## INTRODUCTION

Optical methods continue to surprise us. The Abbé limit, of approximately  $\lambda/2$ , was once thought to be an insurmountable barrier to their exploitation, but the ingenuity of physicists continues to confound this unduly pessimistic outlook. There are currently a number of tools, including near-field,<sup>[1]</sup> two-photon,<sup>[2]</sup> fluorescence-based,<sup>[3]</sup> and plasmonic techniques<sup>[4]</sup> that all offer subdiffraction limit spatial resolution. Moreover, while the end of photolithography has been forecast for about two decades, the semiconductor device industry remains firmly wedded to it as its primary manufacturing tool, and electronic engineers have been very creative in adapting it to facilitate the onward progress of their industry along the path charted by Moore's Law. However, at the very smallest length scale, electron beam lithography has continued to be seen as the gold standard fabrication tool. While electron beam methods are serial ones and do not readily translate into a manufacturing environment, they have been thought to offer a degree of resolution beyond the reach of photolithography.

Here we review new work that suggests this view is incorrect. By using scanning near-field photolithography (SNP), it is possible to generate structures in organic monolayers that are comparably small to anything fabricated by electron beam lithography. Importantly, however, these approaches, based on the excitation of photochemical reactions, are capable of being implemented under ambient conditions or even under fluid. Although such near-field lithographic tools are in their infancy, they offer exciting prospects for use in lithography at extremely small length scales, along with a capability to manipulate biomolecular and organic molecular systems that are inaccessible to electron beam methods. Combined with multiplexing, they may, given their lower cost, offer much greater potential for commercial exploitation than has ever been the case for electron beam lithography, and they may prove a valuable tool in the drive toward highly miniaturized molecular devices and materials.

## NEAR-FIELD SCANNING OPTICAL MICROSCOPY

In surface microscopy, near-field scanning optical microscopy (NSOM, also known as scanning near-field optical microscopy, or SNOM) has provided access to nanometer-scale optical characterization. The original concept for NSOM was developed by Synge, early in the 20th century. His ideas revolved around the use of small optical apertures to characterize materials. Ordinarily, when light is passed through an optical aperture smaller than the Abbé limit, it undergoes diffraction, imposing a lower limit on resolution (also called the diffraction limit). Synge proposed that an optical aperture could be used for subdiffraction limit imaging provided it was brought adequately close to a solid surface.<sup>[5–7]</sup> Under such conditions, illumination occurs in the near field, effectively meaning that light from the aperture interacts with the sample before diffraction can occur (Fig. 1). Although the underlying concept was very simple, its realization in practice was much more challenging, because for it to be effective, the separation between the aperture and the sample must be very small indeed (nm distances) and must be maintained within a very small range of tolerance during the course of the whole experiment. The empirical corroboration for Synge's ideas was eventually provided in 1972 by Ash and Nichols,<sup>[8]</sup> who achieved a resolution of  $\lambda/60$  with 3 cm microwaves. Although this result was impressive, it represented, at that wavelength, a resolution that was still a macroscopic distance.

A significant leap forward was made by Betzig and Trautman in 1992. They used an optical fiber, drawn to a narrow apex and coated with a metal film to constrain the electric field, to image samples.<sup>[9]</sup> They claimed that a resolution of 12 nm was feasible, but only after deconvolution of the probe geometry. This spatial resolution has unfortunately not been widely reproduced. While subdiffraction-limit imaging is feasible, and a variety of types of characterization are possible,<sup>[10]</sup> fiber-based approaches have generally proved difficult to implement. Generally speaking, the best resolution achieved has been approximately equal to the probe aperture, typically ca 50 nm, and usually, the

**Fig. 1** By bringing a surface close to a small aperture, it is possible for light to emerge from the aperture without undergoing diffraction.

resolution has been poorer than this—often significantly so. One of the problems of fiber-based methods is that the reproducible preparation of small apertures with high transmissions is difficult.

Recently, there has been a growing interest in the use of what are termed “apertureless” NSOM methods. These exploit the fact that irradiation of a metallic tip held in close proximity to a solid surface using a suitably polarized light may lead to a very pronounced enhancement of the electric field in a small region beneath the tip.<sup>[11]</sup> A variety of optical phenomena may be excited in this way. The tip may, for example, act as an antenna, a phenomenon referred to rather evocatively as the lightning-rod effect, yielding a strongly focused field. A surface plasmon mode may be excited at the tip. Again, the electric field associated with the plasmon excitation exhibits a pronounced confinement. Fluorescence resonance energy transfer between donor and acceptor systems attached to the tip and the sample surface may occur,<sup>[12]</sup> offering exciting prospects for the characterization of biological systems. Two-photon absorption<sup>[13]</sup> and other nonlinear phenomena, such as second harmonic generation,<sup>[14]</sup> have also been reported. While many of these techniques are currently difficult to implement, they offer extraordinary capability. For example, Hartschuh et al. carried out an apertureless Raman investigation of single-walled carbon nanotubes.<sup>[15,16]</sup> They reported Raman spectra from single nanotubes, with a spatial resolution of ca 25 nm. These results constitute an exciting advance for near-field microscopy and spectroscopy. Such progress suggests that after a long gestation period, NSOM may be on the verge of delivering the kind of fruit that it has long promised.

## LITHOGRAPHY USING NSOM

In photolithography, light is typically directed through a mask at a layer of photoresist. The light exposes the

resist, leading to either the cross-linking of oligomeric material or the removal of a photosensitive material, and the formation of a photopattern that may subsequently be used to transfer structures into the underlying substrate. Clearly, it is possible to fabricate smaller features by simply reducing the dimensions of the gaps in the mask through which the light passes, and for many years the semiconductor device manufacturers have been able to do this. However, eventually the diffraction limit is reached. At this point, light is diffracted as it passes through the mask. There are several solutions to this, including reducing the wavelength of the light used. In principle, a photolithography mask may be placed in contact with the sample (rather than being placed away from it, as in projection photolithography), to try to exploit near-field effects. However, the great problem with this is ensuring that the mask remains genuinely within the near-field regime across the whole of its area. The tiniest specs of dust or small variations in substrate topography would mean that significant portions of the mask were not in contact and diffraction would occur.

The adaptation of a scanning near-field optical microscope represents another solution. While mask-based processes offer the advantage of parallel fabrication of large numbers of structures, there are other applications for photolithography, outside of electronic device fabrication, where the ability to excite different processes at different locations on the sample is a distinct advantage (for example, the immobilization of biological molecules using light-directed processes).<sup>[17,18]</sup> Moreover, the development of high-speed scanning systems<sup>[19]</sup> and multiplexing technologies<sup>[20]</sup> both provide potentially important new routes to high-throughput fabrication.

In a fiber-based NSOM system, the aperture at the end of the optical fiber constitutes a nanoscopic light source. Provided the probe is maintained in close proximity to the sample at all times, the dimensions of the illuminated region will be determined, to a first approximation, by the dimensions of the probe. Given that the fabrication of probes with 50 nm apertures is technically feasible with reasonable repeatability, and that the transmission will in any case decrease sharply at smaller aperture dimensions, it would seem, a priori, feasible to aim for a resolution of ca 50 nm in well-optimized circumstances. The first report of the use of NSOM to conduct lithography, by Betzig et al.,<sup>[21]</sup> suggested that this was realistic. Using an optical fiber probe, controlled by shear-force modulation, they wrote structures into a Co/Pt multilayer film using visible light (488 and 514 nm). In regions heated near to the Curie temperature of the medium (ca 300°C), domains were formed with opposite magnetization that could subsequently be imaged using NSOM. When adequate powers (ca 5 mW input power from

an argon ion laser) were utilized, it was possible to write features with diameters of 60 nm. Optimization of the conditions relied upon ensuring that adequate power was passed through the probe to ensure sample heating and, at the same time, that the input power was not great enough to damage the aluminum coating on the probe.

Building on this promising start, Krausch and coworkers utilized an NSOM to expose films of conventional photoresist.<sup>[22–24]</sup> Using an argon ion laser ( $\lambda = 454$  nm), they were able to write structures as small as  $\lambda/5$  (ca 80 nm) into Hoechst Novalack AZ 6612, a resist based on a phenol–formaldehyde resin, which becomes base-soluble on exposure to light. The features formed in the photoresist represented a mechanical replica of the intensity distribution in the optical near field of the tip. It was found that the features could be fitted with a Gaussian intensity distribution with a width of approximately 100 nm, and a height of ca 15 nm. A grating was fabricated with a period of 164 nm and a line width of 82 nm. These results confirmed that by using NSOM, it was possible to break the diffraction limit in lithographic mode by a significant margin.

Smolyaninov Mazzoni, and Davis utilized a standard negative-tone resin-based photoresist (Shipley KTI 747) in studies using UV light from an excimer laser (248 nm).<sup>[25]</sup> Exposure of the resist using an NSOM led to the photochemical generation of a cross-linked network that was insoluble in the developer. The resulting specimens were characterized before development, by using shear-force imaging with the same probe employed to modify the sample, and after development, by AFM. A nonlinear dependence of the feature size on the light power was reported. Under optimal conditions, features of size ca 100 nm could be written with an uncoated optical fiber.

Although these results represented excellent progress, they nevertheless leave much to be desired. In particular, these early studies failed to realize the optimal resolution expected a priori—matching the diameter of the optical fiber aperture. One of the problems was that these photoresist films had a finite thickness—tens of nanometers at best. However, the electric field associated with an optical aperture in the near field is known to diverge comparatively rapidly within dielectric layers.<sup>[11]</sup> This may mean significant spreading of the excitation in the resist layer. Moreover, the approach of Betzig et al. relied upon localized heating; thermal migration away from the region exposed beneath the fiber aperture may lead to an additional broadening effect. These problems were realized by Fujihara and coworkers,<sup>[26,27]</sup> who sought to restrict the thickness of the resist by utilizing monolayer systems. They prepared Langmuir–Blodgett films of a photochromic material containing

4-octyl-4'-[5-carboxypentamethyleneoxy)azobenzene. On exposure to UV light ( $\lambda = 350$  nm), this molecule undergoes a *cis–trans* conformational change. The change may be reversed by the action of heat or light. They reported a resolution of 130 nm. Although this does not represent an improvement on the work described above, it nevertheless suggests that such systems have a useful role to play.

Conjugated polymers have a broad range of potential applications arising from their electrical and optical properties. There has been significant interest in exploiting the susceptibility of conjugated polymers to photooxidation as a means for patterning them at the nanometer scale, using an NSOM to deliver excitation to localized regions in polymer films. Wei et al. studied thin films of (3,4-diphenyl-2,5-thienylene vinylene). They reported comparatively diffuse structures with line widths of ca 200 nm.<sup>[28]</sup> Buratto and coworkers patterned films of poly[2-methoxy, 5-(2'-ethyl hexyloxy)-*p*-phenylene vinylene] using light from an argon ion laser coupled to an NSOM.<sup>[29,30]</sup> They also reported a line width of 200 nm. In part, no doubt, the poor resolution in these studies was a consequence of the finite thickness of the resist. Credo et al.<sup>[30]</sup> also studied the exposure of *tris*-8-hydroxyquinoline aluminum ( $\text{Alq}_3$ ) films. Here there was an additional problem in that active species created by the initial exposure of the sample diffused away from the region of initial exposure. On small length scales, even small amounts of diffusion may cause a significant degradation of the resolution. In studies of self-assembled dye layers, they also reported degradation of resolution; but, in this case, it was because of the migration of energy through the resist material rather than the diffusion of active species. Once again, the finite film thickness (50 nm) may well account for much of the migration of heat energy. Studies of the near-field exposure of conjugated polymer films have generally failed to yield dimensions that are authentically nanometer scaled (i.e., less than 200 nm), and much of this can be attributed to the problems associated with the finite thicknesses of even the highest quality materials prepared by techniques such as spin-coating. More recently, for example, Riehn et al. patterned PPV layers with a resolution of, at best, 160 nm.<sup>[31]</sup> They modeled the behavior using the Bethe–Bouwkamp model, and determined that a surface of constant intensity was formed, which just touched the substrate under a 40 nm precursor film and had an extent of approximately half the diameter of the feature prepared experimentally. They proposed the formation of a central core surrounded by a gel phase. The steep profile of the electric field predicted by their model indicated that the polymer at the top of the sample absorbed 20 times the dose of the polymer at the substrate.

These studies have focused on organic systems. However, some authors have sought to pattern inorganic materials using methods based on near-field microscopy. Madsen et al. used an NSOM coupled to an argon ion laser to write oxide structures into hydrogen-passivated silicon surfaces, which were then used as resists during etching of the Si substrate with KOH.<sup>[32]</sup> The structures observed were complex, but consisted of a central line with a full width at half maximum height of, in one case, 111 nm, and in another, 126 nm. These narrow structures were bordered by slightly wider features attributed to an interference pattern dominated by far-field excitation through the sidewalls of the uncoated fiber used. Narrower structures (50 nm) were observed in the absence of the optical excitation, attributed to the presence of the electrostatic potential between the probe and the amorphous Si layer. Significant improvements were produced when aluminum-coated fibers were used. The Al coating prevented far-field emission through the fiber walls, and resulted in the formation of much better defined structures with widths not much in excess of 50 nm.<sup>[33]</sup> These structures represent some of those most clearly resolved in these early studies.

Herndon et al. also used NSOM-based methods to fabricate structures in hydrogen-passivated silicon.<sup>[34]</sup> They explored wavelengths down to 248 nm, using argon ion and excimer lasers. The threshold dose required to fully expose the resist was found to decline with the wavelength of the light used. However, the lines written had widths that were comparatively large—in the range of 140–320 nm. Like Madsen et al., they also found that modification could occur in the absence of optical excitation.

Hosaka and coworkers examined a different inorganic system, amorphous Ge–Sb–Te films, whose structure could be modified by localized heating by light from a pulsed diode laser, emitting at 785 nm and delivered through an NSOM probe.<sup>[35,36]</sup> They achieved somewhat superior resolution, demonstrating the fabrication of 60 nm structures. A variety of other approaches have been explored, some of which are more complex and use less conventional resist materials. For example, Yamamoto et al. studied the deposition of zinc using the photo-dissociation of gas-phase dimethyl zinc.<sup>[37]</sup> While they reported the formation of sub-100 nm structures, these were comparatively ill defined. Better images were reported of 200 nm zinc structures. Hong et al. combined near-field microscopy with a micropipette filled with photore-sist.<sup>[38]</sup> While their paper demonstrates an innovative modification of the method, they were only able to fabricate structures that were some hundreds of nanometers in size. Finally, Philipona et al. examined the direct attachment of biological molecules to photosensitive monolayers of a diazine molecule.<sup>[39]</sup> This

represented a significant step into a new area of application, but it proved only possible to create comparatively large (hundreds of nanometers) structures.

## PHOTOCHEMISTRY OF SELF-ASSEMBLED MONOLAYERS

Summarizing the progress described above, it may reasonably be said that NSOM-based approaches had yielded new and, in some cases, unique capabilities, without yielding the kind of routinely very high resolution that might have been hoped in the earliest studies. The thickness of the resist layer has been demonstrated to be critical, with the potential for the spread of the excitation, through the divergence of the electric field, the diffusion of reactive species formed by photoexcitation, and thermal migration, increasing with film thickness. Many of these phenomena may be controlled through the selection of an appropriate resist material. In this section, we describe how the use of self-assembled monolayers (SAMs) of alkanethiols adsorbed on gold surfaces has provided unambiguous evidence not only that structures significantly smaller than 100 nm may be fabricated routinely, but also that near-field techniques can rival the power of electron beam lithography for such materials.

Alkanethiols,  $\text{HS}(\text{CH}_2)_n\text{X}$ , adsorb spontaneously onto gold surfaces, forming dense, well-ordered monolayers, SAMs, that provide versatile templates for the construction of complex molecular architectures.<sup>[40]</sup> Li et al.<sup>[41]</sup> and Tarlov and Newman<sup>[42]</sup> reported that on extended exposure to the air, the alkylthiolate adsorbate species was oxidized to yield an alkylsulfonate:

Huang and Hemminger<sup>[43]</sup> and Tarlov, Burgess, and Gillen<sup>[44]</sup> demonstrated that the same process could be initiated by exposure of SAMs to light from a mercury arc lamp. They found that unlike the adsorbates in the pristine monolayer, the sulfonate oxidation products were only weakly bound, and could be displaced, either by rinsing or by immersion in a solution of a second thiol, to generate a chemical pattern. The process is illustrated in Fig. 2, where a carboxylic acid-terminated thiol is photopatterned. After immersion of the sample in a solution of a methyl-terminated thiol, a chemical pattern is formed that may be imaged using a variety of methods including friction force microscopy (FFM). (Fig. 3), scanning electron microscopy (SEM)<sup>[45]</sup> and imaging secondary ion mass spectrometry (SIMS).<sup>[46]</sup> The advantage of depositing both chemistries in a solution-phase self-assembly process is

**Fig. 2** Schematic diagram illustrating the photopatterning of a SAM. A carboxylic acid-terminated SAM is formed and then exposed to UV light through a mask. In exposed areas, the adsorbates are oxidized to weakly bound alkylsulfonates, which are displaced by a contrasting solution-phase thiol in the final step.

that the entire specimen exhibits well-ordered adsorbates with relatively low defect densities.

