl-cyclohexanone<sup>[52,53]</sup> on the Cu(643)<sup>R</sup> and Cu(643)<sup>S</sup> surfaces have revealed enantiospecific adsorption energies. The enantiospecific differences in the adsorption energies of propylene oxide and 3-methyl-cyclohexanone on the Cu(643) surfaces are  $\Delta\Delta E_{\text{ads}} = 0.06$  kcal/mol and  $\Delta\Delta E_{\text{ads}} = 0.22$  kcal/mol, respectively. It is these types of differences in energetics that ultimately lead to enantioselective separations and enantioselective catalytic reactions on chiral surfaces. Such an enantioselective separation of racemic 3-methyl-cyclohexanone has been demonstrated on the Cu(643) surface.<sup>[53]</sup>

In addition to influencing the energetics of adsorption and desorption, the handedness of naturally chiral surfaces can influence the kinetics of surface reactions. Cyclic voltammetry has been used to study the electro-oxidation kinetics of glucose and other sugars on an array of naturally chiral platinum electrode surfaces in aqueous solutions.<sup>[44,54–56]</sup> These studies have shown

that the rates of D-glucose and L-glucose oxidation on naturally chiral Pt electrodes can differ by as much as a factor of three. As in the case of enantioselective hydrogenation on the chirally templated Pt catalysts, the enantioselectivities of glucose oxidation are influenced by the presence of modifiers adsorbed from solutions. In particular, the enantioselectivity of glucose oxidation increases in the presence of sulfuric acid, but decreases in the presence of perchloric acid.

#### Enantiomorphic heteroepitaxial growth of metals on chiral oxides

The nanoscale kinks present on the high Miller index metal surfaces have clearly been shown to exhibit enantiospecific surface chemistry. However, the ultimate utility of surfaces with such chiral structures is dependent on their being produced with high surface area. One approach is to use the chiral surfaces of relatively cheap metal oxides as the substrates for deposition of otherwise expensive catalytic metals such as Pt.<sup>[57]</sup> This is analogous to the enantioselective catalyst mentioned above that was created by the deposition of Ni onto quartz.<sup>[42,43]</sup> In principle, the metal films could be grown epitaxially on metal oxides and, if the metal oxide substrates are prepared with chiral terrace-step-kink structures, the metal film may grow enantiomorphically and retain the chirality of the substrate. Initial work on this problem has suggested that enantiomorphic heteroepitaxial growth of metals on naturally chiral oxide surfaces can be achieved and may serve as a route to inexpensive naturally chiral metal surfaces.

#### Adsorbate-induced formation of naturally chiral surfaces

An adsorbed chiral molecule imparts chirality to a surface merely by its presence. However, it is possible that adsorbate-induced reconstruction of achiral metal surfaces can yield homochiral high Miller index facets with nanoscale kink structures that are naturally chiral. This method of inducing chirality in a surface is distinct from chiral templating in the sense that the chirality of the substrate could be retained even if the adsorbate were removed. This can be thought of as chiral imprinting. Imprinting could serve as a potential route to the inexpensive production of high area chiral surfaces. An example of chiral imprinting arises during amino acid adsorption on the otherwise achiral Cu(100) surface.<sup>[58–60]</sup> Step bunching on the Cu(100) surface in the presence of adsorbed L-lysine causes the formation of a homochiral set of {3, 1, 17} facets. The chirality of the facets is dictated by the chirality of the L-lysine. Although achiral amino acids will induce the formation of {3, 1, 17} facets on the Cu(100) surface, they are present in both *R* and *S* forms.

## TECHNOLOGICAL IMPACT OF CHIRAL SURFACES

The potential technological impact of chiral surfaces is enormous because they can, in principle, play an important role in the processing of chiral pharmaceuticals worth an estimated US\$100 billion per year. At this point in time, the most highly developed application is as stationary phases for chiral chromatography. Chiral columns are often formed by templating of materials such as silica with enantiomerically pure chiral ligands.<sup>[9,10]</sup> Templating has also been shown to produce enantioselective heterogeneous catalysts, which, in principle, offer some advantages over homogeneous catalysts during scaleup. Thus chiral templating of surfaces is a demonstrated technology with growing opportunities for application in pharmaceuticals production.

The study of the enantioselective surface chemistry of naturally chiral surfaces and, in particular, those derived from kinked high Miller index metal surfaces is in its infancy. In principle, they offer potential advantages over templated surfaces in that they may be more thermally and chemically robust because they do not rely on organic ligands as the source of chirality. Another opportunistic niche that the naturally chiral surfaces may fill is in the development of microscale reactors. In reactors based on single-crystalline Si, it is easy to imagine that one could make channels that expose naturally chiral surfaces, and that such an element in a microreactor might then be used for enantioselective chemical processes. Although the impact of naturally chiral surfaces is yet to be determined, there are a number of exciting opportunities. Furthermore, the possible role that naturally chiral surfaces may have played in dictating the origins of the homochirality of life on Earth makes their study intrinsically intriguing.

## CONCLUSION

Of the three types of chiral surfaces described in this article, the most well developed are those that are produced by templating with chiral organic modifiers. Although the mechanisms and adsorbate/substrate interactions that impart enantioselectivity on these surfaces are not understood in great detail, some such surfaces have been highly optimized to give highly enantioselective separations and catalytic reactions. Naturally chiral surfaces can be generated from materials that are chiral in bulk, or achiral materials cleaved to expose surface structures that are chiral at the nanoscale. The crystalline nature of these structures makes them good candidates for a detailed study of the origins of enantiospecificity on their surfaces.

Furthermore, they have demonstrated high enantioselectivity for both reactions and separations. The limitation in their practical use is the need for methods of preparation that yield naturally chiral surfaces in high area form. Although possible routes exist, these have yet to be explored.

## ACKNOWLEDGMENTS

We would like to thank Prof. David Sholl and Prof. Greg Rohrer for their helpful discussions. The authors' work on naturally chiral crystals is supported by the NSF through grant no. CTS-0216170 and by the DOE through grant no. DMR-0079996.

## INTRODUCTION

Nanoparticles and nanodomains are omnipresent in low-temperature environments at the Earth's surface, including the hydrosphere and the atmosphere. This part of the Earth is often referred to as the "critical zone"<sup>[1]</sup> because this zone experiences the greatest impact from human activities. The relatively low temperatures (<100°C) of the critical zone are conducive to the formation and survival of nanoparticles.<sup>[2]</sup> Many trace elements are toxic (Pb, Hg, and As), and their release and mobilization at the nanoscale can cause serious health effects.<sup>[3]</sup> However, other trace elements (e.g., Se) are essential for life forms and have an important impact on the success of different organisms in different ecological systems.<sup>[4]</sup> In addition, the speciation and distribution of trace elements have important implications for geologic processes, such as the formation of ore deposits, environmental contaminations, and geologic age dating using isotopes (e.g., U, Th, and Pb).<sup>[5]</sup> Trace elements in the critical zone are frequently present as dispersed nanoparticles, or in nanodomains that contain the elements at relatively high concentration. Finally, at the nanoscale, the chemical, thermal, and electronic properties of materials can change dramatically from bulk values as a function of size.<sup>[6,7]</sup>

For our understanding of nanoparticles in environmental and geological sciences to continue to develop, our ability to directly study the chemical and structural forms of these particles at continually shorter length scales becomes evermore critical.<sup>[8]</sup> This brief review of traditional analytical techniques illustrates a few of these techniques, their applications, and their limitations. The remainder of this article will focus on the application of high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM)

and associated high-resolution analytical techniques by presenting four examples. These examples will focus on heavy trace elements of importance in the fields of geological and environmental sciences.

## CONVENTIONAL TECHNIQUES

Scanning electron microscopy (SEM) can provide submicrometer morphological information, but the coupled elemental analysis through an energy-dispersive spectrometer (EDX) or a wavelength-dispersive spectrometer (WDS) on an electron microprobe analyzer (EMPA) is limited to a volume of several cubic micrometers. Atomic force microscopy (AFM) and scanning tunneling microscopy (STM) provide surface information at the atomic scale; however, elemental data cannot be obtained except in the case of well-controlled, simple experiments.<sup>[9]</sup> Other techniques that are useful in analyzing ultrafine particles—such as electron energy loss spectroscopy (EELS), which provides elemental and valence information, and secondary ionization mass spectrometry (SIMS), which provides isotopic information—both have beam sizes that cannot resolve individual nanoparticles.<sup>[10,11]</sup> Each of the above techniques, under proper conditions, can provide information about nanoparticle characteristics; however, none of these techniques is capable of locating or providing direct chemical and structural information about an individual particle.

In contrast, transmission electron microscopy (TEM) has become recognized as the most powerful and appropriate technique for the direct investigation of nanoscale particles. Coupled with EDX, STEM has been applied to the characterization of colloids.<sup>[12,13]</sup> With traditional STEM resolution, the size of particles studied is typically

limited to the range of 100–1000 nm, and only major element compositions can be routinely determined. For smaller particles (<100 nm), conventional transmission electron microscopy (CTEM) and associated spectroscopies have been commonly applied to the structural and elemental characterization of nanoparticles.<sup>[14–16]</sup> The major limitation to CTEM is that image contrast is minimal (except at the highest magnifications and, subsequently, the smallest field of view). This makes locating specific nanoparticles (i.e., those that host the elements of interest) in a bulk sample extremely difficult. The difficulty in locating the element of interest limits the utility of CTEM to real-world environmental samples that contain only trace concentrations of an element of interest (e.g., a few parts per million).

In such cases, when the particles of interest consist of relatively heavy elements situated in a lighter matrix material, HAADF-STEM is a powerful method for locating and studying the nanoparticles of interest, as the image contrast is strongly correlated with atomic number.

## ANALYTICAL TECHNIQUES

To study a sample by TEM, a sample must be made thin enough to allow transmission of the electron beam. Sample preparation for advanced TEM is a critical step that can affect the ultimate resolution and the ability to perform the desired analyses on a given sample. For particulate samples, a fine size fraction of particles (<1  $\mu\text{m}$ ) is dispersed onto a 3-mm grid that is covered by a film of lacey carbon. The carbon, which is transparent to the electron beam, acts as a support for the particles. For rock or mineral samples, the sample is mechanically polished to a thickness of  $\sim 10 \mu\text{m}$ . Final thinning is carried out using an ion milling system where a beam of Ar ions bombards the sample to create a nanometer-scale thin edge on the sample.

Samples illustrated in this article were studied using a JEOL JEM2010F high-resolution transmission electron microscopy analytical electron microscopy (HRTEM-AEM) with HAADF-STEM imaging. Fig. 1 shows a schematic illustration of the HAADF-STEM.

**Fig. 1** Schematic illustration of the electron microscope configuration used in the HAADF-STEM mode (JEOL JEM2010F). Source: From Ref.<sup>[17]</sup>.

In contrast to CTEM mode where elastically scattered electrons are diffracted by the sample to create an image, an HAADF image is created by electrons that are scattered by thermal diffuse scattering. The amount of scattering is dependent on the average atomic number of the scatterer (i.e., the sample). As shown in Fig. 1, the HAADF detector is an annular dark-field detector that collects electrons scattered at an angle between 50 and 110 mrad. The final image is produced by rastering the electron beam across the sample in two dimensions to produce an image in which contrast is proportional to atomic mass. The intensity profile in HAADF-STEM for some elements was simulated<sup>[17]</sup> with the code developed by Kirkland<sup>[18]</sup> (Fig. 2). In general, a heavier element shows a higher signal in an HAADF-STEM image; however, other factors that can affect the HAADF-STEM image contrast include: 1) specimen thickness: a thicker area shows a brighter contrast; 2) crystal structure: an amorphous domain will produce less contrast than a crystalline phase of similar concentration. The lack of structural configuration results in a loss of efficient thermal diffuse scattering; and 3) density: low-density areas produce less contrast than high-density regions of similar composition. A more rigorous treatment of HAADF theory is given in Kirkland.<sup>[18]</sup>

Elemental data are collected using an EDX detector, which collects X-rays emitted from the sample as a result of the sample–electron beam interaction. The energy of an X-ray emitted is characteristic of the generating atom. Elemental data can be collected from a single point as small as 0.2 nm, or the beam can be moved across the sample in a grid to create an elemental map. While collecting an elemental map, TEM samples have a tendency to drift. To minimize the effect of specimen drift, a computer-controlled drift

correction mode is used to track sample movement during mapping.

## EXAMPLES

### Uranium Nanocrystals in Atmospheric Particulates

The first example is uranium in an urban aerosol.<sup>[19]</sup> Public exposure to ionizing radiation comes mostly from natural sources, accounting for over 80% of the average individual dose of less than 4 mSv/year. The principal source of radioactivity is from radionuclides in the decay chains of <sup>238</sup>U, <sup>235</sup>U, and <sup>232</sup>Th. Fly ash from coal combustion is one of the major sources of release of radioactive elements. Although the total radioactivity of these nuclides is low and accounts for only a small fraction of the radiation exposure from natural sources, the radioactivity associated with uranium and thorium in airborne particulates continues to be of concern. In addition, recent results have shown that very-fine-sized particulates (less than 2.5 μm in diameter) in air pollution can produce significant effects on health.<sup>[20]</sup> Thus it is important to develop an understanding of the association of radioactive elements with atmospheric particulates. The questions of importance are: 1) What is the solid-state speciation of radioactive elements in the atmosphere? 2) In what size range of particulates are the radioactive elements associated? 3) How are the trace elements associated with particulates? Ultimately, these data are required for the determination of pathways of the exposure of the public to technogenic sources of radioactivity. To address these questions, atmospheric particulates from an area of Detroit, MI were examined in detail using advanced TEM techniques. Previous success in directly studying such samples has been largely limited because of the low concentrations (less than 10 ppm) and extremely small particle size (a few tens of nanometers) of the aerosol samples. However, because the radioactive elements of interest are relatively heavy elements (i.e., U and Th), HAADF-STEM could be used to scan relatively large areas of the sample to search for particles of interest.

The sample studied was composed of mainly quartz, gypsum, clays, and Fe oxides with a measured bulk U concentration of 9.2 ppm (0.25 ng/m<sup>3</sup>). This U concentration is comparable to average crustal compositions in the Earth<sup>[21]</sup> and is lower than the concentration of U in soot from coal-fired power plants.<sup>[22]</sup> Based on correlation analysis using the other elements analyzed, both coal combustion and traffic pollution have contributed significantly to the material collected in these samples.

Fig. 2 Simulated contrast profile in HAADF-STEM calculated for some elements. The atoms of a given element were placed in a row at 1-nm intervals. Source: From Ref.<sup>[17]</sup>.

TEM analysis revealed a considerable amount of soot (carbonaceous matter) at the surface of the mineral particles. The soot particles in these aerosol samples were a few tens of nanometers in size and had rounded shapes (Fig. 3A). Using HRTEM, each soot particle showed a range in crystallinity from nearly amorphous to highly crystalline carbonaceous matter (Fig. 3B and C). The crystallinity of carbon depends on the ambient environment of formation, especially the temperature and cooling history. In general, higher temperatures produce a more crystalline form of carbon.<sup>[23]</sup> The varying degrees of crystallinity of the samples from Detroit suggest that these particulates have experienced a variety of

**Fig. 3** Carbonaceous matter in the soot of aerosol (A). Rounded carbon particles from a connected mass form larger particles. HRTEM of the carbonaceous matter shows various degrees of crystallinity from a small amount of rounded fringes (B) to the very crystalline carbon (C). *Source:* From Ref.<sup>[19]</sup>.

thermal histories, thus consistent with a variety of sources. Of particular interest are HRTEM images (Fig. 3B and C) of crystalline soot that show a lattice fringe spacing of  $\sim 0.35$  nm, which is comparable to those of either graphite or fullerene.

The HAADF-STEM image showed a high density of bright-contrast particles less than 10 nm in size (Fig. 4A). STEM-EDX maps of the square region in the HAADF-STEM image reveal that the particles consist of uranium and oxygen (Fig. 4A). Further analysis using HRTEM reveals that U-bearing particles were encapsulated in a well-crystallized carbonaceous graphite or spherical fulleroid matrix, as shown in Fig. 4B. By HRTEM, it was established that the uranium-bearing particles are individual nanocrystallites (Fig. 5A) of uraninite ( $\text{UO}_{2+x}$ ,  $x = 0-0.25$ ;  $Fm\bar{3}m$ ), based on lattice spacings in the image and diffraction maximum in the fast Fourier transform (FFT) (Fig. 5C) of the boxed region in the HRTEM image (Fig. 5B).

The encapsulated uraninite in this “fulleroid shell” appears to be partially protected from ambient oxidizing

**Fig. 4** (A) HAADF-STEM image reveals the occurrence of many heavy particles less than 10 nm in size. The insets are elemental maps of uranium and oxygen by STEM-EDX. conditions of the atmosphere. This further reduces mobility in the environment, as oxidized species of uranium are much more mobile in solution. The present results provide the basis for a detailed determination of uranium bioavailability, and also new insights into the process of transportation of uranium by aerosols.

### Heavy Element Colloids at the Nevada Test Site

Migration of plutonium and other radiotoxic elements is a serious issue in the disposal of radioactive waste in a geologic repository. In general, colloids, which are defined as particles less than 10  $\mu\text{m}$  in diameter, are thought to play an important role in the migration of elements through groundwater systems.<sup>[24–26]</sup> Thus the adsorption of radionuclides on colloids has been extensively studied.<sup>[27–29]</sup> Recently, the ratio of  $^{240}\text{Pu}/^{239}\text{Pu}$  in the groundwater from a well (ER-20-5) that is located 1.3 km away from the Benham nuclear test site was determined to have the same ratio of  $^{240}\text{Pu}/^{239}\text{Pu}$  as Pu at the Benham site.<sup>[30]</sup> This evidence suggests that Pu had been transported through the groundwater at least 1.3 km in 35 years, far faster than the rate predicted by groundwater flow models. Radiochemical analysis of filtered colloids from the well suggested that colloids in the groundwater have absorbed important radioactive elements such Co, Cs, Eu, and Pu.<sup>[30]</sup> However, an important question remained: What is the form of the radioactive elements associated with the colloids? In an attempt to locate and characterize the phase containing these heavy elements in a sample with such low concentrations of the elements of interest

(<math>10^{-14}</math> M of Pu in groundwaters), HAADF-STEM was applied. Samples consisted of solid colloids filtered out of the groundwaters from the same contaminated well at the Nevada test site. Three important and potentially radionuclide elements (Co, Cs, and Eu) were identified in the sample. Based on HRTEM images, Co was identified to exist with Mo and Cr in the structure of awaruite ( $\text{Ni}_2\text{Fe}$ ) (Fig. 6A). The Cs-bearing phase consisted of Cs, O, and U, possibly forming a Cs uranate (Fig. 6B). The Eu-bearing phase was monazite (Fig. 6C). The interesting result is that the three potentially radioactive elements were present not as adsorbed surface species, but structurally incorporated into a mineral. Although Pu has not been detected yet, these results show that the HAADF-STEM is useful for investigating such colloids associated with radioactive trace elements.

### Gold Nanocrystals in a Gold Ore Deposit

The Carlin trend in Nevada hosts some of the largest gold deposits in the United States.<sup>[17,31,32]</sup> Despite the economic and scientific interest these deposits have generated, the large concentrations of gold are present at relatively low concentrations in the host rock (30–150 ppm Au) and have never been directly observed—an attribute that has led to the term “invisible gold” being commonly applied to the gold-bearing rocks of Carlin-type deposits.<sup>[33,34]</sup> The majority of gold in the ore have been shown to be associated with hydrothermally formed arsenian pyrite overgrowths that have formed over pyrite ( $\text{FeS}_2$ ) grains.

Although the presence of gold in the arsenic-bearing rim has been established, the mineralogical state of gold remains in question. In particular, is the gold present structurally incorporated into the mineral, or is it present as native gold inclusions at the nanoscale? The HAADF-STEM image clearly revealed a heterogeneous occurrence of heavy element nanoparticles less than 30 nm in diameter embedded in a matrix containing relatively lighter elements (As, Fe, and S) (Fig. 7A). The EDX mapping of an area containing the bright nanoparticles clearly revealed that Au nanodomains occur within the pyrite matrix (Fig. 7B). HAADF-STEM was also able to show the lattice image of gold nanoparticles in high-resolution mode (Fig. 7C). The lattice image of gold domains showed a perfect array of gold atoms, suggesting that gold atoms do not exist in an interatomic site of pyrite but as gold metal crystals. The FFT image of the high-resolution HAADF-STEM was indexed and determined to be structurally consistent with elemental gold. In this example, the occurrence and form of gold nanoparticles in high enough concentrations to account for the majority of gold in the rim were, for the first time, directly established in samples from a Carlin-type gold deposit.

**Fig. 6** HAADF-STEM image and the elemental maps of groundwater colloids bearing potential fissiogenic elements from the ER-20-5 well at the Nevada test site. (A) A Co-bearing colloid. Cobalt associated with other metallic compounds Ni, Mo, Cr, and Fe. The structure is similar to the alloy phase, awaruite, based on the diffraction pattern. (B) A Cs-bearing colloid. Cesium is associated with only U, whereas Fe and Si maps are derived from background phases. The Cs phase is anticipated to be cesium uranate. (C) An Eu-bearing phosphate phase with a monazite structure contained the other light rare earth elements.

### Lead in an Early Archean Zircon

Zircon ( $\text{ZrSiO}_4$ ) is one of the most thoroughly studied natural phases because of its predominant use in geochronology<sup>[5]</sup> and other isotopic studies.<sup>[35–37]</sup> Zircon has also been proposed as a waste form for

**Fig. 7** (A) A HAADF-STEM image of arsenian pyrite rim developing over pyrite grains from Twin Creeks, NV shows that many bright particles are embedded in arsenian pyrite matrix. (B) The elemental maps indicate that the nanodomains consist of Au. (C) A HR-HAADF-STEM image of a bright nanodomain reveals evidence of crystalline of gold at an atomic scale. Inset: The FFT showing an indexed pattern consistent with native gold. *Source:* Panels a and b from Ref.<sup>[17]</sup>.

immobilization of plutonium from dismantled nuclear weapons<sup>[38]</sup> because it is so physically and chemically durable.<sup>[38]</sup> In each of these applications, the loss of trace elements, in particular U, Pb, and Pu, is of critical interest. Furthermore, elemental loss may be more enhanced by radiation damage caused by the  $\alpha$ -decay of constituent actinides  $^{232}\text{Th}$ ,  $^{235}\text{U}$ ,  $^{238}\text{U}$ , and radionuclides in their decay series.<sup>[39]</sup> The fate of Pb is critical in U–Th–Pb isotopic dating because Pb loss caused by radiation-enhanced

alteration of zircon is a common cause of discordant dates.<sup>[40,41]</sup> Thus the diffusion of Pb, coupled with the diffusion of U and Th, has been extensively studied, and the Pb diffusion rate is generally considered to be faster than that of the tetravalent actinides U, Th, and Pu.<sup>[42,43]</sup>

Although a previous study<sup>[43]</sup> has pointed out that the valence of Pb in zircon must affect the Pb diffusion rate, the form of Pb in zircon has never been determined because of its relatively low concentration in zircon. In this study, zircon crystals from the Jack Hills meta-sedimentary belt, representative of some of the oldest minerals of the Earth (sample 01-JH-54: age range 4.4–3.3 Ga),<sup>[44]</sup> were investigated using advanced TEM techniques. Because zircon is relatively resistant to electron beam effects and the mass of Pb is considerably greater than the elements comprising the zircon matrix (Zr, Si, and O), high-resolution HAADF-STEM and nanoelemental mapping were used to determine the location and distribution of Pb within zircon.

In a well-crystalline area of the zircon sample, HAADF-STEM imaging provides a Z-contrast image in which Pb-rich regions will appear brighter against the lower average atomic mass of the zircon matrix. This technique revealed some relatively high-contrast patches (~5 nm in the diameter) (Fig. 8A), and nano-scale elemental maps confirmed higher concentrations of Pb in these areas. The Zr content was significantly depleted in the Pb-rich region, whereas the Si distribution in the same region did not show any detectable depletion (Fig. 8A). Semiquantitative analyses indicated that the concentration of Pb in the white spots was ~3 wt.% (elemental) (Fig. 8C). High-resolution (HR) HAADF-STEM images of a Pb-rich region show a continuous zircon structure without distortion across the Pb-rich region (Fig. 8C). Because the HR-HAADF-STEM image is formed by an incoherent imaging process,<sup>[45]</sup> the Pb atoms simply appear as brighter spots than Zr, although Zr atoms appear as relatively bright spots compared with Si and O (Fig. 8D and E). The FFT image of Fig. 8C was

**Fig. 8** Patchy concentrations of Pb in zircon. (A) HAADF-STEM image with elemental maps of the boxed region. (B) The EDX spectrum of the bright region in (A) analyzed by a nanoprobe (1 nm in the diameter). Copper peak is derived from Cu grid. (C) HR-HAADF-STEM image from the view along [010] with the inset of the FFT image. (D) The projected position of Zr atoms in zircon structure along [010], based on the configuration of Zr atoms in zircon.<sup>[42]</sup> The radius of the ball is scaled to the ionic radius of  $\text{Zr}^{4+}$ . The box represents the unit cell. (E) A typical image of pure zircon using HR-HAADF-STEM. The relatively heavier element, Zr, shows the brightest contrast compared to Si and O. (F) The inverse FFT image from the opaquely masked the diffraction pattern (inset). (G) The inverse FFT image from the masked diffraction (inset). *Source:* From Ref.<sup>[35]</sup>.

masked to extract structural information (Fig. 8F and G). The filtered image suggest that: 1) Pb atoms were incorporated directly into the zircon structure; and 2) there is no other phase that contains Pb (Fig. 8F and G). Based on the distribution of Pb in this area (Fig. 8A) and the structural information provided by HR-HAADF-STEM (Fig. 8B), we conclude that the Pb substitutes directly for Zr in the zircon structure. The replacement of Zr by Pb without distortion of the zircon lattice requires that the ionic radius of the incorporated Pb be comparable to that of  $Zr^{4+}$ , implying that Pb in zircon is tetravalent. However, the Pb–O system is dominated by PbO under typical geological conditions, with a small stability field for native Pb, whereas the stability field for  $PbO_2$  exists only at far more oxidizing conditions.<sup>[46]</sup> One explanation for the incorporation of tetravalent Pb into the zircon structure is that the compatibility of the size and charge with  $Zr^{4+}$  results in an expansion of the  $Pb^{4+}$  stability field.

In addition to the patchy occurrence of Pb, numerous fission tracks (<5 nm width) created by high-energy (~100 MeV) heavy particles from spontaneous fission events were imaged (Fig. 9A and B). The majority of the fission tracks showed a dark contrast in the HAADF-STEM images; however, one fission track showed bright contrast throughout the length of the entire track (Fig. 9C). The elemental maps indicated that the fission track had a higher concentration of Pb than

the matrix. The HR-HAADF-STEM image of this area (Fig. 9D) indicates that: 1) the edge of the zircon lattice (arrow 1) shows a lattice image with higher contrast than the bulk zircon matrix, suggesting the incorporation of Pb atoms in the zircon lattice adjacent to the fission track. The incorporation of Pb in the surrounding zircon matrix could be caused by diffusion from accumulated Pb in the fission track; 2) there is no continuous lattice within the track (arrow 2). The interface between the zircon matrix and the fission track (arrow 3) shows a disordered array of bright contrast, suggesting that the accumulated Pb is not in a crystalline phase, or, if crystalline, is without any preferred orientation relative to the surrounding zircon structure. In addition, the oxygen distribution in this area does not show any evidence of O depletion in the fission track, which indicates that Pb is not present as elemental Pb.

The occurrence of Pb in the fission track is obviously not original because spontaneous fission occurred after zircon formation. Thus Pb accumulated in the track by diffusion, which, in the case of the images shown in Fig. 9C and D, appears to be at the end of the fission track. A similar texture of U or Th accumulation in the fission track was not observed. In general, fission tracks are amorphous regions,<sup>[47]</sup> as anticipated by irradiation experiments using highly energetic heavy ions.<sup>[39]</sup> The Pb that has accumulated in the fission track observed here suggests that Pb has diffused through the amorphous

**Fig. 9** Pb accumulation in a fission track. (A) Bright-field TEM image of a fission track. (B) HRTEM image of the fission track from the view along [010]. The direction of the fission track is parallel to the (010) plane. (C) HAADF-STEM image of the fission track with the elemental maps of the boxed area. (D) HR-HAADF-STEM image of the fission track (the boxed area in panel C) from the view along [010]. Source: From Ref.<sup>[35]</sup>.

volumes, such as fission tracks, as well as metamict domains resulting from the accumulation of  $\alpha$ -decay event damage. In fact, previous experiments<sup>[48,49]</sup> on the Pb diffusion rate in zircon have predicted that Pb diffusion through highly damaged paths would increase the diffusion rate. These results show the importance of Pb diffusion through amorphous domains that result from radiation damage.

## CONCLUSION

Each of these briefly described examples demonstrates that HAADF-STEM is a powerful technique for the investigation and identification of trace elements in nanoscale particles (either crystalline or amorphous). This is a particularly useful technique when relatively heavy elements occur at extremely low bulk concentrations (parts per billion to parts per million). When there is a relatively large difference in atomic mass among constituent elements, HR-HAADF-STEM can provide useful information on the elemental distribution at the near-atomic scale. Once the nanoparticles are located by HAADF-STEM, characterization can be also completed using HRTEM. The combination of HAADF-STEM, STEM-EDX mapping, and HRTEM is presently the only method that can provide a complete characterization of each heavy trace element at the nanoscale. HAADF-STEM-EDX is a breakthrough technique that will have many applications in nanogeoscience and environmental science.

## ACKNOWLEDGMENTS

The authors are grateful to Drs. M. Kawasaki and S. Johnson (JEOL USA, Inc.) for technical advice in the use of the HAADF-STEM. Profs. S. E. Kesler and G. J. Keeler (University of Michigan) and Dr. A. B. Kersting (Lawrence Livermore National Laboratory) kindly provided the samples. We thank Drs. J. F. Mansfield and C. J. Wauchope for daily maintenance of 2010F. Electron microscopy was completed at the Electron Microbeam Analysis Laboratory (EMAL) at the University of Michigan. This work was supported by the University of Michigan's GeoScience and Engineering Initiative and the Environmental Management Sciences Program of DOE (DE-FG07-97ER14816).

# Environmental Nanoparticles

Alexandra Navrotsky

Department of Chemical Engineering and Materials Science, University of California–Davis, Davis, California, U.S.A.

## INTRODUCTION

Nanoparticles have no exact definition, but they are aggregates of atoms bridging the continuum between small molecular clusters of a few atoms and dimensions of 0.2–1 nm and chunks of solid containing millions of atoms and having the properties of macroscopic bulk material. In water, nanoparticles include colloids; in air, they include aerosols. Nanoparticles are ubiquitous. We pay to have them. We pay more to not have them. They occur as dust in the air, as suspended particles that make river water slightly murky, in soil, in volcanic ash, in our bodies, and in technological applications ranging from ultratough ceramics to microelectronics. They both pollute our environment and help keep it clean. Microbes feast on, manufacture, and excrete nanoparticles.

Understanding nanoparticle formation and properties requires sophisticated physics, chemistry, and materials science. Tailoring nanomaterials to specific applications requires both science and Edisonian inventiveness. Applying them to technology is state-of-the-art engineering. Tracing their transport and fate in the environment invokes geology, hydrology, and atmospheric science. Applying them to improving soil fertility and water retention links soil science and agriculture to surface chemistry. Understanding their biological interactions brings in fields ranging from microbiology to medicine. Probing the impact of nanoparticles on humans and of human behavior on the production and control of nanoparticles requires the behavioral and social sciences, e.g., in dealing with issues of automotive pollution. The purpose of this review is to describe some of the unique features of nanoparticles and to discuss their occurrence and importance in the natural environment.

Although we often think of the natural environment as that part of the planet which we can see, a somewhat broader definition includes the “critical zone”: the atmosphere, hydrosphere, and shallow portion of the solid earth that exchange matter on a geologically short time scale, on the order of tens to thousands of years. This critical zone affects us directly, and our activities influence it. Because of the active chemical reactions continuously taking place in the critical zone, and because its temperatures and pressures are

relatively low and it is dominated by water, solids are constantly being formed and decomposed. Many of these solids start out as nanoparticles; many remain so. In a yet broader sense, our entire planet from crust to core, the solar system, and the galaxy are part of our environment.

## PHYSICAL CHEMISTRY OF NANOPARTICLES

A major feature of nanoparticles is their high surface-to-volume ratio. Fig. 1 shows the volume fraction within 0.5 nm of the surface for a spherical particle of radius  $r$ . One can think of this fraction either as the fraction of atoms likely to be influenced by processes at the surface, or as the fraction of the volume of a material that could be taken up by a 0.5-nm coating of another material. In the first case, because the surface dominates chemical reactivity, the increased surface to volume ratio means that nanoparticles dominate chemical reactions. In the second case, the ability to carry a substantial coating offers a mechanism for the transport of nutrients or pollutants.

Many oxides are *polymorphic*, exhibiting several crystal structures as a function of pressure and temperature. Often, nanosized oxide particles crystallize in structures different from that of large crystals of the same composition.<sup>[1]</sup> Examples are  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>, a defect spinel rather than  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>, corundum,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, the defect spinel maghemite rather than  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, hematite, and the anatase and brookite forms of TiO<sub>2</sub> rather than rutile. From arguments based on transformation sequences and the occurrence of phases, it was long argued that there may be a crossover in phase stability at the nanoscale if the structure which is metastable for large particles has a significantly lower surface energy.<sup>[2]</sup> This has been proven for alumina and titania in recent calorimetric studies (Fig. 2).<sup>[3,4]</sup> The resulting transformation enthalpies and surface energies, and those of other related systems are shown in Table 1. Another interesting feature is that the hydrous phases AlOOH boehmite and FeOOH goethite have significantly lower surface energies than their anhydrous counterparts, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>.<sup>[5,6]</sup> Whether this is a general feature of hydrous minerals with hydroxylated surfaces is not yet known.

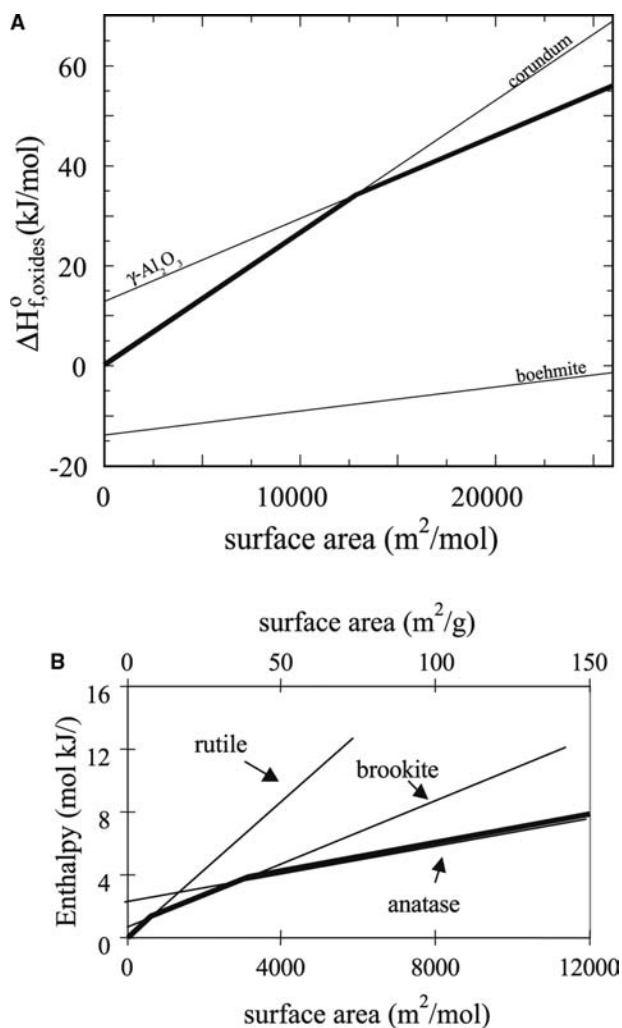

**Fig. 1** Volume fraction of a nanoparticle within 0.5 nm of the surface as a function of particle radius. *Source:* From Ref.<sup>[41]</sup>. Kluwer Academic Publishers.

As particles become less than about 10 nm in size, their X-ray diffraction patterns are broadened sufficiently that they begin to appear “X-ray amorphous” (Fig. 3). This term lacks exact definition. High-resolution electron microscopy may still detect periodicity, and short-range order is certainly present.<sup>[7]</sup> The identification of structure in 1–10 nm particles is very difficult, and phases are empirically described as, for example, “two line ferrihydrite,” based on x-ray diffraction patterns.<sup>[8]</sup>

## NANOPARTICLES IN SOIL AND WATER

Soil is a complex aggregate of inorganic, organic, and biological material.<sup>[9]</sup> Its constituents of largest size are rocks and gravel, small animals, plant roots, and other debris. Smaller mineral grains, clumps of organic matter, and microorganisms make up an intermediate size fraction. The smallest particles, ranging into the nanoscale, are clays, iron oxides, and other minerals. These are often heterogeneous and coated by other minerals and organic matter. The entire composite is porous and hydrated. The percolation of water in soil transports both nanoparticles and dissolved organic and inorganic species. The texture and porosity, as well as the chemical composition and pH, are crucial to biological productivity. The surfaces of nanoparticles provide much of the chemical reactivity for both biological and abiotic processes.

Major aluminosilicate minerals in soils include clays, zeolites, and poorly crystalline phases (Table 2). These can change their water content in response to ambient conditions, often swelling in wet seasons, and shrinking in dry seasons. These nanophase materials are major controllers of soil moisture and

**Fig. 2** (A) Enthalpies of alumina polymorphs as a function of surface area. *Source:* From Ref.<sup>[3]</sup>. (B) Enthalpies of titania polymorphs as a function of surface area. The heavy lines show the stable polymorphs in each size range. *Source:* From Ref.<sup>[4]</sup>. PNAS.

permeability. Iron and manganese oxides are another class of major soil minerals. Their extensive polymorphism at the nanoscale makes them highly variable. They sequester and/or transport and make available the essential plant nutrient iron, as well as other essential transition metals (cobalt, copper, zinc, etc.). They frequently carry coatings of other metal oxides and oxyhydroxides, including toxic metals such as lead and chromium. They also frequently have organic coatings. Sulfates, including the jarosite–alunite family of hydrated [(K, Na), (Al, Fe)] sulfates, are another important constituent. In alkaline and arid environments, other sulfates and halides form, and their formation, dissolution, and transport is a major issue in heavily irrigated regions. How much these processes are controlled by nanoscale phenomena is not known.

**Table 1** Energetic parameters for oxide and oxyhydroxide polymorphs

Formula	Polymorph	Metastability (kJ/mol)	Surface energy (J/m <sup>2</sup> )
Al <sub>2</sub> O <sub>3</sub> <sup>a</sup>	Corundum ( $\alpha$ )	0	2.6
	Spinel ( $\gamma$ )	13.4	1.7
Fe <sub>2</sub> O <sub>3</sub> <sup>b</sup>	Hematite	0	0.8
	Maghemite	20	0.8
TiO <sub>2</sub> <sup>c</sup>	Rutile	0	2.2
	Brookite	0.7	1.0
	Anatase	2.6	0.4
AlOOH <sup>d</sup>	Diaspore	0	?
	Boehmite	4.9	0.5
FeOOH <sup>b</sup>	Goethite	0	0.3
	Lepidocrocite		0.3

<sup>a</sup>From Ref.<sup>[3]</sup>.<sup>b</sup>From Ref.<sup>[6]</sup>.<sup>c</sup>From Ref.<sup>[4]</sup>.<sup>d</sup>From Ref.<sup>[5]</sup>.

Groundwater is constantly in touch with soil and rock, and minerals are dissolving and precipitating as it flows. The load of fine sediments in streams and groundwater can be substantial, especially during spring floods. The Missouri River is called “the Big Muddy” because of its load of particulate matter, a large fraction of which is of nanoscale dimensions. The yearly flooding of the Nile, depositing fertile soil with its large nanoparticle content, made ancient

Egyptian civilization flourish. Today, one of the major concerns of our system of dams, especially in the arid western United States, is interference with the normal cycle of sediment transport and “silt up” of the lakes behind the dams. Silt is partly nanoparticles.

Contaminants and pollutants in water can be transported as aqueous ions (dimensions <0.5 nm), as molecular clusters (0.5–2 nm), as nanoparticles (2–100 nm), as larger colloids (100–1000 nm), and as macroscopic particles (>1  $\mu$ m). These size range distinctions are rather arbitrary and serve to illustrate the continuity between the dissolved and the solid state. Several examples illustrate this complexity. Aluminum oxyhydroxide particles can transport transition metals such as nickel, cobalt, and zinc, seemingly as adsorbed coatings. Initially thought to be loosely bound metal complexes at the surface of the aluminum oxyhydroxide mineral grain, these are now realized to be precipitates, only a few atomic layers thick, of mixed double hydroxides of the hydrotalcite family, in which anions such as carbonate play an essential role.<sup>[10]</sup> The transport of plutonium through groundwater is a concern in old plutonium processing facilities such as the Hanford, WA atomic energy reservation, in the Nevada nuclear test site, and in the planned nuclear waste repository at Yucca Mountain, Nevada. There remain questions of permeability and the adhesion of particles to the rock and engineered barrier walls, of colloid transport, of biological transport, and of mineral precipitation which can change the rate of progress of a contamination plume. Linking laboratory scale, field

**Table 2** Major soil minerals and constituents

Type	Composition	Structures
Clay	Hydrated aluminosilicate	Layered
Zeolite	Hydrated aluminosilicate	Three-dimensional porous
Salts	NaCl, Na <sub>2</sub> SO <sub>4</sub> , CaSO <sub>4</sub>	Ionic crystals
Carbonates	CaCO <sub>3</sub> –MgCO <sub>3</sub> –FeCO <sub>3</sub>	Calcite, dolomite, others
Allophane	Hydrated aluminosilicate gel	Amorphous
Iron oxides	Fe <sub>2</sub> O <sub>3</sub> , FeOOH	Various polymorphs
Aluminum oxides	AlOOH, Al(OH) <sub>3</sub>	Various polymorphs
Quartz	SiO <sub>2</sub>	Quartz
Manganese oxides	Mn <sub>2</sub> O <sub>3</sub> , MnOOH, MnO <sub>2</sub>	Various polymorphs
H <sub>2</sub> O	H <sub>2</sub> O	Water, ice, vapor
Organics	C–H–N–O	Large surface area amorphous colloids
Jarosite–alunite	Alkali (Fe, Al) sulfates	Ionic double salts

scale, and simulation studies of nanoparticle transport is an essential area of research for understanding radioactive and chemical contamination and geologic processes involving uranium and other actinides.<sup>[11]</sup>

When particles are below 5 nm in size, several other effects must be considered. Whereas for larger particles, most of the atoms are in specific planes or faces, for smaller ones, an increasing number of surface atoms must sit at the intersection of facets, in presumably even higher energy sites. An alternate, more macroscopic way of describing this is to consider the surface as curved, rather than as a series of planes. Then the surface energy per unit area is no longer a constant, but potentially increases quite rapidly with decreasing particle size. This unfavorable energy may be relaxed by the adsorption of various molecules on the surface, and there is evidence that the adsorption coefficient of organics rises steeply at very small particle size.<sup>[12]</sup>

The flocculation of colloids depends on the surface charge; the pH of which the surface is neutral is the “point of zero charge.”<sup>[13]</sup> Does this depend on particle size? This is an area of active research.