The mechanism of photooxidation has been the subject of some debate. Early on, it was proposed by Hemminger and coworkers that the process was initiated by the formation of hot electrons at the gold surface. However, this idea did not have direct support.

**Fig. 3** An  $80\ \mu\text{m} \times 80\ \mu\text{m}$  FFM image of a patterned SAM. The pattern consists of regions functionalized by  $\text{HS}(\text{CH}_2)_{11}\text{CH}_3$  (dark contrast) and  $\text{HS}(\text{CH}_2)_{10}\text{COOH}$  (bright). Source: From Ref.<sup>[55]</sup>.

Studies in the authors' laboratory demonstrated that for SAMs adsorbed on both gold<sup>[47]</sup> and silver surfaces,<sup>[48]</sup> the rate of oxidation decreased with increasing adsorbate chain length, correlating with the decrease in alkyl chain mobility associated with the increased dispersion interaction between long alkyl chains, and suggesting that penetration of oxygen species to the air–sulfur interface was the rate-limiting step. For adsorbates capable of forming hydrogen bonds between their terminal groups, the rate of oxidation was found to be even slower,<sup>[49]</sup> suggesting that the resulting network of hydrogen bonding interactions impeded the diffusion of oxygen. A radical proposal was made by Bohn and coworkers<sup>[50,51]</sup> and by Norrod and Rowlen,<sup>[52]</sup> who suggested that the process was not in fact a photochemical one, but involved the ozonolysis of adsorbate molecules. Critically, all of the studies published till date had utilized mercury arc lamps, which typically exhibited broad emission spectra. They suggested that short wavelength light generated by a mercury arc lamp could initiate ozone formation, and that ozone species could oxidize the adsorbate molecules in the SAM. In studies of the oxidation of hexadecanethiol SAMs, they claimed that the interposition of a filter that blocked short wavelength radiation between the lamp and the source extinguished the photooxidation process.<sup>[50]</sup>

This finding, if correct, would have meant that it will be difficult to utilize such approaches for near-field excitation, because a methodology based upon the creation of gaseous reagents would be unlikely to yield significant spatial control of reactivity. However, using a lamp equipped with a filter designed to eliminate ozone formation, Brewer et al. provided clear evidence that oxidation of SAMs could occur in the absence of ozone.<sup>[53]</sup> It was found that monolayers of carboxylic acid-terminated SAMs on both gold and silver surfaces oxidized rapidly to yield alkylsulfonates when exposed to light with a wavelength of 254 nm. Recently, a more detailed kinetic study has been carried out using static SIMS, to determine rates of photooxidation.<sup>[54]</sup> Significant differences were observed between the rates of oxidation under these well-defined conditions and those measured using mercury arc lamp sources. Unexpectedly, when exposed to 254 nm light, acid terminated thiols oxidize much faster than methyl-terminated adsorbates—the direct opposite of the observation made earlier for an arc lamp source. This is explained by differences in the mechanisms of oxidation. The dominance of intermolecular interactions in determining the rate of oxidation during exposure to the arc lamp source suggests that gaseous reagents are important under those conditions, in agreement with the predictions of Bohn and coworkers.<sup>[50]</sup> However, when a well-defined light source emitting at 254 nm is used, these species are absent, and it is

believed that hot electron formation provides the main impetus for SAM oxidation. Measurements of the contact potential differences of SAMs on Au and Ag have yielded data that reveal differences in SAM work functions that are consistent with such an explanation.<sup>[54]</sup> In particular, it was found that the work functions of carboxylic acid-terminated SAMs are larger than the energy of a 254 nm photon. As a result, absorption of a UV photon may lead to the promotion of an electron from the Fermi level to an excited state, but not to photoemission. These excited electrons may tunnel into an antibonding state in the adsorbate sulfur atom, leading to oxidation. In contrast, the work functions of methyl terminated SAMs are smaller than the photon energy, meaning that photoemission may occur. Photoemitted electrons will have small kinetic energies, and most likely be scattered by the alkyl chains above the surface, but nevertheless the number of electrons available for the initiation of oxidation will be significantly reduced. The transfer of hot electrons from the Fermi level to the adsorbate sulfur thus becomes the rate-limiting step, although adsorbate order still plays a role. For example, carboxylic acid-terminated thiols pack less closely on silver than on gold, and a concomitant increase was reported in the rate constants for photooxidation.

## NANOPHOTOPATTERNING OF SAMS

These findings indicate that SAMs are a suitable system for developing into a resist for ultra-high resolution photolithography. Not only are the monolayers very well defined, but also, through the use of hot-electron stimulated oxidation of the adsorbate sulfur atom, produce a resist that may effectively be regarded as the monatomic layer of sulfur atoms that forms at the gold–adsorbate interface. This clearly represents the thinnest conceivable resist layer. A priori, therefore, one would expect to be able to exploit the full potential for spatial resolution offered by near-field lithographic techniques, with the resolution being determined, as a first approximation, by the diameter of the aperture in the NSOM probe. Fig. 4 illustrates the process schematically. An NSOM fiber, coupled to a suitable light source (a frequency-doubled argon ion laser, emitting at 244 nm is well suited to the purpose) is traced across the sample surface. Wherever the probe travels, the adsorbate molecules are exposed to UV light, leading to their oxidation to alkylsulfonates. On immersion of the sample in a solution of a contrasting thiol, the oxidation products are displaced by solution-phase thiols, which adsorb at the surface and form a chemical pattern: The new adsorbate occupies the exposed areas, while the original adsorbate continues to occupy the rest of the surface.

**Fig. 4** A schematic diagram illustrating the application of SNP. A sample is exposed to UV light from an NSOM (A), leading to local oxidation (B) and either replacement of the oxidation products by a contrasting thiol (C), or etching of the gold underlying the oxidized regions (D). *Source:* From Ref.<sup>[56]</sup>.

Initial studies were very promising.<sup>[57]</sup> Monolayers of carboxylic acid-terminated thiols were formed and selectively exposed to UV light from an NSOM probe. On immersion in a solution of methyl-terminated thiol, the oxidation products were displaced leading to a chemical pattern. Fig. 5 shows scanning probe microscopy data on such samples. In this illustration, the adsorbate molecules had identical chain lengths. As a result, the AFM topographical image shows no contrast. The only difference between the two regions of the surface is in the identity of the terminal group. Friction force microscopy (FFM) is a powerful tool for probing the compositions and molecular organization of molecular monolayers. FFM provides a convenient mean for quantifying the extent of SAM photooxidation. In Fig. 5, the FFM image reveals clear contrast between regions of the surface with different chemistries: the lines of methyl-terminated thiols exhibit dark contrast compared to the surrounding carboxylic acid-terminated regions of the surface, because they have smaller coefficients of friction than the high surface energy, polar adsorbates.

The lines in Fig. 5 have widths of ca 40 nm. In our experience, this level of performance can be reproduced routinely provided probes of adequately good quality are used. However, this does not represent the limit of performance achievable by SNP. Indeed, even the achievement of a line width of 40 nm deserves comment, because this is smaller than the diameter of the aperture in the probe. A priori, one would have

**Fig. 5** Friction force (A) and topographical (B) AFM images of lines of methyl-terminated thiols written into a carboxylic acid-terminated SAM using SNP. *Source:* From Ref.<sup>[57]</sup>.

expected the best performance to yield a feature size comparable to the aperture diameter, because of the extent to which the electric field associated with the optical near field diverges under the aperture. Resolutions better than the aperture diameter have proved to be readily reproducible. Recently, line widths of ca 20 nm were reported in SAMs of alkanethiols (Fig. 6), corresponding to a resolution of  $\lambda/12$ .<sup>[58]</sup> This significantly exceeds the performance of previous photolithographic techniques. However, this does not represent the limit of performance: recently a line width of 9 nm (i.e.,  $\lambda/27$ ) was achieved. For these materials, this kind of performance matches the resolution of electron

**Fig. 6** Matching the performance of electron beam lithography by photochemical means. Lines of methyl-terminated thiol only 20 nm wide written into an acid-terminated SAM by SNP. *Source:* From Ref.<sup>[58]</sup>.

beam lithography, which is an impressive achievement for an ambient technique that utilizes significantly less complex and less expensive apparatus. However, the question arises, how is it feasible to achieve such a resolution, when the aperture in the NSOM probe is, at best, 50 nm in diameter?

It has been observed that the resolution achievable in SNP is dependent upon the morphology of the underlying substrate. The substrates upon which our SAMs are prepared are typically polycrystalline, consisting of grains that have diameters in the range of 10–100 nm. The grain size may be readily varied by altering the rate of deposition of the metal. As the grain size of the gold substrate decreases, so does the line width. This is illustrated graphically in Fig. 7. As the grains become larger, the line width increases, reaching a limiting value that is approximately equal to the diameter of the aperture in the probe. The limit

**Fig. 7** The variation in line width as a function of the grain size of the underlying gold film in SNP. *Source:* From Ref.<sup>[58]</sup>.

**Fig. 8** Lines of methyl-terminated adsorbates fabricated in a carboxylic acid-terminated SAM formed on an atomically flat gold substrate. *Source:* From Ref.<sup>[58]</sup>.

of large grain size is represented by an atomically flat, epitaxially deposited gold film. For such a substrate, we were only able to achieve a grain size comparable to the diameter of the aperture (Fig. 8). These data may be rationalized in the following way. When a metallic asperity is exposed to optical excitation in the near field, it may function like an antenna, causing a very pronounced enhancement in the intensity of the electric field in a small region around the apex of the asperity. This phenomenon is referred to as the “lightning-rod effect” and it forms the basis of apertureless NSOM (see below). We have speculated that the grains in the gold film function like an array of antennae, leading to a confinement of the excitation as the probe traverses the sample and resulting in the photochemical reaction being confined to a very small region of the surface. Although this sounds like a rather specific phenomenon, it may in fact be applicable to a wide range of systems. For example, a variety of metals and some semiconductors are known to yield a similar effect (it is thus not confined to gold). Moreover, there are potentially exciting possibilities if one could utilize an apertureless excitation, by combining this substrate-mediated localization with further confinement by the tip itself. Such phenomena may also be helpful in imaging applications of NSOM. An “inverted lightning rod effect” may thus prove a valuable tool for the manipulation and characterization of surface structure on even smaller length scales than those indicated in Fig. 6.

Samples patterned using SNP may be utilized in a variety of ways. For example, aldehyde-functionalized polymer nanoparticles have been attached to

amine-terminated regions in carboxylic acid-terminated SAMs. Proteins may also be patterned using SNP. In protein patterning on any length scale, the most difficult problem is the prevention of nonspecific adsorption, because proteins tend to adhere strongly to most surfaces. On the nanometer scale, any such problems are accentuated. In a region of several  $\mu\text{m}^2$ , a few nonspecifically adsorbed protein molecules may be missed; compared to a feature of size comparable to a protein molecule, they will be much more problematic. One particularly significant contribution to the field of protein adsorption has been the use of oligo(ethylene glycol) (OEG)-terminated thiols to resist protein adsorption.<sup>[59]</sup> These are so effective in reducing non-specific adsorption that it becomes insignificant even on molecular length scales. Using SNP, regions in an OEG-terminated SAM may be selectively oxidized and replaced, either with an adsorbate that does not resist protein adsorption, leading to localized adsorption on transfer to the biological medium, or with an adsorbate to which proteins may be covalently attached. One approach adopted in the author’s laboratory is to introduce carboxylic acid-terminated adsorbates into regions of an OEG-terminated SAM and then attach proteins using well-established carbodiimide-coupling chemistry, originally established for use on larger length scales. In conjunction with SNP, this approach yields protein features with line widths smaller than 100 nm.<sup>[60]</sup>

Structures formed by SNP have also been used to fabricate 3-D structures in metal films.<sup>[56,61]</sup> After exposure of a SAM to UV light from the NSOM probe, the sample may be immersed in a solution of an etchant for the underlying substrate, such as the ferri/ferrocyanide etchant reported by Xia et al.<sup>[62]</sup> Fig. 9 shows an AFM image of a structure fabricated in a monolayer of hexadecanethiol using this approach, together with a cross-section through the structure. The AFM data indicate that the width of the nanotrench is only 50 nm. Recent work using electron microscopy to characterize similar structures suggests that in such circumstances the AFM image probably gives a significant overestimate of the trench width because of the convolution of the topographical profile of the surface with the tip geometry. However, even at a width of 50 nm, such data provide clear evidence that this is a convenient and powerful approach to the patterning of metal films. Subsequently, the gold nanostructures may be used as masks for anisotropic etching of the underlying substrate.

These data provide clear evidence that SNP is a powerful tool for patterning SAMs of alkanethiols. However, there are strong reasons to believe that similar performance levels should be feasible for other materials. The basis for the extremely high resolution achieved for alkanethiol systems is the exploitation of

**Fig. 9** AFM image of nanotrenches etched into gold using an SNP-patterned SAM of hexadecanethiol as the resist.

a specific photochemical reaction that is confined to a functional group (the thiol head group) distributed with monolayer coverage on a solid surface. There is a large group of systems that fit this classification. Current work in the author's laboratory is focused on monolayers on silicon and other surfaces and initial results are very promising.<sup>[61]</sup> In principle, it seems that SNP should be extendable to a broad class of organic monolayer systems.

## APERTURELESS METHODS

Apertureless methods have recently made an enormous impact on surface characterization by NSOM, enabling significant improvements in spatial resolution to be achieved. Till date, they have been little used for lithography. However, Royer and coworkers have provided evidence that apertureless techniques offer significant potential in lithographic applications. Their motivation was to use photosensitive films as a means of observing the field enhancement beneath an apertureless NSOM probe.<sup>[63,64]</sup> Azobenzene films were spin-coated onto glass with a thickness estimated to be 200 nm. Despite the thickness of the resist layer, it proved possible to fabricate lines with a width of ca 50 nm and dots as small as 30 nm.<sup>[65]</sup> These samples were subject to the limitations of the resist films employed in previous studies using aperture-based

methods, but the resolution was significantly improved and approached the performance achieved for SAMs. Given the advances in resolution from those systems to the thiol-on-gold system, it is possible that SAMs may yield even greater enhancements in resolution in conjunction with apertureless lithography.

The principal problem with apertureless methods is the far-field exposure of the region around the tip, which may lead to complications in lithographic operation because it may cause exposure of the resist. Although the electric field may be enhanced directly under the tip, the finite period of time required to write structures means that the far-field exposure may nevertheless be substantial. However, one route of potential value in this respect is the use of non-linear optical processes, such as two-photon absorption. Because the cross-section for two-photon absorption is related to the square of the electric field strength, significantly greater absorption will occur under the tip than in the surrounding regions, potentially enabling near-field modification in the absence of significant far-field exposure. The feasibility of such approaches has been demonstrated by Yin et al.,<sup>[66]</sup> who fabricated features with widths of ca 70 nm in a photoresist film.

## CONCLUSIONS

Scanning near-field photolithography is a technique that offers great promise in the fabrication of molecular nanostructures. While early attempts to utilize near-field scanning optical microscopes to pattern materials yielded mixed results, alkanethiol SAMs provide simple, convenient and highly effective resists, enabling the initial hopes for the methodology not only to be realized, but also to be surpassed. Operating under ambient conditions, and requiring no special sample preparation procedures, it facilitates the fabrication of structures comparably small to those made by electron beam lithography. The resulting structures may readily be utilized for the immobilization of biological molecules and for the etching of 3-D structures into the underlying substrate. It is thus clear that the careful selection of resist materials enables SNP to compete very favorably with other nanofabrication techniques. Moreover, it offers the benefits of ambient operation. Because there is a large number of photochemical reactions that may be used to modify surfaces, techniques based on near-field optical excitation are extremely attractive and potentially offer enormous flexibility for the fabrication of complex molecular nanostructures. In conjunction with apertureless excitation, it is not inconceivable that a resolution significantly better than 10 nm may be achieved, reflecting advances in near-field microscopy. Combined with the ability to selectively excite

photochemical transformations, this would represent a powerful capability. There are good grounds, therefore, for continuing to explore the possibilities offered for nanofabrication by near-field optical processes.

# Scanning Probe Lithography: Polymeric and Biomolecular Nanostructures

Stefan Zauscher

*Department of Mechanical Engineering and Materials Science, Duke University,  
Durham, North Carolina, U.S.A.*

## INTRODUCTION

One central goal of materials engineering is to produce hierarchical materials that are ordered over a range of length scales and in which larger-scale structural and physicochemical properties are controlled by molecular characteristics.<sup>[1]</sup> Fabricating molecular, polymeric, and biomolecular structures on surfaces and controlling their architecture on the nanometer length scale is important for a wide range of applications. For example, the ability to pattern surfaces with polymers and biomacromolecules has important applications in biosensors,<sup>[2]</sup> proteomic chips,<sup>[3]</sup> and nanofluidic devices.<sup>[4]</sup> To date, fabrication of micropatterns and microstructures for these applications has relied on either photolithography<sup>[2,5,6]</sup> or an ensemble of related techniques termed “soft lithography”,<sup>[7]</sup> that use elastomeric stamps or molds. These techniques have been extremely successful at the micrometer length scale or larger, but have a number of inherent limitations that preclude their extension to the nanometer length scale. X-ray lithography<sup>[8–10]</sup> requires expensive mask alignment equipment, and the photoresists and developers commonly used are incompatible with many organic and biomolecules. Furthermore, like electron beam lithography,<sup>[8,11,12]</sup> it requires expensive ultrahigh vacuum equipment.

This review will focus on methods that allow for molecular-level control in the fabrication of polymeric and biomolecular nanostructures using scanning probe lithography (SPL),<sup>[13–15]</sup>. Among all the available nanofabrication techniques, SPL has unique advantages because of its simplicity and capability to both manipulate and image nanostructures on surfaces. In contrast to other nanofabrication methods, SPL, which is capable of resolution less than 50 nm<sup>[16]</sup> is technologically simpler, significantly cheaper, and therefore a much more widely accessible method to most researchers, requiring only a scanning probe microscope (SPM) such as a scanning tunneling microscope (STM),<sup>[17]</sup> an atomic force microscope (AFM)<sup>[18]</sup>, or a near-field scanning optical microscope (NSOM)<sup>[19,20]</sup> (Fig. 1).

SPL can behave like an interactive plotter, registering with nanostructures on a surface, while offering resolution comparable to electron beam lithography.<sup>[21]</sup> The slow-speed serial nature of the lithography process can be circumvented by employing cantilever arrays.<sup>[22]</sup>

## METHODOLOGY

Direct manipulation of both self-assembly and supramolecular chemistry are critical to materials engineering on the nanoscale. Generally, two fabrication approaches are used: a “bottom-up” or “grafting from” approach, which constructs supramolecular ensembles by synthesis of functionalized, small molecular units, using, for example, surface initiated polymerization; and a “grafting to” approach that seeks to directly manipulate and position macromolecules, proteins, or ligands on a surface with nanometer precision.

### Self-Assembled Affinity Templates

Highly ordered and spatially confined self-assembled monolayers (SAMs) serve as initiator platforms for polymerization of polymer brushes and as growth templates for directed self-assembly of synthetic and biomolecules. The molecules forming these “affinity templates” are typically bifunctional, where the surface binding group (silane<sup>[23]</sup> or thiol<sup>[24,25]</sup>) is chosen to match the substrate chemistry. The linker, usually an inert hydrocarbon chain, connects the surface binding group with the ligating, functional head group, often a hydroxyl (–OH) or carboxyl (–COOH) group.

### Surface-Initiated Polymerization

Attaching polymer brushes<sup>[26]</sup> with thicknesses on the molecular scale to solid surfaces allows one to tailor the surface properties of materials by imparting desirable energetic, mechanical, and electrical functionalities. The in situ formation of polymer brushes in a “grafting-from” approach, using patterned SAMs of

**Fig. 1** Schematic view of scanning probe microscopes. (A) Scanning tunneling microscope (STM), (B) atomic force microscope (AFM), and (C) near-field scanning optical microscope (NSOM).

an initiator, provides spatial flexibility and achieves higher packing densities than possible in a “grafting-to” approach.<sup>[27,28]</sup>

Seminal work by Prucker and Rühle<sup>[27,28]</sup> led the way for generating polymer brushes in a “grafting from” approach using free radical polymerization. Although the templated fabrication of polymeric

nanostructures from the “bottom-up” has been prototypically demonstrated, and many methods to initiate polymerization reactions have been used (e.g., anion,<sup>[29]</sup> cation,<sup>[30]</sup> radical,<sup>[27]</sup> plasma,<sup>[31]</sup> condensation,<sup>[32]</sup> photochemical,<sup>[33]</sup> electrochemical,<sup>[34]</sup> and ring-opening metathesis polymerization.<sup>[35–37]</sup>), preparation of precisely patterned, surface-attached polymeric structures with controlled lengths, conformational geometries, functionality, and properties is still in its infancy. So far, atom-transfer radical polymerization (ATRP) has been the workhorse polymerization methodology used by researchers attempting to prepare surface-attached polymer brushes of controlled structure<sup>[38,39]</sup> This transition metal-based, controlled radical polymerization chemistry produces functional polymers with defined molecular weight and polydispersity, and as a result of the “living” nature of the catalyst, allows the ready synthesis of block copolymers.

### Protein Grafting

The precision with which one can organize large molecular structures, such as proteins, depends on the quality and chemical functionality of the affinity template nanostructure.<sup>[40]</sup> Ideally, the template surface and background polymers are chosen so that the protein to be grafted selectively links either with the template or the background only. Some approaches for protein grafting or “immobilization” rely on physisorption, while others make use of chemical bonds between protein and substrate, particularly if the patterned protein is subjected to hydrodynamic or other physical forces. Covalent immobilization methods include formation of amide, imine, and disulfide bonds. While these approaches are relatively simple, they often preclude direct control over protein orientation on the surface, which is problematic if protein binding to its recognition partners is desired. Recently, Hyun et al.<sup>[41]</sup> developed a new nanofabrication method allowing control over molecular orientation by using molecular recognition mediated protein immobilization.

### SCANNING PROBE LITHOGRAPHY

Shortly after the invention of the scanning probe microscope, it was realized that the tips used for imaging could also be used to modify the surfaces. Since then, many SPL techniques have been developed based on various chemical, physical, and electrical modifications of surfaces, including mechanical scratching,<sup>[42–44]</sup> electrochemical anodization of silicon surfaces,<sup>[45,46]</sup> decomposition of self-assembled

monolayers,<sup>[45,47–49]</sup> electric field induced chemical reactions,<sup>[50,51]</sup> and electrochemical reactions in solution using electrochemical STM tips.<sup>[52–57]</sup> Several comprehensive reviews of SPM related lithography can be found in the literature.<sup>[16,58]</sup>

Depending on the instrument design, either the probe tip scans relative to a stationary sample surface, or the surface is scanned relative to a stationary tip. Scanning is typically achieved through piezoelectric actuators. The requirement for accurate tip positioning has driven SPM design to use closed-loop scanning to compensate for the non-linear and often hysteretic behavior of piezoelectric actuators. Increasing interest in scanning probe lithography has also spurred the development of user interfaces that allow the user to program arbitrary motions of the tip relative to the sample,<sup>[59]</sup> and several SPM manufacturers now offer lithography packages. Current methods for fabricating polymer nanostructures include nanoshaving and nanografting, dip-pen nanolithography (DPN), direct-write DPN, and near-field scanning optical lithography.

### Nanoshaving and Nanografting

Perhaps the simplest method for fabricating patterned substrates is nanoshaving, in which SAM adsorbates are mechanically displaced while the cantilever tip is dragged over the surface, leaving behind a patterned surface.<sup>[42,44,60]</sup> Large contact pressure during patterning<sup>[44]</sup> creates large shear forces that exceed the displacement threshold of the usually chemisorbed molecules (Fig. 2A). In nanografting, the AFM tips

are again used to displace thiol molecules from adsorption sites; however, cantilever and SAM are now immersed in a solution of a different thiol<sup>[43]</sup> (Fig. 2B).

These thiols in solution immediately self-assemble on the newly exposed gold surface left behind as the tip shaves the matrix SAM. The resulting SAM patterns can now be used as affinity templates for protein immobilization<sup>[40]</sup> or for surface initiated nanopolymerization.

### Dip-Pen Nanolithography

More recently, a new SPL technique, “dip-pen” nanolithography (DPN),<sup>[61,62]</sup> has permitted patterning of monolayer films of thiolated organic molecules with sub-100-nm resolution onto gold substrates. The technology uses the spontaneous condensation of water vapor between the AFM tip and substrate to transport organic molecules from the AFM tip to the surface in the area specifically defined by the tip–surface interaction<sup>[63]</sup> (Fig. 3).

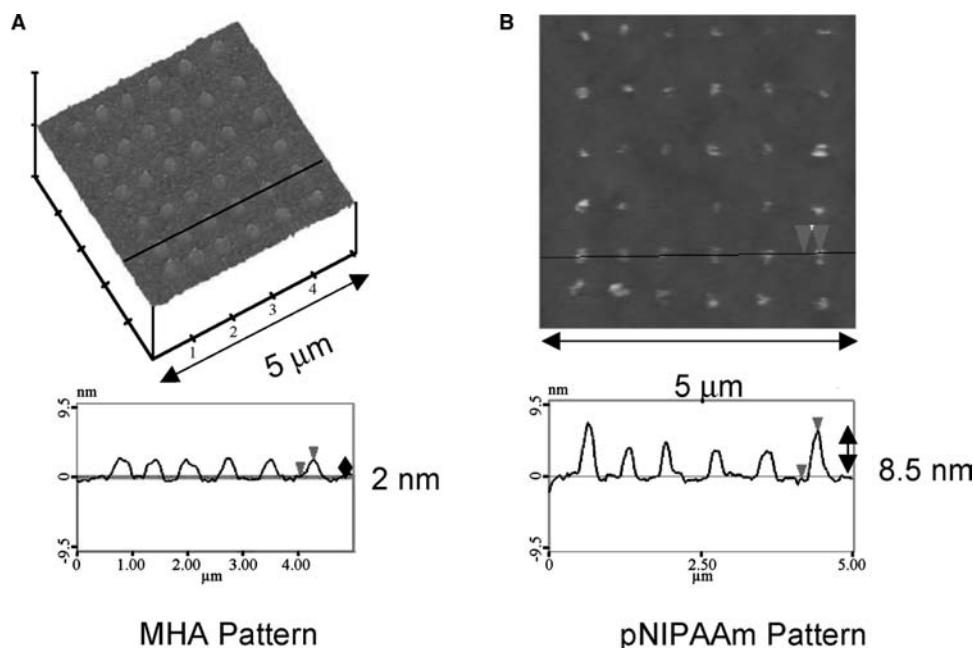

To draw on a familiar analogy, the AFM tip acts as a “pen,” the organic molecules act as “ink,” and the surface acts as “paper” to “draw” the nanostructures. DPN allows direct patterning of nanoscale structures in both serial and parallel fashions.<sup>[64]</sup> Attractive features of DPN over most other SPL techniques are its simplicity—it requires no liquid cells—and its ability to create various nanostructures in a “direct-write” fashion. Furthermore, as long as the tip can be inked with a solution containing the reactant of interest and a capillary meniscus maintained between the tip and surface, there appears to be little limitation on the types of molecules that can be transferred onto a

**Fig. 2** Schematic diagrams of two basic manipulation mechanisms using AFM: (A) nanoshaving and (B) nanografting. The corresponding imaging (I) and fabrication (II) modes are depicted in the top and bottom rows, respectively. *Source:* From Ref.<sup>[44]</sup>. © 2000, American Chemical Society.

**Fig. 3** Schematic representation of dip-pen nanolithography (DPN). A water meniscus forms between the AFM tip, typically coated with a  $\omega$ -functionalized alkane thiol (e.g., mercapto-hexadecanoic acid) and a gold substrate. The size of the meniscus, which is controlled by relative humidity, affects the thiol transport rate, the effective tip–substrate contact area, and DPN resolution.

**Fig. 4** Surface initiated nanopolymerization (SINP) of *N*-isopropylacrylamide (NIPAAm) on a mercaptohexadecanoic acid (MHA) pattern, conjugated with free radical initiator. (A) AFM lateral force height image of MHA patterned with DPN and typical cross section (contact mode in air). (B) AFM height image of the corresponding pNIPAAm pattern and typical cross section (TappingMode® in air). surface. Thus DPN enables a large number of additive chemical reactions to be performed on diverse substrates with nanometer resolution comparable to that achieved with electron-beam lithography. However, to achieve this nanometer resolution, DPN requires molecularly smooth gold substrates.

Recently, Ahn, Lee, and Zauscher<sup>[65]</sup> combined surface initiated polymerization with DPN in a fabrication process termed “surface initiated nanopolymerization” (SINP) to fabricate patterned, surface-confined, stimulus-responsive polymer brushes (Fig. 4). In this approach, mercaptohexadecanoic acid (MHA) was patterned on gold thin films by DPN (Fig. 4A) and subsequently conjugated with a free radical initiator. The cross-sectional profile of a pattern with 300-nm dots reveals that the polymer brush height at the periphery of the pattern is larger than that in the center (Fig. 4B).

These and other results suggest that the rate of polymerization, and thus the brush height in uncontrolled free radical polymerizations of *N*-isopropylacrylamide (NIPAAm), are affected by pattern size. This may likely be attributable to the density of initiator immobilized on the surface and limited monomer diffusion to the surface of the growing brush (1-D).<sup>[28]</sup> Diffusional freedom is larger at pattern boundaries (2-D) and polymer growth is usually larger there.

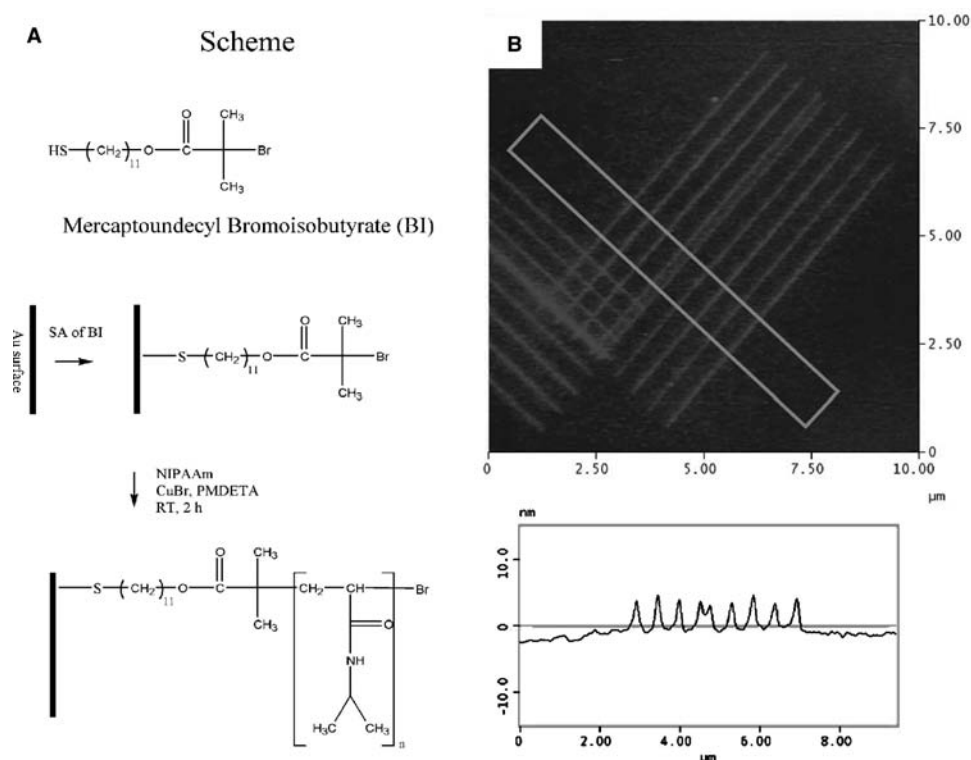

Controlled/living radical polymerization methods, such as atom transfer radical polymerization (ATRP),

decrease the probability of bimolecular termination reactions, yielding polymer brushes of uniform molecular weight and controlled composition. Kaholek et al.<sup>[66]</sup> succeeded in fabricating stimulus-responsive polymer patterns with linewidths of 200 nm, by directly patterning the initiator thiol using DPN, and subsequent amplification of the pattern using ATRP of NIPAAm in an organometallic catalyst solution (Fig. 5).

The preparation of patterned protein surfaces using DPN was first demonstrated by Demers et al.<sup>[67]</sup> and Lee et al.<sup>[68]</sup> who physisorbed lysozyme and immunoglobulin G (IgG) onto DPN nanopatterned mercaptohexadecanoic acid (MHA) templates, achieving feature sizes on the order of 100 nm. By backfilling with a protein-resistant oligoethylene glycol-terminated alkanethiol SAM,<sup>[69]</sup> they avoided non-specific protein adsorption that could have led to large background signals and complicated differentiation between active and inactive areas of the substrate.