How do nanocrystals form from solution? The classical picture of nucleation and growth by addition of single atoms or ions is probably inadequate.<sup>[14]</sup> There is increasing evidence for clusters of atoms or ions in solution which contain 5–50 atoms and clearly show some of the structural features of the solid. An example is the Keggin-molecular cluster containing 13 aluminum atoms shown in Fig. 4.<sup>[16]</sup> It appears stable over a wide range of neutral to basic pH, and is probably a major precursor to and a dissolution product of aluminum oxyhydroxides.<sup>[17]</sup> The growth of TiO<sub>2</sub> anatase may occur by the oriented attachment of ~3-nm particles.<sup>[18]</sup> The growth of zeolites templated by organics may involve 3-nm cuboctahedral clusters.<sup>[19]</sup> Nanoclusters have been invoked in

the growth of sulfides in ore-forming solutions.<sup>[20]</sup> Characterization of such nanoscale precursors in aqueous solutions remains a major challenge.

The coarsening and phase transformation of nanoscale precipitates upon heating is equally important to the sol–gel synthesis of ceramics and the geologic compaction and diagenesis of buried sediments. Loss of water, loss of surface area, and phase transformations to the stable bulk polymorph are closely interlinked.<sup>[14]</sup> A nanoparticle with dimensions below 5 nm probably cannot maintain defects or dislocations; they can migrate to the surface and be annihilated.<sup>[21]</sup> An aggregate of such single domain nanocrystals, with disorder and impurities at their surfaces, may be a common morphology in nature. Such aggregates give smaller average particle size from X-ray peak broadening than from gas adsorption [Brunauer–Emmett–Teller (BET)] measurements.

**Fig. 4** Al<sub>2</sub>O<sub>8</sub>Al<sub>28</sub>(OH)<sub>56</sub>(H<sub>2</sub>O)<sub>24</sub><sup>18+</sup>(aq) (often called Al<sub>30</sub>) cluster of 2 nm dimensions, which is intermediate in structure and properties between isolated ions and solid aluminum. Source: W.H. Casey, personal communications. From Ref.<sup>[15]</sup>.

Magnetic nanoparticles cannot hold a direction of magnetization for a long time because of thermal fluctuations.<sup>[22]</sup> The magnetic iron oxides found in magnetotactic bacteria, which are single domain particles, neither too large nor too small, provide orientation in the Earth's magnetic field (see below). On a geologic time scale (millions of years), magnetization of largely nanophase iron oxides provides a record of the variation of the Earth's magnetic field through time, including periodic reversals of north and south poles. Thus the ability or inability of nanoparticle oxides to retain magnetization is of critical importance.

## NANOPARTICLES IN THE ATMOSPHERE

Atmospheric particles include dust (rock and soil), sea salt, acids including sulfuric, organics (especially carbon), inorganics, and, of course, water and ice (Table 3). The atmosphere can carry particles of spherical equivalent diameters from 1 to  $10^5$  nm. Often, a trimodal distribution of particle sizes, with peaks in number density near 5, 50, and 300 nm, is seen.<sup>[23]</sup> The smaller particles account for most of the reactive surface area but little of the total mass.

Atmospheric particles affect the environment in many ways.<sup>[23,24]</sup> They reduce visibility (smog, haze) primarily through light scattering. They act as nuclei for water vapor condensation and cloud formation.

Many particles have core-shell structures and coatings

They are involved in radiative forcing, changing the ratio of absorbed sunlight to reflected sunlight. Thus they are implicated in global climate change. Their effect on radiative forcing can be positive (more energy adsorbed) or negative (more energy reflected), leading to warming or cooling, respectively.<sup>[23,24]</sup> Their net effect is a subject of vigorous research and controversy.

Anthropogenic particles contribute disproportionately to the fine particle fractions.<sup>[23]</sup> These may have very significant effects on climate and (see below) health. Soot (carbon) from burning coal and oil and from automobile (especially diesel) emissions contribute greatly to the atmospheric load of nanoparticles.

Particles in the atmosphere travel a long way. Dust from Africa is seen in Florida; industrial emissions from China are detected in North America. Particles are removed from the atmosphere by diffusion and gravitational settling (aided by small particles coalescing into larger ones) and by rain. The residence time of nanoparticles in the atmosphere ranges from minutes to days.<sup>[23]</sup>

Atmospheric nanoparticles are more involved in gas phase reactions than particles in soil and water.<sup>[24]</sup> Their formation may involve combustion synthesis, as in industrial or automobile emission. Mineral nanoparticle surfaces may catalyze the oxidation of SO<sub>2</sub> and NO<sub>2</sub>, leading to sulfuric and nitric acid. These acids can exist as gaseous species, liquids, or solid hydrates at low temperature. Nanoparticles are invoked in the depletion of atmospheric ozone by catalytic production of reactive chlorine compounds. Changes of phase (liquid to solid) are critical to the chemistry of sodium chloride and sodium nitrate particles, with their water content being controlled by available humidity.

Mineral dust particles may provide critical nutrients (e.g., iron) to the surface of the ocean far from land. The ocean's biological productivity is often limited by the availability of these nutrients; thus such inorganic nanoparticles may significantly influence the global cycling of carbon through ocean biomass.<sup>[25]</sup>

## NANOPARTICLES IN SEDIMENTS, ROCKS, AND THE DEEP EARTH

The debris of rock weathering is brought down river to the ocean in sediments consisting of nanoscale particles of clay, small quartz grains, and other minerals. Indeed, the terms "clay" and "silt" have a classic connotation of size fraction, although the former also implies a structural group of minerals, the layered aluminosilicates. In the ocean, carbonates precipitate, dissolve, and reprecipitate as a complex function of depth.<sup>[26]</sup> Both silica and various polymorphs of calcium carbonate (calcite, aragonite, vaterite) are produced by organisms such as diatoms, foraminifera, and

corals. Their debris rains down on the ocean bottom, forming sediments which often show annual cycles in composition and texture and which bear records of climate change, shifts in ecosystems, and catastrophic events such as meteor impacts.<sup>[27]</sup> These sediments start off largely nanoscale. They coarsen and dehydrate with time and depth of burial. The evolution of their organic matter leads to petroleum. The evolution of their minerals, involving coarsening and compaction, called diagenesis, leads to rocks such as limestones and shales. The nanoscale processes that take place (dehydration and organic loss, phase transformation, coarsening and densification) are natural analogs of ceramic processing which starts with nanoscale precipitates or gels.

Natural processes involving changes in temperature, pressure, acidity, and oxygen fugacity cause the concentration of trace metals into ore deposits. These often occur in hydrothermal systems, spatially contained circulations of hot, pressurized, metal-rich aqueous solutions. Our ability to mine low-grade deposits by chemical leaching techniques brings us into the world of nanoparticles and reactions at mineral surfaces. There is increasing evidence that microorganisms play an active role in ore deposition.<sup>[28,29]</sup> Hot springs at the surface produce deposits of nanoscale amorphous silica and other minerals, which may also be closely linked to microbial activity.<sup>[30]</sup>

At temperatures above a few hundred degrees Centigrade and pressures above a few kilobars, coarse-grained metamorphic and igneous rocks predominate. The interior of the Earth is layered, with seismic discontinuities delineating the crust, upper mantle, transition zone, lower mantle, and core. These discontinuities represent regions of rapidly changing density, mineralogy, and chemistry.<sup>[31]</sup> Ongoing phase transitions and chemical reactions can decrease the grain size of a material and render it easier to deform.<sup>[32]</sup> Thus nanoscale phenomena, occurring at specific locations, may play a disproportionate role in processes such as subduction, plate tectonics, earthquake generation, and volcanism. Shock processes, (e.g., meteor impact, nuclear detonation) also produce nanoparticles.

When a volcano erupts explosively, a plume of dust particle is sent into the atmosphere, sometimes reaching the stratosphere. These particles make beautiful sunsets but they also exert a significant cooling effect on climate for several years and pose a significant aviation hazard. Combining sedimentation, coarsening, subduction, volcanism, and weathering, there is an ongoing global geochemical cycle of nanoparticles, analogous in some ways to global geochemical cycles of elements such as carbon. However, the mass balances, or imbalances, in global nanoparticle production and consumption through time have not been characterized.

## NANOPARTICLES BEYOND THE EARTH

In the early stages of planet formation, dilute and more or less uniform gas condensed to form a series of mineral particles, with the order of condensation described by thermodynamic calculations based on the volatility and stability of these phases.<sup>[37]</sup> The more refractory oxides condensed earlier than those with higher volatility. These particles accreted, under the influence of gravity, to form our solar system. What was the nature of these initial particles? What was their size distribution? Were they crystalline or amorphous? Were metastable polymorphs formed? While the initial high temperatures might argue against such metastability, the low pressures and condensation from a vapor argue for it. In technological processes, chemical vapor deposition produces nanoscale amorphous silica “snow,” and combustion produces soot and inorganic nanoparticles. The role of nanoparticles in planetary accretion has not yet been explored. The change in stability at the nanoscale, which will be different for various compositions and polymorphs, may alter the sequence of condensation of phases. Are the particles now present in space as interplanetary dust partly or mostly nanoparticles?

The surfaces of the Moon and Mars, subject to “space weathering” by bombardment with meteorites of all sizes, contain an extensive fine grained dust or soil layer.<sup>[32]</sup> Samples of lunar soil, brought back by the Apollo missions, contain a distribution of particle sizes of spherules and irregular shards. Their particle size distribution appears not to have been a subject of active interest, but clearly a significant number are in the nanoregime. The red surface of Mars appears to be dominated by various fine-grained or nanophase iron oxides. Until Martian sample return missions, planned to occur in the next decade or two, bring some of this material to Earth, we must rely on remote sensing technology (spectroscopic techniques) and instrumentation on Martian landers (possibly Mossbauer spectroscopy, X-ray fluorescence, and X-ray diffraction) to obtain information on the composition and structure of Martian soil. Considering the difficulty of characterizing iron oxide nanoparticles in the best laboratories on Earth, definitive conclusions about the nature of Martian soil are unlikely until we have some samples in hand. Meteorites believed to be from Mars contain micron-sized spherules, which were proposed to be biological in origin. This sparked much recent controversy and it is by no means settled whether these structures are fossil microorganisms or the product of inorganic nanoscale crystal growth processes.<sup>[33,34]</sup>

## NANOPARTICLES AND LIFE

Microbial communities are rich in the production and utilization of nanoparticles.<sup>[35]</sup> Table 4 lists some examples. In addition to aerobic respiration (the enzymatic oxidation of carbohydrates and other organics with molecular oxygen to produce water, carbon dioxide, and energy stored as high-energy phosphate linkages) organisms use many other strategies to extract energy from the environment. The following biological reactions produce or consume nanoparticles. Dissolved Mn(II) or Fe(II) can be oxidized by oxygen, producing Mn(III), Mn(IV), or Fe(III) oxide nanoparticles, while organics can be oxidized by manganese or iron oxides, producing soluble Mn(II) and Fe(II) species. Some bacteria can also utilize the U(IV)–U(VI) couple as an energy source. Because hexavalent uranium is much more soluble than tetravalent, biological processes that accelerate its production are of concern in modeling nuclear waste leaching. The sum of these two groups of redox processes is the oxidation of organics by oxygen, akin to respiration. The important difference is that the organic food source and the oxygen source can be spatially separated in the sharp gradients in oxygen and organic contents that frequently occur in sediments, and different communities of organisms participate in the two processes. In marine sediments, sulfate is the dominant biological electron acceptor and is more important than oxygen. Bacterial sulfate reduction produces sulfide which often precipitates as nanophase metal sulfide minerals. Sulfide and sulfur oxidizing bacteria typically live in specialized environments where there is enough oxygen to oxidize sulfur but not so much that chemical oxidation swamps biological oxidation. This oxidation consumes solid sulfur and sulfides, and produces soluble sulfate.

Organisms utilize nanoparticles in processes other than respiration. Bacterial precipitation of sulfide minerals, e.g., ZnS and UO<sub>2</sub>, may also be a mechanism

of detoxification.<sup>[36]</sup> Similar detox processes may occur in plants. Magnetotactic bacteria synthesize and align single domain magnetic iron oxide and iron sulfide particles in structures called magnetosomes.<sup>[37]</sup> Such bacteria align themselves both north–south and vertically in the Earth's magnetic field. The navigational (homing) capabilities of bees, pigeons, and probably other higher organisms utilize magnetic field orientation sensed by magnetic iron oxide particles in their brains. Similar particles, although at lower abundance, occur in many mammals, including *Homo sapiens*.<sup>[38]</sup> There has been a debate in the public sector whether the magnetic fields produced by high-voltage power lines are potentially dangerous to human health. In contrast, the use of magnets in alternative medicine, and the market for magnetic pillows, back supports, etc. suggests, or at least hopes for, a beneficial effect of the interaction of magnetic fields with animals. Key to either harmful or helpful biological effects is a mechanism for the magnetic field to interact with living cells. Interaction with biological magnetic nanoparticles may provide such a mechanism, but very little is known at present.

Nanoparticles have other documented health effects.<sup>[39]</sup> When inhaled into the lungs, particles cause an inflammatory response, which contributes to allergies, asthma, and cancer.<sup>[48]</sup> The detailed mechanism of this response, and how it depends on surface area, particle size, or specific particle chemistry, is not clear. The harmful effects of inhaled particles may be enhanced by other pollutants, particularly ozone, typically present in smog. Nanoparticles penetrate deep into the lungs. Many are returned with exhaled air, some stick to the surfaces of the alveoli, and some may even penetrate into general blood circulation and be transported to other organs. Studies linking detailed nanoparticle characterization, biochemical and physiological processes, and health effects are just beginning to be carried out. It is likely that not all particles have

**Table 4** Example of interactions of microorganisms and nanoparticles

Class of organisms	Example	Nanoparticle interaction
Iron and manganese oxidizing bacteria	<i>Thiobacillus</i>	Oxidize soluble Mn <sup>2+</sup> and Fe <sup>2+</sup> to insoluble higher oxides
Iron and manganese reducing bacteria	<i>Shewenella</i>	Reduce insoluble Mn and Fe oxides to soluble forms oxidize sulfide to sulfate to sulfide precipitate
Sulfur reducing bacteria	<i>Thiobacillus</i>	Reduce sulfate to sulfur in sulfide
Magnetotactic bacteria	<i>Aquaspirillum magnetotacticum</i>	Nanoparticles of Fe <sub>2</sub> O <sub>3</sub> , Fe <sub>3</sub> O <sub>4</sub> , and/or iron sulfides
Uranium reducing bacteria	<i>Geobacter, shewenella</i>	Soluble U <sup>6+</sup> → insoluble U <sup>4+</sup>
Fungi	Specific strains unknown	Oxidize Mn <sup>2+</sup> , precipitate MnO <sub>2</sub>
Diatoms	Various	Precipitate silica
Foraminifera	Various	Precipitate CaCO <sub>3</sub> calcite and aragonite

comparable effects, and understanding which are the most dangerous could lead to rational, rather than arbitrary, emission standards for automotive and industrial particulates.

In the early Earth, prebiotic processes culminated in the origin of life.<sup>[40]</sup> Because the synthesis of complex organic molecules competes with their destruction by hydrolysis and other degradation, it is possible that the most successful synthesis could have occurred in sheltered and catalytic environments, such as those provided by mineral surfaces, nanoparticle surfaces, and pores within mineral grains. Present-day organisms utilize a wide variety of elements (e.g., Fe, Co, Ni, Cr, Zn, Se) in specific enzymes. Although large amounts of such elements are toxic, trace amounts are essential. The active centers in enzymes utilizing these trace elements often consist of clusters of metal atoms, sometimes associated with sulfide. Are these fine-tuned by evolution from earlier simpler metal clusters and nanoparticles existing in the environment? Thus nanoparticles may play a role not just in the sustenance of life but in its origin.

## CONCLUSIONS

Nanoparticles play diverse roles in the environment and are involved in both abiotic and biologically mediated chemical and physical processes. Their high surface area, chemical reactivity, polymorphism, and unique properties involve nanoparticles in a disproportionately large fraction of the chemical reactions occurring on and in the Earth and other planets. Understanding this involvement is itself evolving into a new field of study in the environmental and Earth sciences, which is beginning to be called "nanogeoscience." Nanogeoscience will take its place alongside other new areas such as astrobiology and biogeochemistry, fields that link physical, chemical, and biological processes viewed in the context of the long time and distance scales natural to the Geosciences.

## INTRODUCTION

Surfactant microstructures provide a unique environment for the enzymatic synthesis of polymers. Surfactants can create large oil–water interfaces, which can be exploited for biocatalysis where the enzyme is resident in the aqueous phase and the monomer is resident in the oil phase or at the oil–water interface. The polymerization of substituted phenols using an oxidative enzyme, horseradish peroxidase (HRP), is explored. The surfactant microstructures used in enzymatic synthesis include the system of bis(2-ethylhexyl) sodium sulfosuccinate (AOT) water-in-oil microemulsions, cetyltrimethylammonium bromide (CTAB) micelles, and a novel gel system formed by the addition of lecithin and water to AOT water-in-oil microemulsions. The monomers partition to the oil–water interface, and polymerization is extremely feasible.

The use of enzymes in synthesis represents an inherently environmentally benign approach to chemical processing. In addition to catalytic function at or near ambient conditions, the exquisite specificity of enzyme biocatalysis can be potentially exploited to develop processes with minimal side products. Advances in large-scale enzyme production and purification, and synthetic enzyme mimetic chemistry, are eventually expected to lead to enzyme-based processes that are economically viable.<sup>[1]</sup> The use of enzymes to synthesize polymers is one such area of research undergoing rapid development.<sup>[2]</sup> Enzymatic polymerization

exhibits a wonderful aspect of biomimetics, as enzymes function in the biological world in the synthesis and degradation of polysaccharides, proteins, polyphenols, and polynucleic acids. If such enzyme action can be exploited in the *in vitro* synthesis of polymers with commercial significance, it may be possible to obtain polymers with unique material properties that are inherently biodegradable and in specific cases, biocompatible. Examples of enzyme biocatalysis for polymer synthesis include the use of lipases for polyester synthesis,<sup>[3]</sup> peroxidases for polyphenol synthesis,<sup>[4]</sup> and cellulases for polysaccharide synthesis.<sup>[5]</sup>

In developing enzymes for synthesis, the reaction environment plays a vital role in determining the activity and catalytic efficiency of the enzyme. The ability of enzymes to function in nonaqueous environments when properly conditioned has brought about the development of an entire field of biocatalysis in organic solvents.<sup>[6]</sup> A parallel development is the field of enzyme chemistry in surfactant systems, in particular the system of water-in-oil microemulsions, conventionally referred to as reversed micelles.<sup>[7]</sup>

## OVERVIEW

In this entry, a variety of self-assembled surfactant systems are investigated for enzymatic synthesis of nanostructured polymers and polymer–ceramic composites. Specifically, reversed micelles, micelles, and a novel

surfactant gel mesophase are used as templating environments to generate conjugated polymers with conductive and luminescent properties. Finally, enzymatic polymerization is coupled with mesoporous silica synthesis to fabricate structured polymer–ceramic nanocomposites.

### ENZYMATIC SYNTHESIS OF POLYPHENOLS AND POLYAROMATIC AMINES

The concepts of enzymatic polymer synthesis in surfactant systems with a focus on the synthesis of polyphenols and polyaromatic amines are presented. Phenolic polymers have a variety of conventional applications in making resins for coatings, laminates, etc.<sup>[8]</sup> The traditional technology for making these polymers involves a formaldehyde-based high-temperature process, where undesirable side reactions lead to poor control of polymer structure and molecular weight. In addition, concern over the toxicity of

formaldehyde necessitates the study of alternative technologies to produce such polymers. The enzymatic approach using an oxidative enzyme such as horseradish peroxidase eliminates the need for formaldehyde. The reaction has a mechanistic analogy to the synthesis of lignin<sup>[9]</sup> and is illustrated through the simplified mechanism shown in Fig. 1A, where reaction is initiated by the addition of H<sub>2</sub>O<sub>2</sub>. Phenoxy radical centers initially formed on the monomer or growing chains migrate to the ortho positions (the para position, although mechanistically allowed, is less favored) after which coupling through condensation occurs. A molecular space-filling model of polyphenol illustrates the curvature of the chains obtained when the hydroxyl groups lie on the same side of the polymer backbone. In the unfolded state, the polymer assumes an open structure.

A variety of monomers can be used in the synthesis of modified phenolic polymers and copolymers with novel functional characteristics (Fig. 1C). As an example, the multiring naphthol and hydroxypyrene

**Fig. 1** (A) Simplified schematic of the polymerization of alkyl substituted phenols. The arrows (in the phenoxy radical) indicate coupling in the ortho position. (B) Molecular model of polyphenol folding due to monomer alignment at an oil–water interface. (C) Various monomers that can be used for the synthesis of functional polymers.

based polymers are intrinsically photoluminescent.<sup>[11]</sup> Since these polymers are conjugated, there may be opportunities to develop new classes of electroluminescent and photoluminescent polymers. The use of monomers such as hydroxythiophenol allows the synthesis of polymers that are capable of binding to inorganic sulfide nanoclusters (e.g., CdS, PbS) with semiconductor properties.<sup>[12]</sup> This may lead to new possibilities in the preparation of polymer–nanoparticle films and composites with electrooptical properties. Polymers made with dihydroxynaphthalene may be redox active and may have electrochemical applications in battery and sensor development.<sup>[13]</sup>

In principle, the enzymatically synthesized polyphenolics have similar applications to the phenol–formaldehyde resins that are chemically synthesized.<sup>[14]</sup> However, there are unique aspects related to the enzymatically synthesized material. In contrast to phenol–formaldehyde polymers, these polyphenolics lack the intervening methylene bridge between the aromatic groups, as illustrated in the simplified mechanistic scheme of Fig. 1A. The polymer is therefore conjugated and thus has a variety of potential applications in electro-optics.<sup>[15]</sup> A specific property that is being investigated is the use of these materials in non-linear optics (NLO), in particular for applications based on the optical third-order non-linear susceptibilities ( $\chi^{(3)}$ ).<sup>[4,15]</sup> In such materials, higher-order terms become significant in the expansion of the material polarization ( $P$ ) in terms of an applied electric field ( $E$ ).

$$P = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \dots$$

While details of the physics behind NLO materials can be found in several excellent sources (e.g., Prasad and Williams),<sup>[16]</sup> the relevance of NLO polymers to applications in optical switching, waveguide technology, laser protection, etc. is well recognized. Thus, the enzymatically synthesized polymers have some useful applications in electro-optics.<sup>[17]</sup> The polyaromatic amines synthesized through the enzymatic process are especially promising as materials with high  $\chi^{(3)}$  values of up to  $10^{-7}$  esu, among the highest reported for organic materials.<sup>[17]</sup>

A unique and suitable environment for the enzymatic synthesis of polyphenols and polyaromatic amines is needed. The monomers are typically water insoluble, and therefore intrinsically incompatible with the water-soluble enzyme. Therefore, a unique system in which both enzyme and monomer are contacted efficiently is needed. One approach involves using a two-phase oil and water system; however, the agitation needed to enhance enzyme–monomer contact may shear-deactivate the enzyme. A second approach entails activating the enzyme in organic solvents, feasible for polyphenol synthesis.<sup>[4,6]</sup> A third approach

encompasses the use of surfactants to incorporate water into an organic phase (or vice versa). This approach has the advantage that the enzyme and the monomer reside in close proximity and the enzyme experiences minimal agitation.

## POLYMER SYNTHESIS IN REVERSE MICELLES

The AOT water-in-oil microemulsion system represents an effective system to synthesize polyphenolics and polyaromatic amines. Fig. 2 illustrates the system and the rationale for synthesis in this medium. The enzyme is catalytically active in the water core, and the organic bulk phase sustains the monomer and the surfactant hydrocarbon chains. An interesting aspect of synthesis in reversed micelles is the partitioning of the polar monomer to the oil–water interface (depicted by the arrow of Fig. 2 with the head of the arrow representing the hydroxyl moieties of the monomer). In addition, hydrogen bonding between the surfactant headgroup and the monomer influences monomer orientation and partitioning at the water–oil interface. A strong indication of such hydrogen bonding is the perturbation of the vibrational frequencies of the surfactant C=O groups on addition of the monomers.<sup>[18]</sup> Such partitioning may result in a prealignment of the monomers before synthesis and may provide a means of monomer replenishment to the vicinity of the enzyme. In addition, the surfactant–monomer

**Fig. 2** (A) Chemical structure of the anionic surfactant sodium bis(2-ethylhexyl) sulfosuccinate. (B) Schematic of enzyme solubilized in the micelle and monomer partitioning to the micelle interface. The arrow refers to the monomer.

**Fig. 3** Scanning electron micrograph of polymer microspheres prepared through synthesis in reverse micelles.

interactions significantly enhance monomer solubility in the reaction medium. The implication is that the hydroxyl groups are on the same side of the polymer backbone as simply illustrated in Fig. 1, noting that the actual C–C bond between aromatic rings has an angle of  $120^\circ$ . In simple molecular models, ortho coupling with proximal hydroxyls on the same side of the backbone induces a natural curvature to the polymer. Indeed, intramolecular hydrogen bonding leads to polymer folding when most of the hydroxyls lie on the same side of the backbone.<sup>[19]</sup> We will return to the concept of polymer curvature in the interpretation of the observations.

Enzymatic polymerization in reverse micelles is a simple procedure.<sup>[20]</sup> In a typical experiment, the enzyme (HRP) dissolved in 0.01 M HEPES buffer (pH 7.5) is added to a dry reversed micellar solution of AOT in isooctane, followed by the addition of the monomer, 4-ethylphenol (EP). The enzyme concentration in the buffer is adjusted so that the final enzyme concentration in the micellar solution is 0.5 mg/mL. The reaction mixture typically has the overall composition 0.5 M AOT, 0.15 M EP, 0.5 mg/mL HRP and a  $w_0$  of 15 ( $w_0$  is the water-to-surfactant molar ratio). The reaction is initiated by the addition of  $H_2O_2$  in aliquots to minimize enzyme deactivation. The reaction is rapid, and within 5–10 min of reaction initiation, over 80% of monomer conversion occurs, with the polymer precipitating out of solution.<sup>[20]</sup>

Fig. 3 illustrates the fascinating microsphere morphology of polymers synthesized and precipitated from reaction in reversed micellar solutions. We have found that as long as the initial surfactant-to-monomer ratio is 2:1 or higher (preferably 3:1) the polymer precipitates in the morphology of microspheres.<sup>[20]</sup> Many of the microspheres are not independent, but

are connected to each other. Although it would appear that the microspheres are a consequence of polymerization around micelle interfaces, the size of these microspheres (0.5–1  $\mu\text{m}$ ) are significantly larger than the micelle size (0.5–5 nm depending on the water level in the micelle).

The large sizes of the microspheres in comparison to micelle dimensions indicate the lack of a direct templating effect produced by synthesis at the micelle oil–water interface. However, in studying the growth characteristics of these microspheres, we have found that they initially have a very low internal density. The microspheres appear to be made up of minute interconnected spherical patches,<sup>[11]</sup> which may have their origin from reaction on the micelle periphery (Fig. 4A). The scanning electron micrograph of Fig. 4B where the shell of a microsphere is broken by gentle sonication correlates well with the initially low internal density of the microsphere. In fact, the internal density of the microspheres can be controlled by adjustment of reaction time and  $H_2O_2$  addition due to remaining enzyme and unreacted monomer in the microspheres. Polymerization continues even after the overall morphology has been achieved, leading to densification. Over a period of about 24 hr, all microspheres fully densify.<sup>[11]</sup> At the other extreme, at very early reaction times (<5 min), sampling of the polymer simply indicates interconnected patches with no overall defined spherical morphologies. The internal morphology and densification characteristics of the microspheres suggest the following mechanism. The initial dense patches are a consequence of reaction at the oil–water interface. The polymer is “sticky” because of the large number of hydroxyl groups, and the hydroxyl groups are capable of hydrogen bonding both within the chain and between

**Fig. 4** (A) Transmission electron micrograph of a polymer microsphere at an initial stage (5 min reaction time) illustrating the low internal density. (B) Scanning electron micrograph illustrating the internal structure of a polymer microsphere.

chains. The intrachain hydrogen bonding may lead to the curvature of the chain, whereas interchain hydrogen bonding can create the connections to polymer growing on separate micelles during micelle collisions. The interplay between these effects leads to the interconnected patches.

The second interesting observation is that during precipitation, the polymer also encapsulates solutes located in the water core of the micelle. The densification observation is clearly a consequence of peroxidase becoming encapsulated in the microspheres. Realizing this, we have attempted to exploit the phenomenon to synthesize polymer–nanoparticle composites. We

propose utilizing these reversed micelles as a microenvironment in which to synthesize inorganic materials that do not grow beyond the nanometer size range.<sup>[22]</sup> Enhanced band gap semiconductor materials (CdS, TiO<sub>2</sub>), magnetic particles, etc. are examples of novel nanoparticles that have been synthesized in reversed micelles. We have attempted to make polymer–nanoparticle composites by first synthesizing the nanoparticles in the micelles, then adding monomer, enzyme, and H<sub>2</sub>O<sub>2</sub> to initiate polymer synthesis. When the polymer precipitates (in spherical morphologies) it incorporates a significant amount of the nanoparticles. For example, we have synthesized superparamagnetic iron oxide in reversed micelles.<sup>[23,24]</sup> In such synthesis, the particle size approaches magnetic domain size, leading to thermally induced randomization of magnetic dipole orientations. The particles therefore do not exhibit magnetic characteristics in the absence of a field (the term superparamagnetism is usually applied to particles that are non-magnetic in the absence of a field as paramagnetic materials are, but on application of an external field exhibit magnetization far in excess of paramagnetic materials). We have then incorporated these particles into the polymer as described earlier, allowing the particles to become dense. Fig. 5 shows a cut section transmission electron micrograph of a polymer particle. The dark specks are the ferrite particles uniformly distributed across the section. The cut section also indicates a significant amount of ferrite entrapment (up to 6% of the polymer weight). We also note that the particle size increases on incorporation of the nanoparticles. The particle deformation in the micrograph is a consequence of the cut section procedure.

**Fig. 5** Cut section transmission electron micrograph of ferrite nanoparticles within a polymer microsphere. The ellipsoidal cross section is induced by the cut section procedure.

## POLYMER SYNTHESIS IN A NOVEL SURFACTANT GEL MESOPHASE

As described in the previous section, synthesis in reversed micelles leads to microspherical polymer particles that precipitate. In an effort to maintain polymer solubility in the reaction medium, we have exploited a surfactant-based gel system to sustain the polymer during synthesis. A rigid, surfactant gel mesophase is formed by a novel transformation from low-viscosity AOT water-in-oil microemulsions to a highly viscous, rigid state. Specifically, we have found that the addition of lecithin (phosphatidylcholine) to the AOT water-in-oil microemulsions results in the formation of a rigid gel when additional water is added to the system. These gel systems are a significant variant of the fascinating organogels discovered by Luisi and coworkers<sup>[25]</sup> based on the system lecithin/water/cyclohexane, and extensively characterized through various spectroscopy and scattering techniques.<sup>[26–28]</sup> Luisi and coworkers used less than 10 wt.% water in the gel system. In the present system, the amount of water can be greater than 50 wt.% with retention of gel stability. In other words, the surfactant gel phase can be sustained with equal volume fractions of water and the organic phase implying the presence of spatially immobilized extended hydrophilic and hydrophobic microstructures. A typical gel has the composition AOT/lecithin/isooctane/water 15/14/29/42 (wt.%).

Fig. 6 illustrates the zero shear viscosity and conductivity trends as the water content of the system is varied. The measurements were performed by adding

water to a system containing 0.8 M AOT and 0.4 M lecithin in isooctane. The quantity  $w_0$  is the molar ratio of water to AOT, and is the quantity typically used to characterize the water content in AOT water-in-oil microemulsions. As Fig. 6 indicates, gelation starts at a  $w_0$  50 with a rigid gel formed at  $w_0$  value of 65. The zero shear viscosity increase of six to seven decades indicates the magnitude of rigidification from a low-viscosity solution. It is also interesting to note that the gelation point correlates rather well with a significant increase in electrical conductivity. The sharp increase in electrical conductivity indicates the formation of percolating water channels in the gel. Small angle neutron scattering (SANS) data indicate that the surfactant gel assumes a columnar hexagonal microstructure at lower water contents and a lamellar microstructure at higher water contents.<sup>[29]</sup>

This novel surfactant gel is hypothesized to serve as a medium in which aqueous synthesis can be combined with organic synthesis, leading to structured composite materials with novel application possibilities. As an example, the organic phase could be used in the synthesis of hydrophobic polymers whereas the aqueous phase can be used in the synthesis of hydrophilic polymers or inorganic materials. Thus, this system may allow the possibility of obtaining structured polymer-polymer nanocomposites or polymer-ceramic nanocomposites. The oil-water interface in these systems may also be exploited in interfacial polymerization. The microaqueous phase may also be used to sustain biomolecules leading to novel systems for enzyme biocatalysis or drug delivery. If synthesis is

**Fig. 6** Viscosity and electrical conductivity data illustrating the conversion from liquid to gel systems upon adding water to AOT + lecithin systems.

performed in simply one of the microphases (organic or aqueous), there is the possibility of generating materials with structured porosities, leading to membrane and separations applications.

Our objective in conducting enzymatic polymerization in these systems is to sustain polymer solubility in the reaction phase. Monomer and enzyme are loaded into the gel, the monomer being soluble in the organic phase (isooctane) and the enzyme being encapsulated in the percolating microaqueous phase. The schematic method is illustrated in Fig. 7, where the hydroxyl moieties of the monomer are represented by an arrowhead. The polymerization is initiated through the addition of hydrogen peroxide in two ways. In one approach, the components to form a surfactant gel (isooctane, AOT, lecithin), 4-ethylphenol, and horseradish peroxidase are combined to form a surfactant gel loaded with monomer and enzyme. After the surfactant gel forms, hydrogen peroxide is injected via a needle several times. After injecting hydrogen peroxide into the gel media, a thin, tan line of poly(4-ethylphenol) (PEP) formed where the needle pierced the gel. As the polymerization reaction continued in the gel system, the tan polymer lines broaden. However,

the polymer remains in the spikes from the hydrogen peroxide injection and does not grow throughout the gel media uniformly. The polymer appears to be initially constrained to the cavities created by the needle, and then slowly grows outward from the cavities. As a second approach to grow polymer throughout the surfactant gel media, the components to form a surfactant gel (isooctane, AOT, lecithin), 4-ethylphenol, and horseradish peroxidase are combined followed by addition of hydrogen peroxide. The solution is then mixed to form a surfactant gel. The hydrogen peroxide is added before gel formation with the intention that the hydrogen peroxide will become better distributed throughout the gel media and encourage the growth of longer polymer chains. During the mixing process, a transition from dark green-blue to blue to gray was observed as the solution forms into a gel. The color change pattern is similar to the color change pattern observed for poly(4-ethylphenol) synthesis in the AOT reversed micellar system. Enzymatic polymerization appears feasible via this method, and this method seems to allow the polymer to grow uniformly throughout the gel media. In addition, the polymer remains suspended during the polymerization reaction.

**Fig. 7** (A) Chemical structure of zwitterionic surfactant phosphatidylcholine (lecithin). (B) Schematic of enzyme solubilized in AOT and lecithin surfactant gel. Monomer partitions to micelle interface (monomer represented by arrow).

Scanning electron micrographs of poly(4-ethylphenol) synthesized in the surfactant gel via both hydrogen peroxide addition methods show polymer particles with spherical morphology (Fig. 8). The polymer particles are well defined and are similar in morphology to poly(4-ethylphenol) synthesized in an AOT water-in-oil microemulsion previously studied in our laboratory. Uniform-sized spherical particles in the range of 0.1 to 1.4  $\mu\text{m}$  are observed for varying water contents. At higher water content, polymer particles synthesized in the surfactant gels show a greater extent of agglomeration, where several particles fuse together forming links and clusters. The AOT and lecithin surfactant gel system is unique in that it produces polymer with a spherical morphology. The molecular weight of polymer synthesized in the surfactant gel system is approximately  $3 \times 10^3$ , comparable to poly(4-ethylphenol) synthesized in AOT reversed micelles. The polymer exhibits a polydispersity of approximately 1.

Fourier transform infrared (FTIR) analysis indicates the formation of polymer in the surfactant gel mesophase. Strong retention of the hydroxyl group is observed. The monomer shows a strong, single C–H bend vibration at  $821\text{ cm}^{-1}$ , indicative of two adjacent hydrogen atoms on an aromatic ring and suggestive of 1,4-disubstituted aromatic rings. The polymer exhibits two C–H out-of-plane bend vibration at  $821$  and  $870\text{ cm}^{-1}$ . The C–H bending vibrations are indicative of an isolated hydrogen on an aromatic ring and a 1,2,4,6-tetra-substituted aromatic ring and ortho-ortho coupling of the repeat units.

To supplement our understanding of the polymer synthesized in the surfactant gel, we shift our focus to investigating the microstructural integrity of the surfactant gel after polymerization. The surfactant gel Wo 90, the surfactant gel Wo 90 containing 4-ethylphenol,

and the surfactant gel Wo 90 containing poly(4-ethylphenol) were examined by polarized light microscopy at  $400\times$  magnification. The surfactant gel Wo 90 has a hexagonal microstructure arrangement. The surfactant gel Wo 90 showed fanlike structures indicative of hexagonal microstructures. Fanlike structures are quite distinct for the surfactant gel Wo 90 containing 4-ethylphenol, suggesting that the microstructure of the surfactant gel is preserved upon the incorporation of the monomer. It is striking that after polymerization in the surfactant gel Wo 90, fanlike structures are observed. The preservation of the fanlike structures throughout enzymatic polymerization indicates that the synthesis of poly(4-ethylphenol) does not appear to destroy the surfactant gel microstructure. In addition to polarized light microscopy, SANS study was performed to further determine the stability of the surfactant gel during the polymerization reaction. SANS data were collected before and after the enzymatic polymerization of poly(4-ethylphenol). The SANS profile without polymerization has a  $q_m$  and a  $q_{ho}$  at 0.052 and  $0.09\text{ \AA}^{-1}$ , respectively, and is in the hexagonal columnar phase. After PEP polymerization, the SANS profile has a  $q_m$  at  $0.048\text{ \AA}^{-1}$  and a  $q_{ho}$  at  $0.085\text{ \AA}^{-1}$  and remains in the hexagonal columnar phase. In terms of overall appearance, the profile has changed very little over the course of the poly(4-ethylphenol) synthesis implying that the microstructure of the gel has changed only slightly after the poly(4-ethylphenol) has been formed. Hence, the polymerization reaction does not disrupt the microstructure of the surfactant gel, which suggests that the surfactant gel system retains its templating effect throughout the polymerization reaction.

In monophasic organic solvents, the enzyme-catalyzed polyphenol synthesis does not lead to a unique morphology. In contrast, synthesis in self-assembled surfactant systems leads to the microsphere morphology, thus revealing that monomer prealignment may lead to oriented chains that fold as a consequence of bond geometry leading to initial dense patches. Interactions between the patches and the continued tendency of the chains to fold may lead to the microspheres.

## POLYMER SYNTHESIS IN MICELLES

Cylindrical micelles have attracted considerable attention because of their unique viscoelastic properties.<sup>[30,31]</sup> Cetyltrimethylammonium bromide (CTAB) forms cylindrical micelles and has gained widespread interest as a template for assembly and subsequent condensation of silicate ions to form hexagonally arranged mesoporous materials such as MCM-41 (siliceous molecular sieve).<sup>[32,33]</sup> The MCM-41S family of mesoporous materials has promising applications

**Fig. 8** Scanning electron micrograph of poly(4-ethylphenol) upon recovery of the polymer from the gel phase.

in separation and selective adsorption,<sup>[34,35]</sup> catalysis,<sup>[36]</sup> and the development of functional materials.<sup>[37]</sup> Researchers have performed extensive studies to fine-tune the pore size of the mesoporous materials. The pore size has been controlled by increasing the length of the alkyl chain of the surfactant and using block copolymers,<sup>[38]</sup> restructuring of the mesopores under mild aqueous conditions,<sup>[39]</sup> and adding auxiliary organic molecules to the synthesis mixture.<sup>[40,41]</sup>

We investigate the feasibility of enzymatic polymerization in CTAB micelles and the effect of polymerization on CTAB micelles. Polyaniline and poly(4-ethylphenol) were polymerized via enzymatic polymerization in CTAB micelles. The polymer is stable in the micellar solution and does not precipitate. Upon polymerization, a color change in the solution is observed and this color change is typical of enzymatic polymerization. Remarkably, the polymer is stable in the micellar solution at high monomer-to-surfactant molar ratios; the polymer does not precipitate even when the moles of monomer exceed the moles of surfactant by six times. A weight average molecular weight of 2300 with a polydispersity of 1.45 is obtained.

FTIR and nuclear magnetic resonance (NMR) analysis provide evidence of the formation of polymer. FTIR analysis shows strong preservation of the OH functional group of poly(4-ethylphenol). FTIR also indicates the presence of two C–H out-of-plane bend vibrations at 821 and 876 cm<sup>-1</sup> for the poly(4-ethylphenol). In comparison, the monomer exhibits only one strong, single C–H bend vibration at 821 cm<sup>-1</sup>, indicative of 1,4-disubstituted aromatic rings. The two C–H bending vibrations observed for the polymer imply that the aromatic groups are 1,2,4,6-tetrasubstituted aromatic rings and the repeat units are linked through ortho–ortho coupling. Both <sup>13</sup>C NMR spectra and <sup>1</sup>H NMR spectra show linewidth broadening in the aromatic region for poly(4-ethylphenol) as compared to the monomer. NMR data provide further evidence of ortho–ortho coupling of the repeat units. Thermogravimetric analysis indicates the polymer synthesized in CTAB micelles is stable until 220°C. In comparison, the monomer shows a 100% weight loss at 150°C. A 15% weight loss at 220°C and a 60% weight loss at 600°C are observed for the polymer.

### BIOMOLECULAR APPROACH TO POLYMER ENCAPSULATION IN MESOPOROUS MATERIALS

Mesoporous materials may serve as host guest molecules for the preparation of nanomaterials with unique properties. Encapsulated conducting polymers exhibit increased mechanical, thermal, and chemical performance compared with pure polymer.<sup>[42]</sup>

Conjugate systems with appropriate end groups<sup>[43]</sup> and confined aromatic systems<sup>[44]</sup> can transfer excitations upon photon absorption or after reduction or oxidation. The desire to miniaturize displays, electronic circuits, and microchips drives the development of mesoporous materials containing conductive polymers.<sup>[45]</sup>

The internal channels of MCM-41 have been exploited as catalytic reactors for the fabrication of aligned polymer fibers<sup>[46–50]</sup> and metal nanowires.<sup>[51,52]</sup> The high pore volume and uniform pore size of MCM-41 allows high polymer loading. Researchers have demonstrated that MCM-41-type structures can serve as a mold for polymerization of ethylene,<sup>[47]</sup> aniline,<sup>[48]</sup> acrylonitrile,<sup>[53]</sup> methyl methacrylate,<sup>[54]</sup> and phenol–formaldehyde.<sup>[55]</sup> In these techniques, the monomers are adsorbed from the gas phase into the mesoporous material, MCM-41, and then polymerized within the mesoporous framework using benzoyl peroxide or anhydrous HCl vapor as initiators. These hybrid materials have the advantages of compositional stability and mechanical strength over their small molecular analogues. A major limitation of this approach has been the low polymer loading and non-uniform distribution of polymer within the mesoporous channels.<sup>[56,57]</sup>

Based on our discovery that polymer is stable in CTAB micelles, we explore the concept of condensing silica around CTAB micelles swollen with polymer. Specifically, the idea of forming polymer in CTAB micelles and then forming silica may lead to a novel composite material with high polymer loading. Polymerization in CTAB micelles is performed as described previously, followed by the addition of a silica precursor such as tetramethyl orthosilicate (TMOS). After silica condensation, a tan slurry forms for mesoporous silica/poly(4-ethylphenol) composites and a reddish slurry forms for mesoporous silica/polyaniline

**Fig. 9** Scanning electron micrograph of poly(4-ethylphenol)/mesoporous silica composites with monomer-to-surfactant molar ratios = 3.

composites. When the slurry settles, the supernatant is clear while the precipitate retains the color of the polymer, suggestive of polymer encapsulation. Fig. 9 shows a typical SEM micrograph of mesoporous silica/polymer composites with varying monomer-to-surfactant ratios.

Powder X-ray diffraction (XRD) of the polymer/mesoporous silica composites was performed to determine ordered structure. XRD data of mesoporous silica without polymer and polymer/mesoporous silica composite are shown in Fig. 10. Before polymer encapsulation, four main peaks at  $2\theta = 2.167^\circ$ ,  $3.736^\circ$ ,  $4.283^\circ$ , and  $5.694^\circ$  exist, corresponding to the  $d$  spacing of

4.125 ( $d_{100}$ ), 2.383 ( $d_{110}$ ), 2.079 ( $d_{200}$ ), and 1.554 nm ( $d_{210}$ ). At ethylphenol-to-CTAB molar ratios equal to 1, the polymer/mesoporous silica composite was observed to have a hexagonal structure, as indicated by the four-peak pattern with reciprocal peak spacings,  $1/d_{hk}$ , ratios of 1,  $\sqrt{3}$ , 2, and  $\sqrt{7}$ . The polymer/mesoporous composite with a monomer-to-surfactant ratio of 1 exhibited four main peaks at  $2\theta = 2.321^\circ$ ,  $3.939^\circ$ ,  $4.659^\circ$ , and  $6.08^\circ$ , corresponding to the  $d$  spacing of 3.806 ( $d_{100}$ ), 2.241 ( $d_{110}$ ), 1.895 ( $d_{200}$ ), and 1.454 nm ( $d_{210}$ ).

A transmission electron microscopy (TEM) micrograph of MCM-41 without polymer shows the hexagonal pore structure consistent with the literature,

**Fig. 10** Powder X-ray diffraction of mesoporous silica containing polymer showing retention of ordered structure after polymer encapsulation, where  $m$  is the molar ratio of monomer to surfactant.

**Fig. 11** Transmission electron micrographs of (A) mesoporous silica without polymer and (B) mesoporous silica/polymer composite with monomer-to-surfactant ratio = 1. Hexagonal structure observed before and after incorporating polymer in silica.

where the pore size is approximately 3.6 nm (Fig. 11A). MCM-41/polymer composites with monomer-to-surfactant ratio of 1 show ordered pores and the electron diffraction pattern shows concentric rings characteristic of a hexagonal arrangement, ratio of radii 1, 3, 4, and 7 (Fig. 11B). The appearance of rings rather than distinctive dots indicates polycrystallinity.

Mesoporous silica without polymer exhibits a large surface area ( $1098 \text{ m}^2/\text{g}$ ) and high pore volume ( $0.65 \text{ cm}^3/\text{g}$ ), similar to reported values in the literature for MCM-41. The total surface area and the pore volume decreases when polymer is incorporated into mesoporous silica. Adsorption/desorption isotherms of nitrogen on mesoporous silica containing poly(4-ethylphenol) indicate the preservation of mesoporosity.

Comparing calcined mesoporous silica/polymer composites to mesoporous silica/polymer composites that are washed with distilled water and not calcined offers critical information about the localization of polymer in the mesoporous silica. The washed composite shows a noticeable disappearance of the adsorption step, a decrease in surface area, and decrease in volume absorbed as compared with the calcined composite. In comparison, mesoporous silica not containing polymer that was washed with distilled water and not calcined showed only a slight decrease in surface area. These observations suggest that the pores are blocked and imply that the mesoporous pores are filled with polymer.

## CONCLUSION

Self-assembled surfactant systems can be exploited in the biocatalytic synthesis of structured polymers with unique properties that are a consequence of chemical structure and/or morphology. Although a precise templating effect from the surfactant microstructure may not be immediately evident, it is clear that the surfactant self-assembly plays an important role in the development of polymer morphology. These systems may be exploited in the development of a variety of polymer-polymer and polymer-ceramic composites. For example, enzymatic polymer synthesis could be coupled with traditional free radical polymer synthesis with vinyl monomers to make novel structured composites. It is also possible to combine enzymatic polymer synthesis with inorganic cluster synthesis to make structured polymer-ceramic nanocomposites. An immobilized surfactant gel phase may offer a simple approach to encapsulating nanoparticles within polymer. Upon polymerization and polymer folding, the polymer may entrap inorganic molecules that are immobilized in the surfactant gel. Continuing work seeks to systematize these studies to develop clear correlations between surfactant microstructure and materials morphology.

## INTRODUCTION

Research on polymer nanocomposites based on layered silicates has exploded over the last decade,<sup>[1–5]</sup> ever since the pioneering work of the organoclay–nylon nanocomposite by Toyota.<sup>[6]</sup> The dispersion of the silicate nanolayer with its high aspect ratio, large surface area, and high stiffness within a polymer matrix results in significant improvement of the properties of polymeric materials, including mechanical properties,<sup>[7]</sup> barrier properties,<sup>[8]</sup> resistance to solvent swelling,<sup>[9]</sup> ablation performance,<sup>[10]</sup> thermal stability,<sup>[11]</sup> fire retardancy,<sup>[11]</sup> controlled release of drugs,<sup>[12]</sup> anisotropic electrical conductivity,<sup>[13]</sup> and photoactivity.<sup>[14]</sup> Layered-silicate nanocomposites have great potential for applications, ranging from automotive and aerospace to food packaging and tissue engineering. Cost and processability are as important to many applications as the property improvements.

Epoxy materials have been widely used in adhesives, coatings, electronic encapsulants, and advanced composites. Since the Pinnavaia group first extended the nanocomposite concept to epoxy systems,<sup>[15]</sup> extensive research on layered-silicate epoxy nanocomposites has been carried out.<sup>[16–45]</sup> This entry is the summary of some of the past research and latest research in our group, which focus on layered-silicate epoxy nanocomposites for aerospace applications. The aerospace epoxy used in the study is made from Shell Epon 862 with Epi-Cure curing agent W. This epoxy system has a high glass transition temperature ( $T_g$ ), good mechanical and physical performance characteristics, and low viscosity, and involves non-4,4'-methylenedianiline aromatic amines. The compatibility of organoclays with aerospace epoxy resin and the preparation of the nanocomposite were studied. Small-angle x-ray scattering (SAXS) and transmission electron microscopy (TEM) were used to characterize the morphology of the nanocomposites. The properties of the nanocomposite, including the dynamic and

static mechanical property and survivability in aggressive environments such as oxygen plasma, were measured. The integrated study of in situ SAXS, differential scanning calorimetry (DSC), and rheology provides information about the viscosity development and processing window, as well as the morphology development and exfoliation mechanism. Morphology development behavior for the epoxy nanocomposites as a function of curing agents, including Jeffamine and curing agent W, is discussed. In addition, epoxy nanocomposites as primer layer for aircraft coatings for improved anticorrosion properties are described.

## LAYERED SILICATE AND LAYERED ORGANOSILICATE

There are many layered silicates, including montmorillonite, illite, vermiculite, hectorite, beidellite, magadiite, kenyaite, kanemite, and crystalite. Among them, montmorillonite is the most popular choice for layered-silicate polymer nanocomposites. Natural sodium montmorillonite is an aluminosilicate composed of two silica tetrahedral sheets and one alumina octahedral sheet with strong covalent bonding within the sheets and weak bonding between the layers. Sodium montmorillonite is hydrophilic in nature and is not compatible with generally hydrophobic organic polymers. However, the weak bonding between the layers makes the cations in the gallery of the layered silicate easily exchangeable. Cations are typically used for nanocomposites with alkyl ammonium. The organic ammonium pendent group on these exchanged cations renders the layered silicate hydrophobic, thus compatible with the polymer matrix. One measure of the hydrophilic or hydrophobic nature of materials is the value of surface tension  $\gamma^-$  (electron donor).<sup>[46]</sup> Materials that have a  $\gamma^{LW}$  (Lifshitz–van der Waals) value of about 40 mJ/m<sup>2</sup> with  $\gamma^-$  higher than 28 mJ/m<sup>2</sup> are hydrophobic; at  $\gamma^-$  smaller

than 28 mJ/m<sup>2</sup>, they are hydrophobic.<sup>[46]</sup> For Wyoming sodium montmorillonite (SWy-1), the  $\gamma^{\text{LW}}$  and  $\gamma^-$  values are 42.9 and 36.7 mJ/m<sup>2</sup>; thus this material is hydrophilic in nature and is incompatible with epoxy. When the native sodium cation is exchanged with an ammonium cation, the charged end of the ammonium cation maintains contact with the silicate nanolayer surface, whereas the alkyl tail is directed away from the silicate nanolayer surface. This results in a reduction of  $\gamma^-$  value. The actual reduction depends on the alkyl chain length. For SWy-1, the  $\gamma^{\text{LW}}$  and  $\gamma^-$  values are 41.7 and 36.2 mJ/m<sup>2</sup> for NH<sub>4</sub><sup>+</sup>-montmorillonite, 41.2 and 9.8 mJ/m<sup>2</sup> for *n*-C<sub>6</sub>H<sub>12</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite, 39.4 and 7.7 mJ/m<sup>2</sup> for *n*-C<sub>8</sub>H<sub>17</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite, and 39.6 and 6.0 mJ/m<sup>2</sup> for *n*-C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite.<sup>[46]</sup> Thus it appears that the organoclay with six-carbon alkyl chain length can still be compatible with epoxy, although it is generally thought that longer alkyl chains in the pendent group are preferred for compatibility with polymers.

Based on this, an investigation of the effect of alkyl chain length on interplanar spacings of layered-silicate epoxy nanocomposites was conducted on four synthetic organoclays, including SC6 (*n*-C<sub>6</sub>H<sub>13</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), SC8 (*n*-C<sub>8</sub>H<sub>17</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), SC12 (*n*-C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), and SC18 (*n*-C<sub>18</sub>H<sub>37</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), and on one commercial organoclay, I.30E, from Nancor. Organoclays SC6, SC8, SC12, and SC18 were prepared by the treatment of sodium montmorillonite with HCl and primary amine (*n*-hexylamine or *n*-octylamine or *n*-dodecylamine or *n*-octadecylamine, respectively). Wide-angle x-ray diffraction (WAXD) studies show that the interplanar spacings of original sodium montmorillonite (SNA), SC6 (*n*-C<sub>6</sub>H<sub>13</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), SC8 (*n*-C<sub>8</sub>H<sub>17</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), SC12 (*n*-C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite), and SC18 (*n*-C<sub>18</sub>H<sub>37</sub>NH<sub>3</sub><sup>+</sup>-montmorillonite) are 12.1, 13.0, 13.2, 16.5, and 18.7 Å, respectively. The interplanar spacings of these organoclays increase with increasing alkyl chain length of the pendent group.

## AEROSPACE EPOXY NANOCOMPOSITES

There are three typical morphologies when a polymer is associated with organically modified layered silicates:<sup>[1–5]</sup> 1) traditional microcomposite—the polymer chain cannot penetrate inside the gallery of the layered silicate, resulting in a phase-separated composite; 2) intercalated nanocomposite—the polymer chains penetrate inside the gallery of the layered silicate and expand the nanolayers, resulting in a well-ordered multilayer morphology with alternating polymeric and silicate layers; and 3) exfoliated nanocomposite—the individual silicate nanolayers are completely separated and uniformly dispersed in a continuous polymer matrix. This is an ideal situation and perfect

morphology. Among the most reported exfoliated nanocomposites, there exist mixed morphologies with combinations of exfoliation and intercalation. The morphology can be determined by x-ray diffraction and transmission electronic microscopy.

There are three main approaches to fabricating layered-silicate polymer nanocomposites:<sup>[3,4]</sup> 1) in situ intercalative polymerization—the organosilicate is swollen in the liquid monomer, the monomer penetrates inside the gallery of the layered silicate, and the polymerization takes place inside the gallery; 2) exfoliation adsorption (solvent-assisted)—the organosilicate is mixed with the solvent, which can penetrate inside the gallery of the organosilicate, enlarge the gallery of the silicate nanolayers to expansion, or delaminate the silicate nanolayers. Simultaneously, the polymer can also dissolve in this solvent. When the mixture of organosilicate and solvent is combined with the polymer, the polymer can penetrate inside the gallery of the silicate nanolayers. The solvent can then be evaporated, leaving the nanocomposite; and 3) melt intercalation—the polymer is heated into the molten state and then mixed with organosilicate. The polymer will penetrate inside the gallery of the silicate nanolayers to expand the gallery to form the nanocomposite. In situ intercalative polymerization involves chemical reactions, whereas exfoliation adsorption and melt intercalation are primarily physical. Epoxy nanocomposites are generally prepared by in situ intercalative polymerization.<sup>[15–45]</sup>

The aerospace epoxy used in the study to be referenced is made from Shell Epon 862 (diglycidylbisphenol-F) with Epi-Cure curing agent W (diethyltoluenediamine). The desired amount of organoclay was added to the Epon 862. The organoclay/Epon 862 mixture was stirred at elevated temperature, then the stoichiometric amount of curing agent W was added to the mixture. The resulting mixture was degassed, cast in the mold, and cured at 121°C for 2 hr and at 177°C for another 2 hr, then cooled to room temperature overnight. DSC studies confirm that all of the nanocomposites were fully cured. All the organoclays, including SC6, SC8, SC12, SC18, and I.30E, can form transparent nanocomposites with the epoxy resin confirming the good compatibility of these organoclays with the Epon 862/W system. It appears that the six-carbon alkyl chain length can render the clay nanolayers sufficiently hydrophobic to be compatible with the epoxy resin, consistent with what the  $\gamma^-$  of the SC6 indicates.

## MORPHOLOGY CHARACTERIZATION

WAXD studies show no peak with  $2\theta$  down to 2° for all of the aerospace epoxy nanocomposite samples even with organoclay loading as high as 15%, indicating a

**Fig. 1** SAXS of Epon 862/curing agent W with different concentrations of I.30E (1%, 3%, 6%, 10%, and 15%).

large interplanar spacing ( $>44 \text{ \AA}$ ). The SAXS of Epon 862/curing agent W with different concentrations of I.30E (1%, 3%, 6%, 10%, and 15%) is shown in Fig. 1. SAXS study indicates that the interplanar spacings of all the nanocomposites with 3% and 6% different organoclay loadings are more than  $100 \text{ \AA}$ , and are 88 and  $69 \text{ \AA}$  for 10% I.30E/Epon 862/W and 15% for I.30E/Epon 862/W nanocomposites, whereas the original interplanar spacing of the organoclays is in the range of  $13\text{--}23 \text{ \AA}$ . The large increase in the interplanar spacing is because of the penetration of the epoxy resin inside the gallery and the expansion of the gallery of the organoclay. This also demonstrates that the dispersion of the nanolayers of the organoclay in the epoxy matrix is pretty good. Even at 10% I.30E loading, which is generally considered a very high loading in nanocomposites, the SAXS data still indicate good dispersion of clays in the matrix.

TEM provides direct imaging of the morphology of nanocomposites. The TEM image of cured 10% I.30E/Epon 862/W nanocomposites is shown in Fig. 2. The dark lines are the cross sections of the silicate nanolayers. The original aggregates of the organoclay were disrupted, and the nanometer-thick individual sheets were well dispersed in the epoxy resin. Although some nanolayers are disordered, others preserve the original ordered structure separated by approximately  $10 \text{ nm}$ , consistent with the SAXS results. The image also indicates that there still exist some ordered structures with disordered structure and some pure polymer domains. The TEM image of the cured 3% SC6/Epon 862/W nanocomposite is shown in Fig. 3. The interplanar spacing between the nanolayers of the ordered gallery is  $\sim 15 \text{ nm}$ , consistent with the SAXS results (a weak 001 reflection at  $140 \text{ \AA}$ ). The dispersions of the layers are very good. However, it is still not strictly an exfoliated nanostructure; rather, it is partially exfoliated with some intercalated structures of very large interplanar spacings ( $\sim 15 \text{ nm}$ ).

**Fig. 2** TEM image of cured 10% I.30E/Epon 862/W nanocomposite.

## PROPERTIES OF AEROSPACE EPOXY NANOCOMPOSITES

The storage modulus and  $\tan \delta$  curves obtained through dynamic mechanical analysis (DMA) of pure Epon 862/W and 1% I.30E/Epon 862/W, 6% I.30E/Epon 862/W, and 10% I.30E/Epon 862/W nanocomposites are shown in Figs. 4 and 5. The DMA data indicate that the increase in the storage modulus of the nanocomposites with different organoclays (1%, 3%, 6%, 10%, and 15% I.30E; 3% SC6; 6% SC8; 6% SC12; and 6% SC18) ranges from 15% to 35% in the glass state and from 15% to 300% in the rubber state. The increase of the storage modulus is attributed to the high aspect ratio and relatively high stiffness of the silicate nanolayers in the epoxy matrix. Based

**Fig. 3** TEM images of cured 3% SC6/Epon 862/W nanocomposite.

on the  $\tan \delta$  curve, the glass transition temperatures of the nanocomposites are from 152°C to 155°C, compared with 154°C of the pure Epon 862/W, except for the 143°C for the 15% I.30E/Epon 862/W nanocomposite. The decrease for the 15% I.30E/Epon 862/W nanocomposite perhaps is caused by the less homogeneous dispersion of the organoclay because of the high concentration of I.30E in the nanocomposite and plasticization effect from the organoclay.

Flexural data from three-point flex testing performed at room temperature and at high temperature (250°F) are shown in Figs. 6 and 7. The flexural modulus of the epoxy is significantly increased because of the organoclays by as much as 85%, with 10% I.30E loading. The improvement in modulus is perhaps because of the good dispersion of the stiffer clay nanolayers in the epoxy matrix, which may transfer and carry more load. However, the strength of the nanocomposites is decreased compared with that of the pristine epoxy resin. The results are similar to the those for the epoxy system reported by Zerda and Lesser<sup>[26]</sup>

**Fig. 5**  $\tan \delta$  curve of cured pure Epon 862/W and 1% I.30E/Epon 862/W, 6% I.30E/Epon 862/W, and 10% I.30E/Epon 862/W nanocomposites.

and Yasmin, Abot, and Daniel<sup>[44]</sup> Strength is more sensitive to the interface and to defects than modulus. The small reduction of strength may be partially attributed to the weak interface between the clay nanolayer and the epoxy because there is no covalent bonding in the interface between the nanoclay and the epoxy matrix. One of the key factors to improving the strength of the nanocomposite is the enhancement of the interfacial interaction between the polymer matrix and the layered silicates. Another possible reason for the reduction is the possible existence of nanovoids inside the nanocomposite system.<sup>[44]</sup> The data also show that the reduction of flex strength of the nanocomposites at elevated temperature is much smaller than that seen by the pristine polymer. Interestingly, the strength of some of the nanocomposites is higher than that of pure resin at 250°F. The cause for this significant phenomenon is under investigation.

The survivability of the nanocomposites in extreme environments may be improved and was assessed here via exposure to oxygen plasma.<sup>[47]</sup> Oxygen plasma contains many species that are extremely strong oxidants and to which polymeric materials are vulnerable. The

**Fig. 4** Storage modulus vs. temperature of cured pure Epon 862/W and 1% I.30E/Epon 862/W, 6% I.30E/Epon 862/W, and 10% I.30E/Epon 862/W nanocomposites.

Fig. 6 Flexural modulus of the pure Epon 862/W and nanocomposites at room temperature and 250°F.

surface erosion thicknesses after a 5-hr exposure to oxygen plasma are 34 and 22  $\mu\text{m}$  for the pure Epon 862/W and 6% for the I.30E/Epon 862/W nanocomposites, respectively, when they were exposed to oxygen plasma. Under this environment, the surface erosion rate of the nanocomposite is retarded compared with that of pure epoxy resin. A possible mechanism for the improved survivability is the ability of the nanocomposite to form intact inorganic layers when exposed to oxygen plasma.<sup>[47]</sup> The preferential oxidation of polymers and the corresponding enrichment of the nanoscale-layered silicates on the surface result in the formation of a ceramic-like inorganic layer, which retards the penetration of the oxygen plasma, thus slowing further degradation. Thus the incorporating organoclays in polymer matrices could increase the survivability of resulting composites in aggressive aerospace environments.

## PROCESSING AND MORPHOLOGY DEVELOPMENT

DSC studies show that the onset temperatures of polymerization are much lower for the Epon 862/W with

Fig. 7 Flexural strength of the pure Epon 862/W and nanocomposites at room temperature and 250°F.

organoclays than those for pure Epon 862/W ( $\sim 65$ – $100^\circ\text{C}$  vs.  $122^\circ\text{C}$ ). The catalytic effect is likely because of the acidity from the ammonium ( $\text{RNH}_3^+$ ) group of the pendent group from the organomontmorillonite.<sup>[15,18,19,39,40]</sup> The mechanism for the catalytic effect that the organoclay has on the epoxy polymerization may be explained as follows: The proton from the ammonium ( $\text{RNH}_3^+$ ) forms a cation with the glycidyl group, causing the functional group to become more electrophilic, which becomes more easily attacked by the nucleophilic curing agent amine. Thus the pendent group ( $\text{RNH}_3^+$ ) inside the gallery will catalyze the polymerization of the epoxy resin, resulting in cross-linking of the epoxy resin inside the gallery at relatively lower temperatures than those outside the gallery.

The addition of particles to a polymer generally increases its viscosity. If the organoclay significantly increases the viscosity of the epoxy resin, processing rates for aerospace composites, such as in resin transfer molding, may be difficult. The viscosity-vs.-temperature curves of the Epon 862/W mixture, the 3% SC6/Epon 862/W mixture, and the 10% I.30E/Epon 862/W mixture, when heated at  $2^\circ\text{C}/\text{min}$ , is shown in Fig. 8. The complex viscosity of the epoxy resin with organoclays (23 P for 3% SC6/Epon 862/W and 30 P for 10% I.30E/Epon 862/W mixture at  $30^\circ\text{C}$ ) is slightly higher than that of Epon 862/W (11 P at  $30^\circ\text{C}$ ). For the sample with 3% SC6 loading, the viscosity is increased very slightly from 0.6 P at  $90^\circ\text{C}$  to 2.7 P at  $140^\circ\text{C}$ , increased significantly from 7.6 P at  $150^\circ\text{C}$  to 108 P at  $160^\circ\text{C}$ , and increased very rapidly from 254 P at  $161^\circ\text{C}$  to 90,200 P at  $165^\circ\text{C}$  and to  $4.6 \times 10^5$  P at  $170^\circ\text{C}$ . This trend is similar to that seen for the 10% I.30E/Epon 862/W mixture. The viscosity is increased slightly from 0.7 P at  $90^\circ\text{C}$  to 4.2 P at  $140^\circ\text{C}$ , increased significantly from 8.4 P at  $145^\circ\text{C}$  to 110 P at  $152^\circ\text{C}$ , and increased again rapidly from 377 P at  $155^\circ\text{C}$  to 1900 P at  $160^\circ\text{C}$  and to  $6.2 \times 10^5$  P at  $170^\circ\text{C}$ . For the sample of pure Epon 862/W mixture, the complex viscosity is increased very slightly to 2.1 P at  $160^\circ\text{C}$ , increased significantly from 2.1 P at  $160^\circ\text{C}$  to 43 P at  $167^\circ\text{C}$ , and very rapidly from 430 P at  $168^\circ\text{C}$  to 13,192 P at  $170^\circ\text{C}$  and to  $5.9 \times 10^5$  P at  $180^\circ\text{C}$ . The rapid increase of the viscosity for the 3% SC6/Epon 862/W and 10% I.30E/Epon 862/W mixture at relatively low temperatures is related to the catalytic effect for the polymerization from the organoclay. Therefore, the incorporation of the organoclay into the epoxy resin does increase the viscosity not only because of the expected effect of particles, but also through the catalytic effect of the organoclays. However, the increase of the complex viscosity is limited and the processing window for the 3% SC6/Epon 862/W mixture and 10% I.30E/Epon 862/W mixture is still quite wide. This is important for subsequent composite processes.

**Fig. 8** Complex viscosity of the mixtures of pure Epon 862/W, 3% SC6/Epon 862/W, and 10% I.30E/Epon 862/W heated at 2°C/min.

In situ SAXS can be used to monitor the morphology development of the nanocomposites; here, some typical data of a 3% SC6/Epon 862/W mixture heated up at 2°C/min obtained at the National Synchrotron Light Source at the Brookhaven National Laboratory on Beamline X27C are shown in Fig. 9. SAXS data show that the initial interplanar spacing of the mixture is  $\sim 85$  Å compared with the original interplanar spacing of SC6 at 13.0 Å. This increase of the interplanar spacing is because of the penetration of epoxy resin into and the expansion of the gallery of the organoclay. The larger expansion of the interplanar spacing for 3% SC6/Epon 862/W mixture (85 Å), compared with that of 3% SC12/Epon 862/W mixture (35 Å),<sup>[40]</sup> is due perhaps to the smaller pendent group of SC6, which makes the migration of the epoxy resin inside the gallery relatively easier. SAXS data coupled with thermal analysis can provide insights into the morphology development mechanisms during the curing process of layered-silicate epoxy nanocomposites. When the temperature is elevated from 60°C to 80°C, the peak corresponding to the interplanar spacing between the nanolayers remains fairly constant. During this period, there is almost no polymerization

occurring, and the heating role in the expansion of the gallery of the nanoclay is very limited. From 80°C to 100°C, the increase of the interplanar spacing is still fairly limited. This is not unexpected as the onset temperature of curing for this mixture occurs at approximately 85°C based on DSC studies; polymerization is just beginning in this temperature region. From 100°C to 170°C, the peak corresponding to the interplanar spacing is shifted first gradually and then quickly from  $\sim 97$  to  $\sim 176$  Å, and the intensity of the peaks increases gradually as well. The quick polymerization in the intragallery because of the catalytic effect from the pendent group in the intragallery results in the consumption of the epoxy monomer inside the gallery and enhances the migration of more epoxy monomers from extragallery to intragallery, thus enhancing the continued expansion of the intragallery. In addition, the exothermal heat of curing provides additional energy to that from the process-imposed heating to help expand the nanoclay sheets. Based on rheological studies (Fig. 8), the viscosities for the 3% SC6/Epon 862/W mixture are 0.8 P at 100°C, 0.9 P at 120°C, 1.1 P at 130°C, 7.6 P at 150°C, 108 P at 160°C, 254 P at 161°C, 1303 P at 162°C, and 90,200 P

**Fig. 9** The in situ SAXS of the mixture of 3% SC6/Epon 862/W heated at 2°C/min.

at 165°C. The low viscosity of the epoxy resin from 100°C to 160°C guarantees that the epoxy resin can easily migrate from extragallery to intragallery. With an increase in temperature, curing of the epoxy resin both intragallery and extragallery results in increasingly high viscosities ( $4.6 \times 10^5$  P at 170°C, and  $8.7 \times 10^5$  P at 180°C). The epoxy is eventually almost fully cured with a viscosity of  $1.0 \times 10^6$  P at 190°C, and the material surrounding the nanolayers of the organoclay at this point is rigid. Ultimately, the interplanar spacing between the nanolayers is around 190 Å at 200°C.

Differences in the nanostructural evolution between the above-discussed SC6/Epon 862/W mixture and the previously studied SC12/Epon 862/W can be observed. The nanostructural or morphological evolution for the SC6-based nanocomposite was via a gradual ordered expansion of the galleries. In contrast, the SC12/Epon 862/W mixture morphological evolution occurs in stages, and experiences a transition from ordered to disordered and then back to order structure.<sup>[39]</sup> For the SC12/Epon 862/W system, the initial interplanar spacing is 35 Å after mixing. During initial curing, the silicate layers are distorted as the intragallery epoxy polymerizes and the outside resin infuses into the gallery through the tactoids edges. The SAXS data show an apparent loss of the peak associated with the initial spacing as the number of ordered scatterers is reduced because of resulting curvature of the nanosheets. As more and more epoxy migrates, the gallery makeup becomes more homogenous, the curvature is reduced, and the ordered (registered) structure is regained. For the SC6/Epon 862/W system, the original interplanar spacing is on the order of ~85 Å after mixing. In this case, the mixing step brings sufficient epoxy into the galleries as the epoxy is less impeded by the shorter alkyl chains (six-carbon chain in SC6 vs. 12-carbon chain in SC12); this results in an almost homogeneously filled gallery prior to heating. Therefore at the onset of polymerization, no distortion occurs and registry is maintained as the organoclay tactoid expands.

In summary, based on in situ SAXS studies, the exfoliation mechanism is seen to take place during curing. This important phenomenon enables low viscosity during the mixing processes and the ultimate formation of the nanoscale morphology during the curing steps of a process. This is vital to ultimate processability and manufacturability of nanotailored reinforced composites for aerospace applications.

### MORPHOLOGY DEVELOPMENT OF EPOXY NANOCOMPOSITES WITH DIFFERENT CURING AGENTS

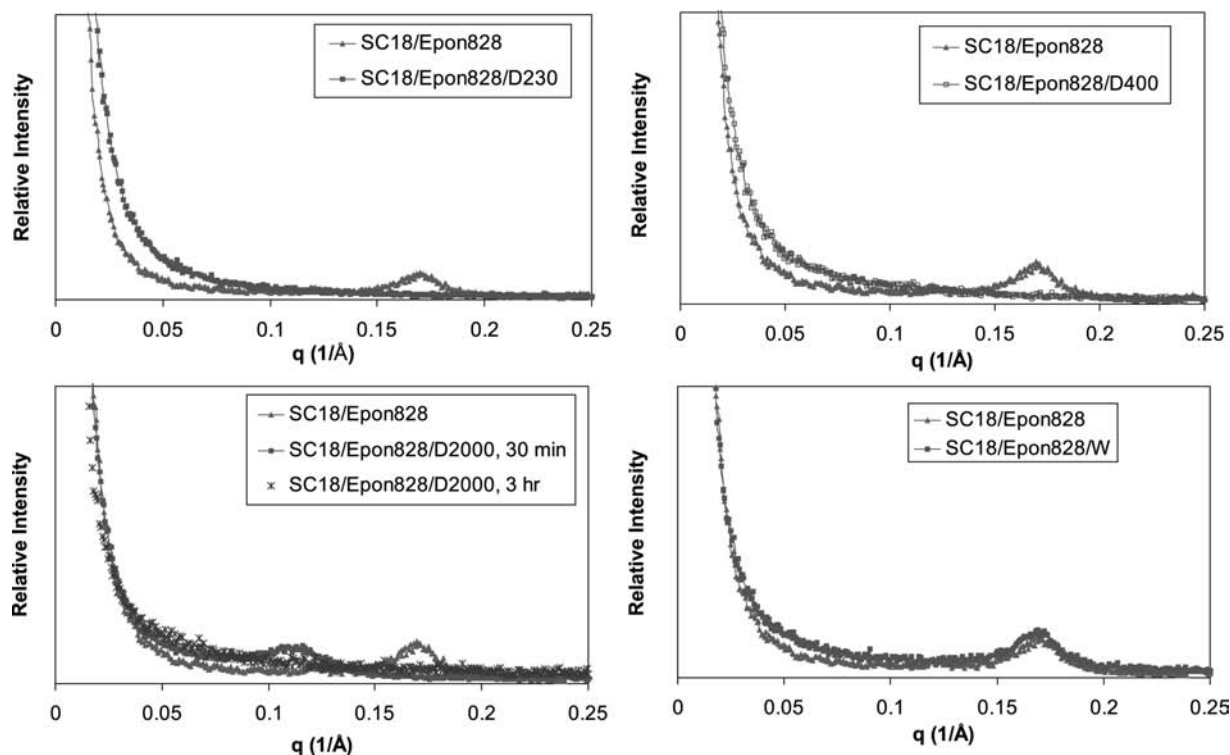

The nature of the selected curing agent plays a role in the morphology development of epoxy nanocomposites.

When Epon 828 is mixed with organoclay SC18, Epon 828 penetrates inside the gallery of the organoclay. The SC18/Epon 828 mixture has a very ordered intercalated structure with an interplanar spacing of ~35 Å compared with the original interplanar spacing of ~18 Å of the SC18. When the mixture of SC18/Epon 828 was mixed with Jeffamine D230 or Jeffamine D400 curing agents and held for 30 min at room temperature, SAXS showed no peaks (Fig. 10). This indicates that Jeffamine D230 can easily penetrate into the gallery of the organoclay, therefore causing separation of the nanolayers and exfoliation. The SAXS shows the same pattern for fully cured systems. When the SC18/Epon 828 mixture was mixed with Jeffamine D2000 and held for 30 min at room temperature, SAXS showed the ordered nanolaminated structure with interplanar spacings of ~55 Å (Fig. 10), again because of the penetration of the Jeffamine D2000 into the gallery of the organoclays and the expansion of the gallery. However, the larger molecular weight of Jeffamine D2000 and the size of the molecule reduced its mobility and penetration into the gallery; therefore an intercalated—instead of an exfoliated—structure is obtained. When the SC18/Epon 828/D2000 mixture was held in 60°C for 3 hr, SAXS showed no peaks (Fig. 10). The high temperature increased the mobility of the Jeffamine D2000 molecule, easing penetration of the gallery and causing the separation of the nanolayers. For the mixture of SC18/Epon 828 with curing agent W, SAXS indicates almost no change of the ordered nanolaminated structure and the interplanar spacings remain essentially constant at ~35 Å (Fig. 10). This suggests that curing agent W is not compatible with the gallery of organoclays, and that there is no or very little penetration of it into the gallery. Exfoliation for the SC18/Epon 828/W system took place during heatup. These observations demonstrate the role that curing agents may play in morphology development. Curing agent W is an aromatic amine containing an aromatic group, whereas the Jeffamine is a polyoxypropyleneamine curing agent containing oxygen with a more flexible chain. Simultaneously, the organoclay contains siloxane backbone with many oxygen atoms inside, which perhaps makes it more compatible with Jeffamine. Such properties and nature of different curing agents cause different exfoliation behaviors for epoxy nanocomposites.

### EPOXY NANOCOMPOSITE AS PRIMER LAYER FOR AIRCRAFT COATING

Nanocomposites offer significant barrier properties, as observed by many researchers to date. Corrosion protection requirements of modern aircraft coating systems become increasingly demanding, and environmental as well as performance enhancements are sought.

**Fig. 10** SAXS of SC18/Epon 828 with SC18/Epon 828/D230, SC18/Epon 828 with SC18/Epon 828/D400, SC18/Epon 828 with SC18/Epon 828/D2000 after 30 min and 3 hr, and SC18/Epon 828 with SC18/Epon 828/W.

The incorporation of nanoclays into epoxy primers offers opportunities to develop environmentally benign, improved anticorrosion protection, which may provide new applications for nanocomposites. The most common primer layer for aircraft coatings is epoxy based on Epon 828 (diglycidylbisphenol-A) with Epi-Cure curing agent 8290-Y-60 [polyethylene polyamine adduct (60) and 2-propoxyethanol (40)]. Epon 828 with Jeffamine D400 curing agent is a model for such primers, and a 2.5% SC18/Epon 828/D400 nanocomposite achieves an essentially exfoliated morphology. This system has very high barrier resistance for anticorrosion protection and can be cured at room temperature within a week, similar to the Epon 828/curing agent 8290-Y-60 system. Corrosion performance was assessed through exposure of AA2024-T3-coated panels to dilute Harrison's solution (a mixture of 0.05% sodium chloride and 0.35% ammonium sulphate) for 24 hr, followed by potentiodynamic polarization scans.<sup>[45]</sup> The corrosion current was 0.4 pA for pure Epon 828/D400, which is representative of very good barrier properties. The 2.5% SC18/Epon 828/D400 nanotailored coating exceeded the epoxy with a corrosion current of 0.2 pA. The improvement in the barrier properties of the SC18/Epon 828/D400 coating is attributed to the dispersion of the platy nanolayers in the epoxy matrix and the resulting tortuous path that they provide for fluids. Nanotailored epoxies and

nanocomposites offer promise for anticorrosion coatings as well as any polymeric material that requires improved barrier properties or reduced permeability.

## CONCLUSION

Both commercially available organoclay (I.30E) and synthetic organoclays (SC6, SC8, SC12, and SC18) are compatible with aerospace epoxy resins such as those studied here. Characterizations of the nanocomposites from WAXD, SAXS, and TEM confirm that their nanostructure can achieve interplanar spacings larger than 100 Å—5–10 times the original organoclay spacings. Even loadings as high as 10% (I.30E) can reach relatively large interplanar spacings as confirmed by scattering and TEM studies. Selection of organoclay treatment is critical because it can affect both the math of morphology development during cure processing as well as the final interplanar spacings. Selection of curing agent can also affect nanostructure morphology. Nanomodified epoxies offer properties that are appropriate to many aerospace applications. The modulus of the nanocomposite is significantly increased over the baseline epoxy from 15% to 35% in the glass state and to 300% in the rubber state, depending on loading as expected. The increase of the storage modulus is attributed to the high aspect

ratio and high stiffness of the silicate nanolayers in the epoxy matrix. The change in the  $T_g$  for the nanocomposite compared with the pure epoxy resin is insignificant.

For the materials reported here, the flex strength of the nanocomposites is decreased compared with that of the pristine epoxy resin. This reduction of strength is perhaps attributed to the weak interface between the clay nanolayer and the epoxy resin—an area to be further addressed. Surprisingly, the strength at high temperature (250°F) of some nanocomposites can be greater than that of pure resin, which may allow for more effective utilization of polymer composites in high-temperature environments. The survivability of aerospace epoxy resins under oxygen plasma and perhaps other extreme environments can be improved through nanotailoring by organoclays as the resulting nanocomposite materials can form inorganic barrier layers. Anticorrosion and other permeability-dependent properties may lead to some near-term aerospace applications. For all properties, nanostructure morphology plays a role.

Processability of nanotailored resins is a factor for many current advanced composite fabrication methods. Initial in-depth studies indicate that nanostructural evolution and viscosity development lend themselves to composite processes. The quick polymerization in the intragallery because of the catalytic effect from the pendent group results in the consumption of the epoxy monomer inside the gallery and makes the migration of more epoxy monomers from extragallery to intragallery, thus causing the expansion of the intragallery during the early stages of processing when viscosity is low. In addition, the exothermal heat from curing provides extra energy, in addition to energy from heating, to help expand the nanoclay sheets. Because the development of exfoliated morphology takes place during the cure for epoxy, as opposed to during the mixture processing step as in the case of thermoplastics, the impact of the organoclay on viscosity during the processing of epoxy nanocomposites is minimized. This is a very attractive attribute from the viewpoint of processing.

Ultimate control of properties through fundamental understanding of process morphology and nanoscale morphology properties is key to aerospace applications. Although there are many opportunities that may open up as a result of the insight into nanotailoring of epoxies through organoclays obtained through studies such as those reported and referenced here, many material developments will be required to fully exploit nanocomposites for the aerospace community, such as interface modifications, and validated analytical predictive tools will eventually be required to guide such material development as well as to predict their long-term performance.

University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A.

## INTRODUCTION

In chemistry (as well as biology and medicine), the concept of molecular structure is axiomatic; its status is essentially that of a cornerstone for predicting and understanding diverse molecular phenomena. Consequently, a lot of attention has been paid to developing molecular geometry predictive computational methods.<sup>[1]</sup> Despite the ability of modern large-scale *ab initio* calculations to accurately predict molecular geometries (in small-size and medium-size molecules), the forces that control the preferred conformer shape remain only partially appreciated.