A method for molecular-recognition mediated, stepwise fabrication of patterned protein nanostructures with feature sizes on the order of 200 nm was recently developed in the author’s laboratory (Fig. 6).<sup>[41]</sup>

In this method, an amine-terminated biotin derivative was covalently conjugated with a chemically activated MHA SAM nanopattern, patterned with DPN on gold. The patterned surface was then incubated

**Fig. 5** Surface initiated nanopolymerization of NIPAAm using atom transfer radical polymerization (ATRP) on directly patterned initiator thiol. (A) Reaction scheme. (B) AFM height image of the resulting pNIPAAm line pattern showing a line width of 220 nm line and a brush height of 5.7 nm (TappingMode<sup>TM</sup> in Milli-Q<sup>TM</sup> water).

with streptavidin whose binding to the pattern was mediated by molecular recognition between biotin and streptavidin. The patterned streptavidin surface functioned as a universal platform for molecular-recognition mediated protein immobilization through use of biotinylated molecules. “Smart,” reversible protein nanopatterns were fabricated by using iminobiotin as the molecular recognition partner. These structures are pH-sensitive and allow for the reversible immobilization of iminobiotin tagged proteins. This latter

characteristic makes possible the regeneration of the nanopattern.

The concept of “smart,” regenerable protein patterns was carried one step further by Hyun et al.,<sup>[70]</sup> who developed a new method for the fabrication of stimulus-responsive polypeptide nanostructures using DPN. They created an array comprising elastin-like polypeptide (ELP) nanodots with a diameter of approximately 200 nm on gold against a non-fouling oligoethylene glycol-terminated alkanethiol SAM (Fig. 7).

**Fig. 6** AFM height images of Biotin-BSA nanopatterns (TappingMode<sup>TM</sup> in Milli-Q<sup>TM</sup> water). (A) 144 dot pattern with average feature size of 230 nm. (B) Zoom of the area indicated by the square in panel (A) and representative cross section showing the typical feature size. *Source:* From Ref.<sup>[41]</sup>. © 2002, American Chemical Society.

**Fig. 7** (A) AFM TappingMode<sup>®</sup> height image of a  $10 \times 9$  elastin-like polypeptide (ELP) dot array in PBS buffer. (B) Enlarged view of area indicated in panel (A) and representative cross section, showing a feature size of about 200 nm.

ELPs, chemically grafted onto self-assembled monolayers on gold, exhibit an interfacial hydrophilic–hydrophobic phase transition in response to increased temperature or ionic strength. This stimulus-response behavior of ELP nanopatterns can be harnessed for the reversible immobilization of small amounts of ELP-tagged proteins from solution, which is important for protein detection and purification on the nanoscale.

### Direct-Write DPN

Direct-write DPN of polymeric and biomolecular structures has great appeal as an efficient nanofabrication method. For example, tip-directed in-situ polymerization potentially eliminates multiple-step processing that currently requires amplification of a pattern in a bulk polymerization step. Even greater advantages present themselves for direct-write DPN of proteins in areas of drug discovery, diagnostics, and proteomics, as it offers the possibility of generating arrays made from more than one protein.

Until recently, DPN has been used to fabricate affinity arrays from small organic molecules that aid in the directed deposition of proteins and biomacromolecules from solution.<sup>[41,68,70]</sup> Demers et al.<sup>[67]</sup> developed a variation of DPN that directly writes oligonucleotides on metals and insulators. A key strategy for the success of this approach was the use of matched ink–substrate combinations, directing the transfer of oligonucleotides onto the substrate. Lee, Kim, and Mikin<sup>[71]</sup> recently developed an innovative approach for directly writing proteins using DPN. This method hinges on the realization that protein transfer from the tip onto the substrate requires a biocompatible and hydrophilic (non-fouling) tip surface layer (Fig. 8).

The latter was achieved by tip-surface treatment with a poly(ethylene-glycol)silane. Directed, and orientationally controlled protein deposition on the

substrate surface is possible by judicious matching of surface and protein functionality.<sup>[71,72]</sup>

Current photolithography, microcontact printing, template synthesis, and scanning electrochemical microlithography techniques can yield conducting polymer microstructures, but these techniques possess significant limitations for patterning structures of  $< 100$ -nm dimensions. The availability of a wide range of monomers enables direct-writing of polymeric materials with a wide range of interesting electronic and electrooptical properties at the nanoscale level. Li, Maynov, and Liu<sup>[73]</sup> have recently introduced a variation of DPN, in which the water meniscus on the AFM tip is not only used as the transfer medium but

**Fig. 8** Protein nanoarray prepared via direct-write DPN. Contact mode height image of a Lysozyme nanodot array with a feature size of about 150 nm. *Source:* From Ref.<sup>[71]</sup>. © 2003 American Chemical Society.

**Fig. 9** Tip-directed electrochemical polymerization of 3,4-ethylenedioxythiophene. AFM height image (contact mode in air) showing two polymer lines each about 50 nm wide. *Source:* From Ref.<sup>[74]</sup>. © 2001, American Chemical Society.

also serves as a nanometer-sized electrochemical cell in which metal salts can be dissolved, electrochemically reduced, and ultimately deposited on a surface.<sup>[73]</sup> They showed that electrochemical DPN can be used to directly fabricate conducting polythiophene nanostructures on semiconducting and insulating surfaces in the sub-100-nm size scale.<sup>[74]</sup> To pattern these nanostructures, a negative bias voltage was applied between the AFM tip and a silicon surface, and the tip was translated across the surface in a preprogrammed pattern. The applied voltage electrochemically polymerized the monomer, resulting in tip-defined deposition of poly-3,4-ethylenedioxythiophene on the substrate (Fig. 9).

### Near-Field Scanning Optical Lithography

To date, photolithography is perhaps the most successful microfabrication technology, as most microelectronic circuits are produced via photolithographic methods. In conventional photolithography, the lateral resolution is determined by the Abbe diffraction limit (a far-field effect), which limits the feature size to about half the wavelength of the radiation used. The diffraction limit can be circumvented if the photosensitive sample is placed in the optical near-field of the focusing elements.<sup>[19,75]</sup> Optical lithography in the evanescent near field is mainly developed as a static patterning process by using a shadow mask in close proximity to a photoresist layer during exposure.<sup>[76]</sup>

In near-field scanning optical lithography (NSOL), this approach is taken one step further by inducing photopolymerization only in the vicinity of the probe tip (Fig. 10A).<sup>[19,75]</sup> In most NSOL techniques, laser radiation is coupled directly into a tapered single-mode optical fiber where the small fiber aperture limits the intensity of the deliverable radiation. Another NSOL

**Fig. 10** Two possible configurations for scanning near-field optical lithography. (A) NSOM aperture probe where radiation enters the region of interest in the near field through the probe. (B) Aperture-less NSOM using far field illumination. Intensity amplification occurs beneath the probe tip in the optical near field.

technique capitalizes on the field enhancement of optical radiation in the near field of a conducting SPM tip due to photon absorption (Fig. 10B).<sup>[77–79]</sup>

This approach is of considerable interest for surface nanopatterning and nanofabrication as it circumvents the use of delicate optical fibers and instead makes use of readily available laser sources and focusing optics.

Wurtz et al.<sup>[79]</sup> report on photopolymerization of a photoresist formulation induced by optical field enhancement in the near field of a conducting tip.<sup>[78,80]</sup> The free radical polymerization reaction was triggered by an actinic light activated sensitizer dye that, in the triplet state, reacts with amine to form free radicals. The threshold energy necessary to trigger a reaction is high and requires relatively large field intensities. Sufficiently large fields were only achieved in close proximity to the tip apex of a conducting AFM cantilever. Polymeric features with 70-nm lateral feature size were fabricated (Fig. 11).

These results are significant because they demonstrate that direct nanopolymerization in the evanescent

**Fig. 11** Aperture-less near-field scanning optical lithography where the optical field enhancement at the tip initiates locally the photopolymerization process. AFM height image (TappingMode<sup>TM</sup> in air) showing a nanometer scale polymer feature polymerized from a photo-polymerizable formulation (resist). *Source:* From Ref.<sup>[39]</sup>. © 2000, Japanese Institute of Pure and Applied Physics.

near-field of a conducting AFM tip is possible, and affords an elegant way for patterning surfaces with polymers.

## CONCLUSION

Advances in the area of scanning probe lithography have made available techniques, such as dip-pen nanolithography and nanografting, that allow fabrication of polymeric structures on surfaces on the nanoscale. While significant progress has been made in nanopatterning of biomacromolecules using affinity templates and direct writing, nanofabrication of polymeric structures from the “bottom up” using scanning probe lithography has only been prototypically demonstrated. Thus there is now a need to build more complex polymeric structures with precisely controlled lengths, conformational geometries, and chemical functionalities. In pursuit of these goals, techniques must be further developed which allow for the controlled synthesis of surface-attached polymers.

Several factors need to be addressed for the viability of SPL as a fabrication technology for polymeric nanostructures beyond the laboratory scale: 1) lateral resolution; 2) alignment; 3) reliability; and 4) throughput. While items 1)–3) are intrinsic capabilities associated with SPMs, a considerable restriction is presented by the slow, serial nature of the patterning process—one tip creates a single feature at a time. Recent developments of massively parallel proximal probe systems have been demonstrated,<sup>[22]</sup> and offer prospects toward achieving cost-effective, high-throughput “direct write” fabrication. The development of complex patterns is only possible through sufficient automation of the instrumentation and through pattern generation making use of computer-aided design (CAD). Progress in this area is of primary importance for the evolution of existing SPL nanofabrication strategies.

## INTRODUCTION

The devices of nanotechnology will require fabrication and characterization tools capable of near-atomic resolution, such as scanning probe devices. These employ a small, ultrasharp tip placed upon the surface of a solid. The tip measures an electrical, mechanical, or thermal property of the surface on a scale that ranges from 100 nm down to the size of a single atom. The most familiar and widely used devices of this class are the scanning tunneling microscope and the atomic-force microscope. The scanning device being discussed here detects the electric fields arising from charge on a surface. It is capable of seeing individual electrons and even much smaller amounts of charge. The device is a marriage of the sharp-tip scanning probe geometry with the single-electron transistor (SET).<sup>[1,2]</sup> The SET is based on the quantum-mechanical phenomenon of electron tunneling and the principle of Coulomb blockade. It has a conductance that is unusually sensitive to an external electric field, such as provided by the charge  $e$  of a nearby electron. A probe with this capability having atomic-scale spatial resolution would potentially be a powerful tool for surface characterization in both technology and surface science. The present-date SET probes have not reached this status. So far the demonstrated resolution for charge on the surface of a solid is of order  $0.001e$  with a spatial resolution of  $\sim 30$  nm. The operation has been restricted to liquid He temperature ( $<4$  K). The performance of SET probes can be expected to improve in the future as new nanoscale fabrication techniques become available.

## NATURE OF THE SINGLE-ELECTRON TRANSISTOR

The SETs used here are based on the metal–metal tunnel junction.<sup>[3]</sup> It consists of two metal electrodes separated by a thin insulating layer a few nanometers thick. Electrons can pass through the thin insulator by quantum-mechanical tunneling. In this process, an electron will spontaneously disappear from one electrode at random times and immediately reappear in the other.

A voltage bias  $V$  applied between the electrodes produces a net tunneling current  $I$ . A tunnel junction between two normal metals shows an ohmic conductance like a resistor. Unlike a resistor, however, the current has a granular nature, as it is made up of the random passage of individual charges of size  $e$ . This granularity is a significant factor in the operation of the SET.

The SET is a two-tunnel-junction device as shown schematically in Fig. 1. It has two conducting leads (X and Y in Fig. 1) that make contact with a much smaller, intermediate metal island (Z in Fig. 1). There may also be a gate (G in Fig. 1) that is capacitively coupled to the island. The island is connected to the leads by tunnel junctions (J1 and J2 in Fig. 1). A fundamental goal of the design is to make the total capacitance of the island,  $C$ , as small as practical. For a fixed geometry this capacitance scales with the size. In most cases, the bulk of  $C$  arises from the two tunnel junctions, where the separation of the conductors is  $\sim 1$ – $2$  nm.

At first sight, this configuration is two ordinary tunnel junctions in series and one might expect ohmic conductance. But the small capacitance  $C$  of the island imposes a strong restriction on the current flow that leads to a more complicated and interesting behavior known as Coulomb blockade. Except for fine details, the behavior can be understood by a simple circuit analysis. Three factors play a major role: the granular nature of the tunneling current, the electrostatic energy involved in changing the charge of the island by a single electron (!), and the use of a gate to modify this energy.

Suppose that electrode Y is at ground potential and a (negative) bias  $V$  is applied to electrode X, causing electrons to flow through the two junctions from X to Y. In the nature of tunnel junctions, this flow is not continuous. It occurs, rather, as an intermittent series of abrupt transfers of individual lumps of charge  $e$  through J1 from X to Z, and concurrently through J2 from Z to Y. For typical SET operation the current magnitude is  $\sim 1$  nA and the time interval between the arrivals and departures of electrons from the island is  $\sim 150$  psec. This is much longer than the tunneling time. Hence for most of the time, no current flows and the charge state of the island stays

**Fig. 1** Schematic of an SET: (A) Input electrode X at bias  $V$ . Output electrode Y at ground potential. Central region Z is insulated from X and Y by a thin insulator (shown in gray). Tunnel junctions J1 and J2 provide electrical contact from X and Y to Z. Current  $I$  flows from X to Y. A nearby gate G with bias  $V_G$  has a capacitance  $C_G$  to Z. (B) Calculated dependence of  $I$  on bias  $V$  and gate bias  $V_G$  for two identical junctions of resistance  $R$  and capacitance  $C'$ . The dependence is nonlinear on a voltage scale of  $e/C$  where  $C = 2C' + C_G$ . For fixed  $V$ ,  $I$  is periodic in  $V_G$  with period  $e/C_G$ . At low  $V$ , the Coulomb blockade suppresses  $I$  over a range of  $V$  and  $V_G$ . At higher  $V$  the dependence is approximately given by  $I = 2R(V - |e/2C|)$ .

fixed. The voltage  $V_Z$  of the island is also fixed and can be calculated by simple electrostatics, using only the mutual capacitances between Z and the other electrodes X, Y, and G, the biases  $V$  and  $V_G$  of X and G, and the number of excess electrons in residence on Z. As the tunneling electrons arrive and depart, they charge or discharge the capacitance  $C$  of the island, causing its voltage  $V_Z$  to increase and decrease by an amount  $e/C$ . The associated charging energy is  $e^2/2C$ . Whenever an arriving electron tunnels through J1, the voltage bias across J1,  $V - V_Z$ , is decreased by  $e/C$ , and that across J2,  $V_Z$ , is increased by this amount, and vice versa for an electron departing through J2. The rates of tunneling of the two junctions are similarly affected.

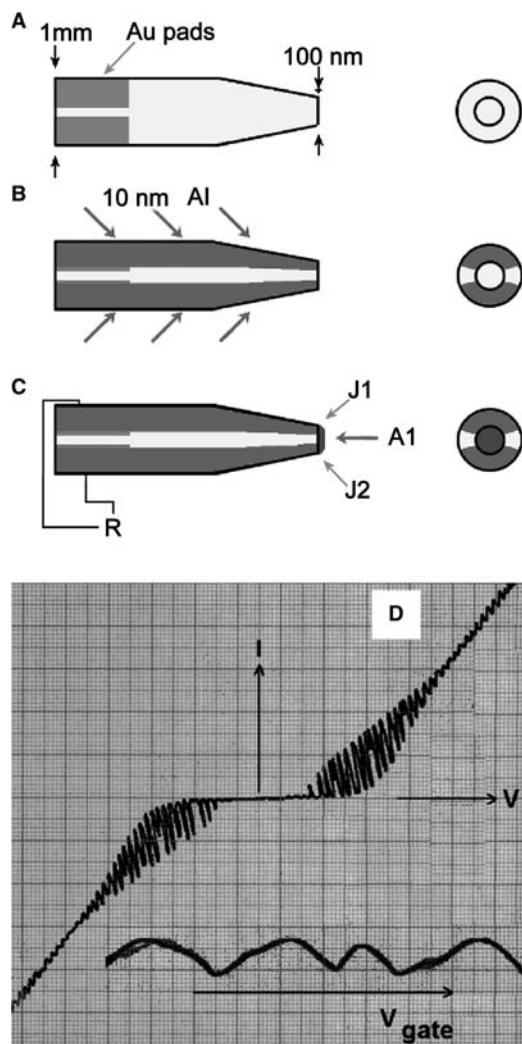

This influence of the charging energy is so strong it can stop the tunneling completely. At  $T = 0$  K, if the voltage bias across one of the junctions is smaller than  $e/2C$ , electrons cannot tunnel through that junction. To do so would impart a negative kinetic energy, in classical terms, to that electron. Moreover, if both junctions have a bias  $< e/2C$  at once, as may happen at total bias  $V < e/C$ , the tunneling events halt altogether. The SET displays a complete Coulomb blockade of the current flow. At finite temperature, the current is still greatly suppressed up to  $T \sim (e^2/2C)/k_B$ . The current is also partially suppressed by this effect at higher  $V$ , up to a few  $e/C$ , while the tunneling events in the two junctions tend to be anticorrelated.