## ETHANE

Single bonds allow facile rotation around the bond, leading to an abundance of conformations for molecules with many such bonds (e.g., alkanes, sugars, and polymers). It is noteworthy that the formulation of fundamental chemical concepts, including that of molecular structure, originated in the framework of carbon chemistry. The simplest model molecule for studying C–C bond rotation is ethane (C<sub>2</sub>H<sub>6</sub>). It is the textbook example of a molecule that can rotate internally around one or more of its bonds so that during a full 360° rotation, it changes between unstable and relatively stable conformations. The equilibrium structure is the staggered (S) structure in which the two methyl (CH<sub>3</sub>) groups are stacked so that the hydrogen atoms are maximally separated (Fig. 1A). As one of its two methyl groups rotates once around the central carbon–carbon bond, the molecule will alternate three times between the preferred staggered conformation (Fig. 1A) and a ~3-kcal/mol<sup>[2,3]</sup> higher-energy unstable eclipsed (E) conformation (Fig. 1B). Schreiner<sup>[4]</sup> has given a careful account of the rich history behind the conviction for hindered rotation in ethane. Ebert and Wagner<sup>[6]</sup> appear to have been the first to propose ethane-hindered rotation in 1929 and 1931, respectively. Their molar heat capacity measurements led to recognition—in the early years of

quantum theory—by Nielson<sup>[5]</sup> and Teller and Weigert<sup>[6]</sup> of the quantum mechanical nature of internal rotation. However, the magnitude of the barrier remained in dispute and it was not until 1936 that Kemp and Pitzer<sup>[7]</sup> established definitively, from precise thermodynamic measurements, that the rotational barrier is appreciable, close to the now-accepted 3 kcal/mol. Wilson,<sup>[8]</sup> realizing that elucidation of rotational barrier origins would lead to an in-depth understanding of the relationship between electronic and molecular structures, published many papers (ethane included) on this topic. More details of the ethane internal rotation history, with additional references, have been given by Payne and Allen<sup>[9]</sup> and Veillard.<sup>[10]</sup>

Early work on the staggered structural preference focussed on the change in exchange repulsion (basically the Pauli principle leading to a tendency of electrons to avoid occupying the same space).<sup>[11]</sup> In this intuitively satisfying model, while ethane rotates toward an eclipsed structure, the electrons in C–H bonds on the different carbon atoms draw closer to each other (Fig. 1B) and experience increased repulsion, which destabilizes the eclipsed structure. Other conjectures included classical electrostatics, van der Waals (dispersion) forces, d-orbital and f-orbital participation, and hyperconjugation.<sup>[12]</sup> A more recent proposal involves quadrupole polarization of the C–C bond density in the eclipsed conformation.<sup>[13]</sup> Hyperconjugation is the term given to stabilizing delocalization effects caused by  $\sigma$ – $\sigma^*$  interactions, analogous to the  $\pi$ -conjugation present in unsaturated molecules.<sup>a</sup> Mulliken,<sup>[15]</sup> as early as 1939, concluded that  $\sigma_{\text{CH}}$ – $\sigma_{\text{CH}}^*$  hyperconjugation plays a role in the torsional potential of ethanelike molecules. However, Mulliken's estimate of the hyperconjugation effect at that time was necessarily crude, seeming to suggest that it was too small to account for the observed 3.0-kcal/mol

<sup>a</sup>Mulliken, Rieke, and Brown<sup>[14]</sup> originally labeled such extended  $\sigma$ -delocalization arising from  $\pi$ – $\sigma^*$  and  $\sigma$ – $\pi^*$  interactions in unsaturated systems as hyperconjugation. The extension to  $\sigma$ – $\sigma^*$  delocalization in fully saturated molecules<sup>[15]</sup> is sometimes termed “secondary hyperconjugation.”

Fig. 1 Ethane internal rotation.

staggered–eclipsed energy difference. This idea was largely forgotten until the simple Huckel molecular orbital (MO) studies of Lowe,<sup>[16,17]</sup> and the analysis in terms of semilocalized orbitals, by England and Gordon<sup>[18]</sup> in the early 1970s, rekindled interest in hyperconjugation as a factor in the ethane torsional barrier.

Building on England and Gordon's finding that overlap between the tails of incompletely localized CH bond orbitals is important in energy analysis, Brunck and Weinhold,<sup>[19]</sup> using semiempirical MOs, showed how the staggered–eclipsed energy difference can arise simply from the change in the overlap of vicinal  $\sigma_{\text{CH}}$  and  $\sigma_{\text{CH}^*}$  orbitals in the *anti* and *syn* arrangements of the staggered and eclipsed conformers (Fig. 2). It is clear that the donor–acceptor interactions are sharply reduced in the *syn* arrangement compared to *anti* because of unfavorable cancellation in the latter case, as the nodal plane of the CH antibond cuts through the main lobe of the CH bond orbital. This visual estimate is confirmed by the overlap integral magnitudes shown in Fig. 2, which strongly favor larger hyperconjugative stabilization in the staggered conformer.

Thus by the turn of the century (i.e., 21st century), the two surviving models for the ethane staggered preference were: 1) lower steric and electrostatic repulsion; and 2) higher hyperconjugative stabilization than for the eclipsed structure. The latter model, although advocated by a substantial segment of the theoretical chemistry community, remained controversial and virtually every undergraduate organic chemistry textbook in 2000 favored the intuitively seductive steric repulsion model. Almost all omitted any mention of the hyperconjugation explanation.<sup>b</sup> Even so, a key step had been made in 1980, which had the potential for allowing a decisive choice to be made between the two models: Brunck and Weinhold's formulation of natural bond orbital (NBO) theory.<sup>[19]</sup> Lowdin<sup>[21]</sup> defined a set of “natural orbitals” describing a system

<sup>b</sup>An exception is Ref.<sup>[20]</sup>, but this volume is rarely used in undergraduate courses.

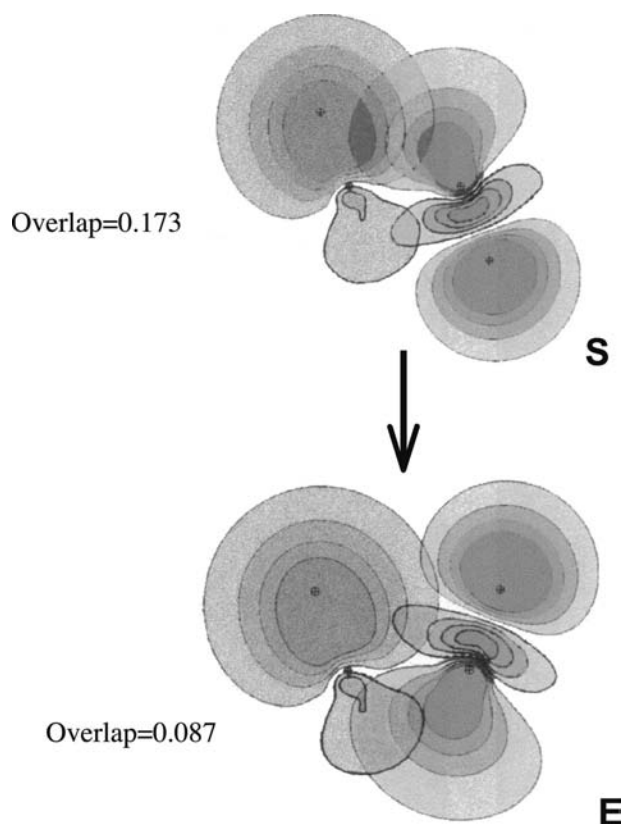

Fig. 2 Leading vicinal  $\sigma_{\text{CH}}-\sigma_{\text{CH}^*}$  hyperconjugative donor–acceptor interaction in the staggered (S) and eclipsed (E) conformers of ethane. Dark shading: antibonding orbitals; light shading: bonding orbitals.

as the unique complete set of orthonormal maximum occupancy orbitals possible within the general double occupancy Pauli restriction. Natural bond orbitals represent an extension of natural orbitals: they are two-centered transforms of MOs into almost doubly occupied bonding orbitals (bonds) and nearly unoccupied antibonding orbitals (antibonds), which fulfill the natural orbital restrictions. They retain the energetic accuracy of MOs; however, they have the desirable property of being able to describe properties of a system in localized terms that are well hidden in the complex forms of MOs.

The NBO scheme allowed  $\sigma-\sigma^*$  delocalization effects, essentially buried in the ethane MOs, to be pinpointed. The resulting energetic analysis favored the hyperconjugative model,<sup>[22]</sup> but a complication arises in evaluating the steric and electrostatic interactions. Steric energetics inherently involve a collective response of the entire N-electron system to the spatial region and, consequently, is sensitive to the details of the staggered  $\rightarrow$  eclipsed torsional coordinate.<sup>[23]</sup> Thus a central point in eliminating repulsive interactions as a factor in determining the staggered structure is including skeletal expansion, explicitly C–C

bond lengthening (i.e., torsion in ethane is not pure rotation).<sup>[24]</sup> Wanting to get away from the pitfalls of energy analysis, Pophristic and Goodman<sup>[25]</sup> carried out a series of ethane geometry optimizations by successive removal of hyperconjugative, Pauli exchange, and repulsive electrostatic interactions (with and without the skeletal relaxations).

Because an individual hyperconjugative interaction is expressed as a charge (electron) transfer between selected bond and antibonds in the NBO description, specific hyperconjugative interactions that influence structural preference can be pinpointed. Table 1 shows the result of geometry optimization with selected charge transfers absent. If the inversion of conformational preference occurs on removal of a specific charge transfer interaction, the controlling factor for ethane's staggered structure has been identified. The "no hyperconjugation" entry in Table 1 shows that preference for the staggered conformation is lost on removal of all charge transfers. Furthermore, the equilibrium conformer of ethane with only the vicinal hyperconjugation (i.e., charge transfer between NBOs on adjacent carbon atoms) removed ("no vicinal hyperconjugation" entry) is eclipsed. If only the geminal hyperconjugation (i.e., charge transfers between the orbitals originating on the same carbon atom) is deleted, the inversion of conformational preference does not occur. The conclusion is that vicinal charge transfer interactions are the ones that keep the molecule in the staggered conformation. By this argument, it is the hyperconjugatively induced preferential stabilization that controls the ethane structure.

Where does this leave the repulsion model? Repulsion involves two types of interactions: exchange, necessarily a short-range effect because of the orbital overlap requirement, and electrostatic or Coulomb involving classical  $1/R$  repulsion between charges. Taken together, these are frequently regarded as "steric repulsion." Figure 3 considers two cases: the real ethane molecule with all interactions present, and a hypothetical one with all of the exchange repulsions removed. One potential curve

**Table 1** Conformational dependence on hyperconjugative interactions<sup>a</sup>

Deleted hyperconjugative interactions	Torsional angle (°)	Corresponding conformer
No deletion	60.0	S

(with all interactions present) represents the energy of the real molecule; the other curve represents the energy of the hypothetical molecule with exchange repulsion absent. The conclusion from Fig. 3 is that the minima of both curves coincide at the staggered conformation, establishing that the staggered conformation is preferred regardless of the presence of exchange repulsion.

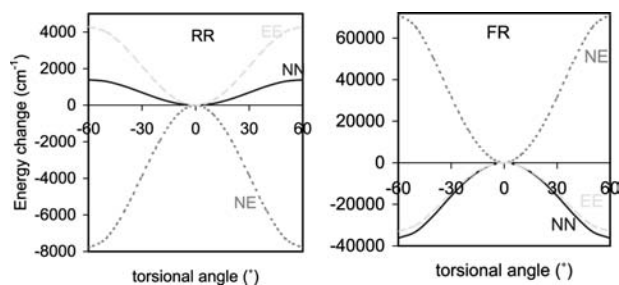

The effect of electrostatic repulsion can be understood by comparing its torsional angle dependence for three cases: rigid rotation (i.e., pure rotation, all skeletal relaxations frozen), partially relaxed rotation (only C–C bond lengthening included), and fully relaxed rotation (all skeletal flexings taken into account). Figure 4 shows that for rigid rotation, both electron and nuclear Coulomb repulsions increase as the torsional angle incrementally increases to the eclipsed conformer. However, when C–C bond lengthening is included as part of the rotational process as it is in fully relaxed rotation, both repulsions decrease, agreeing with Bader et al.<sup>[13]</sup> Thus the central bond stretching that is an intrinsic part of the rotational coordinate, which takes ethane from the staggered structure to eclipsed, reduces the strain that is accumulated in the molecule by rotation alone. The 0.014-Å C–C bond lengthening leads to a large decrease in Coulomb repulsion energies. Therefore electrostatic repulsion does not explain the staggered structural preference in ethane.

The conclusion is that ethane adopts the eclipsed conformation when the vicinal charge transfers are absent, and no inversion of structure occurs on the removal of Coulombic and exchange repulsions. This shows decisively that it is hyperconjugation, not repulsive forces, that determines the staggered equilibrium structure of ethane. A central point in eliminating

**Fig. 3** Torsional angle dependencies of energy of real ethane (solid curve) and hypothetical ethane with exchange repulsion absent (dashed curve). Zero degrees denotes the staggered conformer;  $\pm 60^\circ$  denotes the eclipsed conformer. Source: From Ref.<sup>[25]</sup>.

**Fig. 4** Torsional dependence of nuclear–nuclear (NN; full line), electron–electron (EE; long dash line) repulsion, and nuclear–electron (NE; short dash line) attraction energy changes for rigid (RR) and fully relaxed (FR) rotation in ethane. Corresponding curves for the partially relaxed model (C–C bond lengthening included) are indistinguishable from the FR ones on the figure scale.

repulsive interactions as a factor in determining the staggered structure is the necessity to take into account skeletal expansion, explicitly C–C bond lengthening (i.e., internal rotation is not pure rotation).

## DISILANE AND DIGERMANE

The interest in silicon and germanium group IV analogs of ethane, disilane ( $\text{SiH}_3\text{SiH}_3$ ), and digermane ( $\text{GeH}_3\text{GeH}_3$ ) stems from a combination of two factors. One is the increased separation of the rotating groups (the central Si–Si and Ge–Ge bonds are 0.84 and 0.92 Å, respectively, longer than in ethane; Table 2) and the other is the X–H (X = Si and Ge, respectively) polarity reversal from ethane. These changes are expected to cause hyperconjugative interactions between the  $\text{XH}_3$  groups to become small, if not negligible. An analysis of these ethane congener interactions allows a deepening of the hyperconjugative conformational preference conclusion drawn for ethane itself. Although experiments have not established their equilibrium conformer structure (H atoms contribute little to electron diffraction patterns),<sup>[26]</sup> all calculations conclude that both digermane and disilane exhibit a staggered conformational preference. As expected from the hyperconjugative diminution, the rotational barriers are strongly reduced (Table 3).<sup>[27–32]</sup> As pointed out, these molecules can be thought of as stretched ethanes enriched by additional electrons.

Figure 5 illustrates that hyperconjugative stabilization, the principal barrier forming interaction in ethane, falls to a small fraction of the ethane value (Table 3), as seen from the related reduced overlap between the  $\sigma-\sigma^*$  hyperconjugating orbitals. The absence of significant backside lobe overlap with the middle lobe of the antibond is particularly conspicuous. Is the barrier attenuation primarily because of

**Table 2** MP2/6-311G(3df,2p) optimized geometries of ethane, disilane, and digermane conformers

Source: Ref.<sup>[32]</sup>.

the larger Si–Si and Ge–Ge bond lengths, or because of the X–H polarity reversal? That the attenuation is mostly because of the larger bond lengths can be seen from the barrier energies in two phantom molecules created by expanding ethane to the more open structures of disilane and digermane, respectively, without any electron configuration change (Table 4). These phantom molecules have C–H bonds instead of the Si–H and Ge–H ones in the real molecules. The calculated barrier energies are reduced to even lower values than those found for real disilane and digermane.<sup>[31,32]</sup>

The effect of hyperconjugation alone is sufficient to keep disilane from exhibiting free rotation (Table 2).<sup>[31]</sup> However, the 0.3-kcal/mol hyperconjugation energy, by itself, is insufficient to prevent digermane from going into free rotation. Nevertheless, the role that hyperconjugation plays in rigidizing the digermane equilibrium conformer is shown clearly by the internal rotation potential curves with and without this interaction given in Fig. 6. The 0.3-kcal/mol delocalization energy is substantially smaller than the Boltzmann energy at 300 K. The total energy is actually only

greater than the Boltzmann energy when the torsional angle exceeds 40°. Thus digermane is expected to exhibit large amplitude (~80°) torsional oscillations at room temperature. If vicinal hyperconjugation is removed (dashed curve in Fig. 6), digermane is predicted to go into free rotation at this temperature.

## CONCLUSION

The weight of evidence (particularly direct structural optimizations with missing interactions) indicates that vicinal hyperconjugation controls the staggered structure of ethane. A central point in eliminating repulsive interactions as a factor in determining the staggered structure is the effect of the C–C bond lengthening that accompanies internal rotation (i.e., internal rotation in ethane is not pure rotation). The group IV congeners, disilane and digermane, show greatly attenuated hyperconjugative interactions. In digermane, hyperconjugation stabilization is predicted to be so weakened that it is insufficient to give much rigidity to the molecule at room temperature.

## INTRODUCTION

Single molecule spectroscopy (SMS) has been recently used extensively to study semiconductor nanomaterials, including semiconductor nanocrystals,<sup>[1–4]</sup> and nanostructured conjugated polymers.<sup>[5–13]</sup> SMS has made the complex photophysical processes accessible on these heterogeneous materials that are often obscured in ordinary ensemble measurements. For example, the molecular structure and photophysical dynamics of single isolated polymer chains (molecules) of conjugated polymers have been successfully investigated using SMS,<sup>[5,7–12,14–19]</sup> because the spectroscopy of single polymer chains, as opposed to the bulk material, has the advantage of tremendously reducing the size and complexity.

A new SMS technique has recently been introduced for investigation of functional nanomaterials by involving simultaneously controllable oxidation/reduction or charge injection in an electronic device. The new technique denoted by fluorescence-voltage SMS (*F-V/SMS*) is analogous to current-voltage (*I-V*) measurements for devices and electrochemical cells. *F-V/SMS* has been proven to be a powerful tool for studying the photophysics and charge-transfer processes of conjugated polymers, giving new insights into the complex interaction of excited and charged species that exist in a device environment.

## BACKGROUND

Conjugated polymers are widely used as active materials in a broad range of electronic devices including organic light emitting diodes (OLEDs), photovoltaic devices, thin-film transistors, and chemical sensors.<sup>[20–22]</sup> Fig. 1 portrays a simplified device architecture and associated energy level diagram of a typical two-layer OLED, where electrons and holes are injected from the cathode and anode, recombine close to the interface between the electron/hole transport layers, and electroluminescence is generated from the resulting excitons (excited states). Unfortunately, however, it is extremely difficult to unravel the complex and heterogeneous kinetics in such a device. First, there are many different types of singlet excitons ( $S_1$ ), triplet excitons ( $T_1$ ), and charged species (polarons) in a device, leading to large spatial variations and fluctuations in the kinetics of these species. Second, conjugated polymers have a complex nanostructure associated with morphological features (polymer chain folding, packing, and aggregation), which can seriously impact the operation of a device.<sup>[23]</sup> Third, various dynamical processes involving the exciton–exciton and exciton–polaron interactions (e.g.,  $S_1$ – $S_1$  annihilation,  $T_1$ – $T_1$  annihilation,  $S_1$  quenching by  $T_1$ ,  $S_1$  quenching by holes, and  $T_1$  quenching by holes) make it difficult to analyze the photophysics in organic devices.

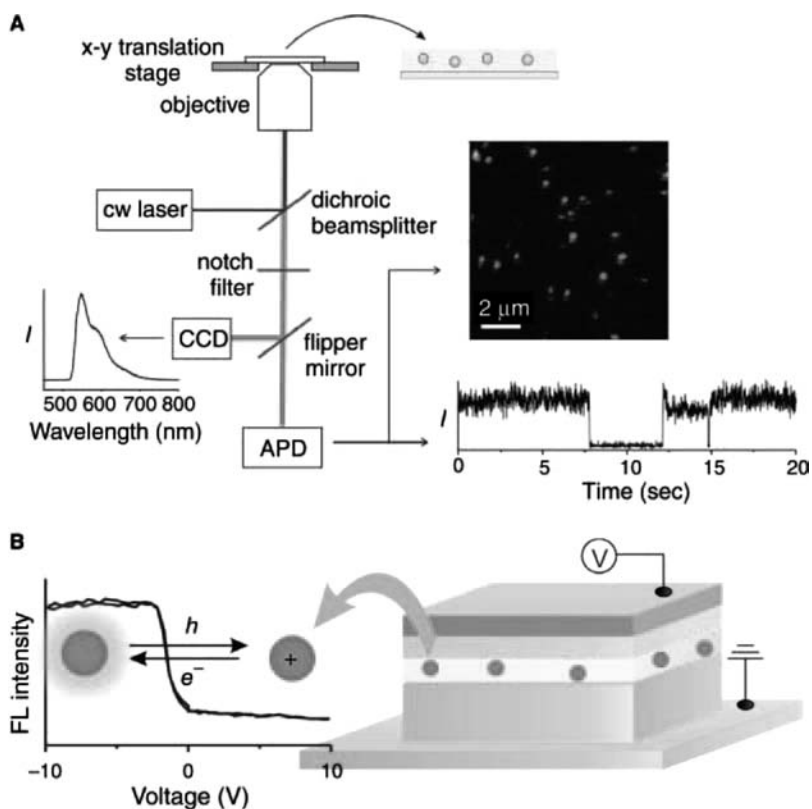

**Fig. 1** A schematic band energy diagram for a two-layer OLED.

Recently, the complicated interaction of excitons and polarons has been successfully approached by using a new technique that allows for SMS in a device environment.<sup>[24–27]</sup> This method involves simultaneous single molecule fluorescence spectroscopy while controlling oxidation/reduction of individual molecules or nanoparticles in an electronic device (Fig. 2B). The technique, which is denoted by *F-V/SMS*, where “*F*” signifies fluorescence intensity, is analogous in several ways to *I-V* measurements for devices and

electrochemical cells. For example, *F-V/SMS* data at different sweep rates can be analyzed to obtain information on both energetics and kinetics of charge transfer (oxidation/reduction) processes involving single molecules. This is achieved by recording the single molecule fluorescence intensity as a function of device bias, which controls the population of polarons. This method also offers a unique means for characterizing the chemical nature of the poorly understood photochemically induced intermediate states of conjugated polymers that are responsible for fluorescence “blinking” and “flickering,” i.e., intermittency. By studying the bias dependence of the SMS during the lifetime of the fluorescence “flickering” intermediate, information on the *oxidation/reduction properties* (e.g., HOMO energies) of the intermediate can be determined.

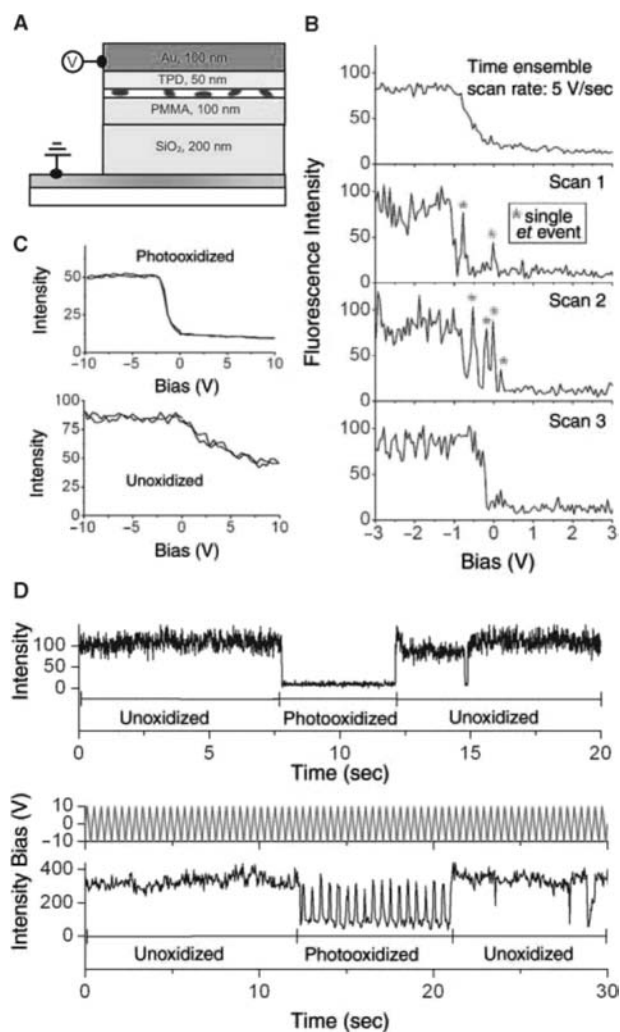

### *F-V/SMS*

An *F-V/SMS* example is presented in Fig. 3, which shows the fluorescence intensity of a single isolated conjugated polymer molecule as a function of the bias voltage  $V$ .<sup>[24,25,27]</sup> The *F-V/SMS* data reveal that a single positive charge (hole) injected from the device induces a significant fluorescence quenching of poly[2-methoxy,5-(2'-ethyl-hexyloxy)-P-phenylene-vinylene]

**Fig. 2** (A) Typical single molecule fluorescence spectroscopy apparatus. (B) Configuration of a typical *F-V/SMS* setup and *F-V/SMS* data.

**Fig. 3** (A) A diagram of a capacitor-like hole-injection device. (B)  $F$ - $V$ /SMS time ensemble and individual scans of an MEH-PPV molecule. (C) Two typical bias-dependent modulation behaviors;  $F$ - $V$  curves collected from (top) a photo-oxidized molecule showing a discrete fluorescence quenching by a hole injection, and (bottom) a unoxidized molecule showing a gradual fluorescence quenching by TPD holes. (D) Intensity vs. time transients of a single MEH-PPV molecule (top) with no bias and (bottom) with triangle wave bias applied.

(MEH-PPV). The capacitor-like hole injection device employed for this study is described in Fig. 3A. In the device configuration, holes are injected from the Au electrode to the hole transport layer of *N,N*-bis(3-methylphenyl)-*N,N'*-diphenylbenzidine (TPD) at positive bias. In typical experiments, fluorescence intensity vs. time transients of isolated single MEH-PPV molecules are collected (Fig. 3D) while a triangular wave bias voltage sequence is repeatedly applied to the device and then the SMS data are averaged over many cycles and replotted in the form of time ensemble  $F$ - $V$  curve (Fig. 3C). The time-ensemble and single  $F$ - $V$

**Table 1** Best-fit kinetic parameters for different MEH-PPV molecules in an inert polymer matrix<sup>a</sup>

Molecule	$k'_{isc}/s$	$k_{QST}/s$
1	$6.0 \times 10^3$	$7.8 \times 10^9$
2	$6.4 \times 10^3$	$1.1 \times 10^{11}$
3	$3.8 \times 10^3$	$3.4 \times 10^{11}$
4	$4.0 \times 10^3$	$1.2 \times 10^{10}$

<sup>a</sup>In the fitting procedures a quantum yield of intersystem crossing of 1.25% was used for MEH-PPV. (From Ref.<sup>[15]</sup>)

scans in Fig. 3B show that the electron transfer process definitely involves a single electron transfer per molecule. The intensity fluctuations at the transition region reflect the stochastic nature of electron transfer, not photon shot noise, which is much smaller.  $F$ - $V$ /SMS data of this type can be used to sort out the complex mechanism of charge transport, interface charging, and actual electron transfer, on a molecule-by-molecule, and a location-by-location basis in a device. The dynamics for oxidation/reduction of MEH-PPV single molecules are controlled by various factors including filling of deep hole traps in the charge transporting layer of the device,<sup>[28,29]</sup> the oxidation/reduction chemical “state” of the MEH-PPV molecule,<sup>[24,25]</sup> and the molecular scale heterogeneity of the device.<sup>[30]</sup> At zero bias, fluorescence vs. time traces from MEH-PPV molecules incorporated in a device were indistinguishable from the molecules in an inert polymer matrix, poly(methyl methacrylate) (PMMA), and showed discrete intensity fluctuations (e.g., Fig. 2A) (Table 1). This behavior is relatively rare in freshly prepared, oxygen-depleted samples, but becomes more common as the sample ages in ambient conditions and oxygen diffuses through pinholes in the Au electrode.<sup>[6,31]</sup> The fluorescence flickering in single conjugated polymer molecules has been attributed to efficient energy funneling to a photo-oxidation-induced quencher site.<sup>[5,6,14,32,33]</sup>

For typical unoxidized MEH-PPV molecules, fluorescence quenching was observed at positive bias (Fig. 3C). The relatively gradual dependence of the quenching efficiency on bias for the unoxidized molecules is consistent with the  $S_1$  quenching by hole polarons present in the hole transport TPD layer. Significantly, while molecules are at the fluorescence flickering intermediate state (photo-oxidized), an extraordinary repairing of photo-bleaching was observed for negative bias, Fig. 3C. The sigmoidal  $F$ - $V$ /SMS data of photo-oxidized molecules near  $-1.5$  V are indicative of a reversible single electron transfer event. This behavior indicates that the long-lived quencher sites can be reversibly oxidized and reduced, and that the photobleached form of the polymer is a charged species such as a MEH-PPV<sup>+</sup>/anion complex. Such a complex could be formed by photo-induced

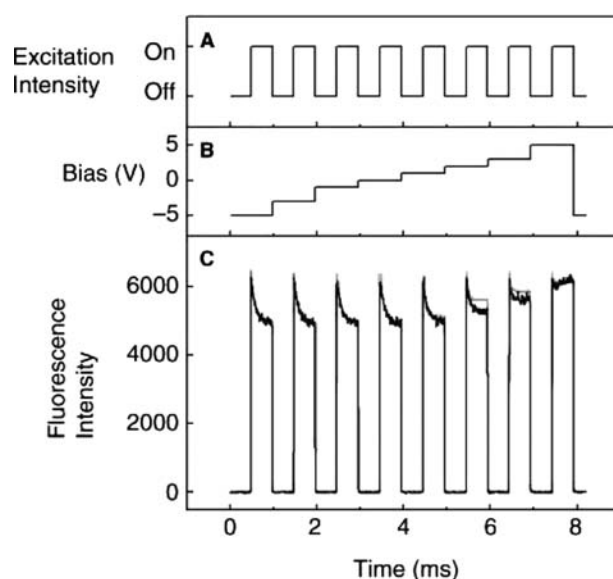

electron transfer between MEH-PPV and oxygen, forming  $\text{MEH-PPV}^+/\text{O}_2^-$ , which could further react with water, a common impurity, resulting in a more stable anion,  $\text{OH}^-$ . The reversible oxidation/reneutralization and extraordinary bias-induced repair process exclude typical  $S_1$  oxygen oxidation products such as dioxetanes and endoperoxides, as these latter species would be expected to exhibit non-reversible reduction/oxidation by charge carriers. Photo-induced electron transfer is indeed consistent with well-known, but poorly understood, persistent photoconductivity of conjugated polymers owing to exposure to air.

### FV-TR-SMS

Several papers have described how  $S_1$  can be quenched by hole polarons, leading to a reduction of the electroluminescence efficiency of a device.<sup>[34,35]</sup> In contrast, the quenching of  $T_1$  by hole polarons has received much less attention. Recently, there has been a growing appreciation that dynamical processes involving the interaction of  $T_1$  with polarons can play an important role in the performance of polymer OLED and related organic electronic devices. For example, it has been shown that  $T_1$  can be “harvested” in OLEDs using  $T_1$  emitters to improve electroluminescence efficiencies.<sup>[36,37]</sup>  $T_1$  can also deteriorate device performance by quenching  $S_1$  and sensitizing  $S_1$  oxygen formation.<sup>[38–40]</sup> Gesquiere, Park, and Barbara<sup>[30]</sup> have used a technique, FV-TR-SMS to obtain quantitative information on the mechanisms and rates of hole polaron-induced quenching of  $T_1$  and  $S_1$ .<sup>[30]</sup> This approach measures the fluorescence intensity of a single molecule embedded in an electronic device while simultaneously modulating the irradiation intensity (Fig. 4A) and the bias on the device (Fig. 4B).

FV-TR-SMS data in Fig. 4C were obtained for a single MEH-PPV nanoparticle in contact with the hole transport layer (TPD) of a hole-injection capacitor-like device structure described in Fig. 3A. The observed FV-TR-SMS data varied for different MEH-PPV molecules but were constant over time for any individual molecule. Negative-bias device environment results are similar to the inert polymer host measurements, consistent with the expectation that at negative bias, the capacitor device is depleted of polarons. This demonstrates that MEH-PPV  $S_1$  and  $T_1$  are not significantly perturbed by the contact with the TPD hole-transport layer. For biases above the threshold for hole injection ( $\sim 1$  V), the FV-TR-SMS data reveal evidence of  $T_1$  quenching by TPD hole polarons ( $p^+$ ),

**Fig. 4** Fluorescence intensity collected for single MEH-PPV molecules while simultaneously modulating (A) the excitation laser intensity and (B) the device bias. This process is repeated over many of these cycles while the data are synchronously time averaged (C).

which presumably occurs by a charge transfer mechanism, perhaps involving the intermediacy of an MEH-PPV hole polaron.  $S_1$  quenching by TPD hole polarons was also observed in these devices.

This mechanism may involve spin-allowed energy transfer or charge transfer.

The data are well fit by our previously described kinetic model<sup>[15,16,30]</sup> (parameters in Table 2) with the exception of the slowly varying intensity changes during each pulse region at positive bias ( $V > V_0$ ). The slowly varying regions are assigned to a non-instantaneous response of the local quasi-Fermi-potential in the device because of the filling of deep hole traps in the hole transporting layer of the device.

A significant result from this study is the observation that  $T_1$  are much more efficiently quenched than  $S_1$ . This is summarized in Table 2, where the efficiency of  $T_1$  and  $S_1$  quenching by hole polarons,  $E_{QT}$  and  $E_{QS}$ , is shown for  $V(t) = 5$  V for various molecules. The more efficient quenching of  $T_1$  occurs despite the fact that the  $T_1$  quenching rate constant ( $k_{QT}$ ) is in fact several orders of magnitude slower than that for  $S_1$  ( $k_{QS}$ ). The more efficient quenching of  $T_1$  is probably owing to a factor of  $10^6$  greater lifetime for the  $T_1$  compared to the  $S_1$ . This result suggests that  $S_1$  and  $T_1$  quenching by hole polarons occurs by different mechanisms. The  $S_1$  quenching process can in principle

**Table 2** Best-fit kinetic parameters for different MEH-PPV molecules in a capacitor device environment.<sup>a</sup>

<sup>a</sup>In the fitting procedures a quantum yield of intersystem crossing of 1.25% was used for MEH-PPV.

<sup>b</sup>No polarons are interacting with the molecule, so no rate constant is reported.

<sup>c</sup>This value is an upper limit for  $k_{QS}$ .

<sup>d</sup>Defined as  $[F(\text{plateau})_{V=5V} - F(\text{plateau})_{V<V_0}]/[F(\text{initial}) - F(\text{plateau})]_{V<V_0}$  in the case of  $T_1$  quenching only. When  $S_1$  quenching is observed the  $T_1$  quenching efficiency is 100%.

<sup>e</sup>Defined as  $[F(\text{initial})_{V<V_0} - F(\text{initial})_{V=5V}]/F(\text{initial})_{V<V_0}$ .

occurs by a spin-allowed energy transfer process, analogous to that described above for the quenching of  $S_1$  by  $T_1$ . The quenching of  $T_1$  by polarons is a spin-forbidden process, and a slower charge transfer mechanism is probably operating for  $T_1$ .

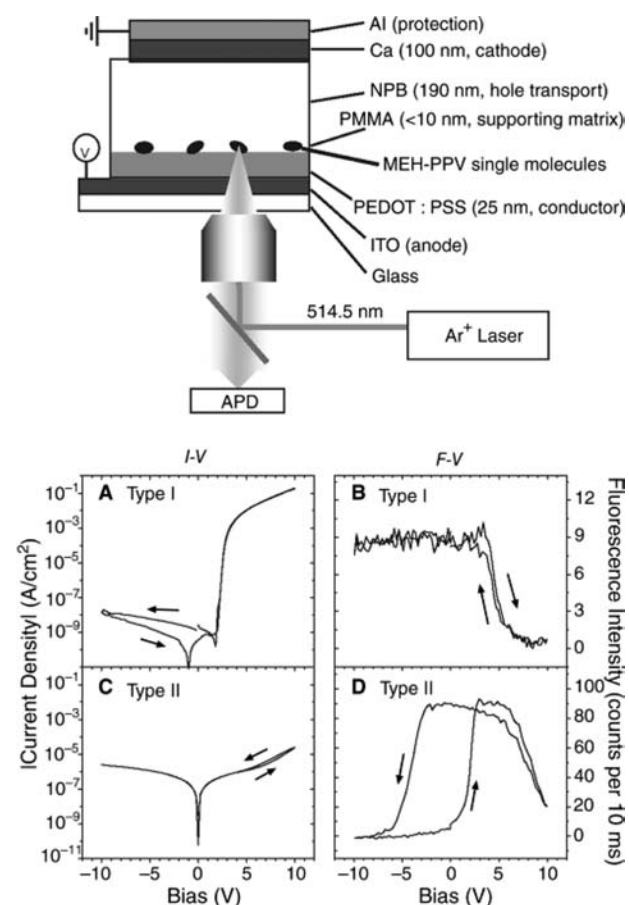

### Probing a Molecular Interface in a Functioning Organic Diode

OLEDs have a multilayer structure that comprises morphologically heterogeneous materials and interfaces. Owing to several complex and poorly understood factors, OLEDs are much less amenable to modeling and simulation than inorganic devices. These devices contain a complex set of polarons and excitons during operation, and are complicated by processes such as interfacial charge transfer, charge trapping by deep acceptor-like states, and electrochemical-like effects owing to impurities. Lee et al.<sup>[26]</sup> have used  $F$ - $V$ /SMS to study a hole-injection/hole-transport interface within a functioning organic diode (Fig. 5). MEH-PPV single molecules were dispersed at the interface between the hole injection and hole transport layers to create and probe  $S_1$  and  $T_1$  at the heterojunction. Fig. 5 shows representative  $F$ - $V$  curves from single molecules along with  $I$ - $V$  data of the diode. Efficient exciton quenching is observed at high forward bias owing to a buildup of interfacial polaron density, Figs. 5A and B. Additionally, for some diodes (denoted as Type II), an unexpected quenching process was also observed at reverse bias, which is ascribed to hole charging of the interface owing to leakage current, Figs. 5C and D.

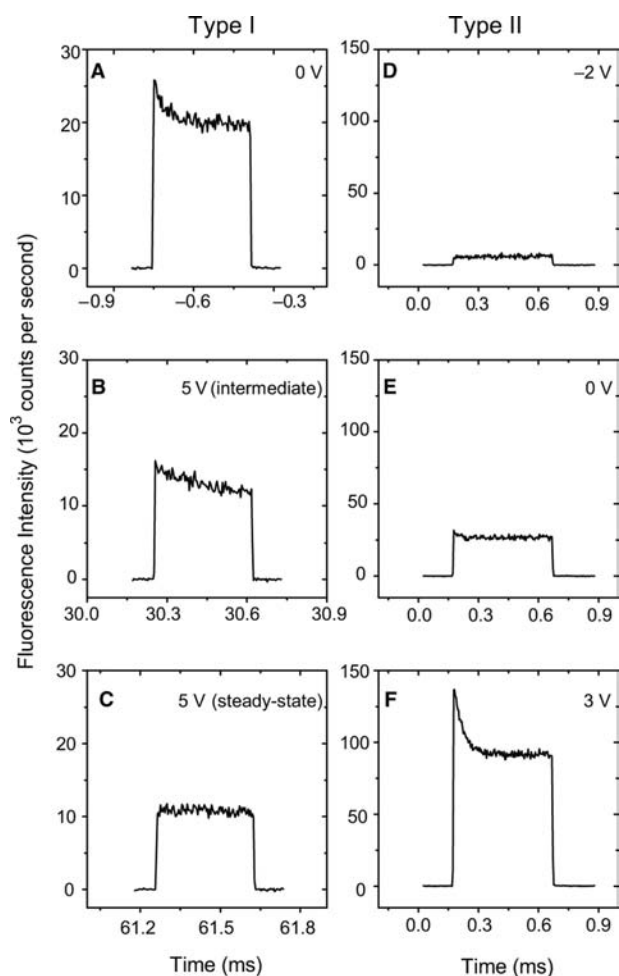

More quantitative information on the rates of hole polaron-induced quenching of  $T_1$  and  $S_1$  was acquired by the FV-TR-SMS. The fact that the  $T_1$  decay at early times is entirely absent indicates that the  $T_1$  lifetime is much shorter than 1  $\mu$ s (the instrument resolution) at 5 V (Figs. 6C and D) owing to highly efficient quenching of  $T_1$  by hole polarons that was accumulated at the [poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate)/ $N,N'$ -diphenyl- $N,N'$ -bis(3-methylphenyl)-1,1'-biphenyl-4,4'-diamine] (PEDOT : PSS) interface.

### CONCLUSIONS

This entry is focused on development of the recently introduced  $F$ - $V$ /SMS technique for semiconductor nanoparticle research. In addition, FV-TR-SMS has shown potential to unravel complex interactions among excitons and polarons in organic devices. Furthermore, these new  $F$ - $V$ /SMS techniques are successfully used to investigate the interfaces in a

**Fig. 5** Basic structure of a hole-only organic diode and  $I$ - $V$  and  $F$ - $V$  data of two different types of diodes.

**Fig. 6** FV-TR-SMS data of MEH-PPV embedded in the two types of organic diodes.

functioning organic diode, leading to new insights on the charging/discharging processes.

## INTRODUCTION

Since the soccer-ball-shaped molecule  $C_{60}$  and other fullerenes became available in macroscopic quantities, a wide variety of derivatives with multiple C–F bonds have been generated and observed in the gas phase. A significant number of these have also been isolated in weighable amounts and characterized by spectroscopic, electrochemical, and diffraction techniques. Those that have had their structures unambiguously determined by single-crystal X-ray diffraction include the fluorofullerenes  $C_{60}F_{18}$ ,  $C_{60}F_{36}$ , and  $C_{60}F_{48}$ ; the trifluoromethyl derivative  $C_{60}F_{17}(CF_3)$ ; the oxafuorofullerene  $C_{60}F_{18}O$ ; and the organofluorofullerene  $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ . In this entry, the major developments in fluorofullerene chemistry will be reviewed, including the synthesis and characterization of selectively fluorinated fullerenes and their physical properties and chemical reactivities that will be important in their consideration for technological applications.

## BACKGROUND

Fluorination was among the first derivitizations proposed for buckminsterfullerene,  $C_{60}$ , the new allotrope of carbon discovered in laser-vaporized graphite in 1985.<sup>[1]</sup> Although it was only known as a gas-phase species at the time, the discoverers speculated that the preparation of fully fluorinated “Teflon-like” ball bearings (e.g.,  $C_{60}F_{60}$ ) might lead to a new era of “superlubricating” materials. Not surprisingly, when  $C_{60}$  became available in macroscopic quantities in 1991,<sup>[2]</sup> its reaction with  $F_2$  was immediately investigated.<sup>[3]</sup> Extensive experimental work followed, with dozens of publications from experts in the specialized and technically demanding field of fluorine chemistry.<sup>a</sup>

<sup>a</sup>Space limitations preclude a complete bibliography of the earliest fluorination papers in this entry.

The history of fluorofullerene (FF) chemistry can be divided into two periods, the first being the initial exploration period from 1991 to 1994. Commonly available fluorinating reagents and well-known methodologies were employed during this time.<sup>a</sup> The substrate for these seminal papers was either a few milligrams of pure  $C_{60}$  or larger amounts of the so-called “fullerene extract,” which was predominantly  $C_{60}$  with the bulk of the remainder being  $C_{70}$ . The purported FF products proved difficult to characterize. Nevertheless, approximate numbers of F-atom substituents (formerly referred to as F-atom addends)<sup>[4]</sup> were reported. Also reported were relative stabilities in various solvents, thermal stabilities, relative solubilities, and, to a limited extent, chemical reactivities, although these early FF products were not pure compounds of definite composition. They were complex, often intractable mixtures, in most cases containing a broad distribution of  $C_{60}F_x$  and  $C_{70}F_x$  molecules. Furthermore, it is now known that some early samples contained significant amounts of oxafuorofullerenes,  $C_{60}F_xO_y$  ( $y = 1$ , 2<sup>[5]</sup> or  $y = 1-18$ <sup>[6]</sup>), making the product mixtures even more complex than originally thought. For these reasons, the early literature should be examined with skepticism and cited with caution. The frequently cited *Nature* paper “No Lubricants from Fluorinated  $C_{60}$ ” is a good example.<sup>[7]</sup> The rapid hydrolysis and low stability of FF samples was reported, but it was the abundant, much more reactive  $C_{60}F_xO_y$  “impurities,” and not the simple  $C_{60}F_x$  FFs, that turned out to be thermally labile and to undergo rapid hydrolysis.<sup>[6]</sup> Another example is a current website that describes the putative  $C_{60}F_{60}$  FF as a “colorless,” “crystalline solid” with a “melting point of 287°C,”<sup>[8]</sup> although the original reports of its preparation and isolation are now widely believed to be incorrect.<sup>[9]</sup> As discussed below, the most highly fluorinated [60]fullerene that has been isolated is  $C_{60}F_{48}$ . The hypothetical molecule containing a closed  $C_{60}$  cage and having one F atom attached to each C atom has not been shown to exist, reports of its aforementioned physical properties (and pending commercial availability!) notwithstanding.

The second period, from 1994 to the present, has been a period of deliberate improvements and innovations in synthetic strategies that resulted in the isolation and complete characterization of several FFs that are 90 + % compositionally pure, including one that is also isomerically pure to within the limit of detection.<sup>b</sup> The breakthrough that inspired this work was the synthesis and <sup>19</sup>F nuclear magnetic resonance (NMR) characterization of ~70% compositionally pure C<sub>60</sub>F<sub>48</sub> from C<sub>60</sub> and F<sub>2</sub> (i.e., direct fluorination).<sup>[10]</sup> Its detailed structure (i.e., the positions of the 48 C–F bonds and the 6 remaining C=C double bonds) could not be unambiguously determined from the NMR data. Assuming, as the authors correctly did, that C<sub>60</sub>F<sub>48</sub> was an intact C<sub>60</sub> cage with 48 F atoms attached to 48 of the 60 C atoms, 14 different isomers were consistent with the NMR data (the total number of possible isomers for C<sub>60</sub>F<sub>48</sub> is greater than 20,000,000). They suggested that the two most likely structures, one with D<sub>3</sub> symmetry and one with S<sub>6</sub> symmetry, were the two predicted by MO calculations to be the most stable thermodynamically, although it was not known whether the fluorination reaction was under thermodynamic or kinetic control. The importance of this paper, overlooking the low yield and poor compositional purity, is that two important features of FF chemistry that served to inspire others had been determined: 1) the final product of direct fluorination is C<sub>60</sub>F<sub>48</sub>, so previously reported products with fewer than 48 F atoms represented incomplete fluorinations; and 2) fluorinated products of certain stable compositions can, in principle, be obtained. Further study of C<sub>60</sub> direct fluorination led to the high-yield preparation of macroscopic amounts of compositionally pure C<sub>60</sub>F<sub>48</sub>,<sup>[11]</sup> which made possible its complete characterization by a battery of physicochemical techniques including X-ray crystallography<sup>[12]</sup> and combustion calorimetry, the latter providing the first experimentally determined enthalpy of formation for any fullerene derivative.<sup>[13]</sup>

The next important development in the preparation of selectively fluorinated fullerenes was reported in 1995 by chemists at the Moscow State University. They used transition-metal fluorides as fluorinating reagents and observed the formation of the selectively fluorinated fullerenes C<sub>60</sub>F<sub>18</sub> and C<sub>60</sub>F<sub>36</sub>.<sup>[14]</sup> This was followed by papers describing the laborious chromatographic separation of dozens of less-abundant products, including FFs with  $x = 2, 4, 6, 8, 16,$  and  $20$ ,<sup>[15–21]</sup> as well as oxafuorofullerenes<sup>[22–24]</sup> and fullerenes containing both F atoms and CF<sub>3</sub> groups.<sup>[23,25]</sup>

<sup>b</sup> *Compositional purity* is the mol% of molecules with a specific molecular formula in a given sample. *Isomeric purity* is the mol% of a specific isomer in a sample having a specific molecular formula.

For the first time, detailed studies of the physical and chemical properties of gram quantities of individual, compositionally pure FF compounds could be carried out, studies that must precede the development of commercial applications of any new compound.

## SYNTHESIS OF FLUOROFULLERENES

### From C<sub>60</sub> and F<sub>2</sub>, XeF<sub>2</sub>, KrF<sub>2</sub>, ClF<sub>3</sub>, or BrF<sub>5</sub>

Until 1995, direct fluorination with F<sub>2</sub> was the most extensively studied method of C<sub>60</sub> fluorination.<sup>[26]</sup> Many different experimental conditions were investigated: reaction temperatures from 25°C to 355°C; a 1-atm continuous-flow reactor or a high-pressure batch reactor; and reaction times from hours to months. In some cases, the in situ mass uptake of the sample was recorded<sup>[3]</sup> or the volatile products were monitored by mass spectrometry<sup>[27]</sup> or infrared (IR) spectroscopy.<sup>[3]</sup> In others, color changes from black to brown to pale yellow to white were noted.<sup>[28,29]</sup>

Direct fluorination occurred slowly at 25°C (weeks), affording mixtures of unreacted C<sub>60</sub> and C<sub>60</sub>F<sub>*x*</sub> FFs with even *x* values from 36 to 46.<sup>[30]</sup> Similar results, but with higher overall conversions, were obtained at 130–250°C.<sup>[29,31]</sup> A complicated two-stage direct fluorination at 250–275°C in the presence of NaF afforded a 56% yield of FF material in 50 hr that was 70 mol% C<sub>60</sub>F<sub>48</sub> according to mass spectrometry.<sup>[10]</sup> In contrast, a one-stage direct fluorination in a flow reactor at 315–355°C afforded a 70% yield of FFs in 3–10 hr that was 95 mol% C<sub>60</sub>F<sub>48</sub> according to electron-ionization mass spectrometry (EI-MS).<sup>[31]</sup> This is still the highest compositional purity reported to date for C<sub>60</sub>F<sub>48</sub>.

Use of the noble gas fluorides XeF<sub>2</sub> and KrF<sub>2</sub>, which are more powerful fluorinating reagents than F<sub>2</sub>, did not afford compositionally pure C<sub>60</sub>F<sub>48</sub>. In the case of XeF<sub>2</sub>, complex mixtures of FFs were isolated.<sup>[28,32]</sup> In the case of KrF<sub>2</sub>, a mass spectrum of the complex mixture of fluorocarbon products showed the presence of non-fullerene C<sub>60</sub>F<sub>*x*</sub> species with  $x > 60$ , which requires C<sub>60</sub> cage rupture and the formation of CF<sub>2</sub> and/or CF<sub>3</sub> groups.<sup>[33]</sup> Such hyperfluorinated species had been previously observed as products of the direct fluorination of C<sub>60</sub> under UV radiation.<sup>[34]</sup>

The use of the reactive interhalogens ClF<sub>3</sub> and BrF<sub>5</sub> did not result in significant yields of any compositionally pure FF.<sup>[5]</sup> To further complicate matters, many products containing multiple Cl or Br atoms in addition to F atoms were obtained based on IR spectroscopy and elemental analysis. It was also reported that “IF<sub>7</sub> did not react [with C<sub>60</sub>] in the gaseous phase.”<sup>[5]</sup>

The reaction of C<sub>60</sub> dissolved in liquid Br<sub>2</sub> (which is known to produce C<sub>60</sub>Br<sub>24</sub>) with BrF<sub>3</sub> was reported to yield C<sub>60</sub>F<sub>24</sub>.<sup>[35]</sup> The stoichiometry was based on the ratio of C 1s and F 1s XPS (X-ray photoelectron spectroscopy) intensities. However, new, unpublished mass spectrometric evidence indicates that the product actually consisted of a distribution of C<sub>60</sub>F<sub>x</sub> compositions with an average *x* value of 24 (N.F. Yudanov and O.V. Boltalina, unpublished data, 2001).

The reaction of C<sub>60</sub> with IF<sub>5</sub> in liquid CCl<sub>4</sub> was reported to yield chlorofluorofullerenes, including C<sub>60</sub>Cl<sub>18</sub>F<sub>14</sub>.<sup>[36]</sup> However, the only method of characterization was low-resolution mass spectrometry, and these data were inconclusive. For example, a sample of C<sub>60</sub>Cl<sub>24</sub> and a sample purported to be C<sub>60</sub>Cl<sub>18</sub>F<sub>14</sub> exhibited similar complex distributions of ions with *m/z* at 1534 ± 2 Da, 1464 ± 2 Da, 1394 Da, 1322 ± 2 Da, etc.

### From C<sub>60</sub> and High-Valent Metal Fluorides

A conceptual breakthrough in the synthesis of selectively fluorinated fullerenes was discovered in 1995, not by synthetic chemists but by mass spectrometrists at Moscow State University (MSU) who were studying the thermochemistry of gaseous ions.<sup>[14]</sup> They used a magnetic-sector mass spectrometer equipped with a Knudsen effusion cell as a chemical reactor. Solid state reactions of fullerenes with various high-valent transition-metal and rare-earth-metal fluorides as fluorinating reagents resulted in the simultaneous generation and mass-spectrometric detection of the volatile products. Because the temperature was programmed to increase over time, a wealth of information on the dynamics of formation and distribution of combinatorial-like mixture of products as a function

of temperature was obtained for each pair of reagents and stoichiometric ratio studied. Significantly, a large fraction of the products formed at a given temperature were condensed on a specially designed collection plate, which allowed for the further characterization of new derivatives by a variety of spectroscopic techniques.<sup>[15,16]</sup>

The Knudsen-cell technique was largely responsible for the rapid development of synthetic fluorofullerene chemistry. It was discovered that heating a 1 : 36 mole ratio mixture C<sub>60</sub> and MnF<sub>3</sub> afforded a 60–70% yield of 90 + % compositionally pure C<sub>60</sub>F<sub>36</sub>.<sup>[37]</sup> Another paper reported that mixtures of C<sub>60</sub> and the ternary metal fluoride K<sub>2</sub>PtF<sub>6</sub> resulted in the selective formation of C<sub>60</sub>F<sub>18</sub> (also with 90 + % compositional purity and in 60–70% yield) with only trace quantities of C<sub>60</sub>F<sub>36</sub> and several other FFs with fewer than 18 F atoms present.<sup>[38]</sup> In general, reactions with high-valent metal fluorides gave products with high compositional purity or, at worst, a narrow distribution of C<sub>60</sub>F<sub>x</sub> compositions. In general, it was also found that the average number of F atoms added to C<sub>60</sub> is correlated with the relative fluorinating strength of the metal fluoride, which to a first approximation increases as the enthalpy change for the reaction

becomes less positive or more negative.<sup>[39]</sup> Additionally, it was found that, for a given metal fluoride, higher temperatures favored the selective formation of FFs with fewer F atoms per C<sub>60</sub> cage. Some representative data are listed in Table 1.

A recent paper reported a series of reactions of C<sub>60</sub> with ternary metal fluorides other than K<sub>2</sub>PtF<sub>6</sub>.<sup>[40]</sup> This is potentially a significant next step for two reasons. First, ternary metal fluorides are more numerous than

**Table 1** Values of *x* for the C<sub>y</sub>F<sub>x</sub> or C<sub>59</sub>NF<sub>x</sub> major products of fullerene fluorinations<sup>a</sup>

Fullerene substrate	Fluorination reagent (temperature range, °C)

Percentage of occupancy, ( <i>x</i> / <i>y</i> ) × 100% <sup>c</sup>	67–80	62–73	49–60	48–60	24–30

<sup>a</sup>Slashes separate *x* values for a distribution of species observed under a given set of conditions. Commas separate *x* values for different species or different distributions of species observed under two different sets of conditions.

<sup>b</sup>The substrate for these fluorinations was (C<sub>59</sub>N)<sub>2</sub>, but the *x* values listed are for a single azafullerenes, which, with an odd number of F atoms, are closed-shell species.

<sup>c</sup>In those cases where products from two different sets of conditions are listed, the percentages of occupancy are for the species with the smallest number of F atoms.

the corresponding binary transition metal fluorides (consider  $K_2MnF_6$  and  $Rb_2MnF_6$  vs.  $MnF_4$  and  $Cs_2PbF_6$  and  $Cs_3PbF_6$  vs.  $PbF_4$ ), so a wider variety of reagents has become available to the synthetic chemist. Second, these ternary compounds are generally weaker fluorinating reagents (i.e., less reactive) than the parent binary metal fluoride. This feature makes them easier to handle in the laboratory environment and, more importantly, opens up the possibility of isolating FFs with lower degrees of fluorination.

The reaction of  $C_{60}$  with  $WF_6$ ,  $TaF_5$ ,  $NbF_5$ , and  $TiF_4$ , which are not particularly strong fluorinating reagents, only produced “adducts” of unknown structure [e.g.,  $C_{60}(MF_n)_x$ ].<sup>[41]</sup> No fluorofullerenes were observed.

### Fluorination of Higher Fullerenes and Some $C_{60}$ Derivatives

Fluorination of the higher fullerenes  $C_{74}$ ,  $C_{76}$ ,  $C_{78}$ , and  $C_{84}$  and of  $C_{60}$  derivatives such as  $(C_{59}N)_2$ ,  $C_{60}Cl_x$ , and  $C_{60}Br_x$  were investigated as these compounds became available in macroscopic quantities. As far as the higher fullerenes and  $(C_{59}N)_2$  are concerned, EI-MS characterization of volatile products generated by the Knudsen-cell technique showed that specific compositions, or narrow ranges of compositions, could be attained with a given high-valent metal fluoride and a given reaction temperature.<sup>[42–44]</sup> Representative data are listed in Table 1. Note that the percentage of occupancy for the  $C_yF_x$  and  $C_{59}NF_x$  compounds with the smaller of the listed  $x$  values parallels the percentage of occupancy for the  $C_{60}F_x$  products with the same fluorination reagent. Some individual higher FFs and  $C_{59}NF_x$  compounds have been isolated, but none has been extensively characterized. Nevertheless, the fact that different  $x$  values or narrow ranges of  $x$  values were observed in each case means that certain  $C_yF_x$  and  $C_{59}NF_x$  compounds may possess a special kinetic or thermodynamic stability similar to the special stabilities possessed by  $C_{60}F_{18}$ ,  $C_{60}F_{36}$ , and  $C_{60}F_{48}$ . Based on this reasoning, likely structures of  $C_{74}F_{38}$  and  $C_{76}F_{20}$ <sup>[44]</sup> and several  $C_{59}NF_x$  compounds<sup>[45]</sup> have been proposed.

Reactions of the halofullerenes  $C_{60}Br_6$ ,  $C_{60}Br_8$ ,  $C_{60}Br_{24}$ ,  $C_{60}Cl_6$ , and  $C_{60}Cl_{24}$  with either  $F_2$  or  $XeF_2$  were reported to produce a variety of FFs, mixed fluorohalofullerenes, and/or oxafuorofullerenes.<sup>[36]</sup> Another study of the reactions of  $C_{60}Br_8$  and  $C_{60}Br_{24}$  with  $XeF_2$  reported similar findings.<sup>[32]</sup> An important goal of these studies was to prepare compositionally pure FFs such as  $C_{60}F_6$ ,  $C_{60}F_8$ , and  $C_{60}F_{24}$  that have not yet been prepared by other methods. However, to date, there is no convincing example of a direct, high-yield  $C_{60}X_x \rightarrow C_{60}F_x$  transformation ( $X = Cl, Br$ ).

## STRUCTURAL CHARACTERIZATION OF FLUOROFULLERENES

### X-Ray Crystallography

The fluorofullerenes and fluorofullerene derivatives that have been structurally characterized by single-crystal X-ray diffraction are all derivatives of  $C_{60}$ . The complete list includes the three FFs,  $C_{60}F_{18}$ ,  $C_{60}F_{36}$ , and  $C_{60}F_{48}$ , and the three FF derivatives,  $C_{60}F_{17}(CF_3)$ ,  $C_{60}F_{18}O$ , and  $C_{60}F_{15}[CBr(CO_2Et)_2]_3$ . From these few structures, an analysis of F-atom addition patterns and of interatomic distances and angles has provided some insight into the mechanisms by which F atoms and other atoms or groups of atoms are added to a given starting material or intermediate. An assessment of the distances and angles also provides insight into the steric and electronic reasons that the underlying  $C_{60}$  cage is distorted, in some cases significantly distorted, from the nearly spherical  $I_h$  symmetry of native  $C_{60}$ .

### $C_{60}F_{18}$

This was the first FF to be structurally characterized.<sup>[46]</sup> Seven different modifications have been studied, a solvent-free modification,<sup>[38]</sup> a toluene solvate,<sup>[46]</sup> and five other arene solvates.<sup>[47]</sup> They all contain the same  $C_{3v}$  isomer of  $C_{60}F_{18}$ . A ball-and-stick plot (BSPlot) of the  $C_{60}F_{18}$  molecule present in the toluene solvate, and its Schlegel diagram, are shown in Fig. 1. The molecule has all 18 F atoms situated on one hemisphere. This undoubtedly makes it highly polar (calculated dipole moments range from 12 to 16 D).<sup>[46]</sup> The Schlegel diagram shows that the 18 F atoms have been added to a contiguous set of C atoms, a common feature of hydrofullerenes but uncommon when larger substituents are present, as in chlorofullerenes and bromofullerenes.<sup>[48]</sup> The Schlegel diagram also shows that the fluorinated hemisphere contains a central, nearly planar, fully aromatic benzenoid ring, with six nearly identical C–C distances, separated from the remainder of the fullerene  $\pi$ -electron system by a belt of  $sp^3$  C atoms each bearing a C–F bond. The BSPlot shows that the fluorinated hemisphere is significantly flattened, so much so that if the unfluorinated hemisphere is superimposed on a molecule of  $C_{60}$ , the C atoms of the benzenoid ring are ca. 0.6 Å closer to the center of the  $C_{60}$  molecule than the C atoms of the antipodal hexagonal ring. The C–F distances are normal. The  $C(sp^3)$ – $C(sp^3)$  distances, many of which are greater than 1.62 Å, are significantly longer than typical organic C–C distances but are not unusual for highly fluorinated or perfluorinated hydrocarbons.<sup>[46]</sup>

**Fig. 1** Ball-and-stick plots and Schlegel diagrams for three structures determined by X-ray crystallography. The open and hatched circles in the plots represent C and F atoms, respectively. The solid circle in the plot of  $C_{60}F_{18}O$  represent the O atom. The solid circles in the Schlegel diagrams represent C–F bonds.

### $C_{60}F_{17}(CF_3)$

This compound was a by-product of  $C_{60}$  fluorination with  $K_2PtF_6$ . It was originally believed to be  $C_{60}F_{18}(CF_2)$ , with the  $CF_2$  group incorporated into a cyclopropane ring.<sup>[49]</sup> The true nature of the structure was revealed by X-ray diffraction analysis. Crystals of this compound were found, both by X-ray and  $^{19}F$  NMR analysis, to contain a  $C_s$  isomer (ca. 68%), the Schlegel diagram of which is shown in Fig. 1, and a pair of  $C_1$  enantiomers (ca. 16% each) having the  $CF_3$  group attached instead to one of the six symmetry-related  $sp^3$  C atoms that are not directly bonded to the central benzenoid ring.<sup>[50]</sup> All of the isomers exhibit threefold rotational disorder in the solid state. Nevertheless, a reasonable structure solution was possible. A BSPlot of the major isomer is shown in Fig. 1. The molecule exhibits the same flattening observed in the structure of  $C_{60}F_{18}$ . It may be mechanistically significant that the major isomer of  $C_{60}F_{17}(CF_3)$  has the  $CF_3$  group attached to the least sterically demanding  $sp^3$  C atoms.

### $C_{60}F_{18}O$

As was the case with  $C_{60}F_{17}(CF_3)$ , the X-ray diffraction analysis of the oxafuorofullerene  $C_{60}F_{18}O$  settled a long-standing problem concerning its structure. It was also a by-product of  $C_{60}$  fluorination with  $K_2PtF_6$ . It had been originally formulated as an epoxide,<sup>[6]</sup> an interpretation that remained unchallenged nearly a decade later.<sup>[20,51–53]</sup> The structure, shown in

Fig. 1, revealed that it is an ether formed (conceptually, not necessarily mechanistically) by the insertion of an O atom into a  $C(sp^3)–C(sp^3)$  bond of  $C_{60}F_{18}$ .<sup>[22]</sup> The structure shown is the major isomer of  $C_{60}F_{18}O$ ; two other isomers were separated by high-performance liquid chromatography (HPLC) and are presumably also ethers, with the O atom inserted into different  $C(sp^3)–C(sp^3)$  bonds. Note that in the major isomer, the O atom has been inserted into one of the three longest  $C(sp^3)–C(sp^3)$  bonds, which average 1.67 Å in  $C_{60}F_{18}$ . The two remaining such bonds in  $C_{60}F_{18}O$  are probably also extremely long, but the threefold rotational disorder in these crystals makes distances and angles involving these C atoms unreliable.

### $C_{60}F_{15}[CBr(CO_2Et)_2]_3$

This compound, originally prepared and characterized by mass spectrometry (A.L. Mirakyan, personal communication to O.V. Boltalina, 2000), was later purified and structurally characterized by single-crystal X-ray diffraction.<sup>[54]</sup> Its structure is related to that of  $C_{60}F_{18}$  except that the three bulky organic substituents are not attached to C atoms contiguous with the belt of 15  $sp^3$  C atoms.

### $C_{60}F_{36}$

There are three isomers known for this composition. The two major isomers have  $C_3$  (>90%) and  $T$  (<10%) symmetry.<sup>[55]</sup> A BSPlot and Schlegel diagram

of the *T* isomer are shown in Fig. 2.<sup>[56]</sup> This structure is severely disordered, so much so that all 36 C–F bonds had to be constrained to have the same distance. There were other constraints imposed on the two independent  $C_{60}F_{36}$  molecules in the asymmetric unit. Nevertheless, four salient features were unambiguously determined. First, this isomer of  $C_{60}F_{36}$  does indeed have idealized (although not crystallographic) *T* symmetry, in agreement with predictions based on  $^{19}F$  NMR spectra.<sup>[55,57]</sup> In accordance with its proper rotational symmetry, *T*- $C_{60}F_{36}$  is chiral and exists as a pair of enantiomers. Second, the 36 F atoms were added to a contiguous set of C atoms, which is consistent with the addition patterns extant in  $C_{60}F_{18}$ ,  $C_{60}F_{17}(CF_3)$ , and  $C_{60}F_{18}O$ . Third, there are four isolated benzenoid rings in this isomer, each of which is planar to within  $\pm 0.02$  Å. The Schlegel diagram in Fig. 2 shows that any three of the four benzenoid rings are symmetrically related by a  $C_3$  axis perpendicular to the plane of the remaining ring. Fourth, the molecule is severely distorted from the nearly spherical structure of  $C_{60}$ . The four benzenoid rings are much closer to the geometric center of the molecule than the corresponding six-membered rings in  $C_{60}$ , while the  $C_6F_6$  hexagons

opposite the benzenoid rings are much farther away from the geometric center. In  $C_{60}$ , the distance from each C atom to the geometric center is 3.57 Å; in *T*- $C_{60}F_{36}$ , the corresponding distances from the geometric center to the benzenoid C atoms and to the antipodal  $C_6F_6$  C atoms are 3.0–3.1 and 3.9–4.0 Å, respectively.

The structure of the  $C_3$  isomer has not yet been determined by X-ray diffraction. Its likely structure, deduced from a careful analysis of 1-D and 2-D  $^{19}F$  NMR spectra, has three benzenoid rings and three isolated C=C double bonds arising from a contiguous addition of F atoms.<sup>[57]</sup> If one of the double bonds were moved by just one C atom, the  $C_3$  axis would be lost and the molecule would have  $C_1$  symmetry. This isomer has recently been isolated and structurally characterized by X-ray diffraction.<sup>[58]</sup>

### $C_{60}F_{48}$

Single crystals of this compound, grown from mesitylene solution, were found to contain nearly equal amounts of  $D_3$  and  $S_6$  isomers. The X-ray diffraction analysis was further complicated by the fact that both isomers appeared to be statistically disordered over two positions. The structure was eventually solved,

**Fig. 2** Ball-and-stick plots and Schlegel diagrams for the *T*-symmetry isomer of  $C_{60}F_{36}$  and the  $D_3$ -symmetry structure of  $C_{60}F_{48}$ , both determined by X-ray crystallography. Two different rotational orientations, A and B, are shown for  $C_{60}F_{48}$ . In orientation B, looking down the  $C_3$  axis, the 12 remaining  $sp^2$  C atoms are represented as grey circles and form the six isolated C=C double bonds, three in the upper hemisphere and three in the lower hemisphere. Elsewhere, the open and hatched circles represent C and F atoms, respectively. The solid circles in the Schlegel diagrams represent C–F bonds. Also shown is the local structure around one of the C=C bonds in  $D_3$ - $C_{60}F_{48}$ . The size of each F atom in this drawing corresponds to its van der Waals radius.

and a BSPlot and Schlegel diagram of the  $D_3$  isomer are shown in Fig. 2.<sup>[12]</sup> As in the other FFs and FF derivatives that have been structurally characterized, the 48 F atoms have been added to  $C_{60}$  in a contiguous manner. There are only 12 remaining  $sp^2$  C atoms distributed over six isolated C=C bonds, each of which is a common edge to a hexagon and a pentagon, the same as for the three isolated C=C bonds in the  $C_1$  and  $C_3$  isomers of  $C_{60}F_{36}$ . Similar to the structure of  $T-C_{60}F_{36}$ , the structure of  $C_{60}F_{48}$  is severely distorted. The distances between the 12  $sp^2$  C atoms and the geometric center are all ca. 3.05 Å, while the distances between  $sp^3$  C atoms that are bonded only to other  $sp^3$  C atoms are all ca. 3.9 Å.

Perhaps the most interesting feature of the structure is that the six remaining C=C bonds are well shielded from external reagents, both by the distortion that draws them closer to the molecular center and by their four adjacent C–F bonds. A diagram showing one of the isolated C=C bonds in  $C_{60}F_{48}$  and its four closest F atoms is also shown in Fig. 2. The size of each F atom corresponds to its van der Waals radius. The four F atoms are nearly coplanar and form an idealized rectangle having two sides of 2.6 Å, two sides of  $3.3 \pm 0.2$  Å, and two diagonals of 4.1 Å. It is rather obvious that the addition of more than 48 F atoms to an intact  $C_{60}$  cage must have a high kinetic barrier if not a high thermodynamic barrier.

Neither the  $D_3$  nor the  $S_6$  isomer has a permanent dipole moment. Therefore  $C_{60}F_{48}$  may be the closest approximation to a spherical “Teflon-like” ball prepared to date. It will be interesting to see what lubricating properties, if any, it possesses.

### Fluorine-19 Nuclear Magnetic Resonance Spectroscopy

Many more FFs have been studied by NMR spectroscopy than by X-ray crystallography, both because many compounds have not yet yielded suitable crystals and because NMR spectra of mixtures can be, in many cases, readily interpreted. Although NMR analysis cannot, in general, lead to unambiguous structure elucidation, it can rule out many structure possibilities on the basis of symmetry (number and intensities of peaks) and coupling-constant patterns.

Nuclear magnetic resonance studies that simply support the results of X-ray structure determinations discussed above will not be included here because of space limitations.

#### $C_{60}F_x$

Small amounts of the FFs  $C_{60}F_2$ ,  $C_{60}F_4$ ,  $C_{60}F_6$ ,  $C_{60}F_8$ ,  $C_{60}F_{16}$ , and  $C_{60}F_{20}$  were isolated by HPLC from the

**Fig. 3** Diagrams showing likely F-atom addition patterns for  $C_{60}F_2$  and  $C_{60}F_4$  and three possible F-atom addition patterns  $C_{60}F_6$ . The solid circles represent C–F bonds. The  $^{19}F$  NMR spectrum of  $C_{60}F_6$  is consistent with the diagram labeled S.

crude reaction products of  $C_{60}$  fluorinations with  $K_2PtF_6$ .<sup>[15–19,21]</sup> Their  $^{19}F$  NMR spectra are consistent with sequential, contiguous addition patterns that result from a series of 1,2 additions of F atoms. Diagrams showing these additions for  $C_{60}F_2$ ,  $C_{60}F_4$ , and  $C_{60}F_6$  are shown in Fig. 3. Note that NMR spectroscopy is a particularly suitable technique for distinguishing between the three patterns shown for  $C_{60}F_6$ . Structure S would result in an NMR spectrum with three equal intensity peaks (this was what was observed), structure O would result in a spectrum with one peak, and structure T would result in a spectrum with four peaks with relative intensities 1:1:2:2. Even in cases where the number of peaks and their relative intensities cannot distinguish between two different patterns, a distinction based on coupling constant patterns may still be possible.

The  $^{19}F$  NMR spectrum of  $C_{60}F_{20}$  is interesting because of its simplicity. It consists of a single peak, requiring that all 20 F atoms are symmetrically related.<sup>[19]</sup> The only possible contiguous addition structure has  $D_{5d}$  symmetry with the 20 C–F bonds arranged on the “equator” of a  $C_{60}$  cage. The structure, shown in Fig. 4, is reminiscent of the planet Saturn, and  $C_{60}F_{20}$  has been tentatively named saturnene.

#### $C_{60}F_xO_y$

The isolation and  $^{19}F$  NMR analysis of small quantities of the oxafuorofullerenes  $C_{60}F_2O$ ,  $C_{60}F_4O$ ,  $C_{60}F_6O$ ,  $C_{60}F_8O$ ,  $C_{60}F_{16}O$ , and several isomers of

**Fig. 4** Schlegel diagram and an artist's rendition of the proposed structure of  $C_{60}F_{20}$  (saturnene). The structure has  $D_{5d}$  symmetry; therefore all 20 F atoms are equivalent. The solid circles in the Schlegel diagrams represent C–F bonds.

$C_{60}F_{18}O$  led to the conclusion that they are all intramolecular ethers like the isomer of  $C_{60}F_{18}O$  that had been structurally characterized.<sup>[18]</sup> Schlegel diagrams for the likely structures of  $C_{60}F_2O$ ,  $C_{60}F_4O$ ,  $C_{60}F_6O$ ,  $C_{60}F_8O$ , based on the distinctive chemical shifts of F atoms on the two ether C atoms, are shown in Fig. 5. The contiguous pattern of F atom addition is clearly seen, and the O atom is always inserted into the weakest  $C(sp^3)-C(sp^3)$  bond.

## PHYSICAL PROPERTIES OF FLUOROFULLERENES

### Solubilities in Organic Solvents

The statement that FFs are more soluble than their parent fullerene can be found in a growing number of publications. Not only is this statement incorrect in many instances, the quantitative data on which it

**Fig. 5** Schlegel diagrams showing likely F- and O-atom addition patterns for  $C_{60}F_2O$ ,  $C_{60}F_4O$ ,  $C_{60}F_6O$ , and  $C_{60}F_8O$  based on  $^{19}F$  NMR spectra. The solid circles represent C–F bonds.

would be properly based have not yet been published in the open literature. Quantitative solubilities could only be measured after selectively fluorinated fullerenes became available in macroscopic amounts. Some of the recently measured solubilities of  $C_{60}F_{36}$  and  $C_{60}F_{48}$  in hydrocarbon solvents are listed in Table 2.<sup>[59]</sup>

It was found that the solubilities of  $C_{60}F_{48}$  in aromatic hydrocarbon solvents were lower, not higher, than the corresponding solubility of  $C_{60}$ . The solubilities for  $C_{60}F_{18}$  were even lower than those for  $C_{60}F_{48}$ . Nevertheless, the solubilities are high enough so that toluene can be used as the eluent for HPLC purifications. On the other hand, the solubilities of  $C_{60}F_{48}$  in aliphatic hydrocarbon solvents were orders of magnitude higher than for  $C_{60}$ , and those for  $C_{60}F_{36}$  were ca. 10–50 times higher than for  $C_{60}$ . In contrast to the solubility of FFs in aliphatic and aromatic hydrocarbon solvents, bromofullerenes have such low solubilities that little synthetic work with them can be anticipated in common organic solvents.<sup>[9]</sup>

Whenever a FF is crystallized from an aromatic hydrocarbon or halogenated aromatic hydrocarbon solvent, one or more solvent molecules per FF are strongly bound in the lattice (see the “[X-Ray Crystallography](#)” section). For example, crystals containing one toluene molecule per  $C_{60}F_{18}$  are stable up to 190°C, at which temperature the solvent evaporates,

**Table 2** Solubilities of fluorofullerenes in hydrocarbon solvents at 25°C<sup>a</sup>

Solvent	Solubility (mmol L <sup>-1</sup> )		Solubility ratio		
	C <sub>60</sub> F <sub>36</sub>	C <sub>60</sub> F <sub>48</sub>	C <sub>60</sub> F <sub>48</sub> /C <sub>60</sub> F <sub>36</sub>	C <sub>60</sub> F <sub>36</sub> /C <sub>60</sub>	C <sub>60</sub> F <sub>48</sub> /C <sub>60</sub>

Mesitylene		0.19(1)			0.09

<sup>a</sup>Solubilities are reported in mmol fullerene per liter of solvent. The molar masses of C<sub>60</sub>, C<sub>60</sub>F<sub>36</sub>, and C<sub>60</sub>F<sub>48</sub> are 720, 1404, and 1632 g mol<sup>-1</sup>.

leaving behind solvent-free C<sub>60</sub>F<sub>18</sub>.<sup>[47]</sup> The structure of C<sub>60</sub>F<sub>48</sub> discussed above was determined with a crystal-line modification containing two mesitylene molecules per FF. A drawing of the formula unit is shown in Fig. 6. The two symmetry-related mesitylene molecules

**Fig. 6** Ball-and-stick plot of the C<sub>60</sub>F<sub>48</sub> · 2 C<sub>6</sub>H<sub>3</sub>Me<sub>3</sub> formula unit determined by X-ray crystallography (C<sub>6</sub>H<sub>3</sub>Me<sub>3</sub> = 1,3,5-C<sub>6</sub>H<sub>3</sub>Me<sub>3</sub> = mesitylene). Hydrogen atoms on the mesitylene molecules have been omitted for clarity. The open and hatched circles represent C and F atoms, respectively. The distances between the three molecules are to scale.

lie directly above and below the molecule along the C<sub>3</sub> symmetry axis. Further solid state and solution studies will be needed to more fully understand the relative solubilities of fullerenes and FFs.

As far as oxygenated solvents are concerned, the early literature must, once again, be approached with caution. For example, acetone and tetrahydrofuran (THF) were used in the early 1990s to extract FFs from reaction vessels.<sup>[28,29]</sup> It was later found that these solvents, as well as methanol, completely degrade FFs with 36 or more F atoms, even to the point of rupturing the C<sub>60</sub> cage.<sup>[60]</sup> The decomposition rate in THF increased as the residual water content of the solvent increased. On the other hand, C<sub>60</sub>F<sub>18</sub> has recently been found to be stable for weeks in carefully dried THF or 1,2-dimethoxyethane.<sup>[61]</sup>

### Thermodynamic Properties

The compositional purity, thermal stability, and availability of gram quantities of C<sub>60</sub>F<sub>18</sub>, C<sub>60</sub>F<sub>36</sub>, and C<sub>60</sub>F<sub>48</sub> have allowed some of their thermodynamic properties to be investigated. Selected data are listed in Table 3.<sup>[13,62–65]</sup>

The vaporization properties of all three compounds have been studied<sup>[66,67]</sup> and parallel the sublimation enthalpies listed in Table 3. The vapor pressure of C<sub>60</sub>F<sub>48</sub> is marginally higher than that of C<sub>60</sub>F<sub>36</sub> (e.g., 0.45 vs. 0.17 Pa, respectively, at 560 K).<sup>[68]</sup> The major isomers of these compounds are either non-polar or have negligible polarity; they are spheroidal, essentially non-polarizable, fluorocarbon nanoparticles with weak intermolecular interactions. In contrast, the vapor pressures of C<sub>60</sub> and C<sub>60</sub>F<sub>18</sub> are orders of magnitude lower, but for different reasons. The extended  $\pi$ -electron system in C<sub>60</sub> renders its polarizable, which leads to a relatively large sublimation enthalpy. On the other hand, the large dipole moment of C<sub>60</sub>F<sub>18</sub> leads to strong intermolecular interactions and a large sublimation enthalpy.

**Table 3** Thermodynamic properties (kJ mol<sup>-1</sup>) of fluorofullerenes and C<sub>60</sub>

<sup>c</sup>Sum of the values in the first two columns except for C<sub>60</sub>F<sub>18</sub>.

<sup>d</sup>Average of the two theoretical values (-1400 and -1500 kJ mol<sup>-1</sup>) reported in Ref.<sup>[65]</sup>.

Combustion calorimetry was used to measure standard molar enthalpies of formation,  $\Delta_f H_m^o$ , both in the solid state and in the gas phase (the two values differ only by the standard molar enthalpies of sublimation).<sup>[13,62,63]</sup> The importance of these measurements is that it allowed the average C-F bond dissociation energies, ca. 290 kJ mol<sup>-1</sup>, to be determined. Temperature-dependent heat capacity measurements for C<sub>60</sub>F<sub>36</sub> revealed an order-disorder phase transition at 329.6 K ( $\Delta_{\text{trs}} H^o = 7$  kJ mol<sup>-1</sup>).<sup>[69,70]</sup> An ordered body-centered tetragonal to plastic face-centered cubic phase transition was also observed in a variable temperature X-ray diffraction study.<sup>c</sup>

### Properties of Fluorofullerene Ions

Ionic properties of FFs have been of particular interest to both gas-phase and solution chemists as the expectation was that addition of many electronegative F atoms should significantly enhance the electron accepting ability of the fullerene. Indeed, the very first measurements of EA(C<sub>60</sub>F<sub>2</sub>)<sup>[71]</sup> and EA(C<sub>60</sub>F<sub>46,48</sub>)<sup>[72]</sup> showed them to be 2.72 and 4.06 eV, respectively, higher than EA(C<sub>60</sub>), which is 2.67 eV.<sup>[73]</sup> Even more remarkable was the discovery made by gas-phase scientists that FFs formed doubly charged anions in the gas phase either under high-energy collisions of C<sub>60</sub>F<sub>x</sub><sup>-</sup> with inert gases<sup>[74]</sup> or as the result of a thermal desorption electron-capture process.<sup>[69,70]</sup> In the latter case, C<sub>60</sub>F<sub>48</sub><sup>2-</sup> was found to be exceptionally stable toward ejection of the second electron under collision conditions, or in the process of metastable decay, this was explained by the existence of the Coulomb barrier to the removal of the excess electron. The ability to form stable negative ions is a manifestation of the exceptional electron-withdrawing character of FFs. Another manifestation was observed in electrochemical studies of C<sub>60</sub>F<sub>48</sub>,<sup>[75]</sup> C<sub>60</sub>F<sub>36</sub>,<sup>[76]</sup> and C<sub>60</sub>F<sub>18</sub>,<sup>[77]</sup> with reported

$E_{\text{red}}$  values of 1.38, 0.58 and 0.04 V, respectively, vs. SCE [cf.  $E_{\text{red}}(\text{C}_{60}) = -0.43$  V vs. SCE].<sup>[77]</sup> The FF C<sub>60</sub>F<sub>48</sub> is believed to have the most positive  $E_{\text{red}}$  among known organic electron acceptors. A comparison of EAs<sup>[77]</sup> and  $E_{\text{red}}$  values shows that, as expected, the electron-accepting ability of FFs increases as the number of F atoms increases.

## CHEMICAL PROPERTIES OF FLUOROFULLERENES

### Formation of Oxafluorofullerenes

In a series of earlier papers,<sup>[5,6,78]</sup> considerable attention was paid to the presence of oxygenated fluorofullerene species C<sub>60</sub>F<sub>x</sub>O<sub>y</sub> in the products of some fluorination reactions (with F<sub>2</sub>, interhalogens, or XeF<sub>2</sub>). The origin of these by-products was believed to be either exposure of fluorofullerenes in air or formation during the synthesis because of the presence of adventitious O<sub>2</sub> or H<sub>2</sub>O. However, the first hypothesis was not confirmed as solid FFs can be kept in open air for years without any change in chemical composition (O.V. Boltalina, unpublished data). The latter reason seems more feasible; moreover, this is confirmed by direct observations by the MSU group of the increased content of C<sub>60</sub>F<sub>34</sub>O (or C<sub>60</sub>F<sub>18</sub>O) in the crude product of reaction between C<sub>60</sub> and MnF<sub>3</sub> (or K<sub>2</sub>PtF<sub>6</sub>), used for large-scale preparation of C<sub>60</sub>F<sub>36</sub> (or C<sub>60</sub>F<sub>18</sub>) under reduced pressure of 10<sup>-2</sup> Torr, in comparison with the product obtained in situ in a mass spectrometer (pressure 10<sup>-6</sup> Torr).<sup>[79]</sup> A similar effect, i.e., the enhanced formation of oxygen-containing species, also occurred in the presence of hydrolysis products of some fluorinating reagents, such as high-valent metal fluorides.

### Addition Reactions

The chemistry of C<sub>60</sub> includes the attachment of pairs of atoms or groups of atoms across double bonds,

<sup>c</sup>Poster presented by O.V. Boltalina et al. at 15th International Conference on Chemical Thermodynamics, Porto, Portugal (July, 2001).

resulting in  $C_{60}X_x$  derivatives, and various types of cycloadditions yielding monoadducts, bisadducts, or polyadducts.<sup>[9]</sup> If a fullerene derivative with some of its reaction sites occupied is used in an addition reaction, one might expect a more restricted set of products with fewer added functional groups. The simplest examples that can be found in the literature are further fluorinations of FF substrates with specific compositions:  $C_{60}F_{18}$ ,<sup>[80]</sup>  $C_{60}F_{36}$ ,<sup>[81]</sup> and  $C_{60}F_{48}$ .<sup>[82]</sup> The latter substrate was used in a reaction with  $F_2$  in an attempt to achieve a higher degree of fluorination. However, the reaction led to the rupture of the fluorofullerene cage. In case of fluorinations of  $C_{60}F_{18}$  with  $MnF_3$  and  $C_{60}F_{36}$  with  $F_2$  or  $XeF_2$ , selective formation of  $C_{60}F_{36}$  and  $C_{60}F_{48}$ , respectively, with the expected isomer compositions, were reported. This is another piece of evidence confirming the stability of specific isomers of [60]fullerenes with 36 and 48 F atoms.