Importantly for device purposes, the Coulomb blockade can be lifted by the voltage  $V_G$  of the gate G. Because the gate is capacitively coupled to the island with mutual capacitance  $C_G$  a fractional portion  $C_G/C$  of  $V_G$  is added to  $V_Z$ . Thus the biases of the two junctions can be adjusted by the gate voltage, one being increased and the other decreased. In this way, the bias of one of the junctions can be increased above  $e/2C$ , causing tunneling to begin again. This modulation of the SET conduction is actually an oscillating function of  $V_G$  with a period  $e/C_G$ . As  $V_G$  is increased electrons are added periodically to the island through one of the junctions resetting  $V_Z$  and the junction biases. Fig. 1B shows the calculated dependence of  $I$  on  $V$  and  $V_G$  for an SET formed by two identical junctions.

Finally, if a charged object is brought near the SET, the island voltage  $V_Z$  is shifted by electrostatic induction, changing the SET conductance. A single electron put very close to the island has the same effect as an increase of the gate voltage by one period. Thus the SET can be used as a sensitive scanning probe capable of detecting tiny amounts of charge.

## THE SINGLE-ELECTRON TRANSISTOR AS A SCANNING DEVICE

To use the SET as a scanning device, it is necessary to achieve a close proximity between the SET island and the surface to be studied. The traditional type of SET fabricated by electron beam lithography on a flat substrate is hard to exploit for scanning. To fabricate an SET in a sharp-point geometry suitable for scanning, an alternative lower-tech approach has been used.<sup>[4]</sup> The substrate is a glass or quartz cylinder of approximately  $\sim 1$  mm in diameter that is sharpened at one end into a micropipette shape. The sharpened end forms a cone with an angle  $\sim 10$ – $20^\circ$ . The very tip is truncated by a small flat area with a  $\sim 50$ -nm diameter. This plateau on the end is where the SET island is to be located. This truncated-cone geometry allows an SET to be formed by a simple angled-evaporation technique, without any lithography.

**Fig. 2** (A–C) Sketch of three stages in the formation of an SET on a sharp tip. Front views are at the left and side views, looking along the tip from the sharp end, are at the right. The size of the plateau at the tip is exaggerated for clarity. (A) Gold contact pads are prepared on the stem of the tip. (B) X and Y electrodes are made by evaporation of aluminum from top and bottom. The aluminum is then lightly oxidized. (C) Al evaporation from the sharp end forms the Z electrode on the plateau and junctions J1 and J2 at the edges of the plateau. The resistance  $R$  is monitored. (D) The upper curve shows the dependence of  $I$  on  $V$  and  $V_G$  for an experimental scanning SET. The oscillations in  $I$  are induced by rapid large oscillations in  $V_G$  as  $V$  is varied slowly. At low  $V$ , the  $I$ – $V$  curve differs from that in Fig. 1B because the electrodes are superconducting here. The lower curve shows the semi-periodic variation of  $I$  at fixed  $V$  for this SET. The irregular period and regions of hysteresis are commonly seen in the scanning SETs. They are due to the very thin, partly granular films used in the fabrication in this geometry.

The process (Fig. 2) has the following steps. First, gold contact pads are prepared along opposite sides of the rod excluding the lower, sharper part of the tip. The rod is then clamped in a detachable part of

the scanning apparatus and electrical connections are attached to the contact pads. Next, aluminum is evaporated from opposing sides producing two separate coatings that are aligned with and overlap the gold pads and extend down the conical part of the tip to the end. The films form the X and Y leads of the SET. During these evaporations the plateau is shadowed and stays uncoated. At this point, a low pressure of oxygen is briefly created in the vacuum system producing a thin oxide coating on the two aluminum films. A final aluminum evaporation is then performed with the sharp end pointing into the evaporant stream. At this orientation the small plateau and the adjacent edges of the X and Y films are coated with a single patch of conducting film. This forms the island Z of the SET. The two junctions are formed by the overlap of the Z film with the oxidized edges of the X and Y films. The sides of the cone and the rest of the rod receive much less evaporant flux owing to the shallow angle of incidence and acquire a much thinner, electrically discontinuous coating. Here it is helpful to monitor the resistance of the device to determine when the region Z first becomes electrically continuous. This completes the formation of the SET scanning tip. Typically, the thickness of the films is  $\sim 10$ – $20$  nm, the size of the SET island is  $< 100$  nm, the total area of the tunnel junctions is  $< 1000$  nm<sup>2</sup>, the junction resistance is  $\sim 1$  M $\Omega$ , and the charging energy  $e^2/2C$  is a few millielectron volts.

The tip, the sample to be studied, and the rest of the scanning apparatus are then cooled to liquid He temperatures. At low temperature the device is tested for characteristic SET behavior. Samples with conducting regions on the surface may be used as a gate to test the response of the SET. The upper curve in Fig. 2D shows the relationship between current  $I$  and voltage  $V$  for a typical SET used for scanning. The bottom curve shows dependence of  $I$  on gate voltage  $V_G$ . The capacitance  $C_G$  between the sample and the island can be determined from the period of oscillations. The value of  $C_G$  serves also to monitor and control the distance between the tip and the sample surface as the tip is lowered to the working height. This capacitance increases approximately logarithmically with decreasing distance at larger separations, and more steeply at smaller separations. Another indicator of the height, particularly at close separation, is provided by the resolution of the features seen in scanning the SET along a line. The final separation between the tip and the sample is  $\sim 5$  nm. At this height, a typical period  $e/C_G$  is  $\sim 30$ – $200$  mV. Any unintentional light mechanical contact made during the approach does not destroy the SET tip. On average, this whole procedure starting from a bare tip has about a 50% success rate in producing a usable scanning device. Typical runs last for periods ranging from days to months.

## IMAGING WITH THE SINGLE-ELECTRON TRANSISTOR

To proceed with the scanning, the SET is biased at fixed voltage and the SET current is recorded. Generally, the operating point is set so that the current varies linearly with the magnitude of electric flux picked up by the island. In cases when the signal is larger than one electron, feedback to the gate is used to extend the linear dynamic range. In this mode, the feedback voltage is recorded in addition to the SET current. The SET tip is scanned in a raster pattern across an area of interest at fixed height.

The signals seen by the SET tip may have several contributions. These include free charges, polarization of dielectrics, and image charges on conductors, as well as signals stemming from external biases on conducting regions, variations in contact potentials, and from current flow. For brevity, these are lumped together as d.c. electric-field signals. In addition, one can measure at the same time an a.c. signal, the response to a low-frequency stimulation of the system. This helps in extracting the small signal of interest from the larger d.c. signal background, e.g., the a.c. voltage pattern caused by an a.c. current flow. Data acquisition rates are about 1 pixel per second for the signal levels of about 0.1% of an electron flux terminating on the island of the SET.

So far, the samples studied with the scanning SET have been heterostructures of GaAs/AlGaAs grown on GaAs chips. The heterostructures contain a high-mobility two-dimensional electron gas, or 2DEG, buried  $\sim 100$  nm below the surface. These devices provide a reasonably well-characterized, clean semiconductor system whose flat surfaces have charge patterns suitable for testing the scanning SET. The main motivation for choosing this system, however, is that the 2DEG displays the quantum Hall effect (QHE),<sup>[5,6]</sup> which has been a long-time major topic of interest in condensed-matter physics. The electric-field images have provided a new tool for investigations of this topic.

### Images of Surface Charge Patterns

Fig. 3A shows d.c. electric-field images seen at the surface of these heterostructures. The pattern appears random with no apparent theme. The typical amplitude corresponds to a few tenths of an electron flux and the spatial size of features is limited by the SET resolution. This type of pattern can be expected. The heterostructure samples contain a fairly high concentration of charged donors,  $>10^{12}$  cm<sup>-2</sup>, at a depth of  $\sim 50$  nm, and a compensating charge density forms on the semiconductor surface. Both of these charge layers contribute to the surface electric fields seen by the SET.

**Fig. 3** (A) A typical electric field image (d.c. signal) seen by a scanning SET in a  $500 \times 500$ -nm area over the surface of a GaAs/AlGaAs heterojunction with an underlying 2DEG. The random pattern is due to the unresolved surface charge density of  $\sim 10^{12}$  charges/cm<sup>2</sup>. (B) The highest resolution electric-field image seen to date, taken in a  $600 \times 600$ -nm region of undoped GaAs. The small peaks have a density of about  $3 \times 10^{10}$  cm<sup>-2</sup> which may be the total number of charges trapped at the surface. (C) Effect of optical illumination on surface charges. The panel shows the difference of electric field images in a  $2 \times 2$ - $\mu$ m area taken before and after brief illumination by a light emitting diode. The white and black spots arise from sites (donor atoms) that acquired or lost a single electron charge.

But the individual charges are too closely spaced,  $\sim 10$  nm, to be resolved. Statistical fluctuations in the charge density would produce a random pattern of the sort seen in Fig. 3A.

The highest surface resolution obtained to date is shown in the image in Fig. 3B. This shows a  $600 \times 600$ -nm region of the GaAs surface where the heterostructure doped regions have been etched away.

The apparent resolution of the structure is  $\sim 30$  nm, and up to  $\sim 0.2$  electrons are induced on the SET island in the regions of maximum signal. The pattern appears to be partly correlated as opposed to the example above. In this undoped region, the surface charge density is much less than that in the doped heterostructure regions, and it is conceivable that the features shown are the individual charges.

The distribution of charges is fixed at low temperature and such patterns persist for weeks. However, an exposure to light excites carriers in the semiconductor and induces changes in these patterns at randomly positioned spots. These changes result from the ionization or neutralization of individual donors or surface sites (Fig. 3C).

### Studies of the Quantum Hall Effect

The QHE is an exotic form of the ordinary Hall effect. This effect, commonly observed in metals and semiconductors, occurs in a conductor subjected to a magnetic field and having a current flowing perpendicular to the field. In this situation a potential, or Hall voltage, is found to be present in the direction transverse to both current and field. This potential arises from the Lorentz force acting upon the electrons. The Hall resistance, the ratio of the Hall voltage to the current, is proportional to the field strength and inversely proportional to the carrier density.

The integer QHE occurs in situations where the Hall resistance of a high-mobility two-dimensional electron (or hole) gas is measured at temperatures  $< 10$  K, and much lower, and in a magnetic field  $B$  of several Tesla.<sup>[5,6]</sup> It is found that whenever the filling factor, the normalized ratio  $\nu = n(h/e)/B$  between the 2DEG density  $n$  and magnetic field  $B$ , is approximately an integer  $N = 1, 2, 3, \dots$ , the Hall resistance does not increase linearly with  $B$  but instead becomes constant exactly equal to  $(h/e^2)/N$ . Here  $h$  is Planck's constant and  $e$  is the electronic charge. This quantization of the Hall resistance is the signal feature of the QHE. The quantization is intimately related with the notion of electron localization. The localization is caused by disorder in the potential seen by the 2DEG electrons. The fascinating physics of the QHE has led to two separate Nobel prizes over the last 20 years.

The scanning SET images taken at the surface of the heterostructures at high  $B$  and low  $T$  show a rich hierarchy of phenomena associated with the QHE.<sup>[7]</sup> On a larger scale there are contact potential features in the 2DEG in the form of linear structures that move about as a function of magnetic field as illustrated in Fig. 4. The four panels show overlapping  $15 \times 15$ - $\mu\text{m}$  areas of a heterostructure having a 2DEG conducting layer 100 nm below the surface. The average 2DEG density

**Fig. 4** Electric-field images related to the quantum Hall effect. These  $15 \times 15$ - $\mu\text{m}$  images are taken in the same general area over the surface of a GaAs/AlGaAs heterojunction with an underlying 2DEG. The density of the electrons in the 2DEG is  $\sim 10^{11} \text{ cm}^{-2}$  but has about  $\pm 30\%$  variation with location. Part of the surface is covered by two t-shaped metal gates. A) d.c. signal (1-V scale) showing a biased gate (white) and an unbiased gate (gray). The remaining surface of the semiconductor is featureless on this scale. B–D) The a.c. signals ( $\sim 1$ -mV scale) seen in this region induced by a small uniform variation of  $n$ . B) Magnetic field  $B \sim 2.3$  T. The white lines are contact potential features occurring at points where the local density  $n$  corresponds to a filling factor of 2 at this field. C)  $B = 2.0$  T. The contact potential features of B) have moved to a region of  $\sim 15\%$  lower density. D)  $B = 4.0$  T. The filling factor is now 1 at the same locations as in C). The unusually large variations in the 2DEG density  $n$  seen here are associated with leakage of surface charge from a biased gate. This charge partially depletes the underlying 2DEG.

is  $\sim 10^{11} \text{ cm}^{-2}$ , varying substantially with location. Magnetic field  $B$  ranges from 2 to 4 T. This corresponds to the regime of the QHE for filling factors  $\nu = 1$  and 2. All images in Fig. 4 are taken in the feedback mode mentioned above. Fig. 4A shows the feedback voltage ( $\sim 1$ -V scale) corresponding to the overall d.c. signal. The primary features are the metal gates patterned on the sample surface. The right gate is biased at  $\sim -0.6$  V producing the largest signal shown as white. The left gate is unbiased but shows up relative to the surrounding semiconductor owing to  $\sim 0.2$  V of contact potential between the two. This large-scale picture has a relatively low resolution because the scanning SET is positioned  $\sim 50$  nm above the surface. While the semiconductor region appears featureless in this image, there is structure on the 50-mV scale near the biased gate.

The signature of the QHE appears at a smaller  $\sim 1$ -mV scale and is superimposed on the much larger signals discussed above. This signal is extracted by an a.c. modulation technique. Applying an a.c. voltage to a gate underneath the 2DEG produces a small variation in the 2DEG density,  $\sim 0.1\%$ . The corresponding a.c. component in the SET signal is displayed in Fig. 4B. The contact potential features are the bright lines located between the gates and in the lower part of the picture. These mark the contours along which the spatially varying carrier density  $n$  is equal exactly to  $n = 2 \times B/(h/e)$  for  $B = 2.3$  T. At lower magnetic field (e.g., Fig. 4C) the contours move to positions of lower local density always appearing at the local filling factor  $\nu = 2$ . By adjusting the magnetic field, one can map out the inhomogeneous density of the 2DEG. Fig. 4D shows the contours at  $\nu = 1$  that appear at exactly the same location as in Fig. 4C for magnetic field two times higher.

The contact potential features result from the energy level structure of the quantum states of a high-mobility 2DEG. At high  $B$ , the energy levels are grouped into a set of narrow energy bands, known as Landau levels, separated by gaps. The lower energy levels are occupied by the 2DEG electrons. The filling factor  $\nu$  is an integer whenever the electrons just fill up a Landau-level band. Additional electrons must be located in the higher Landau band of states, a few millielectron volts up in energy. In an inhomogeneous 2DEG there might be spatial regions with filling factor less than some integer  $N$  where a Landau band is almost filled up and adjacent regions with filling factor greater than  $N$  where the next Landau band is partly filled. An analogous situation is that of p–n junctions in a semiconductor. In a semiconductor with spatial gradients in donor and acceptor density some areas may be p-type and adjacent areas n-type. A contact potential equal to the energy gap develops across the p–n boundaries. A similar effect occurs in the inhomogeneous 2DEG. Here again a contact potential equal to the energy gap occurs between areas having filling factors less than  $N$  and greater than  $N$ . When the charge density is increased uniformly, the boundaries between these two areas shift sideways. The features seen in the a.c. signal in Fig. 4B–D are caused by the movement of such boundaries. With changes in magnetic field  $B$  these boundaries have been observed to move across the sample surface, tracing out the density contours. Such boundaries are seen over a wide range of  $B$  in a variety of twisting shapes, sometimes forming loops indicating local density extrema. The shapes of these boundaries are reflected, to a degree, in the larger-scale variations in the surface potential, indicating that the density is perturbed by the surface charge in these images.

The accepted picture of the QHE assigns a central role to the peculiar behavior of the 2DEG electrons

at these boundaries where the local filling factor is an integer, known also as incompressible strips.<sup>[8]</sup> Current flows without dissipation along these boundaries, perpendicular to the local voltage gradients, and experiences a very high resistance in flowing across the boundaries. The location of the boundaries with respect to the position of the voltage contacts determines whether a quantized Hall resistance will be measured. Single-electron-transistor images of the voltage induced by a flowing current have confirmed that it is much distorted by the presence of such a boundary in the current path.<sup>[7]</sup>

Higher resolution SET images of the boundary regions just described have revealed that they contain an intriguing variety of complicated structure. The structure arises from the localization of some of the 2DEG electrons.<sup>[9]</sup> A typical example is shown in Fig. 5. These panels show the a.c. response of the SET in a  $1 \times 1\text{-}\mu\text{m}^2$  area induced by a small change in the density of the 2DEG, the same way as for

**Fig. 5** Grayscale maps ( $\sim 0.1$ -mV scale) of the a.c. signal seen by the scanning SET. The area is  $1 \times 1\ \mu\text{m}^2$ . The conditions are set similar to Fig. 4D and the fine structure within the strip with local filling factor  $\sim 1$  is studied. The average density is increased by  $\sim 1.8$  electrons/ $\mu\text{m}^2$  between successive panels. Dark color represents positive a.c. signal while bright contours are regions with the phase of a.c. signal opposite to the a.c. excitation at the gate electrode (negative signal). The ring-shaped contours on different panels are seen collapsing to common centers as the density is increased. These sequences of collapsing rings are the visualization of the Coulomb blockade occurring at localized electron sites within the 2DEG. The specific appearances of these charging events are determined by the interaction of the localized electrons with each other and with the scanning SET tip.

Fig. 4B–D. The total number of electrons in the area shown is  $\sim 1300$ . In successive panels an additional  $\sim 1.8$  electrons are added to the area substantially changing the a.c. signal pattern. The strength of the signals ( $\sim 0.1$  mV) occurring in these patterns indicates that the bright features are due to the addition or subtraction of individual electrons from the immediate vicinity of the tip. Theoretical considerations of the QHE lead to the conclusion that the electrons occupying a fully filled Landau band form an insulator-like incompressible fluid. Any small excess or deficit in the complete filling gives rise to a low density of singly charged quasi particles. These are trapped in small variations in the local disorder potential and interact with each other to form, in some theories, a sort of electron glass or crystal. Although the picture is complicated by a fairly strong interaction between the tip and the electrons, it may be that the images shown in Fig. 5 are of such a two-dimensional solid.

## CONCLUSION

The present-day SET scanning devices have been able to make a significant contribution to studies of electronic properties of materials at a nanoscale level complementing other characterization techniques. Smaller devices of the same geometry will have improved spatial resolution and higher operating temperature. Even with the current fabrication procedures some SET scanning devices have been made that have shown operation at around 50 K. It is believed that ultimately an SET of atomic size can be developed, and that its operation and performance will be similar to that of the present-day SETs. This will require new techniques of fabrication, similar perhaps to those considered for molecular electronics.

## ACKNOWLEDGMENTS

We would like to acknowledge Harold Hess, Michael Yoo, Amir Yacoby, Larue Dunkelberger, Robert Chichester, Loren Pfeiffer, and Ken West who contributed equally with the present authors to the development of the technique and the associated research.

# Self-Assembled Monolayers: Adsorption and Desorption from Alkanethiols on Gold

Pieter Stroeve

Department of Chemical Engineering and Materials Science, University of California–Davis, Davis, California, U.S.A.

## INTRODUCTION

There is considerable interest in thin molecular nanofilms made from the self-assembly of species. A current area of research is the assembly of multilayers of alternating surfactants, proteins, and polymers to form macromolecular assemblies with unique functions and properties. Such properties can be directional in conducting electricity and propagating light or transferring mass. An example is the use of different types of surfactants and polymers, in a multilayer stack, to design selective membranes. Another interest is in using biopolymers with surfactants at the solid–water interface for selective barrier coatings for biosensors that may also be compatible with biological species. Yet another possibility is to use the self-assembly of surfactants on the solid–water interface to pattern the deposition of biopolymers on surfactants (Fig. 1). Self-assembled thiol monolayers (SAMs) on gold are often used as model solid–water interfaces, because these surfaces have unique properties. This is yet another area that has become a subject of active research. This entry will review the formation of SAMs and the adsorption and desorption of molecules on the SAMs to create nanofilms.

## SELF-ASSEMBLED MONOLAYERS OF ALKANETHIOLS ON GOLD

Self-assembled monolayers can be formed from alkanethiols on the surface of gold.<sup>[1–4]</sup> Alkanethiol SAMs have become a widely used tool for the design of surfaces and for the study of phenomena on surfaces.<sup>[5–8]</sup> Many studies have focused on SAMs formed on evaporated films of gold and Au(111) single crystals. The SAMs of alkanethiols on gold films are formed by rinsing the gold films with absolute ethanol (100%) followed by immersion in ethanolic solutions of alkanethiols (about 1 mM) for at least 24 hr. Upon removal from solution, samples must be thoroughly rinsed with absolute ethanol and dried under a stream

of nitrogen. X-ray diffraction has been used to show that the predominant crystallographic orientation of evaporated gold deposited on mica<sup>[9]</sup> and silicon single crystals<sup>[10]</sup> is Au(111). The structure of SAMs formed on Au(111) from solutions of long-chain alkanethiols [i.e.,  $\text{CH}_3(\text{CH}_2)_n\text{SH}$ ,  $n \geq 9$ ] has been extensively studied. Scanning tunneling microscopy (STM)<sup>[11]</sup> and electron diffraction<sup>[12]</sup> show that the sulfur atoms form a commensurate  $(\sqrt{3} \times \sqrt{3})R30^\circ$  structure with a nearest sulfur–sulfur spacing of 4.97 Å. Helium atom diffraction,<sup>[13–15]</sup> low energy electron diffraction (LEED),<sup>[16]</sup> grazing-angle X-ray diffraction,<sup>[17]</sup> and atomic force microscopy (AFM)<sup>[18]</sup> show that the alkyl chains form hexagonal lattices with a unit mesh constant of  $\sim 5$  Å that is consistent with the  $(\sqrt{3} \times \sqrt{3})R30^\circ$  structure of sulfur atoms (Fig. 2A). The specific area of each alkyl chain within this structure is  $21.7 \text{ \AA}^2/\text{molecule}$ .<sup>[6,15]</sup> Other studies, however, also indicate the presence of unit cells containing more than one chain. Band splitting in infrared spectra at low temperatures ( $< 300 \text{ K}$ ) suggests a packing structure of two chains per unit cell.<sup>[19]</sup> Helium atom diffraction (temperature  $< 100 \text{ K}$ ) suggests a rectangular  $(3 \times 2\sqrt{3})$  unit mesh of alkyl chains that is commensurate with the  $(\sqrt{3} \times \sqrt{3})R30^\circ$  structure<sup>[20]</sup> (Fig. 2A). The packing arrangement can also be described as a  $c(4 \times 2)$  superlattice of alkyl chains with respect to the fundamental  $(\sqrt{3} \times \sqrt{3})R30^\circ$  structure of sulfur atoms. The existence of a superlattice is supported by results of grazing-angle X-ray diffraction<sup>[20–22]</sup> and ultrahigh vacuum STM.<sup>[23]</sup> Because the nearest sulfur–sulfur spacing (4.97 Å) for the structure shown in Fig. 2A is larger than the closest spacing of the alkyl chains ( $\sim 4.24 \text{ \AA}$ ),<sup>[24]</sup> the alkyl chains tilt from the surface normal to maximize their van der Waals interactions.<sup>[25]</sup> A simple geometric calculation indicates a tilt angle of about  $30^\circ$  from the surface normal. Ellipsometric measurements<sup>[2,3]</sup> in conjunction with grazing-angle infrared spectroscopy<sup>[3,6,10,16,26–28]</sup> have confirmed that the alkyl chains are tilted by about  $30^\circ$  from the surface normal and rotated around the chain axis by an angle (twist angle) of about  $52^\circ$  on surfaces of evaporated gold and Au(111) single

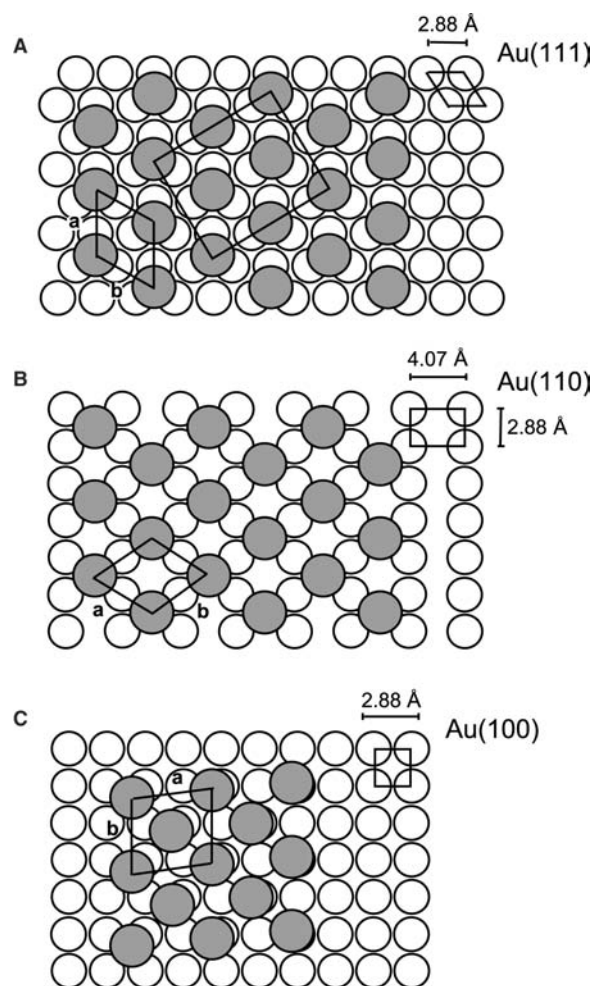

**Fig. 1** Schematic presentation of polymer macromolecules (linear and helical) with different conformations aligned by surface self-assembled, full- (A, B), and hemimicelles (C, D) of surfactants on a self-assembled thiol monolayer on gold.

crystals. Both the position ( $2918\text{ cm}^{-1}$ ) and the width of the absorbance peak corresponding to the asymmetric stretch of the methylene groups suggest the formation of close-packed, crystalline-like monolayers with a nearly all *trans* configuration. The intensities of the symmetric and the asymmetric methyl modes in the IR spectra of odd and even chain lengths are substantially different,<sup>[27,28]</sup> leading to the conclusion that the transition dipole of the symmetric methyl mode in a chain with an odd number of carbons is tilted from the surface normal more than that for a canted chain with an even number of carbons. The reverse situation exists for the asymmetric methyl mode.

Fenter et al.<sup>[22]</sup> have proposed a different structure for SAMs formed from long-chain alkanethiols on Au(111). They interpreted grazing-angle X-ray diffraction patterns to infer the presence of a S–S distance similar to that of a disulfide. This packing arrangement of the sulfur atoms along with a *gauche* defect at the S–C bond leads to the  $c(4 \times 2)$  superlattice.<sup>[20–23]</sup> Results from a simulation based on quantum mechanics are consistent with this structure and suggest that the alkyl chains are canted by  $28.3^\circ$  from the surface normal.<sup>[29]</sup> This tilt angle is close to that estimated from the thiolate structure as stated above.

The packing and orientation of chains within SAMs have been studied on surfaces of gold other than (111), including (110)<sup>[15]</sup> and (100)<sup>[12,15,16]</sup> surfaces. From those studies, it has been shown that the crystal structure of the surface of the gold substrate does influence the structure of a SAM. On a Au(110) surface with a rectangular unit lattice ( $2.88 \times 4.07\text{ \AA}$ ), helium atom diffraction suggests that the terminal methyl groups of docosyl mercaptan [ $\text{CH}_3(\text{CH}_2)_{21}\text{SH}$ ] form a commensurate  $c(2 \times 2)$  structure with  $a = b = 4.99\text{ \AA}$  and  $\alpha = 109.5^\circ$  (Fig. 2B) at low temperatures ( $<100\text{ K}$ ).<sup>[15]</sup>

**Fig. 2** Schematic illustrations of the structure of SAMs formed from alkanethiols on single crystals of gold. Open circles represent gold atoms and shaded circles represent alkyl chains. The chain tilt and twist are not shown for clarity. (A) Au(111). The smaller rhombus shows the Au(111) lattice. The larger rhombus shows a commensurate  $(\sqrt{3} \times \sqrt{3})R30^\circ$  unit mesh with  $a = b = 4.97\text{ \AA}$  and  $\alpha = 120^\circ$  (angle between  $a$  and  $b$ ). The rectangle denotes a  $c(4 \times 2)$  superlattice with respect to the  $(\sqrt{3} \times \sqrt{3})R30^\circ$  structure. (B) Au(110). Also shown is a commensurate  $c(2 \times 2)$  unit mesh with  $a = b = 4.99\text{ \AA}$  and  $\alpha = 109.5^\circ$ . (C) Au(100). Also shown is an oblique incommensurate structure with  $a = b = 5.97\text{ \AA}$  and  $\alpha = 95^\circ$ . Source: Reprinted from Ref.<sup>[30]</sup> with permission.

The resulting area per chain ( $23.6\text{ \AA}^2/\text{molecule}$ ) is larger than that on a (111) surface (as noted above,  $21.7\text{ \AA}^2/\text{molecule}$ ). Thus the chains on the (110) surface tilt more from the surface normal (the tilt angle is estimated to be about  $37^\circ$  based on geometric considerations) than on the (111) surface.<sup>[15]</sup> The structure of SAMs formed on Au(100) [square unit lattice ( $2.88 \times 2.88\text{ \AA}$ )] has also been reported. In a study using electron diffraction, the alkyl chains of

$\text{CH}_3(\text{CH}_2)_{21}\text{SH}$  were found to be packed more densely on Au(100) than on Au(111).<sup>[12]</sup> A study using LEED has shown that  $\text{CH}_3\text{SH}$  forms a commensurate  $c(2 \times 2)$  overlayer on Au(100) when vapor-deposited at 300 K.<sup>[16]</sup> The interchain spacing of this structure is too small, however, to accommodate longer chains with extended all-*trans* conformation. An expanded structure for long chains was suggested. An oblique unit mesh of terminal methyl groups of  $\text{CH}_3(\text{CH}_2)_{21}\text{SH}$  with  $a = b = 5.97 \text{ \AA}$  and  $\alpha = 95^\circ$  on the Au(100) surface (Fig. 2C, two molecules per mesh) at low temperatures ( $<100 \text{ K}$ ) was observed by helium atom diffraction.<sup>[15]</sup> This structure suggests that the alkyl chains are incommensurate with the (100) lattice. The area per chain is  $17.8 \text{ \AA}^2$ , which is smaller than those on Au(111) and (110) surfaces. The above results support the idea that the alkyl chains are packed more densely on Au(100) than on Au(111) and (110) surfaces. A study of IR spectroscopy at low temperatures (160 K) shows that the tilt angle of chains on the Au(100) surface is only  $\sim 14^\circ$  from the surface normal.<sup>[16]</sup> Consequently, the intensities of the methyl stretching modes in the IR spectra between odd and even chain lengths are almost indistinguishable.<sup>[16]</sup>

Hou, Abbott, and Stroeve<sup>[30]</sup> reported an investigation of SAMs formed from alkanethiols on the surface of both electroless gold and evaporated gold supported by a variety of substrates. They adapted the procedure for electroless plating reported by Menon and Martin<sup>[31]</sup> so as to deposit thin films of electroless gold on glass microscope slides, high index glass, and polycarbonate membranes. The capability to form SAMs on electroless gold is important for two principal reasons. First, electroless gold can be easily prepared in any wet chemical laboratory. Second, electroless gold can be deposited onto complex and internal surfaces where procedures of evaporation cannot be used. On both evaporated gold and electroless gold, densely packed SAMs were formed. Because electroless gold has a crystallographic texture that is more dispersed than evaporated films of gold, the structures of SAMs formed on these two surfaces were not identical.

## PROTEIN ADSORPTION AND DESORPTION

Self-assembled monolayers formed from  $\omega$ -substituted alkanethiols on the surface of gold have been used as model surfaces in a number of past studies of the interactions of proteins with surfaces.<sup>[32–35]</sup> Multilayer systems based on biotinylated alkanethiols and streptavidin have been used in schemes for the immobilization of Fab fragments of antibodies on surfaces,<sup>[32]</sup> and SAMs formed from NHS-activated disulfides have been used to form enzyme-based electrodes by covalent

immobilization of glutathione reductase.<sup>[33]</sup> Cytochrome *c*, when adsorbed to SAMs formed from mercaptoundecanoic acid, has also been shown to be active and to possess a formal potential nearly identical to that of cytochrome *c* bound to physiological membranes.<sup>[34]</sup>

Past studies of the interactions of proteins and SAMs formed from alkanethiols on gold have used either planar surfaces prepared by electron beam or thermal deposition of gold<sup>[36,37]</sup> or highly curved surfaces formed by using colloidal gold.<sup>[38–41]</sup> Whereas planar interfaces prepared by the evaporation of gold have surface areas that are too small to be generally useful for biological assays based on measurements of bulk concentrations of analytes, colloidal particles ( $\sim 1\text{--}10 \text{ nm}$  in size) are not large enough to pack (unsupported) in columns through which reagents can be readily passed.