At present,  $C_{60}F_{18}$ , with its bare hemisphere, and other FFs with relatively few F atoms, appear to be the most suitable substrates for addition chemistry. The availability of these compounds allows one to explore reactions similar to those carried out with pristine  $C_{60}$ . At present, only a few examples have been reported: reactions of anthracene with  $C_{60}F_{18}$  and  $C_{60}F_{20}$ <sup>[83,84]</sup> and reaction of  $C_{60}F_{18}$  with tetrathiafulvalene (TTF).<sup>[85]</sup> In the reaction with anthracene, only 1:1 cycloaddition products were formed with both FFs because of steric hindrance caused by the presence of F atoms on the cage, while  $C_{60}$  itself formed monoadducts and several bisadducts in similar reactions. In the case of addition of TTF to  $C_{60}F_{18}$ , six-electron cycloaddition occurred through the terminal C=C bond in the fulvalene (accompanied by elimination of two F atoms) and yielded as a main product an asymmetric  $C_{60}F_{16} \cdot TTF$  monoadduct. Another recent example concerns the  $CF_3$ -radical addition to  $C_{60}F_{18}$ , with silver trifluoroacetate used as source of trifluoromethyl radicals. Gas-phase species with up to six attached trifluoromethyl groups to  $C_{60}F_{18}$  were observed by mass spectrometry.<sup>[44]</sup>

## Substitution Reactions

Earlier reports on the chemical reactivity of FFs involved impure mixtures, so isolation and characterization of the products was not achieved. These studies concerned introduction of the phenyl and methyl groups<sup>[86]</sup> or the formation of various hydroxides and oxides from hydrolysis reaction of relatively compositionally pure  $C_{60}F_{36}$ , although characterization of those products was not complete.<sup>[87]</sup> Two types of substitution reactions were more systematically studied using  $C_{60}F_{18}$  as a substrate: electrophilic substitutions into aromatics in the presence of Lewis acid catalyst

and nucleophilic substitutions. The first study of the phenylation of  $C_{60}F_{18}$ , in which  $FeCl_3$  was used as the catalyst, resulted in the formation of a triphenylated derivative.<sup>[51]</sup> This was followed by a more extensive study of a variety of aromatic addends.<sup>[88]</sup> Monosubstituted, disubstituted, and trisubstituted products  $C_{60}F_{18-n}Ar_n$  were isolated ( $n = 1-3$ ) for  $Ar = 4$ -tolyl, 4-methoxyphenyl, 4-phenoxyphenyl, and 4-chlorophenyl. In all cases, substitution occurred at the three least sterically hindered F atoms (the F atoms outside of the 15-F-atom belt in  $C_{60}F_{18}$ ). For the bulky substituents  $Ar = 2$ -fluorenyl, 2-biphenyl, and 1- and 2-naphthyl, monoadducts  $C_{60}F_{17}Ar$  were the dominant products. The Lewis acids  $SbF_5$  and  $TiCl_4$  were also found to be effective catalysts for these reactions.

The reaction of a fluorofullerene with a bromomalonate diester (Bingel reaction) was first studied by MALDI mass spectrometry and resulted in the substitution of up to three F atoms with bromomalonate groups (A.L. Mirakyan, personal communication to O.V. Botalina, 2000). Later isolation and spectroscopic and crystallographic characterization of the monosubstituted, disubstituted, and trisubstituted products revealed that instead of the expected (by analogy with similar reaction of  $C_{60}$ ) methanofullerene formation, nucleophilic substitution of up to three bromomalonate groups for F atoms in  $C_{60}F_{18}$  occurred, with the three F atoms leaving from the least sterically hindered positions. The trisadduct had a prominent emerald-green color because of the formation of  $18\pi$  annulene belt of electrons with high conjugation.<sup>[54]</sup> This new type of fluorofullerene derivative with various electron-donor substituents was extensively studied with the goal of designing of donor-acceptor systems to be probed in photovoltaic devices.<sup>[89]</sup> Mono- and bis-addition products of the Prato reaction with  $C_{60}F_{18}$  ([3 + 2] dipolar cycloaddition with aldehydes and amino acids) were obtained, with a much greater variety of isomeric products than in the case of Prato reactions with  $C_{60}$ .<sup>[90]</sup>

## CONCLUSION

The first decade of the fluorine chemistry of fullerenes has passed. Joint efforts of research chemists worldwide laid the foundation for further developments in this fascinating branch of fullerene chemistry. At present, fluorine-containing fullerenes represent the largest group of derivatives with the same single substituent that have been synthesized in macroscopic amounts, isolated into specific compositionally and/or isomerically pure compounds, and fully or partially structurally characterized. Fundamental physical quantities such as formation enthalpies, vapor pressures, heat capacities,

reduction potentials, ionization energies, and electron affinities were determined for few specific fluorofullerenes, which constitutes the basis for more advanced theoretical and experimental physical-chemical and chemical studies with these compounds. Developments of new non-conventional approaches to the preparation of fluorine-containing derivatives provides hope that compounds with new compositions and structures will be obtained in the future.

Basic physical properties such as solubility, stability, thermal resistance, and resistance toward light and moisture were studied, all showing that fluorofullerenes represent a promising class of new chemical materials, sufficiently robust to be probed/examined/used for various practical applications. Although the high price remains an obstacle for advancing these materials, as it does for other fullerene-related applications, recent activities of large international companies as well as small nanotech businesses should bring down the prices of fullerenes once planned ton-scale production facilities come on line.

As for the possible applications of fluorinated fullerenes that were discussed in the past decade, which include their use as cathode materials in Li-batteries, as lubricants, and as oxidizing and fluorinating reagents, more research with pure materials under controlled conditions is needed (early reports on the performance of FFs in batteries or as lubricants were based on studies with complex mixtures of FFs contaminated with various oxafuorofullerenes). Current interest in the use of FFs in photovoltaic devices is based on their ability to function as good electron acceptors. In this regard, the report that the charge-transfer lifetime of a complex of  $C_{60}F_{18}$  and tetrathiofulvalene is 780 nsec is very promising.<sup>[91]</sup> The possibility that FFs might be useful in lithography technologies has also been suggested recently.<sup>[92]</sup>

# Fullerenes and Carbon Nanotubes

Laszlo Mihaly

Department of Physics and Astronomy, State University of New York at Stony Brook,  
Stony Brook, New York, U.S.A.

## INTRODUCTION

The Nobel Prize winning discovery of fullerenes<sup>[1]</sup> initiated a new era in carbon chemistry. In addition to the two well-known allotropes, graphite and diamond, a large number of carbon structures were synthesized.<sup>[2–7]</sup> Here we will first discuss the structure of single- and multiwalled nanotubes and the nanotube “ropes.” The fullerene molecule (primarily the most abundant fullerene, C<sub>60</sub>), the polymerized, and doped fullerenes will be considered. We will review some of the physical properties, mostly focusing on the electronic structure: electrical conduction, superconductivity, and magnetism.

## MOLECULAR STRUCTURE

Conceptually, the new structures<sup>[1–7]</sup> can be derived from graphene, an sp<sup>2</sup>-bonded honeycomb lattice of carbon atoms, which is the basic element in the structure of graphite.<sup>[8]</sup> Assume each carbon atom is connected to three neighbors, the bond lengths are fixed to be the same, but the bond angles are a bit variable. If a long strip of graphene is cut out and bent into a cylinder, so that loose carbon bonds match up, we get a nanotube. The matching carbon atoms can be labeled by a chiral vector  $\mathbf{C}_h$ . This vector is represented by two basic vectors ( $\mathbf{a}_1$  and  $\mathbf{a}_2$ ) and by two integers ( $n_1$  and  $n_2$ );  $\mathbf{C}_h = n_1\mathbf{a}_1 + n_2\mathbf{a}_2$  (Fig. 2). Accordingly, the structure of every nanotube is unambiguously characterized by the  $\mathbf{C}_h$  vector; in a shorthand notation  $\mathbf{C}_h = (n_1, n_2)$ , so that  $n_1 \geq n_2$ . Based on the patterns visible on the nanotube they may be called “zigzag” (for  $n_2 = 0$ ; Fig. 1), “arm-chair” (for  $n_1 = n_2$ ), or “chiral” (for any other, see, for example, Fig. 2). The diameter of the nanotube is given by  $d = (a/\pi) [3(n_1^2 + n_1n_2 + n_2^2)]^{1/2}$ , where  $a = 0.144$  nm is the carbon–carbon distance. There is no upper limit on the size of the nanotube, although at large diameter the structure becomes very soft [except for multiwalled nanotubes (MWNT), see later]. For small diameter the carbon–carbon bonds are more strained, and the thinnest stable nanotube corresponds to  $\mathbf{C}_h = (5,5)$  (Fig. 3).

The nanotubes derived from a single graphene strip are called single-walled nanotubes (SWNT).<sup>[4,5]</sup> If a set of subsequently smaller diameter nanotubes are stacked like concentric cylinders, a MWNT is obtained. The distance between the carbon layers in an MWNT is about the same as the distance between the graphene layers in graphite. MWNTs are produced more commonly, and the very first report of nanotubes by Iijima was about MWNTs.<sup>[3]</sup>

A nanotube rope<sup>[10]</sup> is a parallel arrangement of SWNTs in a crystalline order, as shown in Fig. 4. The rope is held together by weak van der Waals forces (just like graphite), but it is extremely strong along the long direction. SWNT strands as long as a few centimeters have been produced.<sup>[11]</sup>

Fullerenes can be viewed as fully closed graphene sheets. The guiding principle is that each carbon atom is connected to three neighbors, and the bond angles must remain close to 120°. The perfect honeycomb lattice satisfies this requirement, as the building blocks are ideal hexagons. However, in order to get closed surfaces, one has to allow for an occasional pentagon in the structure, just as in the domes designed by the architect Buckminster Fuller (hence are the names of “fullerene” and “buckyball”). There is a simple geometrical principle, Euler’s theorem, that connects the number of faces ( $f$ ), vertices ( $v$ ), and edges ( $e$ ) of a closed three-dimensional polyhedron,  $f + v - e = 2$ . If only hexagons and pentagons are allowed, one can easily prove that the number of pentagons is always 12.

The smallest fullerene, C<sub>36</sub>, has the shape of a dodecahedron, with exactly 12 pentagons, and no hexagons. However, this molecule is very reactive,<sup>[12]</sup> as the bond angles are quite stretched. If we look for surfaces where no two pentagons can be nearest neighbor we get the smallest and most abundant stable fullerene, C<sub>60</sub> (Fig. 1). In this molecule the carbon nuclei reside on a sphere of about 0.7 nm diameter, with the electronic wavefunctions extending inside and outside by about 0.15 nm. The diameter of the molecule is approximately 1.0 nm, and there is a 0.4-nm-diameter cavity inside. This molecule still has the same symmetry properties as the dodecahedron (described by the icosahedral symmetry group, I<sub>h</sub>), and the symmetry is preserved even if not all bond lengths are exactly the

**Fig. 1** Four carbon structures, representing diamond, graphite, a typical fullerene ( $C_{60}$ ), and a typical nanotube (10,0 zigzag, see discussion later).

same. In fact, in  $C_{60}$  the edges that separate two hexagonal faces are slightly shorter (0.140 nm) than the edges separating a pentagonal and a hexagonal face (0.146 nm). The chemical bond along the shorter edge is sometimes considered double bond, whereas the others are single bonds. Notice, however, the single bond distance in diamond is 0.154 nm (much longer than 0.146 nm), and the typical double bond in molecules is 0.135 nm (much shorter than 0.140 nm). This already indicates that the simple bond picture does not work for  $C_{60}$ , and the  $\pi$  electrons are, at least partially, delocalized.

The most abundant fullerene higher than  $C_{60}$  is  $C_{70}$ . Its structure can be constructed by adding a “belt” of five hexagons in one of the equatorial planes of  $C_{60}$ . Other fullerenes, such as  $C_{76}$ ,  $C_{78}$ ,  $C_{80}$ , and up, have also been prepared and purified. The number of

**Fig. 2** Schematic illustration of deriving a nanotube structure from graphene. The unit vectors  $\mathbf{a}_1$  and  $\mathbf{a}_2$ , and the chiral vector  $\mathbf{C}_n$  are indicated in the first panel. Bending the graphene strip results in the nanotube shown in the last panel. *Source:* From Shigeo Maruyama, University of Tokyo, [www.photon.t.u-tokyo.ac.jp/~maruyama](http://www.photon.t.u-tokyo.ac.jp/~maruyama).

**Fig. 3** Scanning tunneling microscope image of a nanotube. The peaks correspond to individual carbon atoms; the chirality of the structure is quite visible. *Source:* From Cees Dekker; TU Delft, <http://www.mb.tn.tudelft.nl/nanotubes.html>, see also Ref.<sup>[9]</sup>.

isomers increases rapidly with the increasing fullerene size, representing some difficulty for the determination of their structure (mainly by NMR measurements and theoretical calculations). It is interesting to note that one of the isomers of  $C_{80}$  has the exact shape of an icosahedron (there are also six other isomers with lower symmetry).

Nanotubes with closed ends can be obtained by capping the open ends with a fullerene fragment of appropriate size and shape. For example, the (5,5) nanotube can be capped at the two ends with the two halves of a  $C_{60}$  molecule. Adding more “belts” of hexagons to  $C_{70}$  yields the same structure. In this sense the distinction between nanotubes and fullerenes is somewhat artificial.

## SYNTHESIS

Once synthesized in the laboratory, fullerenes were also discovered in common sooth and in natural minerals,

**Fig. 4** Cross-sectional view of a nanotube rope. *Source:* From Don Noid and Bobby Sumpter, ORNL, [http://www.csm.ornl.gov/SC98/viz/noid\\_multi.jpg](http://www.csm.ornl.gov/SC98/viz/noid_multi.jpg).

but it is still more productive to make them in the laboratory. The most common way of preparing fullerenes and nanotubes is the arc discharge method. The typical apparatus<sup>[2]</sup> consists of a high current source (e.g., and arc welding machine) and a vacuum jar, where a partial pressure (about 100–200 Torr) of He is maintained. Inside the jar two carbon rods are brought into contact to form an arc. A constant distance should be maintained between the rods as the material is gradually converted into carbon soot. In one version of the apparatus the weight of one of the carbon rods maintains a loose contact between the rods. The soot is collected from the inside surface of the jar, and from other parts.

A more precisely controlled preparation method involves laser ablation of carbon.<sup>[1,10]</sup> The graphite target is kept at high temperature (1200°C) in a furnace. A high power laser (typically a Nd:YAG laser operating at several hundred millijoules of power) is aimed at the target and produces a carbon plasma. A flow of inert gas carries the end products and deposits them in a colder part of the apparatus.

In both cases the reaction products are mixtures of various fullerenes, nanotubes, and amorphous carbon, although by properly setting and controlling the preparation conditions the relative quantity of the end

**Fig. 5** Nanotubes grown by chemical vapor deposition on a pattern of catalyst deposited on a substrate. *Source:* Laszlo Forro, EPFL, Lausanne.

products can be influenced greatly. Nevertheless, the separation and purification of the components is a critical part of the process. Various organic solvents (such as toluene or tetrahydrofuran) can be used to dissolve fullerenes or disperse the nanotubes. High-performance liquid chromatography (HPLC) is used to separate the different fractions. Once a solid phase is obtained fullerenes can be further purified by sublimation (e.g., C<sub>60</sub> sublimates at 430°C). Smaller quantities of higher fullerenes can also be purified by gas-phase separation methods.

A third approach, primarily used in the production of SWNTs, is based on chemical vapor deposition (CVD). This method involves a carefully prepared catalyst, and it can be used to grow large quantities of ordered nanotubes.<sup>[13]</sup> It is generally believed that SWNTs are more readily obtained if the reaction temperature is not too high. Note that in the arc discharge method the reaction happens at temperatures larger than 3000°C, whereas in CVD the temperature of the reaction can be kept below 1000°C. Fig. 5 shows a pattern of “nanotube forest” synthesized by CVD.

## MOLECULAR PROPERTIES

The unsaturated nature of the sp<sup>2</sup> bonds is responsible for several interesting properties of fullerenes and nanotubes. Functionalization (attaching other molecules with desirable properties) can be carried out easily. A pretty good description of the electronic properties can be obtained by assuming that three of the four valence electrons of each carbon are tied up in the three  $\sigma$  bonds, and by considering the behavior of the remaining one electron. There is a large body of literature dealing with these issues (see, for example, Refs.<sup>[6,7]</sup>); we will focus on one of the fullerenes, C<sub>60</sub>. We will also discuss the electronic states in a single SWNT.

## Electronic States in C<sub>60</sub>

C<sub>60</sub> has 240 valence electrons, but each carbon atom has three sigma bonds to its neighbors, using up a total of 180 electrons for this purpose. The energy of these electrons is well below the Fermi surface. They stabilize the structure, but they will not contribute to the conduction. The remaining 60 electrons are distributed around the molecule on orbitals that originate from the (much less tight) carbon-carbon  $\pi$  orbitals. There are two important differences between these orbitals and the  $\pi$  electrons of a graphene plane. First, the three bonds around a carbon atom in C<sub>60</sub> (or in any other fullerene) do not make a plane. Whereas in graphene the electrons had equal probability of being “below” and “above” the plane, in fullerenes the  $\pi$  electrons tend to spend more time outside of the ball than inside. Second, in C<sub>60</sub> the C–C bond lengths are not uniform, the  $\pi$  electrons are not truly delocalized around the six-member carbon rings (like in benzene or graphene), but they are distributed over 30 “bulges” of electronic orbits that stick out of the C<sub>60</sub> molecule. A somewhat lower electron density belongs to the other 60 orbits connecting the carbon pairs with longer bond lengths.

The first insight to the nature of the molecular orbitals can be obtained by borrowing ideas from the early days of nuclear physics, when the quantum mechanics of particles confined into a spherical potential well was first considered. In this case the states are still labeled by quantum numbers  $n$ ,  $l$ , and  $m$ , just like in the hydrogen atom, but the peculiar degeneracy of the different angular momentum states, which characterizes the textbook treatment of the hydrogen atom, does not apply. In steep-walled potential well (like in a nucleus or in a C<sub>60</sub> molecule) the lower  $l$  states will have lower energy.

Let us consider 60, noninteracting electrons, confined to a sphere on a high  $n$  orbit with various  $l$ 's. The first two electrons will fill up  $l = 0$  state. Proceeding to higher  $l$ , one has to count the number of available states,  $N = 2(2l + 1)$  (where the first factor of 2 stands for spin). It is easy to see that by reaching  $l = 4$  altogether 50 electrons are consumed. The remaining 10 electrons will all go to the  $l = 5$  state.

In reality the situation is much more complex. The potential does not have the spherical symmetry; each carbon atom creates its own potential well for the electrons. Nevertheless, a more exact treatment of the electrons (e.g., a Hückel molecular orbital calculation) shows that the above arguments work well for  $l = 0, 1, 2, 3, 4$ . For higher energies the “spherical potential” approximation does not work anymore. In order to go any further we need to look at the energy splitting due to the true atomic potentials. In the real

C<sub>60</sub>  $l$  is not a good quantum number, and the electronic orbitals should be labeled according to the irreducible representations of the icosahedral symmetry group. The orbitals available for the remaining 10 electrons are, in the order of increasing energy, the  $h_u$ , the  $f_{1u}$ , and the  $f_{1g}$  levels. The degeneracy of these levels (including spin) is 10, 6, and 6, respectively. The  $h_u$  level is completely filled by the 10 remaining electrons, becoming the highest occupied molecular orbit (HOMO), and the  $f_{1u}$  level becomes the lowest unoccupied molecular orbit (LUMO). The HOMO–LUMO gap is about 2 eV.

The energy gap between the filled and empty electronic states causes the molecule to be non-reactive, and it accounts for the insulating nature of the C<sub>60</sub> solid. The empty  $f_{1u}$  level can hold six electrons, and a proper addition of electrons to the molecule (sometimes called “doping”, in analogy to adding electrons to a pure superconductor) should result in dramatic changes in the properties, including higher reactivity and metallic character. Two possible ways will be discussed here shortly: adding an atom inside the C<sub>60</sub> cage (endohedral doping) and exchanging a carbon atom to another one (on-site doping; Fig. 6). The third (and most fruitful) method, exohedral doping, when the donor atom is placed in-between the C<sub>60</sub> molecules, will be considered later.

Endohedral C<sub>60</sub> molecules can be prepared by a “brute-force” method, where ions of atoms are accelerated and implanted to the C<sub>60</sub> cage.<sup>[14]</sup> The ions should have just enough energy to open up the cage and enter. The first collision should absorb and redistribute a good part of the initial kinetic energy so that the atom does not escape the cage. Endohedral molecules of M–C<sub>60</sub> with M = N, P, Li, Ca, Na, K, Rb were produced this way in small quantities. A larger yield can be achieved by coevaporation<sup>[15]</sup> of the carbon and the metal in an arc-discharge chamber (typical for fullerene production). In this process mostly higher endohedral fullerenes, such as M–C<sub>82</sub> (where M is a metal atom), can be extracted from the soot on a chromatographic column.

Fig. 6 Endohedral and on-site doping of a C<sub>60</sub> molecule.

Electron spin resonance spectroscopy (ESR) studies and detailed quantum chemical calculations show that the endohedral dopant atom does not always transfer its charge to the cage. If the dopant remains neutral, it stays in the center of the cage, like in  $N-C_{60}$ .<sup>[16]</sup> Compounds such as  $La-C_{60}$  are very interesting, as complete charge transfer from La to the  $C_{60}$  cage results in a triply charged molecule.

On-ball doping has been achieved by replacing one carbon atom with a nitrogen atom obtaining  $C_{59}N$  (azafullerenes).<sup>[17]</sup> The replacement of N for C adds one extra electron to the cage, changes the structure locally, lowers the symmetry of the molecule, and splits the degeneracy of the electronic orbitals. Furthermore, this chemical substitution renders the molecule very reactive with a high electron affinity. At ambient temperature the  $C_{59}N$  exists only in a dimerized phase.

### Electrical Conduction in Nanotubes

In order to understand the electrical properties of a nanotube, we first have to look at a single graphene sheet. Graphene is on the borderline of being metallic: the band structure calculation results in a “zero-gap semiconductor” behavior.<sup>[18]</sup> Fig. 7 shows an illustration of the electron energy as a function of the two-dimensional wave vector. The Brillouin zone of graphene is a hexagon, and the allowed electronic states (wave vectors) correspond to the points inside the hexagon; the electronic bands reach the Fermi level

**Fig. 7** Schematic representation of the energy bands in graphene. The possible electron states are constrained in a hexagon in the base plane. The lower band is full, the upper band is empty. The energy of the electrons is zero (equal to the Fermi energy) at the six corners of the hexagon.

**Fig. 8** The six corners of the hexagon correspond to electronic states available for conduction. The lines represent the allowed electronic states in a zigzag and an armchair nanotube.

at the six corners of the hexagon. Therefore the Fermi “surface” consists of six points, as indicated in the two panels in Fig. 8. (In graphite the influence of the neighboring layers causes the bands to cross the Fermi level, and there will be finite Fermi surface, yielding a semimetallic behavior.)

By bending the graphene sheet into a nanotube the most drastic change will be the constraint introduced due to the periodic boundary condition along the circumference of the cylinder. Accordingly, in the direction perpendicular to the tube axis the allowed wave vectors will be constrained to lines. The larger the diameter of the nanotube the more dense are the lines. Naturally, for a very large diameter nanotube the allowed wave vectors are just about the same as for the graphite, and the properties are also similar. However, for smaller diameters the constraint is really important. As shown in the two panels of Fig. 8, the relative orientation of the lines corresponding to the allowed states is sensitive to the actual structure of the nanotube.<sup>[8,19]</sup> For armchair nanotubes one of the lines always intersects the corner of the hexagon, therefore these nanotubes are metallic; for the zigzag structure it is possible that the lines miss the corners, and in those cases the nanotube is semiconducting. By carrying out this analysis in more detail, we obtain that a nanotube is metallic if the integers in the chiral vector describing the structure  $C_h = (n_1, n_2)$  satisfy  $n_1 - n_2 = 3j$ , where  $j$  is an arbitrary integer. More detailed calculations, taking into account the curvature of the graphene sheet, lead to the conclusion that for  $n_1 = n_2$  (armchair) the nanotubes are metallic, for  $n_1 - n_2 = 3j$  there is a tiny gap at the Fermi surface, and for all other cases the gap is large.

Much progress has been made in the experimental test of these predictions.<sup>[20]</sup> One prefers to work with a SWNT, because for a MWNT it is unlikely that all of the component nanotubes are of the same type (metal or semiconductor). The first conductance

measurements were done on a nanotube rope, a collection of similar SWNTs. Several single SWNTs of various chirality have been tested later. The measurements largely support the conclusions drawn above. For the complete interpretation of the experimental results one needs to step beyond the simple theory of bulk metals: the electrical leads to the nanotube must be treated as tunneling contacts. The resonance between higher quantum levels and the Coulomb repulsion of electrons on the nanotube play important roles.<sup>[21,22]</sup>

## FULLERENE SOLID

The vast majority of research on the fullerene-based solids was done on  $C_{60}$ . The molecule dissolves in various solvents. Crystallization from solution usually yields a structure that includes the solvent molecules.<sup>[23]</sup> However, sublimation in vacuum or inert gas atmosphere may yield pure  $C_{60}$  crystals of several millimeters or even centimeter size. In the solid form the centers of the fullerene molecules are ordered in a face-centered cubic (fcc) crystal lattice (Fig. 9).

At room temperature the fullerene molecules rapidly and randomly rotate between various orientations.<sup>[24]</sup> In time average the molecules look like spheres and all of the molecular sites are equivalent. (The well-defined molecular center and a nearly free molecular rotation are not a unique property of the fullerene molecule. It is characteristic to many organic solids, where the binding is due to van der Waals forces, and the molecule has “rounded” symmetric shape, like solid  $CH_4$  and  $CCl_4$ .)

The nearest neighbor  $C_{60}$ – $C_{60}$  distance corresponds to the diameter of the molecule. At room temperature the size of the cubic unit cell is 1.417 nm, and the nearest neighbor distance is 1.002 nm. As the temperature is lowered, the rotation of the molecules stops. The center of the molecules remains in about the same place, but the incompatibility of the icosahedral molecular symmetry and the cubic lattice symmetry makes it impossible to describe the structure in terms of the

**Fig. 9** A pure fullerene crystal, and the illustration of the structure of the fullerene solid. *Source:* From Ref.<sup>[33]</sup>.

simple fcc lattice, with one  $C_{60}$  molecule of fixed orientation each unit cell. The freezing of the rotational motion actually happens in two stages. First, at 261 K the rotational axis of each molecule becomes constrained. The building block of the new structure consists of four  $C_{60}$  molecules arranged at the vertices of a tetrahedron, with each one of them spinning around a different, but well-defined axis.<sup>[25–28]</sup> Then, at lower temperatures, the rotation around these axes slows down and stops gradually. Below about 90 K the molecules are entirely frozen, but they never order perfectly.

## Doped Fullerenes

The linear size of a fullerene molecule is 10 times larger than a typical atom. Even in a close-packed fcc structure, large empty spaces between the molecules are freely available for smaller atoms, ions, or molecules. Because of the unsaturated character of the C–C bonds on the fullerene, there are plenty of electronic states to accept electrons from appropriate donors. The combination of alkali and alkaline earth elements with fullerenes results in an unusual variety of  $A_nC_{60}$  materials that are mostly near-stoichiometric (A can stand for Na, K, Rb, Cs, Ca, Sr, and Ba). Organic and inorganic molecules were also used to produce charge transfer salts with fullerenes. The term “doped fullerene” is often used to describe the product (although in its original sense, “doping” means a small, nonstoichiometric amount of charge transfer, typically in a semiconductor).

In the fcc structure the interstitial sites have either octahedral or tetrahedral symmetry. The tetrahedral sites are smaller, and there are twice as many of them as octahedral sites. A series of  $A_nC_{60}$  (with  $n = 0, 1, 2, 3, 4, 6, 10$ ) materials are based on the original fcc structure of pure  $C_{60}$ . Several other compounds are known where the  $C_{60}$  abandons the close-packed structure.<sup>[29–34]</sup> Two of these, the body-centered tetragonal  $A_4C_{60}$  and the body-centered cubic  $A_6C_{60}$ , are illustrated in Fig. 10. There is also a series of compounds with alkaline earth metals. Based on the simple

**Fig. 10** The leftmost structure corresponds to  $A_3C_{60}$ , with  $A = K, Rb, Cs$ , (or a mixture of these). If the dopant is an alkaline-earth metal (denoted by B), the structure is  $B_3C_{60}$ . The  $A_4C_{60}$  and  $A_6C_{60}$  structures shown here are known to exist with  $A = K, Rb$ , and  $Cs$ .

electron band arguments, the HOMO level of the  $C_{60}$  can accept a total of six electrons. Anything less than that should result in a partially occupied electron band and lead to a metallic behavior in the solid state. Surprisingly, at room temperature and ambient pressure, only  $AC_{60}$ , and  $A_3C_{60}$  are metals (for a review, see Ref.<sup>[33]</sup>).

### Superconductivity and Magnetism in Fullerenes

A class of alkali-metal-doped fullerenes, with chemical composition  $A_3C_{60}$ , is metallic at room temperature<sup>[35]</sup> and turns into superconductor at low temperature.<sup>[36]</sup> The transition temperature is unusually large; for example, in  $Rb_3C_{60}$  it is 32 K.<sup>[37]</sup> In contrast to other exotic superconductors (such as the copper-oxide-based high-temperature superconductors), the superconductivity in fullerides is well understood in terms of the theory developed in the 1960s by Bardeen, Cooper, and Schrieffer (BCS). The formation of Cooper pairs (two electrons that are held together by some attractive force) is the key element of the BCS theory. In the  $A_3C_{60}$  fullerides the conduction electrons are donated by the alkali metal atoms to the  $C_{60}$  molecules, the electrons easily hop between the molecules (because of the overlap of the molecular orbitals), and the attractive interaction is mediated by the deformation of the molecule induced by the presence of the electron.

When  $C_{60}$  is combined with the strong electron acceptor tetrakis(diethylamino)ethylene (TDAE) each fullerene molecule loses an electron. It was expected that this material will also be a metal, and perhaps a superconductor, too. Instead, it turned out to be an insulator, but when it was cooled to low temperature a strong magnetism was detected.  $(TDAE)C_{60}$  is a ferromagnetic compound with a Curie temperature of 16-K.<sup>[38,39]</sup> It is very rare to find ferromagnetic behavior with no transition metal (such as iron or nickel) in the chemical formula.  $(TDAE)C_{60}$  held the record of being the highest temperature truly organic ferromagnet.

### Polymerization of Fullerenes

The ability of the  $C_{60}$  molecule to form covalently bonded polymers was first noticed in laser-irradiated thin films of  $C_{60}$ .<sup>[40]</sup> The polymerization happens in a Diels–Alder-type (2 + 2) cycloaddition reaction when the double bonds on two fullerenes are broken up and cross links are formed. This reaction has a large activation energy, and at room temperature it is extremely slow. It is believed that (2 + 2) cycloaddition also occurs in high-pressure/high-temperature polymerization of fullerenes.<sup>[41]</sup> Some of these high-pressure synthesized disordered polymers are very attractive

**Fig. 11** The low-temperature structure of  $RbC_{60}$ . The polymerized  $C_{60}$  chains are quite visible. *Source:* From Joseph Lauher, SUNY, Stony Brook, <http://sbchem.sunysb.edu/msl/fullerene.html>.

for applications, as they can exhibit mechanical properties stronger than diamond.

In doped fullerenes polymerization can happen without exposing the material to light, high temperature, or pressure. The best known examples are  $KC_{60}$  and  $RbC_{60}$ , where the fullerene molecules form linear chain structures (Fig. 11). The formation of these chains happens spontaneously as the material is cooled slightly below room temperature.<sup>[42]</sup> There are dramatic changes in the electrical conductivity and in the other properties; most notably the material becomes stable in air (otherwise all alkali-doped fullerene compounds decompose rapidly in air). This is a reversible transition, and the material turns back to the monomeric form if the temperature is raised. A slightly different polymer is formed in  $Na_4C_{60}$ . In this compound, sheets of  $C_{60}$  molecules are formed so that there is a single bond between the nearest neighbors.

### CONCLUSION

Inorganic fullerenes and nanotubes have been prepared in binary composition; for example, the graphite-like solid lubricant  $MoS_2$  served as the basis for a series of compounds.<sup>[43]</sup> However, only carbon has the extraordinary chemical flexibility to serve as the sole basic unit of such a variety of compounds. The materials discussed here are testing grounds for important concepts in condensed matter theory; at the same time there is a constant effort to find potentially useful applications. Fullerene-like structures are known in more complex materials, including biologically important molecules,

including the HIV virus.  $C_{60}$  was investigated as a potential drug delivery agent, it may have antiviral activity,<sup>[44]</sup> and endohedral  $C_{60}$  compounds can be possibly used as a spin label (or relaxation agent) in magnetic resonance spectroscopy.<sup>[45]</sup> Bulk quantities of nanotubes are considered for reinforcement additives in metals and for storage of hydrogen gas.<sup>[46]</sup> In scanning tunneling and force microscopy the nanotubes may serve as the sharpest possible microscope tip. Single nanotubes were shown to work as single-electron transistors, reaching the ultimate limit of nanoscale electronics.<sup>[47,48]</sup> Electron emission and light emission from the tips of the nanotubes have been seen at relatively low applied voltages, and according to a recent press release from Motorola, the nanotube-based “nanoemissive display (NED) technology enables manufacturers to design large flat panel displays that exceed the image quality characteristics of plasma and LCD screens.” The strange structures, discovered during the search for new molecules in the interstellar medium,<sup>[1]</sup> may have a real impact on our everyday life in the not-too-distant future.

# Fullerenes: Chemistry

Mark S. Meier

Department of Chemistry, University of Kentucky,  
Lexington, Kentucky, U.S.A.

## INTRODUCTION

Fullerenes are the most exciting new set of chemical structures discovered in the last part of the 20th century. The advent of these novel structures has led to fascinating new scientific questions and to intriguing potential applications. This article provides an overview of the structures of the common members of the fullerene class of carbon allotropes and introduces the essentials of fullerene reactivity. Specific types of reactivity discussed herein include reactions of fullerenes with nucleophiles and electrophiles, oxidations and reductions, as well as reactions with metals and cycloaddition reactions. A glimpse of the potential applications of these fascinating molecules is also provided. The focus will be on the chemistry of  $C_{60}$  as it is the most available and the best-understood member of an expanding set of chemical structures. The chemistry of  $C_{70}$  is discussed briefly as well, demonstrating how strain directs the reactivity of this less-symmetrical structure.

## STRUCTURE

Fullerenes are hollow clusters of carbon atoms. The name fullerene is a shortened form of *buckminsterfullerene*, a name that pays homage to the designer of the geodesic dome.<sup>a</sup> The structure of  $C_{60}$  is reminiscent of that famous dome, being a near-perfect sphere formed from a set of fused rings in the same manner as a soccer ball.  $C_{70}$  is similar, having the same general structure with an extra “belt” of 10 carbon atoms. Common members of this class of structures include  $C_{60}$ ,  $C_{70}$ ,  $C_{76}$ , and  $C_{84}$ , although small amounts of larger structures (“higher fullerenes”) are formed along with the more common species. As the number of carbon atoms increases, the number of possible structures increases, and indeed multiple isomers of several of the higher fullerenes have been observed.<sup>b</sup> New fullerene species

have been prepared from other fullerenes, albeit in low yield.<sup>c</sup>

The  $C_{60}$  cage ( $I_h$  symmetry) measures 7 Å across. The  $C_{70}$  “rugbyball” shape ( $D_{5h}$  symmetry) is 7 Å across and 10 Å long. These highly curved structures place carbon in a strained geometry. Trivalent carbon ( $sp^2$  hybridization) typically leads to a planar geometry. In fullerenes, the bonding arrangement at carbon is far from planar—the three bonds form a shallow pyramid.<sup>[4,5]</sup> The strain in  $C_{60}$  is significant (over 400 kcal/mol) and is responsible for much of the reactivity of fullerenes.<sup>[6]</sup>

The bonding pattern in these molecules may be better illustrated through a “Schlegel” diagram, which is a flattened projection of the three-dimensional structures shown in Fig. 1. In these diagrams, the pattern of 5-membered and 6-membered rings is easily seen.

Only the pattern of  $\sigma$  bonds is shown in Figs. 1 and 2. There is an extensive (and critically important) set of  $\pi$  bonds that involves every carbon atom in the molecule. It is clear from the reactivity of  $C_{60}$  as well as from theory that these bonds are not localized between pairs of carbon atoms, but are instead delocalized over the surface of the fullerene cage. There is some debate over whether fullerenes can be properly classified as aromatic.<sup>[7]</sup> Aromaticity is normally associated with significant electronic ring currents, diminished reactivity, and diminished bond length alternation. Fullerenes display a degree of bond length alternation. The bonds that form the fusion of a 6-membered ring with a 5-membered ring are somewhat longer (bond length of 1.46 Å) than the bonds that form the fusion of two 6-membered rings (1.40 Å), but this amount of bond length alternation is also found in some molecules commonly considered to be aromatic (Fig. 3).

Fullerenes are much more reactive toward addition reactions than are classical aromatic compounds such as benzene. This likely reflects the relatively poor overlap of p-orbitals (splayed apart as a result of the curvature of structure), as well as the tremendous release of strain that results from conversion of carbon atoms

<sup>a</sup>For a detailed discussion of fullerene nomenclature, see Ref.<sup>[1]</sup>.

<sup>b</sup>For an example, see Ref.<sup>[2]</sup>.

<sup>c</sup>For an example, see Ref.<sup>[3]</sup>.

Fig. 1 The two most common fullerenes: (A)  $C_{60}$  and (B)  $C_{70}$ .

from highly strained  $sp^2$  geometry to a much less strained  $sp^3$  geometry. Ring currents in fullerenes are segregated into opposing diamagnetic and paramagnetic currents that sum to 0 in the case of  $C_{60}$  and to small values for the other fullerenes. It is clear that traditional notions of aromaticity and indeed some of the traditional hallmarks of aromaticity, which were originally developed for planar, monocyclic systems, are not easily applied in the case of these spherical, polycyclic structures. A novel  $2(N + 1)^2$  rule has been proposed as a guideline for aromaticity in spherical systems.<sup>[8]</sup>

$C_{60}$  has three degenerate Lowest Unoccupied Molecular Orbitals (LUMOs) and can be reduced to the

$C_{60}^{n-}$  anions, where  $n$  is 1–6. The reduction can be achieved electrochemically, by electron transfer from various anions, or by direct reduction with metals. Reviews on electron-transfer reactions of fullerenes<sup>[9]</sup> and of the preparation and properties of the anions (fullerides) and the less well-known cations (fullerenium ions) have been published.<sup>[10]</sup>

### Synthesis

These beautiful molecules were first detected in the plume above a laser-evaporated carbon target and have also been formed on a large scale in electric arcs

Fig. 2 Planar projection of  $C_{60}$ , showing the pattern of 5- and 6-membered rings.

Fig. 3 A common type of drawing of  $C_{60}$ , showing double bonds at the site of the shortest bonds and not showing the back side of the ball.

between carbon electrodes and in particular types of flames.<sup>[11–13]</sup> The precise mechanism by which fullerenes form is not known, but they seem to occur during the condensation of carbon plasmas. There has been a total synthesis of  $C_{60}$  reported,<sup>[14]</sup> but the ease, low cost, and scalability of arc and of flame methods clearly make these the preferred routes. In essentially all cases, the dominant fullerene formed is  $C_{60}$ , and the amounts of the higher fullerenes ( $C_{70}$  and higher) diminish rapidly, to the point where miniscule amounts of fullerenes larger than  $C_{84}$  are formed. In 2003, a large-scale facility dedicated to fullerene production was established, using the flame method.

Purification of fullerenes is usually accomplished by chromatography, and numerous methods have proven effective. On large scales, short silica/carbon columns are most appropriate. On smaller scales, sublimation can be used to produce highly pure, solvent-free fullerenes.

Fullerenes are typically dark, sometimes lustrous, solids. The liquid phase has not been observed, but the solids sublime well under high vacuum. The solubility of fullerenes is negligible in hydrocarbon solvents, but reasonable in aromatic and halogenated aromatic solvents.<sup>d</sup> Larger fullerenes are typically less soluble than smaller ones.

## CHEMICAL REACTIVITY

When macroscopic amounts of fullerenes became available for study around 1990, it did not take long to discover that these molecules were quite reactive.<sup>e</sup> Because fullerenes themselves have no chemical groups available for substitution, they can react only in

<sup>d</sup>For an extensive list of the solubility of  $C_{60}$  in different solvents, see Ref.<sup>[15]</sup>.

<sup>e</sup>A number of key early studies of the chemical reactivity of fullerenes are contained in Ref.<sup>[16]</sup>.

Fig. 5 The structure of  $C_{60}H_{18}$ .

addition reactions.<sup>[17]</sup> The driving force for these reactions is provided (in part) by the release of strain from pyramidalization. The chemistry of fullerenes has turned out to be very rich.<sup>f</sup>

## Hydrogenation

Hydrogenation of fullerenes is easily accomplished under a variety of conditions. The simplest hydrogenated fullerenes,  $C_{60}H_2$  and  $C_{70}H_2$  (Fig. 4), have been made by reduction with  $BH_3$ , with Zn, with diimide, and with other reagents.<sup>g</sup> In both of these cases, the two hydrogen atoms are bonded to adjacent carbons, as this arrangement is more stable than arrangements that place the hydrogen atoms farther apart. Interestingly,  $C_{60}H_2$  is a remarkably acidic compound for a hydrocarbon, with a  $pK_a$  below 5.

As expected, more highly hydrogenated compounds can be obtained, and compounds out to  $C_{60}H_{36}$  have been prepared, using transfer hydrogenation,  $Li/NH_3$ , or high-pressure catalytic hydrogenation. While  $C_{60}H_{18}$  is isolated as a single species,  $C_{60}H_{36}$  is isolated as a mixture of isomers. The structure of  $C_{60}H_{18}$  has been established as having a “turtle-shell” shape (Fig. 5).

## Oxidation

Treatment of  $C_{60}$  with most oxidizing agents results in the formation of  $C_{60}O$ . This compound is less soluble than  $C_{60}$  itself and less chromatographically mobile. Multiple oxidations occur with excess oxidizing agent,

<sup>f</sup>Excellent reviews include Refs.<sup>[18–22]</sup>.

<sup>g</sup>For reviews of hydrogenated fullerenes, see Refs.<sup>[23,24]</sup>.

Fig. 6 The monooxides of  $C_{60}$  and  $C_{70}$ .

and multiple isomers of the  $C_{60}O_x$  product are formed. These oxides are increasingly insoluble and difficult to characterize. Oxidation of  $C_{70}$  is somewhat more complex, as multiple isomers of the monoadduct are possible. The two predominate isomers formed are shown in Fig. 6.

### Cycloadditions

Fullerenes react readily in a variety of different cycloadditions.<sup>h</sup> These reactions often proceed at room temperature, although multiple additions occur. In most cases, a single cycloaddition to  $C_{60}$  will produce a single isomer of monoadduct, but a second cycloaddition produces a mixture of isomeric diadducts. Reactions on less-symmetrical higher fullerenes are even more problematic. In practice, reactions are usually limited to less than 50% conversion to maximize the yield of monoadduct.

A number of different [2 + 2] cycloadditions have been reported. For example, benzyne adds in a [2 + 2] manner to produce a new 4-membered ring fused to  $C_{60}$  (Fig. 7). This reaction is thermal, although there are analogous photochemical reactions between fullerenes themselves, for example, the photopolymerization of  $C_{60}$ . While strong dienophiles will react with  $C_{60}$ , they do so in a [2 + 2] manner rather than the [4 + 2] manner of the classical Diels–Alder reaction.

A number of different [3 + 2] cycloadditions have been reported, leading to a rich variety of products. Nitrile oxides add to  $C_{60}$  to form isoxazolines, azomethine ylids add to form pyrrolidines, and diazoalkanes add to form pyrazolines. The latter case is one of the most important reactions in fullerene chemistry, and the  $C_{60}$ –pyrazoline adduct is thermally unstable and decomposes to new products. In the case of  $Ph_2CN_2$ , the primary product is the methanofullerene. However, in the case of  $CH_2N_2$ , the product is a novel compound  $C_{61}H_2$ , known as a homofullerene or

Fig. 7 The [2 + 2] cycloaddition of benzyne to  $C_{60}$ .

a “fulleroid.”<sup>i</sup> Fulleroids are fullerenes that have been “inflated” by the addition of a carbon atom and the opening of one of the original C–C bonds in the cage. The opened bond is typically the bond that formed the fusion of a 5-membered ring with a 6-membered ring (Fig. 8).

Similar chemistry occurs with alkyl azides, leading to the formation of azafulleroids. Azafulleroids have served as the starting material for the formation of  $C_{59}N$ -based species, a rare example of a fullerene cage with a heteroatom replacing one of the carbon atoms<sup>[26]</sup> (Fig. 9).

Fullerenes undergo a number [4 + 2] cycloadditions, with the fullerene functioning as the 2-electron component. Reaction with dienes such as cyclopentadiene yields adducts, and, as is often the case, multiple additions can occur.

Of the various 1,3-dipolar cycloaddition reactions that have been demonstrated on fullerenes, the addition of azomethine ylids has proven to be particularly versatile. This reaction converts a fullerene into a fulleropyrrolidine (Fig. 10). The nitrogen atom provides a convenient point of attachment for a host of different groups.

A tandem [4 + 4]/[2 + 2 + 2] cycloaddition route has been used to generate a novel fullerene ( $C_{62}$ ) that is not formed in significant amounts in arc reactors (Fig. 11).

### Addition of Nucleophiles

Fullerenes react in a manner not unlike electron-deficient alkenes. Strong nucleophiles add readily and often add repeatedly if conditions are not carefully controlled. Examples of carbon nucleophiles that react with  $C_{60}$  include alkyl lithium reagents, alkyl magnesium (Grignard) reagents, acetylide anions, and cyanide. Addition of several equivalents of nucleophile is a common side reaction. Organocuprates also add readily, resulting in a symmetrical cyclopentadienyl pattern. Heteroatom nucleophiles, including amines, are also known to add to  $C_{60}$ .

<sup>h</sup>For a review of cycloadditions of fullerenes, see Ref.<sup>[21]</sup>.

<sup>i</sup>For a detailed discussion of the nomenclature of fullerenes (including homofullerenes), see Ref.<sup>[25]</sup>.

Fig. 8 Formation of a fulleroid via addition of diazomethane to  $C_{60}$ .

One of the most useful reactions in all of fullerene chemistry is the addition of dialkyl bromomalonate anion. This reaction, often called the Bingel reaction, results in formation of a cyclopropane (Fig. 12). Most likely, this reaction involves addition of the enolate nucleophile, followed by displacement of the bromide ion by the resulting fulleride anion. This reaction has produced  $T_d$ -symmetrical species that display luminescence. Luminescence from fullerenes and fullerene derivatives is uncommon.<sup>[27]</sup>

### Addition of Radicals

Radicals add readily and repeatedly to fullerenes.<sup>[28]</sup> Alkyl radicals can add over 30 times to  $C_{60}$ . Sulfur- and nitrogen-based radicals have been observed to add to fullerenes. The tendency for multiple additions and multiple isomers has limited the synthetic utility of this reaction. However, radical addition to fullerenes has been used as method for covalent incorporation of fullerenes into polymers.

### Addition of Electrophiles

Halogenation of fullerenes is easily accomplished with a variety of reagents. The resulting compounds are reactive under a variety of conditions, establishing the halogenated compounds as useful synthetic

intermediates. Addition of  $F_2$ ,  $Br_2$ , and  $Cl_2$  to  $C_{60}$  are all known, but addition of  $I_2$  is not favorable. Reaction of  $C_{60}$  with neat  $Br_2$  produces  $C_{60}Br_8$  and  $C_{60}Br_{24}$  (Fig. 13).<sup>[29]</sup> The addition is reversible, as both products lose  $Br_2$  upon heating.

Chlorination with  $ICl$  produces  $C_{60}Cl_6$ , an interesting compound with an isolated cyclopentadienyl substructure. The presence of chlorines opens up new chemical possibilities, and these atoms have been substituted by methoxide and by aromatic rings.<sup>[30]</sup> Dissolving  $C_{60}Cl_6$  in benzene with  $AlCl_3$  brings about a classical Friedel–Crafts reaction, producing  $C_{60}Ph_5Cl$  (Fig. 14).<sup>[31]</sup> This compound has been used to make metal–cyclopentadienyl complexes.

Fluorination has resulted in a number of different highly fluorinated species (up to  $C_{60}F_{48}$ ),<sup>[32]</sup> and these are typically reactive toward nucleophiles, including weak nucleophiles such as water. In many cases, the addition patterns seen in fluorination reactions mimic the pattern seen in hydrogenation.

Fuming sulfuric acid adds to  $C_{60}$  to produce cyclic sulfates. These can be hydrolyzed to produce polyhydroxylated compounds known as fullerols. These compounds are usually isolated as complex mixtures, containing species with different numbers of hydroxyl groups and numerous isomers for each molecular formula. Fullerols are notable as one of the few classes

Fig. 9 The  $C_{59}N$  dimer.

Fig. 10 A fulleropyrrolidine.

Fig. 11 The structure of  $C_{62}$ .

of fullerene derivatives that are commonly water-soluble.

### Electrophilic Substitution

The chemistry of most aromatic hydrocarbons is characterized by substitution reactions, in which an attacking electrophile replaces a peripheral hydrogen. The lack of peripheral groups (the lack of a periphery!) makes it impossible to do a true substitution reaction on a fullerene, but fullerene derivatives can participate in these reactions. The halides have proven to be useful in electrophilic aromatic substitution reactions. Dissolving  $C_{60}Cl_6$  in benzene with  $AlCl_3$  brings about a classical Friedel–Crafts reaction, producing  $C_{60}Ph_5Cl$ .

### Multiple Additions

While a single isomer results from addition of one group to  $C_{60}$ , addition of a second group can result in large number of different isomers. Two isomers are the most common, but in most cases, complex mixtures of many isomers result.

A template-directed approach has been used to address this problem. This approach relies on the initial addition that connects a template to the fullerene. The template bears reactive groups that lead to additional reactions on the fullerene, but only at sites that can be reached by the template.<sup>j</sup>

### Metal Complexes

Fullerenes form complexes with a wide array of transition metals,<sup>[34,35]</sup> essentially always in a  $\eta - 2$  manner.<sup>k</sup> These complexes are often very insoluble,

<sup>j</sup>For an example, see Ref.<sup>[33]</sup>.

<sup>k</sup>For an example of a pentahapto metal complex, see Ref.<sup>[36]</sup>.

Fig. 12 Cyclopropanation of  $C_{60}$ .

but a number have been crystallographically characterized. Complexes with platinum and iridium are common, and a typical example is shown in Fig. 15.

Alkali metals and alkaline earth metals generally undergo electron-transfer reactions with fullerenes, leading to  $M_xC_{60}$  species, where  $x$  depends on how strongly reducing the metal is. In solution, the exact species formed depends on the metal and on the solvent.

The most novel aspect of the organometallic chemistry of fullerenes is the chemistry of endohedral fullerenes. Endohedral complexes of fullerenes are composed of one or more atoms *inside* of a carbon shell. Such species are commonly denoted as “ $M@C_{60}$ ,” meaning atom  $M$  *inside*  $C_{60}$ .<sup>[37,38]</sup> There is very little free space inside of a fullerene, so only individual atoms or small groups of atoms can be accommodated.

Endohedral fullerenes can be prepared in a number of different ways. It is possible to drive small inert gas atoms directly into the interior of a fullerene. This is the common synthetic route for species such as

Fig. 13  $C_{60}Br_{24}$ , showing one side of the structure.

Fig. 14 Preparation and reactions of  $C_{60}Cl_6$ .

$^3He@C_{60}$  and  $^3He@C_{70}$ . This procedure requires high temperature ( $>600^\circ C$ ) and pressures ( $>2000$  atm) and results in low ( $\leq 0.1\%$ ) incorporation.<sup>[39]</sup> Regardless of the difficulty, these  $^3He$  complexes have proven invaluable for the  $^3He$  NMR signal, which has been used to determine the number of isomers of a fullerene (or fullerene derivative) present in a sample and as a probe of the internal electronic environment.

A second route to endohedral fullerenes is to form the fullerene around the endohedral atom(s). This is most commonly performed by using a metal-doped carbon rod in an arc reactor. The resulting endohedral complexes are then isolated from the resulting soot and purified by chromatography. A wide range of endohedral complexes has been formed by this method, and the carbon shell formed around the metal is often (usually) not a  $C_{60}$  or a  $C_{70}$  shell.

The most common members of this class of compound are species such as  $La@C_{82}$ . Much larger shells and much smaller shells have been observed ( $La_3@C_{106}$ ,  $U@C_{28}$ ). Multiple atoms can be encapsulated, including a mixture of metals and non-metals ( $Sc_3N@C_{82}$ ).

### The Chemistry of Higher Fullerenes

Higher fullerenes ( $C_{70}$  and larger fullerenes) have received much less attention than has  $C_{60}$ .<sup>[40,41]</sup> The

Fig. 15 A typical transition metal complex of  $C_{60}$ ,  $(Ph_3P)_2PtC_{60}$ .

limited availability and high price of these molecules have made it difficult to undertake extensive studies of their chemistry. Thankfully, the reactivity of the higher fullerenes is very similar to that of  $C_{60}$ . However, because  $C_{70}$  and the higher fullerenes are less symmetrical than  $C_{60}$ , there are more options for the site of the first addition, for the second addition, and so on. Hirsch–Bingel reactions on  $C_{70}$  have been used to identify the most reactive site, the second reactive site, and so on.<sup>[42]</sup> As expected, the most reactive site on  $C_{70}$  is the  $C=C$  bond between the most pyramidalized carbons in the molecule. The second most reactive site is typically at the opposite pole of the molecule. The last to react are usually the carbons closest to the equator.

There are exceptions to this rule. Addition of chlorine, as well as reduction with  $Zn(Cu)$ , results in addition near the equatorial belt. This pattern may result from a different mechanism (radical?) than is operating. As a result, reactions on the poles and near the equatorial belt are known.

### APPLICATIONS

A variety of applications have been proposed for fullerenes based on the potential exploitation of the electronic or optical properties. The quantum yield for production of the triplet excited state of  $C_{60}$  is nearly unity, and  $C_{60}$  is an efficient sensitizer for producing singlet oxygen. The high molar absorptivity and absorption at the long-wavelength end of the visible spectrum, coupled with being an efficient sensitizer, makes fullerenes good candidates in photodynamic therapy. Fullerenes exhibit non-linear optical behavior, and so optical limiting applications are possible.<sup>[43]</sup> Fullerene derivatives have also been used in enzyme inhibitors, and fullerene derivatives have shown activity against a number of tumor cells lines.<sup>[44]</sup> Fullerenols have shown some promise as MRI contrast agents.

Most of the potential applications lay in the electronic and materials areas. Transistors have been made from  $C_{60}$  films and from  $C_{70}$  films.<sup>[45]</sup> Much excitement was generated when the superconductive  $M_3C_{60}$

species were discovered, and these fulleride films and  $T_c$ 's as high as 33 K have been measured in  $Cs_2RbC_{60}$ . While some advances beyond 33 K have been reported, to date, the  $T_c$ 's of fullerene-based superconductors have not surpassed copper oxide-based materials.

## CONCLUSION

Fullerenes are closed shells formed of carbon atoms. The chemistry of these novel forms of carbon is similar to electron-deficient alkenes, in that the fullerenes react with nucleophiles faster than with electrophiles. The chemistry of fullerenes is largely addition chemistry, and a host of reagents is known to add to  $C_{60}$  and other fullerenes. Most addition reactions will proceed multiple times, and conversions are typically limited to ~50% to produce the highest yield of mono-adduct. Multiple additions generally result in complex mixtures of isomers. Higher fullerenes ( $C_{70}$  and larger) pose even more daunting regiochemical problems. Template-directed methods can help produce di-adducts, triadducts, and higher adducts with predictable regiochemistry.

Frederick, Maryland, U.S.A.

## INTRODUCTION

Buckminsterfullerene  $C_{60}$  was first detected in the time-of-flight mass spectrometer from the product of laser vaporization of graphite<sup>[1]</sup> and later obtained in large quantity from electric arc resistive heating of graphite rods.<sup>[2,3]</sup> The four characteristic peaks in the infrared (IR) spectrum of  $C_{60}$  revealed its truncated icosahedron structure,<sup>[3]</sup> which was further confirmed by nuclear magnetic resonance (NMR) spectroscopy.<sup>[4-6]</sup> Separation and characterization of fullerenes  $C_{70}$ ,<sup>[4,5,7]</sup>  $C_{76}$ ,<sup>[8]</sup>  $C_{78}$ ,<sup>[9-12]</sup>  $C_{82}$ ,<sup>[11]</sup> and those with even higher carbon atom counts followed. High-performance liquid chromatography (HPLC) has proved to be a powerful technique to separate fullerene isomers, while  $^{13}C$  NMR is the method of choice to characterize them.

The cage-like structure of a fullerene consists of 12 five-membered rings and a number of six-membered rings depending on the number of carbon atoms.<sup>[13]</sup> It was postulated that the five-membered rings need to be separated from each other to reduce the localization of the strain caused by the bending of the  $sp^2$ -hybridized carbon atoms. This is the essence of the isolated pentagon rule (IPR),<sup>[13]</sup> which dramatically reduces the possible number of isomers for a given fullerene family. Fig. 1 shows the major isomers of fullerenes  $C_{60}$  to  $C_{84}$ . On the other hand, it is still common that several IPR isomers of a fullerene have same point-group symmetry and have same  $^{13}C$  NMR patterns. For instance, isomers **1**, **5**, **21**, and **22** of fullerene  $C_{84}$  all have  $D_2$  symmetry and give 21 NMR peaks with equal intensity. One of the two major isomers of  $C_{84}$  has  $D_2$  symmetry as observed in experiment, but its structure cannot be determined from the one-dimensional (1-D) NMR spectrum.<sup>[11,12]</sup> Relative energies calculated using quantum mechanics are helpful, but not definitive in determination of the molecular structure. Accurate theoretical chemical shifts predicted by high-level quantum mechanical calculations have been shown to result in unambiguous assignment for those isomers.<sup>[14,15]</sup>

This entry reviews the identification of the fullerene isomers based on theoretical  $^{13}C$  NMR chemical shifts. All the studied isomers have been separated by HPLC

and characterized by NMR spectroscopy, and their NMR chemical shifts are taken from literature. We first briefly review the experimental aspects of the generation, separation, and characterization of fullerene isomers and earlier theoretical attempts to assign these isomers. Subsequently, the predicted NMR spectra for nine isomers of fullerenes  $C_{70}$ ,  $C_{76}$ ,  $C_{78}$ ,  $C_{80}$ , and  $C_{84}$  are compared with experimental data, demonstrating the accuracy of the density functional theory (DFT) calculated chemical shifts and, at the same time, confirming the experimental structural assignment. The discrepancy between experiment and theory in the NMR spectra of the  $D_{5d}$  isomer of fullerene  $C_{80}$  is discussed. Then the predicted NMR spectra for fullerenes  $C_{82}$  to  $C_{90}$  are summarized, and the identification of 11 previously unassigned isomers is achieved for which good experimental spectra are available. The reported results on theoretical NMR chemical shifts for charged and substituted fullerenes are also briefly reviewed. Finally, the relationship between chemical shift and local connectivity, and the energetics of the stable fullerene isomers are discussed.

## EXPERIMENTAL ISSUES

Fullerenes were first detected in the product of laser vaporization of graphite.<sup>[1]</sup> Although this method gave sufficient amounts of fullerenes for mass spectroscopic measurement, it is not suitable to produce samples large enough for separation. Gram-scale samples of fullerenes were obtained by resistive heating,<sup>[2,3]</sup> electric arc discharge,<sup>[16]</sup> and plasma discharge of graphite.<sup>[17]</sup> Fullerenes up to  $C_{108}$  have also been obtained from the condensable material from flat premixed benzene/oxygen/argon flames.<sup>[18,19]</sup> Recently, the rational chemical synthesis of  $C_{60}$  has been achieved by laser irradiation<sup>[20]</sup> of polycyclic aromatic hydrocarbon  $C_{60}H_{30}$  and later in isolable quantities by flash vacuum pyrolysis<sup>[21]</sup> of  $C_{60}H_{27}Cl_3$  at  $1100^\circ C$ . Because no other fullerenes were produced as byproducts, this method raised the possibility of producing fullerenes by target-specific synthesis.

**Fig. 1** The major isomers of fullerenes  $C_{60}$ ,  $C_{70}$ ,  $C_{76}$ ,  $C_{78}$ ,  $C_{80}$ ,  $C_{82}$ , and  $C_{84}$ .

The resulting fullerenes are normally first extracted using various organic solvents, then separated by HPLC. Characterization of the fullerenes includes mass spectrum, UV-Vis, IR, and NMR measurements. Among the characterization techniques, 1-D  $^{13}\text{C}$  NMR spectrum is easily obtained and directly related to the molecular structure, thus commonly used for fullerenes. The  $^3\text{He}$  NMR spectra have also been used to distinguish among isomers as well as to probe the magnetic shielding environment inside the fullerene cavity.<sup>[22,23]</sup> We will focus in this entry on the identification of fullerene isomers based on 1-D NMR spectra.

## EARLIER THEORETICAL ATTEMPTS

Much attention was focused on the energetic aspects of fullerenes, while considerably less effort has been paid to their magnetic properties. The magnetic susceptibility of buckminsterfullerene  $C_{60}$  was studied in the early theoretical studies<sup>[24–26]</sup> before the fullerene samples were obtained. After fullerene samples became available, the prediction of NMR chemical shifts has been an active subject to identify the observed isomers. Fowler and Manolopoulos<sup>[13,27]</sup> presented all mathematically possible structures for fullerenes  $C_{60}$ – $C_{100}$  and compiled the structures for all IPR-abiding isomers. Häser et al.<sup>[28]</sup> used the gauge-independent atomic orbital-coupled perturbed Hartree-Fock (GIAO-CPHF/DZP) method to calculate the chemical shifts of  $C_{60}$  and  $C_{70}$ . In the first attempt to identify the observed  $D_2$  isomer of  $C_{84}$ , Schneider et al.<sup>[29]</sup> calculated the NMR spectra for isomers **5**, **22**, and **23**

(isomer numbering after Fowler and Manolopoulos,<sup>[13]</sup> which will be followed here) using the GIAO-SCF/TZP level of theory. They concluded that isomer **22** was the most likely structure because the spectral span of isomer **5** was much larger than that of the observed isomer and isomer **22** was favored over isomer **21** on energetic grounds. The calculated NMR spectral spans were used to rule out the  $D_2(I_h)$  isomer of  $C_{80}$  as the experimentally observed  $D_2$  isomer.<sup>[30]</sup> Heine et al.<sup>[31]</sup> used the individual gauge for local orbitals-density functional based tight binding (IGLO-DFTB) method to study fullerenes  $C_{70}$ ,  $C_{76}$ ,  $C_{78}$ , five isomers of  $C_{84}$ ,  $(C_{36})_2$ , and  $(C_{60})_2$ . Qualitative agreement with experiment was achieved for the experimentally distinguished isomers, and assignment of the  $D_2$  isomer as **22** was supported. A full survey of the 24 isomers of  $C_{84}$  was later reported.<sup>[32]</sup> The structure of  $C_{70}$  was solved by Hedberg et al.<sup>[33]</sup> in gas-phase electron diffraction experiments with the help of NMR chemical shifts calculated at the GIAO-SCF/TZP level of theory. Accurate chemical shifts of  $C_{60}$  and  $C_{70}$  were calculated using Hartree-Fock (HF) and DFT methods by Bühl et al.<sup>[34]</sup>

## COMPUTATIONAL METHOD

While the relative energies of the fullerene isomers calculated from total electronic energies by various quantum mechanical methods play an important role in determining the structures of the observed isomers, it is not definitive because the observed isomers have to survive the high temperature used in the production process. Direct comparison between accurate theoretical chemical shifts and experimental values is necessary to assign the observed fullerenes as NMR is the commonly used characterization technique and chemical shift directly relates to the chemical environment of the nucleus. In early 1998, it appeared to us that the calculation of NMR chemical shifts for molecules of the size of fullerenes became practical using ab initio or DFT methods with medium basis sets. Because the DFT method<sup>[35]</sup> in the form of B3LYP<sup>[36,37]</sup> hybrid functional had been shown to give better geometries and vibrational frequencies for a wide range of molecules than ab initio HF method, it was tested to predict the NMR chemical shifts of isomers **22** and **23** of fullerene  $C_{84}$ .<sup>[15]</sup> The results were in very good agreement with experimental data and led to the prediction of NMR chemical shifts for other fullerenes and subsequent assignment of their isomers. The calculation of NMR properties of fullerenes has recently been reviewed by Heine.<sup>[38]</sup>

To perform NMR calculations, good geometry is required.<sup>[39]</sup> Starting from model building or downloaded coordinates,<sup>[40]</sup> we first optimized the

geometries using the PM3 semiempirical method.<sup>[41]</sup> Frequency analyses were normally performed at this level to ensure that the structures are indeed minima. The structures corresponding to true minima were further optimized using B3LYP functional<sup>[36,37]</sup> and the STO-3G, 3-21G, and 6-31G\* (or 6-31G for C<sub>86</sub>, C<sub>88</sub>, and C<sub>90</sub>) basis sets. The main purpose of this practice is to save computer time by always starting from the best available geometry; it also gives structures and energy values at the intermediate theoretical levels. Geometry optimizations normally converge after about ten cycles at the B3LYP/STO-3G level and after about four or five cycles with larger basis sets. Because the numbers of IPR isomers for the large fullerenes are very large (46 for C<sub>90</sub>),<sup>[13]</sup> we have limited the calculations using the larger basis sets on the isomers of fullerenes C<sub>86</sub>, C<sub>88</sub> and C<sub>90</sub> that have relative energies less than 25 kcal/mol at the B3LYP/STO-3G level. The default settings for convergence criteria and the default integration grid were used. All geometry optimizations were performed using Gaussian 98 program.<sup>[42]</sup>

The NMR shielding tensors were evaluated employing the GIAO method<sup>[43]</sup> at the geometries optimized at the highest level. The 6-31G\* or 6-31G basis sets were used for all fullerene isomers depending on the basis set used for geometry optimization. A larger 6-311G\*\* basis set was also used for selected isomers. The NMR calculations were carried out using the PQS program.<sup>[44]</sup> The <sup>13</sup>C NMR chemical shifts were obtained by converting the isotropic shielding constant by the following formula:

$$\delta(i) = \delta(C_{60}) + \sigma(C_{60}) - \sigma(i) \quad (1)$$

where the experimental chemical shift of C<sub>60</sub>,  $\delta(C_{60})$ , is taken as 143.15 ppm, after Avent et al.,<sup>[45]</sup>  $\sigma(C_{60})$  is the calculated chemical shielding for C<sub>60</sub>, and  $i$  is the carbon atom under consideration. The experimental chemical shift of C<sub>60</sub> is used as a second reference to correct the systematic error of about 4 ppm in the calculated chemical shifts when only TMS is used as the reference.<sup>[14]</sup>

### VALIDATION OF PREDICTED <sup>13</sup>C NMR CHEMICAL SHIFTS FOR FULLERENES

In this section, we show that the DFT-calculated <sup>13</sup>C NMR chemical shifts for fullerenes agree well with experimental values for the fullerene isomers that can be identified based on the 1-D NMR pattern. It is shown that the spectral span, grouping of the peaks, and the relative positions of the half-intensity peaks with respect to those of full-intensity peaks are important features in comparing theoretical and experimental NMR spectra. An empirical trend emerges to

indicate that the NMR peaks above 140 ppm are better reproduced than peaks below 140 ppm.

### Buckminsterfullerene C<sub>60</sub>

The icosahedral symmetry of fullerene C<sub>60</sub> renders all of its 60 carbon atoms equivalent, giving one signal in the NMR spectrum. The observed chemical shift for C<sub>60</sub> ranges from 142.68<sup>[4]</sup> to 143.2 ppm.<sup>[5,8,10]</sup> The chemical shift predicted at the B3LYP/6-31G\* level is 138.72 ppm.<sup>[14]</sup> This is in very good agreement with experiment, considering that <sup>13</sup>C NMR signal spread over a wide range of 0–200 ppm. The deviation between our prediction and experiment is 3.96 to 4.48 ppm depending on which experimental value is used. This difference is comparable to deviations of earlier theoretical values,<sup>[34]</sup> ranging from ~6 ppm for GIAO-HF to ~1 ppm for GIAO-UDFT-BPW91 methods. Because this deviation is mainly systematic for fullerenes,<sup>[31]</sup> we use the chemical shift of C<sub>60</sub> as a second reference in calculating chemical shifts for other fullerenes.

### Fullerene C<sub>70</sub>

Fullerene C<sub>70</sub> has D<sub>5h</sub> symmetry that gives five different sets of atoms. Five NMR peaks were observed in experiment and assigned to the five sets of atoms based on both 1-D and 2-D NMR measurements.<sup>[4,5,7]</sup> The NMR spectrum of C<sub>70</sub> calculated at the B3LYP/6-31G\* level of theory correctly shows the required two full-intensity peaks and three half-intensity peaks.<sup>[14]</sup> Fig. 2 shows the experimental and predicted NMR spectra for C<sub>70</sub>. The calculated spectral span and the distribution of the peaks are in good agreement with experiment. Similar results were also reported by Bühl et al.<sup>[34]</sup> and Heine et al.<sup>[31,32]</sup> Because all five peaks have been experimentally assigned, the case of C<sub>70</sub>

**Fig. 2** <sup>13</sup>C NMR spectra of C<sub>70</sub> by (i) experiment,<sup>[4]</sup> (ii) experiment,<sup>[10]</sup> and (iii) calculated by B3LYP/6-31G\*. All spectra are referenced to C<sub>60</sub> at 143.15 ppm. Source: From Ref.<sup>[14]</sup>. © 2000 American Chemical Society.

presents a unique example to assess the quality of the predicted chemical shifts. A one-to-one comparison gives 0.70, 0.24, -0.26, 1.09, and 1.32 ppm deviations with respect to the experimental values of Taylor et al.<sup>[4]</sup> Because the chemical shifts are referenced with respect to the experimental value of C<sub>60</sub> at 143.15 ppm and this is the center of the normal spectral span of fullerenes, it is expected that peaks far away from the spectral center have larger deviations than those close to the center. It seems, however, that the peaks below 140 ppm have larger deviations from experimental values than those peaks above 140 ppm. In the case of C<sub>70</sub>, the deviation for the most upfield peak (1.32 ppm) is almost twice that for the most downfield peak (0.70 ppm). This trend becomes clear when we consider more NMR spectra of fullerenes. Therefore we expect a 1–2 ppm overestimation for peaks below 140 ppm and a much better comparison for peaks above 140 ppm.

### Fullerene C<sub>76</sub>

Two IPR structures are possible for fullerene C<sub>76</sub>,<sup>[13]</sup> but only one isomer with D<sub>2</sub> symmetry has closed-shell electronic configuration, thus stable under normal conditions. Experimentally, 19 NMR peaks have been reported with equal intensity.<sup>[8]</sup> The 19 peaks form five groups from downfield to upfield, containing 1, 6, 8, 3, and 1 peaks. These five groups and the spectral span were well reproduced in the predicted NMR spectrum,<sup>[14]</sup> as shown in Fig. 3. Fifteen peaks occurring between 140 and 150 ppm appear to agree with experiment much better than the four peaks below 140 ppm. Overestimations of chemical shifts of as much as 2.22 ppm from experiment were calculated for the four

**Fig. 3** <sup>13</sup>C NMR spectra of C<sub>76</sub>:1 by (i) experiment,<sup>[8]</sup> (ii) experiment,<sup>[10]</sup> (iii) experiment,<sup>[12]</sup> and (iv) calculated by B3LYP/6-31G\*. All spectra are referenced to C<sub>60</sub> at 143.15 ppm. Source: From Ref.<sup>[14]</sup>. © 2000 American Chemical Society.

peaks below 140 ppm. The chemical shifts of C<sub>76</sub> earlier predicted by IGLO-DFTB were able to give a good estimate on the spectral span but failed to show the subtle distribution of the peaks.<sup>[31,32]</sup> A one-to-one assignment of the NMR peaks based on our predicted chemical shifts was not possible because of the crowdedness of the spectrum. It is, however, obvious that the NMR chemical shifts calculated at the B3LYP/6-31G\* level are accurate enough to determine the isomeric structure when good experimental spectrum from isomer-pure sample is available.

### Fullerene C<sub>78</sub>

Three of the five IPR isomers of C<sub>78</sub> have been characterized by NMR spectroscopy.<sup>[9–12]</sup> Isomer **1** (D<sub>3</sub>) has 13 NMR peaks with equal intensity, which can be divided into four groups with 2, 2, 7, and 2 peaks from downfield to upfield. The predicted NMR chemical shifts gave good agreement with experiment in terms of distribution of peaks and spectral span.<sup>[14]</sup> It became obvious from our theoretical result that two NMR peaks occur in the 132–135 ppm region instead of three as reported in Ref.<sup>[10]</sup> The deviations from experiment for the two most downfield peaks, 0.18 and -0.17 ppm, are much smaller than those for the two most upfield peaks, 1.70 and 0.89 ppm, illustrating the much better reproduced chemical shifts for peaks above 140 ppm.

Isomers **2** and **3** both have C<sub>2v</sub> symmetry, but show different NMR patterns: the ratio of full-intensity peaks:half-intensity peaks is 18:3 for isomer **2** and 17:5 for isomer **3**. The spectral spans were well reproduced for these two isomers by our DFT calculations.<sup>[14]</sup> The distribution of the peaks was also in agreement with experiment, thus confirming earlier assignment of the isomeric structures. Also reported were the chemical shifts for isomers **4** and **5** of C<sub>78</sub>, which could facilitate their identification if they are observed.

### Fullerene C<sub>80</sub>

The NMR spectra of six IPR isomers of C<sub>80</sub> predicted by DFT calculations have been reported, including isomers **1–5** and a D<sub>2</sub> distorted form of isomer **7**(I<sub>h</sub>).<sup>[46]</sup> The NMR spectra of isomer **2** (D<sub>2</sub>) show good agreement between theory and experiment.<sup>[30]</sup> At the downfield end, a group of three peaks were well reproduced in the spectra calculated using B3LYP hybrid functional and the 6-31G, 6-31G\*, and 6-311G\*\* basis sets. Sixteen peaks occurring at the middle of the spectrum in the calculated spectra also agree with experiment. One peak at the upfield end tends to be underestimated by large basis set than by medium basis

**Fig. 4**  $^{13}\text{C}$  NMR spectra of  $\text{C}_{80}:1$  by (I) experiment,<sup>[47]</sup> (II) calculated by B3LYP/6-31G\*, (III) by B3LYP/6-311G\*\*, (IV) HF/6-31G\*, and (V) BP86/SVP.<sup>[49]</sup> All spectra are referenced to  $\text{C}_{60}$  at 143.15 ppm.

set. Overall, the distribution for most of the peaks was well reproduced.

The NMR spectrum of another observed isomer,  $\text{C}_{80}:1$ , shows large discrepancy between DFT results<sup>[46]</sup> and experiment,<sup>[47]</sup> as shown in Fig. 4. This isomer has  $D_{5d}$  symmetry, thus shows three full-intensity peaks and two half-intensity peaks. The DFT-predicted spectrum shows that the two half-intensity peaks occur at downfield positions than the full-intensity peaks, which is consistent with experiment. The separation within the four downfield peaks seems to be comparable with that in experiment. However, one full-intensity peak in the DFT results occurs at around 90 ppm, far below the normal NMR ranges for fullerenes. Switching to a gradient-corrected pure functional such as BLYP did not improve the result.<sup>[48]</sup> Furche and Ahlrichs<sup>[49]</sup> also reported similar chemical shifts for the  $D_{5d}$  isomer of  $\text{C}_{80}$  using the BP86 functional.

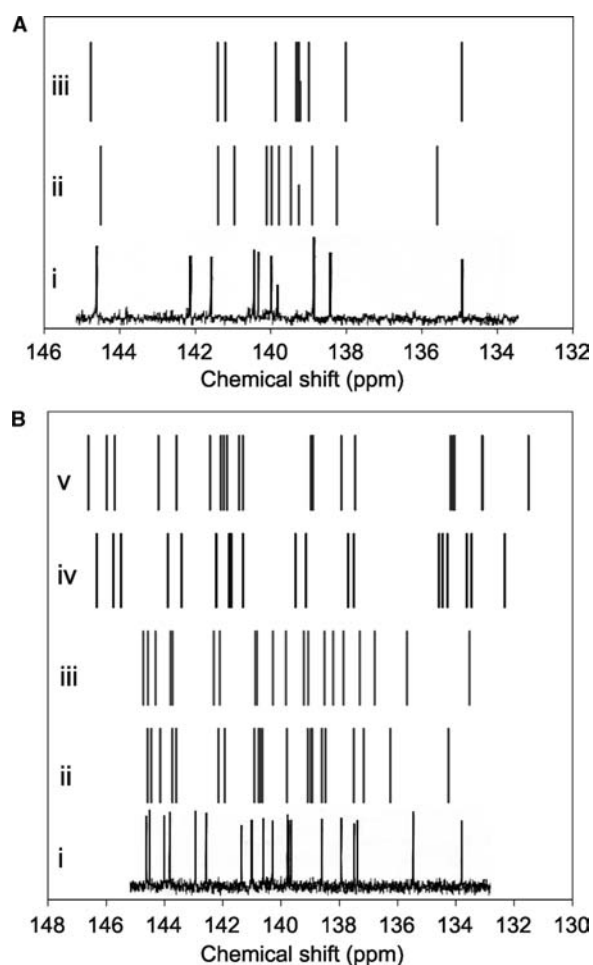

To solve the apparent discrepancy, we have carried out NMR calculations at the HF/6-31G\* level.<sup>[48]</sup> The chemical shifts are all in the 120–155 ppm range that is normal for fullerenes, and the peak positions are in good agreement with experiment. On the energetic aspect, isomer **1** is predicted at the B3LYP/6-31G\* level to be 2.20 kcal/mol less stable than isomer **2**, but its HOMO-LUMO gap is only 0.986 eV, which is much smaller than that of isomer **2** (1.346 eV). At the HF level, its HOMO-LUMO gap is 4.56 eV, still slightly smaller than that (4.97 eV) of isomer **2**, but much larger than those (~3.2 eV) of isomers **3–5**. This shows that the wrong chemical shifts from DFT calculations can be related to the severely underestimated HOMO-LUMO gap.

Isomers **3**, **4**, and **5** have small HOMO-LUMO gaps and high relative energies at both DFT and HF levels.<sup>[46,48]</sup> These isomers also have NMR peaks at

beyond the normal 120–160 ppm range, suggesting that the electron distribution in the molecule is less optimal.

### Fullerene $\text{C}_{84}$ : Two Major Isomers

Two major isomers of  $\text{C}_{84}$  were among the first observed fullerene species<sup>[11,12,50]</sup> and have drawn much research interest. Because isomer **23** ( $D_{2d}$ ) can be uniquely identified by 1-D NMR spectrum among the 24 possible IPR isomers<sup>[13]</sup> and isomer **22** ( $D_2$ ) has been identified by 2-D NMR experiment on the  $^{13}\text{C}$ -enriched sample,<sup>[51]</sup> they represent interesting testing cases for the DFT-calculated chemical shifts.

**Fig. 5** Theoretical and experimental  $^{13}\text{C}$  NMR spectra of  $\text{C}_{84}$ . (A) Spectra of **23**( $D_{2d}$ ) by experiment (i), B3LYP/6-31G\* (ii), and B3LYP/6-311G\*\* (iii). (B) Spectra of **22**( $D_2$ ) by experiment (i), B3LYP/6-31G\* (ii), and B3LYP/6-311G\*\* (iii), and of **21**( $D_2$ ) by B3LYP/6-31G\* (iv), and B3LYP/6-311G\*\* (v). Experimental spectra reproduced from Ref.<sup>[53]</sup>. Source: From Ref.<sup>[15]</sup>. © 2000, The Royal Society of Chemistry and the Centre National de la Recherche Scientifique.

We used density functional theory at the B3LYP level with the 6-31G\* and 6-311G\*\* basis sets to predict the chemical shifts for these two isomers and isomer **21** ( $D_2$ ).<sup>[15]</sup> Isomers **22** and **23** were isoenergetic and both have large HOMO-LUMO gaps. Fig. 5 shows their theoretical NMR spectra in comparison with experiment. Both DFT results for isomer **23** are in very good agreement with experiment in terms of the spectral span and peak positions. The rms deviation calculated for all 11 chemical shifts were 0.464 and 0.556 ppm for 6-31G\* and 6-311G\*\* basis sets, respectively. We note that because one-to-one peak assignment was not possible, the rms deviation will likely be larger when the peaks are assigned. However, the change would be small and thus it would not affect our conclusion. It is evident that the accuracy of the calculated chemical shifts allows identification of isomeric structures of fullerenes.

Earlier calculated NMR results could not unambiguously distinguish between isomers **21** and **22**.<sup>[29,31,32]</sup> Our DFT-calculated chemical shifts, as shown in Fig. 5B, clearly differentiate these two isomers.<sup>[15]</sup> Both spectral span and peak distribution conclusively favor isomer **22** over isomer **21** as the observed species. The rms deviations of chemical shifts between theory and experiment were 1.944 and 0.512 ppm for isomers **21** and **22** at the B3LYP/6-31G\* level, respectively. Essentially same values of rms deviation were obtained from calculations using a larger basis set 6-311G\*\*. Again, we note that, while the rms deviation values will likely change when all NMR peaks are assigned, the conclusion will hold. This assignment was further supported by the large differences in the relative energies (16.04 kcal/mol) and the HOMO-LUMO gaps of isomers **21** and **22**.

## IDENTIFICATION OF FULLERENE ISOMERS BY NMR SPECTRA

As the results for the nine observed isomers of fullerenes  $C_{70}$  to  $C_{84}$  have shown, the DFT-calculated NMR chemical shifts are accurate enough to determine the molecular structures for the observed fullerene isomers. In the mean time, care needs to be taken in the cases where the DFT-calculated HOMO-LUMO gap is too small. In the following section, we summarize theoretical NMR results for fullerenes  $C_{82}$  to  $C_{90}$  and for charged and substituted fullerene species, focusing on the identification of the observed isomers when experimental spectra of good quality are available. The calculated NMR chemical shifts for the isomers that have not been isolated have also been reported in the literature and should facilitate in determining the molecular structures when new isomers are observed.

## Fullerene $C_{82}$

Fullerene  $C_{82}$  poses the first challenge to successively identify an isomer based on theoretical  $^{13}C$  NMR chemical shifts. One major isomer having  $C_2$  symmetry was observed in experiment with some minor isomers whose symmetry could not be determined.<sup>[11]</sup> Of the three  $C_2$  isomers (**1**, **3**, and **5**), isomer **3** was predicted to have the lowest energy and a large HOMO-LUMO gap from our DFT calculations.<sup>[52]</sup> Its predicted chemical shifts compare favorably with experiment, as shown in Fig. 6. The two NMR peaks at the downfield end of the spectrum are well separated from the rest in both theory and experiment. The separation of a group of six peaks at the upfield end from the group at the middle of the spectrum is less obvious in the 6-31G\* results than in the 6-31G results. The spectral spans from theoretical results of both basis sets also show isomer **3** as the observed isomer. Thus the excellent agreement of the NMR spectrum together with the low energy and large gap allowed us to identify the observed  $C_2$  isomer as isomer **3**.

The predicted chemical shifts of isomers **1**, **2**, **4**, and **5** fell in the normal range for fullerenes, whereas the chemical shifts of isomer **6** have values as low as 113.50 ppm.<sup>[52]</sup> Because the four isomers have relatively low energy and large HOMO-LUMO gaps, their observation may be possible and the predicted chemical shifts could facilitate their identification.

## Fullerene $C_{84}$

Nine isomers have been obtained and characterized by NMR spectroscopy.<sup>[11,12,50,53–55]</sup> As discussed above,

**Fig. 6**  $^{13}C$  NMR spectra of  $C_2$  isomers of fullerene  $C_{82}$  for (i) isomer **3** by experiment,<sup>[11]</sup> (ii) isomer **3** calculated by B3LYP/6-31G, (iii) isomer **3** calculated by B3LYP/6-31G\*, (iv) isomer **1** calculated by B3LYP/6-31G\*, and (v) isomer **5** calculated by B3LYP/6-31G\*. All spectra are referenced to  $C_{60}$  at 143.15 ppm. Source: From Ref.<sup>[52]</sup>. © 2001 American Chemical Society.

structures of the two major isomers **22** ( $D_2$ ) and **23** ( $D_{2d}$ ) of fullerene  $C_{84}$  have been assigned,<sup>[15]</sup> and here we look at the minor isomers.

A second  $D_{2d}$  isomer of  $C_{84}$  was observed and assigned as isomer **4** based on the ratio of the full-intensity peaks:half-intensity peaks.<sup>[54]</sup> In our DFT results at the B3LYP/6-31G\* level, isomer **4** has a relative energy of 14.64 kcal/mol and a HOMO-LUMO gap of 2.13 eV.<sup>[56]</sup> The predicted NMR chemical shifts were in good agreement with experiment. Three full-intensity peaks are well separated from each other at the 131–138 ppm region, while the rest of the full-intensity peaks are found at 143–149 ppm. The half-intensity peaks are all above 140 ppm, consistent with experiment.