Dubrovsky et al.<sup>[42]</sup> reported modification of the surface properties of microparticles of silica (silica gel) by electroless deposition of gold on the surface of silica gel and self-assembly of monolayers formed from  $\text{X}(\text{CH}_2)_{11}\text{SH}$  [ $\text{X} = \text{CH}_3, \text{OH}, \text{COOH}$ , and  $(\text{OCH}_2\text{CH}_2)_2\text{OH}$ ] on the surface of the deposited gold. Whereas the proteolytic enzyme subtilisin BPN' adsorbed irreversibly from aqueous solution (100 mM Tris buffer, 10 mM  $\text{CaCl}_2$ , pH 8.6) on the surface of untreated silica gel, reversible adsorption of subtilisin BPN' was achieved on silica gel coated with gold and derivatized with SAMs formed from  $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_2(\text{CH}_2)_{11}\text{SH}$ . The results demonstrated the usefulness of gold-coated silica gel for preparation of supports for chromatography and biological assays with controlled surface properties.

The extent of irreversible adsorption of subtilisin BPN' onto bare silica gel and modified silica gel was determined by measuring the absorbance of a solution of enzyme before and after passage through a column containing gel. The measurements were performed in Tris buffer at pH 8.6, which corresponds to the isoelectric point of subtilisin BPN' and a maximum in the hydrolytic activity of the enzyme. First, the column was contacted with 3 mL of Tris buffer containing 32 nmol of subtilisin BPN' for 40 min. Following this contact period, a 14-mL buffer was passed through the column and eluent samples of 1 mL each were collected. The concentration of enzyme in the eluent was measured and the amount of enzyme adsorbed to the gel was determined. The amount of enzyme irreversibly adsorbed to the gel after the completion of elution is shown in Table 1. Whereas 14 nmol of subtilisin BPN' was irreversibly adsorbed to untreated silica gel, Dubrovsky et al.<sup>[42]</sup> observed no irreversible adsorption of the enzyme onto gel presenting di(ethylene glycol) groups. The gold-coated gel (not treated with a SAM) irreversibly adsorbed 8 nmol of subtilisin

**Table 1** Moles of subtilisin BPN' irreversibly adsorbed (in 100 mM Tris buffer at pH 8.6) on the following surfaces: Bare silica gel; silica gel covered with a layer of electroless gold; and silica gel covered with a layer of electroless gold and derivatized with SAMs formed from  $\text{CH}_3(\text{CH}_2)_{11}\text{SH}$ ,  $\text{HO}(\text{CH}_2)_{11}\text{SH}$ , and  $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_2(\text{CH}_2)_{11}\text{SH}$

Stationary phase (500 mg)	Irreversibly adsorbed subtilisin BPN' (nmol)
Silica gel (untreated)	14
Electroless gold on silica gel	8
$\text{CH}_3(\text{CH}_2)_{11}\text{SH}$ on electroless gold on silica gel	2
$\text{HO}(\text{CH}_2)_{11}\text{SH}$ on electroless gold on silica gel	1
$\text{HO}(\text{CH}_2\text{CH}_2\text{O})_2(\text{CH}_2)_{11}\text{SH}$ on electroless gold on silica gel	0

Source: From Ref.<sup>[42]</sup> with permission.

BPN', and thus the SAM is needed to prevent irreversible adsorption. Because the bare silica gel irreversibly adsorbs subtilisin BPN' whereas the gold-coated silica gel supporting the SAMs formed from  $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_2(\text{CH}_2)_{11}\text{SH}$  does not, one can conclude that electroless gold in combination with the SAMs can be used to block sites on the silica gel responsible for irreversible adsorption of subtilisin BPN'. It can also be seen that the extent of irreversible adsorption of subtilisin BPN' to the SAMs presenting hydroxyl (OH) and methyl groups ( $\text{CH}_3$ ) is also small. In these cases, however, the volume of buffer required to elute a specified fraction of the adsorbed protein was greater than for SAMs presenting di(ethylene glycol) groups.

## SURFACTANT ADSORPTION AND DESORPTION

An improved understanding of surfactant adsorption and desorption on solid–aqueous interfaces is of crucial importance in many practical applications including detergency, wetting, pharmaceuticals, biomaterials, cosmetics, decontamination, and oil recovery.<sup>[43]</sup> Atomic force microscopy has been used to image surface-adsorbed surfactant structures directly in surfactant solutions.<sup>[44]</sup> In addition to monolayers and bilayers, a wide variety of surface micelles on solid surfaces have been found, such as hemicylinders, cylinders, hemispheres, and spheres. It is now generally accepted that hemimicelles may be formed by the adsorption of charged surfactants on hydrophobic surfaces. The formation of full micellar structures is often found in the adsorption of charged surfactants on hydrophilic surfaces.

Knowledge of the aggregate structure of the adsorbed surfactant layer, as well as the surface excess concentration and the rates of adsorption and desorption, is necessary to fully characterize the adsorption behavior, which is dependent on the interaction of the surfactant with surfaces of different nature and charge. Soluble surfactants can associate with surfaces due to van der Waals forces or coulombic interactions with hydrophobic or charged portions of the surface to form different surface structures.<sup>[44–48]</sup> The literature on surfactant adsorption on solid–liquid interfaces often contains kinetic adsorption data where mass transfer in the fluid played a role. Although such studies have merit in comparing different conditions, the presence of mass transfer complicates analysis, and, consequently, the intrinsic kinetics is usually not reported.

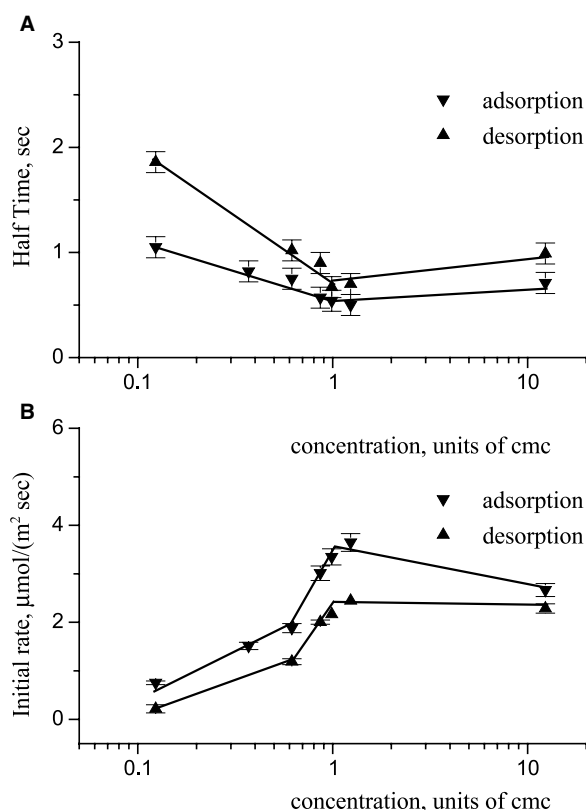

Sodium dodecyl sulfate is a well-studied material because of its practical importance. Sodium dodecyl sulfate is known to hydrolyze over time to form dodecanol, which enhances the adsorption of sodium dodecyl sulfate (SDS) below the critical micelle concentration (cmc) (8.1 mM) and decreases the adsorbed amount above the cmc.<sup>[49]</sup> The dodecanol impurity can exist in commercially available SDS if used as received. Thus SDS must be purified before use in adsorption studies. There exists a large amount of information on the structure and equilibrium of SDS adsorption on a variety of surfaces using AFM, Fourier transformed infrared spectroscopy (FTIR), and other surface-sensitive techniques. However, less attention has been given to SDS adsorption and desorption kinetics because of the difficulty of exploring fast kinetic processes. Sigal, Mkrbich, and Whitesides<sup>[45,46]</sup> employed a BIACore surface plasmon resonance (SPR) in a flow configuration to elucidate information on equilibrium adsorption and adsorption kinetics of SDS on hydrophobic and hydrophilic surfaces made by SAMs on gold. Assuming first-order kinetics, the maximum adsorption constant their SPR equipment could measure was  $k_a < 0.1 \text{ sec}^{-1}$ . Because of these limitations they did not report specific values for the adsorption and desorption kinetics. Levchenko et al.<sup>[50]</sup> constructed a SPR system with a laminar flow cell and high SPR measurement rate that allowed monitoring the adsorption kinetics at various flow rates with  $k_a$  of up to  $10 \text{ sec}^{-1}$ . By increasing the flow rate in the flow cell (expressed in terms of the Reynolds number), the limit at which kinetics controls the process of adsorption or desorption could be achieved so that the intrinsic kinetics could be measured. Consistent with previous results in the literature, they found that recrystallization of SDS was necessary to eliminate trace amounts of dodecanol. The SDS adsorption and desorption rates increased with bulk SDS concentration in the monomer regime reaching a maximum at

the cmc. At and above the cmc of SDS, the adsorption and desorption rates became nearly constant as shown in Fig. 3. The experimental results show that the SDS monomers play a dominant role in the adsorption and desorption on SAMs, and that micelles in the solution do not increase the adsorption rate when mass transfer limitations are negligible. The data suggested that the kinetics of adsorption and surface micelle formation for hemicylinders is a slower process than the adsorption and formation of hemispheres.

## ADSORPTION AND DESORPTION OF POLYMERS

Copolymers that have constituent blocks with different affinities for their surroundings exhibit amphiphilic properties; that is, they, like more conventional surfactants, self-organize or self-assemble at interfaces and in solution to minimize contact between less compatible parts. This behavior can be exploited to change the properties of surfaces and to enhance solubilities in solution. Lately, the emphasis has shifted toward the

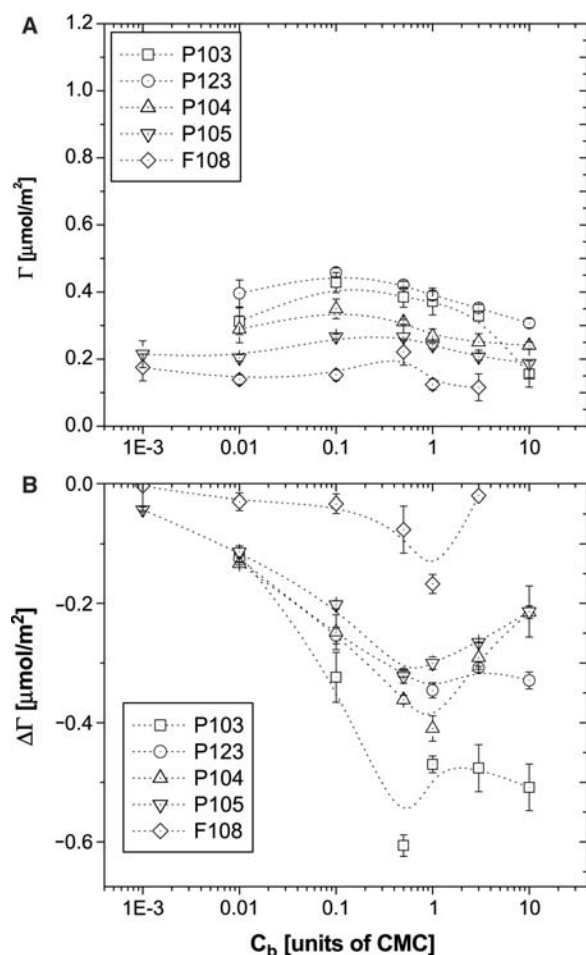

design and creation of functional, adsorption-driven, self-assembled nanostructures.<sup>[51–53]</sup> Understanding the modality of interactions between polymers and surfaces is fundamental in the pursuit of this task. Brandani and Stroeve<sup>[54]</sup> reported on the equilibrium behavior of adsorption (and desorption) from solution of a series of copoly(ethyleneoxide–propyleneoxide–ethyleneoxide), PEO–PPO–PEO triblock copolymers (Pluronic) on a gold surface modified by a methyl-terminated self-assembled monolayer of a long-chain alkanethiol ( $\text{CH}_3(\text{CH}_2)_{10}\text{SH}$ ). The simplified notation  $E_nP_mE_n$  for Pluronic PEO–PPO–PEO will be used here, where  $n$  and  $m$  are the repeat units. Brandani and Stroeve<sup>[54]</sup> monitored the adsorbed amounts of Pluronic on the hydrophobic SAM with SPR. The study showed that the adsorbed amounts go through a maximum near the cmc, as shown in Fig. 4, and thus the process was not consistent with a Langmuir isotherm. The occurrence of non-Langmuir-type behavior for Pluronic or similar systems has already been seen in the past.<sup>[55,56–59]</sup> The maximum is generally attributed to polydispersity, and in fact it has been reported that these polymers have a bimodal distribution with an additional lower molecular weight, more hydrophobic fraction.<sup>[60]</sup> Brandani and Stroeve<sup>[54]</sup> found that the adsorption–desorption process was partially irreversible as shown in Fig. 5. They employed AFM in the liquid environment on a selected number of cases to discern the morphology of the copolymer-coated surfaces. Atomic force microscopy observations showed that globular micelle-like aggregates were present at the surface for the more hydrophobic species P103 ( $E_{17}P_{60}E_{17}$ ). In contrast, a uniform

**Fig. 3** Half times (A) and initial rates (B) of SDS adsorption on and desorption from SAMs of undecanethiol as a function of surfactant concentration. The cmc is 8.1 mM. Source: Reprinted from Ref.<sup>[50]</sup> with permission.

**Fig. 4** Adsorption isotherms for Pluronic P103 ( $E_{17}P_{60}E_{17}$ ), P123 ( $E_{19}P_{69}E_{19}$ ), P104 ( $E_{27}P_{61}E_{27}$ ), P105 ( $E_{37}P_{56}E_{37}$ ), and F108 ( $E_{132}P_{50}E_{132}$ ). Source: Reprinted from Ref.<sup>[54]</sup> with permission.

**Fig. 5** Desorption isotherms for Pluronic P103 ( $E_{17}P_{60}E_{17}$ ), P123 ( $E_{19}P_{69}E_{19}$ ), P104 ( $E_{27}P_{61}E_{27}$ ), P105 ( $E_{37}P_{56}E_{37}$ ), and F108 ( $E_{132}P_{50}E_{132}$ ): (A) residual amount left on the surface at the end of the desorption experiment; (B) absolute change in surface excess concentration (residual minus adsorbed amount at the start of the desorption experiment). *Source:* Reprinted from Ref.<sup>[54]</sup> with permission.

monolayer-like morphology was observed for the more hydrophilic Pluronic P105 ( $E_{37}P_{56}E_{37}$ ).

In another study, Brandani and Stroeve<sup>[61]</sup> reported on the kinetic rates of adsorption from solution of the same family of Pluronic on a gold surface modified by a methyl-terminated self-assembled monolayer of a long-chain alkanethiol ( $\text{CH}_3(\text{CH}_2)_{10}\text{SH}$ ). They monitored the kinetics with the SPR technique, whose high time resolution (0.1 sec) allowed them to follow the evolution of these systems even for characteristic times of a few seconds. The adsorption and desorption data were analyzed in the context of a mass transfer corrected Langmuir kinetics model. While the model was only able to reproduce the observations for very dilute solutions, or for the initial stages of the processes, it nevertheless allowed the authors to discriminate the onset of different mechanisms of adsorption.

The study showed that, for a series of compounds with the same length of the PPO block, the character of the adsorption process was affected by the relative balance of the hydrophilic and hydrophobic content within the copolymer: higher hydrophobic content leads to enhanced adsorption rates past the cmc. This was consistent with observations from their earlier study of the morphology of polymer-coated surfaces by AFM.

Brandani and Stroeve<sup>[62]</sup> also reported on Pluronic adsorption and desorption from SAMs of a hydrophilic thiol. The thiols adsorbed at much lower surface concentrations compared to the studies on hydrophobic SAM.<sup>[61]</sup> Brandani and Stroeve<sup>[62]</sup> reported that the adsorbed amounts, at equilibrium, go through a maximum near the critical micelle concentration and that the adsorption–desorption process is reversible for the Pluronic that adsorb in relatively significant amounts. They observed enhanced adsorption rates past the CMC regardless of the relative balance of the hydrophilic and hydrophobic content within the triblock copolymer. The triblock species with a higher hydrophobic content exhibited higher equilibrium adsorption values but lower kinetic rates.

## MACROMOLECULAR ASSEMBLIES

Using SDS as a surfactant and poly(diallyldimethylammonium chloride) (PDDA) as a polyelectrolyte, Artyukhin et al.<sup>[63]</sup> formed a surfactant–polymer macromolecular complex on a model surface of a positively charged 2-aminoethanethiol (cysteamine) SAM on gold. First, SDS adsorption on cysteamine and subsequent adsorption of PDDA on the preformed SDS layer achieved the complex formation. Successful deposition of the PDDA layer on SDS without noticeable surfactant desorption showed that the complex formation was a fast process. The presence of SDS–PDDA complex on a cysteamine-modified gold substrate was observed by SPR and FTIR. Surface

plasmon resonance experiments on the kinetics of SDS adsorption followed by the adsorption of a flexible chain cationic polyelectrolyte are shown in Fig. 6. The PDDA can be adsorbed on SDS adsorbed on a positively charged SAM.<sup>[63]</sup> The decrease after the water rinse is due to the change in the refractive index, and not due to loss of PDDA or SDS. At equilibrium, the final thickness of SDS is 1.7 nm and for PDDA it is 1.1 nm, as calculated from the reflectance vs. angle scan curves (not shown). These thickness values are similar to those found for singular component adsorption,<sup>[63]</sup> indicating similar thicknesses (Table 2). Artyukhin et al. found that sequential adsorption of surfactants and polyelectrolytes to form stable surfactant–polymer complexes at the solid–water interface is possible if the adsorption rate of the polyelectrolytes is faster than the desorption rate of the surfactant.<sup>[63]</sup> Thus, it is critical to know the intrinsic rates of adsorption and desorption of surfactants on SAMs, and of polymers on surfactants. Kinetic rates can also give insight on the physics of adsorption. It should be of interest to study the use of externally applied voltages to a surface to influence the kinetics of adsorption and desorption of surfactants and polymers.