A second  $D_2$  isomer was tentatively assigned as isomer **5**.<sup>[54]</sup> Its experimental NMR spectrum has a single peak well separated from others at the downfield end and four peaks separated at the upfield end. Our theoretical spectrum of isomer **5** reproduced these features very well, confirming the earlier assignment.<sup>[56]</sup> The calculated spectral span, 21.17 ppm, is in excellent agreement with the measured value (22.10 ppm). Similarly, good agreement was also obtained for the spectral span (15.13 ppm) of the observed  $C_2$  isomer and that of isomer **11** (15.15 ppm), whereas the calculated spectral spans for other  $C_2$  isomer are much larger.

Two  $C_s$  isomers were isolated from graphite soot of DC arc discharge.<sup>[54]</sup> Both isomers have two half-intensity peaks and 41 full-intensity peaks, which suggests that they are isomers **14** and **16** but no final assignment could be reached. The spectral spans are very close, being 15.29 and 15.51 ppm for  $C_s(a)$  and  $C_s(b)$ , respectively, and the full-intensity peaks are very crowded. Because of this, the assignment of these isomers has to be based on the chemical shifts of the half-intensity peaks. The two half-intensity peaks of isomer **14** occur at 132.22 and 148.49 ppm in our B3LYP/6-31G\* results,<sup>[56]</sup> in good agreement with those of  $C_s(b)$  occurring at 134.33 and 148.44 ppm. On the other hand, the two half-intensity peaks of isomer **16** occur at 136.12 and 141.01 ppm, consistent with those of  $C_s(a)$  appearing at 137.03 and 141.76 ppm. Thus isomer  $C_s(a)$  is isomer **16** and isomer  $C_s(b)$  has the structure of isomer **14**.

Two highly symmetric isomers, **19** ( $D_{3d}$ ) and **24** ( $D_{6h}$ ), have also been characterized.<sup>[55]</sup> The predicted general pattern of the six full-intensity peaks of isomer **19** was in agreement with the experiment.<sup>[56]</sup> The two half-intensity peaks appear at 133.85 and 136.86 ppm, which is different from experimental values of 136.39 and 147.81 ppm. Other authors have suggested that the half-intensity peak at downfield region is misassigned.<sup>[32]</sup> This appears to be likely because the measurement was taken from mixture samples. For

isomer **24**, the two full-intensity peaks are in fair agreement between theory and experiment,<sup>[56]</sup> whereas the position of one of the three half-intensity peaks is shown to be misassigned in experiment. Future NMR measurement on isomer-pure samples is highly desirable for these isomers.

### Fullerene $C_{86}$

Two isomers of  $C_{86}$  with  $C_2$  and  $C_s$  point group symmetry have been isolated using the multistage HPLC method.<sup>[57]</sup> Based on earlier energy calculations,<sup>[58]</sup> they were provisionally assigned as isomers **17**( $C_2$ ) and **16**( $C_s$ ), respectively. Our calculated NMR chemical shifts at the B3LYP/6-31G level confirmed this assignment.<sup>[59]</sup> The calculated spectral span, 20.25 ppm, of isomer **17** is in excellent agreement with the experimental value, 20.28 ppm. The other  $C_2$  isomers (**2**, **3**, **4**, **6**, and **14**) all have much larger spectral spans. A single isolated peak at the downfield end, a single isolated peak at the upfield end, and the crowded middle part of the NMR spectrum are well reproduced in our theoretical results for isomer **17**.

Two  $C_s$  IPR isomers, **15** and **16**, have the ratio of full-intensity peaks/half-intensity peaks<sup>[13]</sup> that was observed in experiment. In addition to the low energy and large HOMO-LUMO gap, isomer **16** has a calculated spectral span of 17.73 ppm, in good agreement with experimental value of 17.99 ppm for the  $C_s$  isomer. The distribution of the NMR peaks also supports the experimental assignment.<sup>[59]</sup>

### Fullerene $C_{88}$

Three isomers of  $C_{88}$  were separated and characterized by NMR as  $C_{88-1}(C_s)$ ,  $C_{88-2}(C_2)$ , and  $C_{88-3}(C_2)$ .<sup>[57]</sup> Isomer **17**( $C_s$ ) has the lowest energy and a large HOMO-LUMO gap in our DFT results.<sup>[60]</sup> The chemical shifts of isomer **17** calculated by B3LYP/6-31G have two distinct half-intensity peaks at the downfield end, which is consistent with experimental spectrum. The 42 full-intensity peaks occur within the 130–147 ppm range in theory, comparing well with the experimental range of 131–148 ppm. Similar comparison was also obtained for the 6-31G\* results.

Of the five  $C_2$  isomers studied, isomers **7** and **33** have low energies and have been proposed as the observed isomers.<sup>[57]</sup> All  $C_2$  isomers have 44 NMR peaks with equal intensity. The spectral spans for isomers **7** and **33** are 20.68 and 18.29 ppm,<sup>[60]</sup> respectively, suggesting that they correspond to  $C_{88-2}$  and  $C_{88-3}$ , respectively. Detailed comparison on the peak positions shows that two peaks at the downfield end of the B3LYP/6-31G\*-calculated spectrum of isomer **7** are separated from others, which agrees with the

spectrum of  $C_{88-2}$ . The downfield end of the predicted NMR spectrum of isomer **33** is crowded, in consistency with the spectrum of  $C_{88-3}$ . Thus our DFT results strongly suggest  $C_{88-2}$  as isomer **7** and  $C_{88-3}$  as isomer **33**.

### Fullerene $C_{90}$

Isomer **45**( $C_2$ ) of  $C_{90}$  is the most stable isomer in our DFT results, while isomers **28**( $C_2$ ), **30**( $C_1$ ), **32**( $C_1$ ), **35**( $C_s$ ), **40**( $C_2$ ), and **46**( $C_{2v}$ ) show significant stabilities.<sup>[61]</sup> The chemical shifts for these isomers all occur in the normal range of 125–155 ppm for fullerenes. Isomers of  $C_{90}$  have been observed only in mixture, and this prevents the determination of molecular structures because of the large number of NMR peaks. Five weak experimental NMR peaks were reported in literature, which led to the speculation of the existence of isomer **36**( $C_{2v}$ ).<sup>[62]</sup> Our DFT calculations show that isomer **36** has very high energy, thus unlikely to be the source of the observed weak NMR peaks. A comparison of the predicted chemical shifts suggests that the five weak peaks are more likely from the stable isomers **35** and **46**.<sup>[61]</sup> Future measurements on isomer-pure samples are needed to elucidate the ground-state structures of fullerene  $C_{90}$ .

### Charged and Substituted Fullerenes

Besides the pristine fullerenes, the charged and substituted fullerenes have also been subjected to theoretical

NMR studies using DFT methods, and the NMR chemical shifts calculated at B3LYP/6-31G\* or comparable levels of theory have been used for identification of the fullerene species. The hexa-anions of fullerenes  $C_{76-D_2}$ ,  $C_{78-D_3}$ ,  $C_{78-C_{2v}}$ ,  $C_{84-D_2}$ , and  $C_{84-D_{2d}}$  have been recently obtained from lithium reduction of neutral fullerenes and characterized by NMR spectroscopy.<sup>[63]</sup> DFT-calculated chemical shifts were used to assist the determination of the reduction states of the multiply charged anions. The chemical shifts of the hexa-anions are deshielded comparing to the neutral fullerenes.

The carbocation  $C_{59}N^+$  has recently been obtained from the oxidation of  $(C_{59}N)_2$  by crude hexabromo(*N*-phenyl)carbazole and characterized by MS, X-ray, NMR, UV-Vis, and infrared spectroscopy.<sup>[64]</sup> Theoretical NMR chemical shifts calculated at the B3LYP/6-311G\*\* level are in good agreement with experiment. The majority of the NMR peaks cluster around 144 ppm, showing the overall positive charge of the cation.

The  $^{13}C$  NMR chemical shifts of the proposed aza[60]fullerene  $C_{48}N_{12}$ <sup>[65]</sup> have been recently predicted using DFT method.<sup>[66]</sup> Compared with  $C_{60}$ , most NMR peaks of  $C_{48}N_{12}$  have lower chemical shifts.

### NMR CHEMICAL SHIFTS AND LOCAL GEOMETRY

Nuclear magnetic resonance chemical shifts are determined by the electronic configuration of the molecule and are affected by the local structure close to the

**Fig. 7** Theoretical  $^{13}C$  NMR chemical shifts and POAV angles of isomers **4**, **5**, **11**, **14**, **16**, **19**, and **22–24** of fullerene  $C_{84}$  calculated by B3LYP/6-31G\*. The py-type carbons are represented by squares, the cor type are represented by crosses, and the pc type are represented by circles. *Source:* From Ref.<sup>[56]</sup>. © 2001 American Chemical Society.

atom. Diederich et al.<sup>[8,10]</sup> have suggested that the carbon site in fullerenes be divided into three types: pyracylene (type 1, pc), corannulene (type 2, cor), and pyrene (type 3, py). The chemical shifts should fall in the pc > cor > py order. Heine et al.<sup>[31,32]</sup> plotted the chemical shifts against the  $\pi$ -orbital axis vector (POAV) angle<sup>[67]</sup> and found a marked upward trend of chemical shifts with increasing POAV angle for pc and cor sites but no apparent trend for py sites.

We have also studied the relationship between chemical shift and local geometry in the context of POAV angle.<sup>[14,46,52,56]</sup> The chemical shifts are, in general, larger for type pc than cor, which in turn are larger than py. There is, however, no clear range where each type will occur and the chemical shifts of different types are in fact often mixed. To thoroughly study the relationship between chemical shift and local geometry, we have considered further neighbors of a given atom and arrived at 15 structural motifs.<sup>[56]</sup> Fig. 7 shows the graph of chemical shifts vs. POAV angles for the nine observed isomers of C<sub>84</sub>. Distinct ranges of POAV angles and chemical shifts are seen for each of the five motifs of the py type. Two and three groups of POAV angles are obvious for the cor and pc types, respectively, but the chemical shifts for these sites occur throughout the 130–150 ppm range.

## ENERGETICS OF STABLE FULLERENES

We have been using low relative energy and large HOMO-LUMO gap as indicators of the stability of

**Fig. 8** The relative energy and HOMO-LUMO gap for the isomers of fullerenes C<sub>78</sub> to C<sub>90</sub>. The observed isomers are represented by solid circles.

fullerene isomers. Here we show a statistical graph of the energy and gaps for the observed isomers in Fig. 8. The majority of the observed isomers have relative energies less than 10 kcal/mol at the B3LYP/6-31G\* level. The highest energy of the observed isomers is for C<sub>84</sub>:5 with 15.94 kcal/mol. The HOMO-LUMO gaps for observed isomers are all in the range 1.35–2.34 eV. Note that the gap (0.99 eV) for C<sub>80</sub>:1 is wrong in the DFT calculations. Therefore for a fullerene isomer to be isolable, it should have a low relative energy and large HOMO-LUMO gap.

## CONCLUSION

Theoretical NMR chemical shifts calculated using density functional theory at the B3LYP/6-31G\* level have been shown to be accurate to unambiguously determine the molecular structures of the observed fullerene isomers. For the isomers of fullerenes C<sub>70</sub>, C<sub>76</sub>, C<sub>78</sub>, C<sub>80</sub>, and some isomers of C<sub>84</sub> where the NMR spectral patterns uniquely correspond to the structures, the predicted chemical shifts are in very good agreement with experiment. The spectral spans and the distribution of the NMR peaks are well reproduced for these cases. Comparing the predicted and experimental chemical shifts of isomers **22** and **23** of fullerene C<sub>84</sub>, rms deviations were 0.464 and 0.512 ppm, respectively. The calculated NMR chemical shifts allowed the identification of the previously unassigned fullerene isomers: C<sub>82</sub>:3, C<sub>84</sub>:5, C<sub>84</sub>:11, C<sub>84</sub>:14, C<sub>84</sub>:16, C<sub>84</sub>:22, C<sub>86</sub>:16, C<sub>86</sub>:17, C<sub>88</sub>:7, C<sub>88</sub>:17, and C<sub>88</sub>:33. The calculated NMR chemical shifts also proved necessary in determining the charge status of the charged and substituted fullerene species. The local geometry at the sp<sup>2</sup>-hybridized carbon in fullerenes has been shown to have some effect on the chemical shift, but lack any linear relationship. The observed fullerene isomers all have low energies and large HOMO-LUMO gaps among the set of possible IPR isomers for each fullerene family. Because of the high accuracy of the DFT-calculated chemical shifts, we expect the calculation of NMR chemical shifts to be performed commonly in various areas of chemical research because the computers are becoming faster and the programs capable of calculating chemical shifts are becoming easier to use.

## ACKNOWLEDGMENT

The author thanks Prof. Miklos Kertesz of Georgetown University for continued encouragement and insightful discussions. A Visiting Fellowship Award from the National Cancer Institute at Frederick, NIH to the author is gratefully acknowledged.

# Fullerenes: Magnetic Behavior

T. L. Makarova

Department of Experimental Physics, Institute of Physics, Umeå University, Umeå, Sweden

## Abstract

The discovery of fullerenes opened new possibilities in design and synthesis of new materials, and particularly exciting have been the substances exhibiting different types of collective behavior: superconductivity, ferromagnetism, antiferromagnetism, and spin density wave. This review collects the experimental studies of the following fullerene-based magnets: complexes of fullerenes with organic and organometallic donors; fullerene-containing supramolecular complex substances; rare earth elements intercalated compounds; endohedral fullerenes; polymerized and hydrogenated fullerenes. The ability of polymerized fullerene matrix to act as a magnetic coupling unit between paramagnetic centers is presented. Applications of magnetic fullerenes in nano- and biotechnological areas are briefly described.

## INTRODUCTION

Fullerenes are among the most non-magnetic known substances: they do not exhibit either strong paramagnetism or strong diamagnetism. The foretellers<sup>[1]</sup> and discoverers<sup>[2]</sup> of spherical carbon molecules expected a strong diamagnetic response owing to the ring currents around the cage. It was found, however, that C<sub>60</sub> fullerene exhibits five times smaller magnetic susceptibility than benzene.<sup>[3]</sup> At room temperature, the specific magnetic susceptibility ( $\chi_{1/g}$ ) of the C<sub>60</sub> fullerene is  $\chi_{1/g}(C_{60}) = -0.35 \times 10^{-6} \text{ cm}^3/\text{g}$  and molar susceptibility  $\chi_M(C_{60}) = -252 \times 10^{-6} \text{ cm}^3/\text{mol}$ .<sup>[4]</sup>

There are still debates whether fullerenes can be classified as a novel class of aromatic compounds.<sup>[5]</sup> From the point of view of a physicist, fullerenes possess a three-dimensional delocalized electronic structure, and all 60  $\pi$ -electrons equally contribute to the transport and polarization phenomena. From the chemical point of view, the bond length alternation, high chemical reactivity, and the enthalpy of formation values speak against aromaticity.<sup>[6]</sup> The existence of different types of bonds in fullerenes indicates that there is a partial localization of the  $\pi$ -orbitals. The extensive cyclic delocalization of electrons determines the magnetic properties of fullerenes. Extremely small diamagnetism of fullerenes arises from the cancellation effect between paramagnetic currents around the pentagons and diamagnetic ring currents around the hexagons.<sup>[7]</sup> Ring currents induced by the presence of an external magnetic field have been investigated in polymerized fullerenes. Extremely large ring currents are obtained in polymerized molecules with a particular number of molecules in a polymerized pattern.<sup>[8]</sup>

During the storage of fullerene in air, the magnetic properties change: a noticeable increase in paramagnetic term at low-temperature appears. This paramagnetic Curie-term is usually explained by the absorption

of oxygen, but recent experiments have shown that the paramagnetic properties of an O<sub>2</sub> molecule disappear when oxygen is incorporated into the fullerene lattice, and the paramagnetic term arises from the low-temperature chemical interaction of oxygen with fullerene.<sup>[9]</sup> The source of the paramagnetic response could be stable defects, such as a C<sub>60</sub><sup>+</sup> or C<sub>60</sub><sup>-</sup> ions observed in many EPR experiments. Addition of charge drastically changes the magnetic properties of fullerenes, and they demonstrate different types of collective behavior: superconductivity, ferromagnetism, antiferromagnetism, and spin density wave.

## MAGNETISM OF FULLERENE CHARGE-TRANSFER COMPLEXES

The studies of the reduction of fullerene C<sub>60</sub> with strong organic donors has led to the discovery of the compound tetrakis(dimethylamino) ethylene-C<sub>60</sub> (TDAE-C<sub>60</sub>), which showed a ferromagnetic transition at a temperature of 16 K, thus demonstrating that high-temperature  $\pi$ -electron magnetism is a reality.<sup>[10]</sup> The discovery of ferromagnetic transition in TDAE-C<sub>60</sub> appeared to be the first fact that disproved the opinion that strong magnetism is a property of elements with d and f electrons. Later, magnetic transitions were discovered in (NH<sub>3</sub>) K<sub>3</sub>C<sub>60</sub> antiferromagnet, and the AC<sub>60</sub> and Na<sub>2</sub>AC<sub>60</sub> (A = K, Rb, Cs) polymers (reviewed in Ref.<sup>[11]</sup>).

Tetrakis(dimethylamino) ethylene-C<sub>60</sub> behaves as a soft ferromagnet with a very small coercive force and remnant magnetization (2 Oe and  $M_r \sim 3 \times 10^{-4} \text{ emu/g}$  correspondingly).<sup>[12]</sup> The ultimate proof for the ferromagnetism of this compound came from the  $\mu\text{SR}$  experiments,<sup>[13]</sup> which showed the presence of an internal field, and also demonstrated strong inhomogeneity of

the field. The samples exhibited strange aging effects: ferromagnetism increased during the sample storage. The reason for both inhomogeneity and aging was understood later: it was shown experimentally and theoretically<sup>[14]</sup> that a direct connection exists between the orientation of C<sub>60</sub> molecules and the magnetic interactions in the system. In the as-prepared polycrystalline samples, the molecules were randomly oriented, and thus the system simultaneously exhibited the properties of both soft ferromagnet and a spin glass. The orientational dependence of fullerene magnetism was clarified by the experiments on single crystals. It was shown that this compound has two modifications: ferromagnetic  $\alpha$ -TDAE-C<sub>60</sub> and paramagnetic  $\alpha'$ -TDAE-C<sub>60</sub> modification. The  $\alpha'$  modification is metastable and transforms into the stable  $\alpha$  modification by thermal treatment. Thus, the riddle of the coexistence of the long-range ferromagnetic order and the short-range spin-glass disorder was resolved.

The microscopic understanding of TDAE-C<sub>60</sub> magnetism started from the fact that this compound appears in two modifications. The difference between  $\alpha'$  and  $\alpha$ -TDAE-C<sub>60</sub> is in relative rotation of C<sub>60</sub> molecules around their threefold axis.<sup>[15]</sup> Thus, it was shown that the magnetic properties of the compound are dictated by the relative orientation of the fullerene molecules. Magnetic resonance data provided evidence for the correlation between spin and orientational ordering of Jahn–Teller-distorted C<sub>60</sub> ions.<sup>[16]</sup>

The discovery of ferromagnetism in TDAE-C<sub>60</sub> initiated the works in the following directions: (i) reduction of higher fullerenes with TDAE; (ii) reduction of C<sub>60</sub> with other strong donors; (iii) producing C<sub>60</sub>-containing supramolecular complex substances; (iv) combining C<sub>60</sub> with rare earth elements.

## REDUCTION OF HIGHER FULLERENES WITH TDAE

Until now, the role of TDAE in the magnetism is not quite clear because the TDAE<sup>+</sup> spins are mutually cancelled in both  $\alpha'$  and  $\alpha$ -TDAE-C<sub>60</sub>. The attempts to create a ferromagnet from higher fullerenes reduced with TDAE were unsuccessful: C<sub>70</sub>, C<sub>84</sub>, C<sub>90</sub>, and C<sub>96</sub> readily form the charge-transfer complexes with TDAE,<sup>[17]</sup> but ferromagnetism was never observed. Moreover, the experiment with the molecular alloys TDAE-(C<sub>60</sub>)<sub>1-x</sub>(C<sub>70</sub>)<sub>x</sub> showed that the magnetic properties of the alloys were monotonically changing from ferromagnetic TDAE-C<sub>60</sub> to paramagnetic TDAE-C<sub>70</sub>. The Curie temperature  $T_c$  also linearly decreased with the increase in C<sub>70</sub> content. These experiments confirmed once more that it is C<sub>60</sub> rather than TDAE, which plays the role of magnetic unit in this ferromagnetic organic compound. Fullerene

C<sub>60</sub> doped with a strong organic donor TDAE is the only fullerene that shows bulk ferromagnetism.

## REDUCTION OF C<sub>60</sub> WITH ORGANIC OR ORGANOMETALLIC DONORS

The number of organic and organometallic donors that are able to ionize the fullerene molecules is limited.<sup>[18]</sup> metallocenes, porphyrines, and unsaturated amines, the most known representative of the latter is the above-mentioned TDAE.

There were attempts to combine C<sub>60</sub> with other organic or organometallic donors to form charge-transfer (CT) salts. Other amines similar to tertiary amine TDAE did not produce magnetic substances. For example, tertiary amine diazobicyclononene (DBN) and diazobicycloundecene (DBU) formed covalent bonds with C<sub>60</sub>, and therefore, only a few percent of spins survived. Nevertheless, in the case of DBU-C<sub>60</sub>, these residual spins showed a short-range magnetic order below 70 K.<sup>[19]</sup>

It was reported that the CT complexes with metallocenes: decamethylferrocene (Cp<sub>2</sub><sup>+</sup>Fe), cobaltocene (Cp<sub>2</sub>Co), and nickelocene (Cp<sub>2</sub>Ni) showed ferromagnetic characteristics,<sup>[20,21]</sup> but the synthesis and magnetic properties of charge-transfer complexes of C<sub>60</sub> with the metallocenes were not reproducible.

The next attempt to create fullerene-based magnets was functionalizing of C<sub>60</sub> and subsequent combining with organic or organometallic donors to form charge-transfer complexes. The first compound of this type, dinitro-spiromethanofullerene (C<sub>61</sub>“NO<sub>2</sub>”) doped with bicyclopentadiene cobalt (Cp<sub>2</sub>Co or cobaltocene) showed the ferromagnetic transition at 8 K.<sup>[22]</sup> Another cobaltocene C<sub>60</sub> derivative, 1-(3-aminophenyl)-1H-methanofullerene[C<sub>60</sub>], became magnetic below 19 K, and this temperature was higher than for TDAE-C<sub>60</sub>.<sup>[23]</sup> These studies contributed to the understanding of ferromagnetism in TDAE-C<sub>60</sub>, where the role of TDAE remained unknown. In the cobaltocene derivatives, the cobaltocene is present in its oxidized state Cp<sub>2</sub>Co<sup>+</sup>. It has spin  $S = 0$  and does not contribute to the magnetic signal. Magnetic ordering in the fullerene ferromagnets is established by the  $S = 1/2$  on fullerene moieties.

## IONIC MULTI-COMPONENT COMPLEXES

A novel approach for ionizing the C<sub>60</sub> molecule has been suggested.<sup>[24]</sup> This method produces ionic multi-component complexes, which consist of a charged fullerene and two donors, D1 and D2. The first donor D1 forms a supramolecular packing pattern and the second donor D2 ionizes the fullerene molecule.

The method was used for obtaining porphyrin-based and TDAE-based complexes, as well as tetrabenzylphenylenediamine (TBPDA) complexes.<sup>[25]</sup>

An example of this approach is shown in the work<sup>[26]</sup> in which the donors D2 in different spin states (0,  $1/2$ ,  $3/2$ ) were considered. A neutral part of these complexes, i.e. D1 is TBPDA. For the role of the second donor D2, several donors were chosen: 1) decamethylchromocene ( $\text{Cp}^*_2\text{Cr}$ ) with the spin  $3/2$ ; 2) decamethylcobaltocene ( $\text{Cp}^*_2\text{Co}$ ), which is diamagnetic ( $s = 0$ ); 3) TDAE with  $s = 1/2$ . In the case of a diamagnetic donor, the EPR signal was attributed to  $\text{C}_{60}^{\bullet-}$  ( $\text{Cp}^*_2\text{Co}^+$  is diamagnetic), whereas for the paramagnetic donors, the EPR line demonstrates a resonating signal between  $\text{C}_{60}^{\bullet-}$  and the cation owing to indirect coupling. The EPR signals from cobaltocene-complex and TDAE-complex are split into two components below 50 and 60 K. The magnetic moments of all three compounds decrease below 50–100 K. Both effects are associated with the formation of field-induced short-range antiferromagnetically ordered clusters. For all compounds, it was shown that D1 cations do not noticeably affect the antiferromagnetic interaction of spins due to their isolation by the benzyl groups of TBPDA. Large distances between the fullerenes is a reason for relatively weak antiferromagnetic interactions between the spins residing on  $\text{C}_{60}$ .

### INTERCALATION OF MAGNETIC IONS

The tetrahedral and octahedral voids of the  $\text{C}_{60}$  lattice are able to incorporate foreign atoms. Intercalation of alkali metals into  $\text{C}_{60}$  crystal leads to superconductivity, and it was expected that intercalation of rare earth ions like europium and cerium will produce novel magnetic substances. Europium has a magnetic moment of  $7\mu_B$  in the divalent state, while it is non-magnetic in the trivalent state. In a fulleride  $\text{Eu}_6\text{C}_{60}$ , europium ions are in the divalent state and they order ferromagnetically below 12 K. Below  $T_c$ , this compound shows giant magnetoresistance.<sup>[27]</sup> Substitution of Eu with non-magnetic Sr ions in  $\text{Eu}_{6-x}\text{Sr}_x\text{C}_{60}$  ( $x = 1-5$ ) has not influenced the transition temperature,  $T_c$ . In addition,  $\text{Eu}_6\text{C}_{60}$  showed a huge negative magnetoresistance at and below  $T_c$ . Evidently, there exists a strong interaction between conduction carriers and localized magnetic moments, namely, the strong  $\pi$ - $f$  interaction in  $\text{Eu}_6\text{C}_{60}$ . This fact indicates that the ferromagnetism in  $\text{Eu}_6\text{C}_{60}$  comes from the indirect exchange interaction via  $\text{C}_{60}$  molecules, which is quite in contrast with the case of magnetic semiconductor  $\text{EuO}$ .

Magnetic properties of the cerium-intercalated compounds are complicated: the competition of superconductivity and ferromagnetism has been observed.<sup>[28]</sup> This compound exhibits the superconducting behavior

with the transition temperature 13.5 K. However, very weak magnetic field (2 Oe) destroys superconductivity, and this compound shows a transition to ferromagnetic ground state at 15 K. Superconductivity is suggested to be a property of the doped  $\text{C}_{60}$  subsystem, whereas ferromagnetism is ascribed to the superexchange interactions between  $\text{Ce}^+$  ions.

Intercalation of  $\text{C}_{70}$  with europium affords two kinds of magnetic compounds, a canted antiferromagnet  $\text{Eu}_x\text{C}_{70}$  ( $x$  approximates 3) and a ferromagnet  $\text{Eu}_x\text{C}_{70}$  ( $x$  approximates 9) with transition temperatures of 5 and 38 K, respectively.<sup>[29]</sup>

### HIGH-TEMPERATURE FERROMAGNETISM IN FULLERENE COMPOUNDS

Ferromagnetism in  $\text{C}_{60}$ -containing macromolecular polymer was first reported in 1994<sup>[30]</sup> and magnetism has been ascribed to the radical adducts represented as  $\text{C}_{60}\text{R}_n$  ( $\text{R} = \text{H}, \text{F}, \text{CF}_3$ ), where  $n$  is odd. The films were produced by ultrasonic dispersion of  $\text{C}_{60}$  in dimethylformamide solution of polyvinylidene fluoride and subsequent vacuum evaporation of the solution. The Curie point and magnetization were 370 K and 0.210 emu/g. The contamination with Fe, Mn, Cr, Co, and Ni were less than 0.001, 0.0005, 0.001, 0.002, and 0.005 wt.%, respectively, and it could not account for the observed magnetization.

Room-temperature ferromagnetism in fullerene hydride  $\text{C}_{60}\text{H}_{36}$  has been reported with  $M_s = 0.04 \text{ emu/g}$ <sup>[31]</sup> and in  $\text{C}_{60}\text{H}_{24}$  with  $M_s = 0.046, 0.054,$  and  $0.16 \mu_B/\text{C}_{60}$  (i.e.  $1.2 \text{ emu/g}$ ).<sup>[32]</sup> Measured by the atomic-emission analysis, the concentration of all detected metals in the sample with the highest magnetization of  $0.16 \mu_B/\text{C}_{60}$  was the following: Fe: 0.01; Ni: 0.002; Pd: 0.01; Al: 0.05; Cu: 0.1 (wt.%). Seeing that the magnetization due to the metallic impurities could be only on the level of a few percents from the observed value, the magnetic ordering is an intrinsic property of hydrofullerites. A circumstantial evidence of the intrinsic nature of ferromagnetism is aging: one-year storage brings the samples to a diamagnetic state.

Room-temperature ferromagnetism of fullerenes photopolymerized in the presence of oxygen was first reported in 1996.<sup>[33]</sup> Polymerized fullerene is a specific form of pure carbon in which spheroidal carbon molecules are connected by covalent bonds. The samples of commercial  $\text{C}_{60}$  powder were exposed to oxygen under the action of strong visible light. This process leads to photo-induced polymerization of  $\text{C}_{60}$  units within a surface layer of the crystallites. The thickness of the photo-transformed layer is controlled by the light penetration depth and is of the order of  $0.5 \mu\text{m}$ . The saturation value for the partially polymerized sample was only

$1.4 \times 10^{-2}$  emu/g corresponding to  $0.001 \mu_B/C_{60}$ . However, the residue of the solution in toluene, i.e., a photo-polymerized part of the sample, exhibited a hundred times larger magnetization corresponding to  $0.1 \mu_B/C_{60}$ .

Another group<sup>[34]</sup> verified the existence of a ferromagnetic phase in fullerene photopolymers by three methods: SQUID measurements, ferromagnetic resonance, and low-field non-resonance derivative EPR signal. The room temperature value of saturation magnetization for photolyzed  $C_{60}$  is 0.04 emu/g. The experiments were conducted in a chamber with flowing oxygen, which excludes any possibility of penetration of metallic particles during the experiment. The impurity concentration was measured by means of inductively coupled plasma, which indicated that the signals from all metals were below 100 parts per  $10^9$ ; independent analysis by the plasma-induced atomic absorption spectroscopy confirmed the iron level to be a few parts per  $10^9$ .

In a number of papers,<sup>[35,36]</sup> magnetism of fullerenes polymerized by high-temperature-high-pressure treatment has been reported. A systematic study of synthesis conditions for the production of the ferromagnetic phase<sup>[35]</sup> showed that the phase is formed in the vicinity of fullerene collapse. Gradual transformation of polymerized fullerenes from a paramagnetic through a ferromagnetic (with magnetic moment  $0.34 \mu_B$  per  $C_{60}$  molecule) to a diamagnetic state, as a function of preparation temperature, was monitored.<sup>[35]</sup>

However, studies performed after the first publication revealed considerable (174 ppm) iron content measured locally by the PIXE on some parts of the surface of samples reported in Ref.<sup>[34]</sup>. These findings are described in detail in Refs.<sup>[37,38]</sup>. Later part of the authors retracted from this paper because the Curie temperature of about 500 K is close to that of iron carbide,  $Fe_3C$ .<sup>[39]</sup> Anyway, the  $Fe_3C$  scenario of Ref.<sup>[40]</sup> cannot give the universal interpretation of the literature data such as the trend in the synthesis condition, influence of heat treatment on magnetic behavior, and the observation of the magnetism up to 800 K both in pressure-polymerized and photo-polymerized fullerenes. The temperature stability of magnetic fullerenes exceeds the depolymerization temperature for polymeric phase, and a theoretical approach to give explanation to this fact is developed in Ref.<sup>[40]</sup>. In all described cases, the authors note that the samples do not demonstrate bulk ferromagnetism, but instead contain islands of magnetic phase in a non-magnetic matrix.

## FULLERENES AS A MAGNETIC COUPLING UNIT

Several scenarios that account for (or predict) the magnetism of fullerenes have been suggested. In the models

of ferromagnetic fullerenes, the following possibilities are considered: (i) a fraction of the fullerene cages are broken, and, thus, unpaired electrons appear at the dangling bonds; (ii) the shape of the fullerene cage changes as a result of Stone–Wales transformations; and (iii) fullerenes remain intact, but unpaired electrons are formed at interfullerene links. In an alternative approach (iv), a high-spin ground state of fullerene polymer is considered.

Theoretically, the ability of  $C_{60}$ -fullerene to act as a magnetic coupling unit between radical centers has been evaluated using ab initio method. The results indicate that functionalized  $C_{60}$ -fullerenes have a very good potential to couple radical centers. Depending on the relative position of the two radical centers, the resulting interaction is ferro- or antiferromagnetic.<sup>[41,42]</sup>

A scenario in which structural defects (vacancies) and  $sp^3$ -hybridized atoms interact is described in a series of works.<sup>[43,44]</sup> A correlation should exist between spin moments for magnetic ordering to appear. Since the defects are widely spaced, interaction between them is indirect and needs a mediator. The dipole moment induced by a vacancy can play the role of such a mediator. The Coulomb interaction between localized charges and electric dipoles ensures a means for the exchange interaction between magnetic moments.

Long-range spin coupling has been considered through the investigation of an infinite, periodic system of polymerized  $C_{60}$  network.<sup>[45]</sup> It was shown that chemically bonded hydrogen plays a vital role, providing a necessary pathway for the ferromagnetic coupling of the considered defect structure.<sup>[46]</sup>

A model of fullerene ferromagnetism, which does not require ad hoc constructed defects, has been suggested.<sup>[47]</sup> In this model, the presence of some paramagnetic impurities in fullerene matrix (e.g. hydrogen, fluorine, as well as carbon from partially destroyed fullerenes) leads to a formation of the paramagnetic fullerene ions  $C_{60}^\pm$  as a result of the reaction with charge and spin transfer. Paradoxically, this is an impurity-based model, and at the same time this model is based on intrinsic properties of fullerene matrix. Paramagnetic impurities play only the passive role of net charges and spin sources. According to this model, diamagnetic  $C_{60}$  molecules transform into stable paramagnetic species ( $C_{60}^\pm$  ions or fullerene radical adducts  $C_{60}R$ ) and become magnetically active due to the charge and spin transfer from dopants. Whether the electron comes from a donor to a  $C_{60}$  or goes from  $C_{60}$  to an acceptor, its spin is transferred to the fullerene in any case being well localized at the lattice site. The model is supported by ab initio calculations, the main result of which is that in the  $[2 + 2]$ -cycloadduct polymerized phase, the effective exchange interaction between the paramagnetic fullerene ions is ferromagnetic, strong, and of long range. The coupling between paramagnetic species

**Fig. 1** The charge (A) and spin (B) density spatial distribution in the triplet spin state of the tetragonally polymerized fullerene  $C_{60}$  doped with hydrogen.

(nearest neighbours and next nearest neighbours) in polymerized fullerene matrix is examined, and it is shown that exchange integral is of the order of several tenths of an electronvolt.<sup>[53]</sup> Figure 1 illustrates this model for the case of tetragonally polymerized fullerene and for the case when the spins are situated at the next nearest neighbors (rather than the nearest neighbors). Figure 1A shows the Mulliken charge distribution, and Fig. 1B depicts the spin distribution.

Remarkably, the spin density is zero on the bonds bridging the molecules, so that one can assign a spin to each of the doped buckyballs. Thus, the spin of an individual charged molecule is well defined, and  $C_{60}$  molecules play the role of the sites on which spins reside. The ab initio calculations for this pattern give large positive splitting between the triplet and singlet ground states, and its value  $E_{\uparrow\uparrow} - E_{\downarrow\downarrow} = 0.68$  eV is enough to account for the high-temperature ferromagnetism.

Analysis of various experimental data, including pure organic ferromagnetic substance TDAE- $C_{60}$ , antiferromagnetic ground states encountered in various alkali or lanthanide fulleride salts,  $\pi$ - $f$  interactions through  $C_{60}$  in metal-intercalated fullerenes, magnetism of polymeric networks, and other experimental examples show that in many cases, fullerene  $C_{60}$  works either as a magnetic unit, or a magnetic coupling unit.

## FULLERENES IN MAGNETIC RESONANCE IMAGING

One of the main reasons for studying the magnetic properties of fullerenes is the perspective applications in medicine, as carbon is a biocompatible element. At present, progress is made for the Gd-based water-soluble metallofullerenes. They are regarded as a possible new generation of magnetic resonance imaging (MRI) contrast agents, sensibilizers for the photodynamic therapy of tumors. Their proton relaxivities are greater than those of commercially available MRI contrast agents, but the

main advantage is that they offer a safe alternative to the existing substances. Toxic gadolinium is isolated from the tissues by the carbon cages. For these purposes, water-soluble Gd-based endohedral metallofullerenes ( $Gd@C_{82}(OH)_x$ ,  $Gd@C_{60}(OH)_x$ , and  $Gd@C_{60}[C-(COOH)_{10}]$ ) have been extensively studied.<sup>[48]</sup> Other water-soluble multi-hydroxyl lanthanoid (La, Ce, Gd, Dy, and Er) endohedral metallofullerenes [metallofullerenols,  $M@C-82(OH)(n)$ ] have been synthesized and characterized for the use of MRI contrast agents<sup>[49]</sup> or an X-ray contrast material.<sup>[50]</sup>

A novel photosensitizer with magnetic resonance imaging activity was designed from fullerene ( $C_{60}$ ) for efficient photodynamic therapy of tumor.<sup>[51]</sup> Gadolinium-based compound  $C_{60}$ -PEG-Gd (where PEG is polyethylene glycol) maintained an enhanced MRI signal at the tumor tissue. Injection of  $C_{60}$ -PEG-Gd plus light irradiation showed significant tumor PDT effect, which depended on the timing of light irradiation. Trimetallic nitride endohedral metallofullerene  $Gd_3N@C-80$ <sup>[52]</sup> showed MR imaging relaxivity markedly higher than that for commercial agents (e.g., gadodiamide). The use of functionalized  $Gd_3N@C-80$  at concentrations an order of magnitude lower resulted in equivalent visualization in comparison with commercial agents.

Paramagnetic  $Gd@C_{82}$  fullereneol was tested as a contrast agent.<sup>[53]</sup> Cellular labeling with  $Gd@C_{82}$  is feasible and can produce T1-enhanced cells on magnetic resonance imaging. This study suggests that further investigation of Gd fullereneols for tracking studies of viable cells, including stem cells, is warranted. Thus, fullerenes bring to medicine a new type of magnetic agents, which are water-soluble and non-toxic.

## FULLERENE-BASED QUANTUM COMPUTER

Recently, an interest in the magnetic properties of endohedral fullerenes was renewed when a concept for a spin quantum computer based on the endohedral fullerenes has been proposed.<sup>[54,55]</sup> This computer uses the electron spin of a doped atom, i.e., nitrogen or phosphorus, caged in a fullerene. The carbon cage protects the spin and keeps it in the symmetrical environment; hence, the spin system is highly shielded from the environment. Combined electron and nuclear spin pseudo-entangled states can be prepared in the multi-level quantum system of a nitrogen atom with electron spin  $3/2$  and nuclear spin  $1/2$  encaged in the endohedral fullerene.<sup>[56]</sup>

Two types of endohedral fullerenes are considered as building blocks for the quantum computer,  $^{15}N@C_{60}$  and  $^{31}P@C_{60}$ . In these fullerenes, the nuclear spin of the encapsulated atom is a spin  $1/2$ . It is coupled to three uncoupled electrons located in the

**Fig. 2** Graphical visualization of the solid-state spin quantum computer based on endohedral fullerenes. *Source:* Adapted from Ref.<sup>[60]</sup>.

highest energy level of the encapsulated atom. In a system of aligned fullerenes, the two neighboring spin sites communicate via electronic coupling. The entire system is exposed to a static and homogeneous magnetic field, and the interaction with this field induces a Zeeman splitting in the nuclei and electrons, which can be measured by the resonance techniques.

This approach has real promises to become a reality because the state-of-the-art technology is able to provide the necessary components and processes: (i) fullerene technology including the endohedral ones is mature; (ii) manipulation of fullerene molecules is fairly easy; (iii) writing and reading procedures are performed via pulsed electron-spin resonance; (iv) addressing is provided by local magnetic fields or field gradients; (v) the qubit–qubit interaction is mediated by magnetic dipolar coupling and can be controlled via the direction of the magnetic field with respect to the distance vector of the qubits. Figure 2 illustrates the computer design.

Many experimental and theoretical efforts were made to create a technology based on endohedral fullerenes.<sup>[57]</sup> In one of the projects, the construction of the quantum computer requires linear chains of endohedral fullerenes, which can be achieved by embedding them in a liquid crystal matrix.<sup>[58]</sup> The readout of a qubit in fullerene-based quantum computing can be made using the scanning tunneling microscope.<sup>[59]</sup> A scheme was proposed to implement the two-qubit gates and to compose a universal set of quantum gates in fullerene-based quantum computation.<sup>[60]</sup>

## CONCLUSIONS

Fullerenes in their pristine and polymerized form are diamagnetic substances. Doped with donors, they exhibit different types of magnetic behavior, including

soft ferromagnetism, antiferromagnetism, spin density wave, and superconductivity. In all cases, fullerenes play an active role in the establishment of the collective behavior. In the charge-transfer salts, the ferromagnetic or antiferromagnetic ordering is established by the  $S = 1/2$  on fullerene moieties. In the metal-intercalated fullerenes, superconductivity arises due to the doped  $C_{60}$  subsystem, whereas ferromagnetism is due to the superexchange interactions between metallic ions mediated by the  $C_{60}$  molecules. There have been reports about high-temperature ferromagnetism in polymerized and hydrogenated fullerenes and some charge-transfer salts, but these samples do not demonstrate bulk ferromagnetism, and instead contain islands of magnetic phase in a non-magnetic matrix, which complicates the identification of the magnetic unit. These reports initiated a large number of theoretical investigations, which showed that intrinsic high-temperature magnetism of fullerenes is a feasible possibility.

It is difficult to expect practical applications for the superconducting fullerenes, because they are unstable in air, or for magnetic charge-transfer salts, which have low transition temperatures. Magnetic properties of fullerenes have recently found an unexpected usage as the basic module for quantum computers. It is expected that fullerenes will be applied in diverse fields varying from nano- to biotechnological areas, to magnetic resonance imaging, photodynamic therapy of tumors, drug delivery for the treatment of brain tumors, and quantum computing.