## CONCLUSION

Unique macromolecular structures can be assembled on SAMs of alkanethiols. The advantage of the use of SAMs on gold is that these model surfaces are well characterized and reproducible in any laboratory. Further, by using functional groups, the surfaces can be tailor-made to be hydrophobic, hydrophilic, charged, or to have reactive chemical groups at the surface. The competition of adsorption and desorption on the surfaces needs to be taken into account when macromolecular assemblies are created by depositing several layers of molecules on top of each other.

Generally, for physisorption of molecules on molecular layers, the desorption rate for molecules in the last deposited layer must be much lower than the adsorption rate of the next deposited species to form the next layer of molecules. The competitions between desorption and adsorption rates can be understood from measurement of the intrinsic kinetics of the kinetic processes. In the case of chemisorption of different molecules on a previously deposited molecular layer, the rate of chemisorption of the new molecules must be much faster than the rate of desorption of the previously deposited molecules.

## INTRODUCTION

Self-assembled monolayers (SAMs) are highly organized nanoscale films formed by the chemisorption of organic molecules (e.g., alkanethiols and alkanesiloxanes) onto solid substrates (e.g., Au and Si). The organized structure, chemical design flexibility, and facile preparation of SAMs have made them popular models for the study of interfacial phenomena and important systems in the development of new technologies. For example, there is current interest in using SAMs as the template for molecular resists, nanopatterned surfaces, and highly selective sensors. However, some of these applications require specific properties that demand the selective chemical and physical modification of existing SAMs. In addition to their potential technological applications, a study of the chemical transformations that accompany the modification of SAMs can also provide a detailed molecular-level understanding of the interfacial processes that accompany reactions at polymeric surfaces.

Modification of SAMs can be accomplished using either wet chemical or vacuum-based treatments. A number of advantages are inherent in the use of vacuum conditions during the modification of SAMs, including better control over the extent of reaction and the greater ease of in situ reaction monitoring. In this entry, we focus on the chemical processes that accompany the vacuum-based modification of several chemically distinct types of SAMs adsorbed on Au substrates, specifically alkanethiolate SAMs, semi-fluorinated SAMs, and alkanethiolate SAMs functionalized at the vacuum/film interface. The chemical modification of these SAMs has been investigated during exposure to three distinctly different types of reactive species, specifically ionizing radiation, atomic radicals, and vapor-deposited metal atoms.

One of the frequent motivations for the chemical and physical modification of SAMs is the desire to selectively modify or control the interfacial properties

of the organic interface. Results from our investigations indicate that the surface selectivity of a given modification treatment is strongly dependent on both the nature of the reactive species and the chemical composition of the SAM. For example, because of the greater penetration depth of electrons and X-rays relative to the thickness of typical SAMs, the modification of SAMs by ionizing radiation results in a nonsurface-selective process initiated by electron-stimulated bond cleavage events throughout the film. These events produce an initial period of modification characterized by desorption and structural disordering, leading to the formation of a cross-linked carbonaceous overlayer.

## OVERVIEW

The surface-selective modification of SAMs is favored by the presence of labile chemical bonds at the vacuum/film interface and reactive gas-phase species. For example, the initial reactivity of vapor-phase Ti atoms with nitrile-terminated SAMs leads to the selective formation of TiN at the vacuum/film interface. Similarly, reactions of atomic oxygen (AO) and chlorine with alkanethiolate SAMs are initially dominated by reactions at the vacuum/film interface, leading to the incorporation of new oxygen and chlorine-containing carbon functional groups, respectively. In contrast, reactions of AO with semifluorinated SAMs are initiated at the film/substrate interface, leading to desorption of intact adsorbate chains.

SAMs are organized molecular assemblies typically attached to solid substrates through the formation of a covalent bond between the head group of the adsorbate and the surface of the solid substrate (Fig. 1). The ordered structure that subsequently develops during adsorption is derived, in part, from intermolecular forces that exist between the hydrophobic chains of adsorbate molecules. Through the appropriate choice

**Fig. 1** Schematic of a SAM, where X represents the head groups that chemisorb the adsorbate to the solid substrate and Y represents the chemical functionality expressed at the SAM surface.

of adsorbate, controlled chemical functionalities can be expressed at the surface of the SAM (Fig. 1). These organic layers can be bound to a number of substrates including noble metals (Au, Ag, and Cu),<sup>[1]</sup> semiconductors (Si),<sup>[2]</sup> and oxide surfaces<sup>[3]</sup> by using an appropriate head group. Compared with thin films prepared by chemical vapor deposition (CVD) or molecular beam epitaxy, SAMs exhibit a number of advantages, which include: 1) ease of preparation; 2) the ability to tailor the chemical identity of end groups and thus the chemical characteristics of the organic interface (Fig. 1); and 3) local and long-range order.

The study of SAM systems has resulted in an improved molecular-level understanding of the factors that control adhesion,<sup>[4]</sup> wetting,<sup>[1]</sup> and friction.<sup>[5]</sup> Related studies have focused on examining the potential technological applications of SAMs. For example, octadecyltrichlorosilane SAMs coated on  $\text{Si}_3\text{N}_4$  tips have been found to improve the quality of images<sup>[6]</sup> obtained during atomic force microscopy (AFM) measurements by avoiding the unwanted effects of water adsorption on the tip. The chemical and physical design flexibilities of SAMs also make them attractive candidates for the creation of highly selective electrodes and sensors,<sup>[7]</sup> modeling and immobilization of artificial biomolecular surfaces,<sup>[8]</sup> miniaturization of electronic components,<sup>[9–11]</sup> and creation of molecular switches.<sup>[12]</sup> SAMs have also been considered as candidates for the creation of patterned surfaces that could be useful in the construction of microelectronic components,<sup>[13–16]</sup> whereas nanoparticles functionalized by SAMs have been proposed for the creation of selective DNA sensors.<sup>[17]</sup>

These applications of SAMs for new technologies have also led to the development of surface modification methodologies that can modify their physical and chemical properties. For example, in the design

of chemical sensors, the surface of SAMs must be modified/controlled so that they exhibit exclusive adhesion properties toward the target analyte.<sup>[7]</sup> Similarly, in creating miniaturized electronic components, the non-conducting surface of SAMs needs to be modified through the selective incorporation of metals at the film's interface.<sup>[10]</sup>

The two main approaches to the modification of SAMs employ either wet chemical or vacuum-based treatments. Wet chemical treatments are easily accessible experimentally and can be used to incorporate new surface functionalities into SAMs. For example, the bromination of hexadecylsiloxane SAMs on Si substrates<sup>[18]</sup> can be accomplished through UV irradiation of the SAM while immersed in a  $\text{CCl}_4$  solution containing dissolved  $\text{Br}_2$ . Although wet chemical methods are generally experimentally facile, modification can result in the loss of structural integrity of the SAM<sup>[19]</sup> and contamination of the surface. Vacuum-based modification protocols offer the advantage of being solvent-free, fast, and environmentally benign. In addition, in situ surface-sensitive analytical techniques such as X-ray photoelectron spectroscopy (XPS) and reflection absorption infrared spectroscopy (RAIRS) can be employed to measure and control the extent of the modification.

Under vacuum conditions, SAMs can also serve as effective models for polymeric interfaces and thereby provide detailed mechanistic information regarding molecular-level events that accompany modification processes.<sup>[20]</sup> In this respect, SAMs offer a number of important advantages over bulk polymeric substrates. SAMs can readily be created free from impurities whose presence would otherwise compromise the interpretation of changes in the film's chemical and physical characteristics. In contrast, polymeric interfaces often contain additives or surface impurities.<sup>[11]</sup> The ultrathin nature of SAMs ( $< 100 \text{ \AA}$ ) also facilitates the quantitative analysis of changes in the film's chemical composition using electron-based surface spectroscopic techniques, whereas analogous studies on polymers are often overwhelmed by the signal contribution from bulk species. In addition, the ultrathin nature of the film facilitates the determination of erosion by monitoring the intensity of the substrate signal.<sup>[21,22]</sup> In contrast to bulk polymeric films, the temperature of SAMs can also be controlled by heating or cooling the solid substrate,<sup>[21]</sup> enabling temperature effects to be investigated.

In this entry, we focus on the vacuum-based physical and chemical modification of semifluorinated and alkanethiolate-based SAMs adsorbed on Au substrates during exposure to a range of reactive species, including electrons, vapor-phase metal atoms, AO, and atomic chlorine. Emphasis is placed on the modification process and its dependence on the interplay between the reactive species and the chemical nature of the SAM.

## EXPERIMENTAL

### Surface Analysis

XPS and SAM modifications were performed in the same ultrahigh vacuum (UHV) chamber, with typical base pressures on the order of  $5 \times 10^{-9}$  Torr. Details of the UHV system and associated capabilities can be found in previous publications.<sup>[23–25]</sup> All XPS spectra were collected using a non-monochromatic Mg K $\alpha$  anode operating at 15 kV and 300 W with 45° take-off angle, relative to the sample normal. Binding energy scales were referenced to the CC/CH<sub>2</sub> peak in the C(1s) region centered at 284.6 eV. XPS data fitting was performed using 100% Gaussian peaks and Shirley background subtractions.

### Sample Preparation

Polycrystalline gold substrates were cleaned by Ar<sup>+</sup> sputtering and then placed into 5-mM solutions of relevant thiols for 10–24 hr. Semifluorinated SAMs were prepared using 1*H*,1*H*,2*H*,2*H*-perfluorodecanethiols (HS(CH<sub>2</sub>)<sub>2</sub>(CF<sub>2</sub>)<sub>7</sub>CF<sub>3</sub>), alkanethiolate SAMs from hexadecane thiols (HS(CH<sub>2</sub>)<sub>15</sub>CH<sub>3</sub>), and nitrile-terminated SAMs from 12-mercaptododecanenitrile (HS(CH<sub>2</sub>)<sub>11</sub>CN). Following immersion, samples were washed in ethanol, water, and hexane, placed into the spectrometer's fast-entry load-lock cell, and pumped to high vacuum ( $2 \times 10^{-5}$  Torr), before being introduced into the UHV chamber.

### X-ray-Induced Modification of SAMs

X-ray-induced modification of SAMs was accomplished with a nonmonochromatic X-ray source operating at 15 kV and 300 W.

### Radical Modification of SAMs

Atomic oxygen and chlorine used during the chemical modification of SAMs were generated using a thermal gas cracker (TC-50; Oxford Applied Research). This gas cracker thermally dissociates molecular gases such as oxygen or chlorine into a stream of atomic, low-energy reactive species to produce a mixture of O(<sup>3</sup>P) and O<sub>2</sub>, or Cl(<sup>2</sup>P) and Cl<sub>2</sub>, hereafter referred to as atomic O (AO) or atomic Cl, respectively. A description of the radical source can be found in previous publications.<sup>[21,22,26]</sup>

### Vapor-Phase Metallization of SAMs

The metal evaporation source used to deposit Ti, Fe, Ni, Cu, and Au on the nitrile-terminated SAM was

prepared by tightly winding wires of each of the aforementioned metals around a 0.5-mm-diameter Ta or W filament. The metal source was resistively heated using a d.c. power source. To avoid the effects of secondary heating, a Ta shield with a 0.5-mm-diameter hole was placed in front of the evaporation source.

### X-RAY AND ELECTRON-INDUCED MODIFICATION OF SEMIFLUORINATED SAMs

The interaction of X-rays and electrons with SAMs is important in a number of scientific and technological applications. For example, X-ray and electron-induced changes in SAMs can be utilized for surface patterning at the nanometer scale, finding use in a variety of fields that include microelectronics and sensor design.<sup>[27]</sup> X-ray modification can also be used to induce chemical changes in SAMs. This is well illustrated in a study by Dressick et al.,<sup>[13]</sup> where X-ray treatment of SAMs containing benzyl chloride groups led to selective C–Cl bond cleavage and the subsequent formation of surface aldehyde and/or ketone groups. Electrons have also been shown to be effective in releasing important bioregulatory drugs such as nitric oxide from surface-functionalized SAMs.<sup>[28]</sup>

The study of the interaction of X-rays and electrons with SAMs can also be used to model the X-ray-induced modification of polymers by providing detailed information about the chemical nature of the species evolving at the surface, rates of reactions, and irradiation-induced structural changes.<sup>[20,23]</sup> Understanding of these events can also help in predicting the lifetimes of polymers used as coatings on spacecraft as they enter low Earth orbit.<sup>[23,29]</sup> Furthermore, it is important to understand the interaction of ionizing radiation with SAMs to elucidate the unintentional modification that can occur during the spectroscopic characterization of organic films with electron-based spectroscopic techniques such as XPS and low-energy electron diffraction (LEED).<sup>[30]</sup>

Studies have shown that X-ray-induced changes in organic films are initiated by secondary electrons ejected from the film and the substrate during X-ray excitation. The idea that electrons, and not X-rays, are responsible for the changes in the SAM on X-ray exposure has been demonstrated by Laibinis, Graham, and Biebuyck<sup>[31]</sup> and Graham et al.<sup>[32]</sup> where the rate of defluorination for –CO<sub>2</sub>CF<sub>3</sub> and –NHCOF<sub>3</sub> terminated SAMs was found to scale with the substrate's secondary electron yield. In another study, Moon et al.<sup>[27]</sup> followed the modification of nitrobenzaldimine monolayers as a function of the incident photon energy (300–800 eV). Results showed that the modification rates were similar regardless of the incident photon energy, supporting the idea that the secondary

substrate electrons, rather than the primary photons, are responsible for the chemical and physical modification of the organic film.

In the following discussion, we present results from the X-ray-induced modification of semifluorinated SAMs [derived from  $\text{CF}_3(\text{CF}_2)_7(\text{CH}_2)_2\text{SH}$ , hereafter referred to as CF-SAMs] adsorbed on Au,<sup>[20,23,30,33]</sup> focusing on the chemical changes that SAMs undergo and the consequential physical modification to the film. The use of semifluorinated SAMs enables the employment of XPS to quantitatively measure the chemical changes taking place under X-ray exposure, including the loss of fluorine, carbon, and sulfur.

### X-ray-Induced Modification of Semifluorinated SAMs

For short exposures (<120 min), the X-ray-induced modification of CF-SAMs leads to competing electron-stimulated C–F, C–C, and S–Au bond-breaking processes. This fact is illustrated in Fig. 2 by the decrease in the F(1s):Au(4f), C(1s):Au(4f), and S(2p):Au(4f) ratios. Stochastic simulations indicate that the relative magnitude of rate constants associated with these bond-breaking processes decreases in the order of C–F > S–Au > C–C during this initial period of X-ray exposure.<sup>[33]</sup> The simultaneous occurrence of these events is indicative of the lack of selectivity inherent in the X-ray-induced SAM modification process. This results from the fact that the X-ray penetration depth is much greater than the thickness of the film, leading to the release of secondary electrons that react throughout the entire SAM. Fig. 3 pictorially illustrates the desorption of F species, intact adsorbate chains, and alkyl fluoride ( $\text{C}_x\text{F}_y$ ) fragments that result from C–F, S–Au, and C–C bond-breaking events, respectively. In a separate near-edge X-ray absorption fine structure spectroscopy (NEXAFS) study, analogous results have been found to accompany the electron-induced modification of alkanethiolate SAMs adsorbed on gold, leading to simultaneous C–H, C–C, C–S, and S–Au bond cleavage.<sup>[34,35]</sup>

During the initial period of X-ray-induced modification, carbon-containing radicals produced from C–F and C–C bond-breaking events remain tethered to the Au substrate. Bimolecular reactions between proximate carbon-containing radicals lead to the formation of a disordered cross-linked structure.<sup>[36]</sup> Similarly, Au–S bond cleavage leads to the ejection of some intact adsorbate chains and also to the production of radiation-induced C–S–C bonds, localized at the film/vacuum interface.<sup>[34,35,37]</sup> These transformations characterizing the initial period of X-ray-induced modification to CF-SAMs are depicted

**Fig. 2** Variation in the chemical composition of a semifluorinated SAM [ $\text{CF}_3(\text{CF}_2)_7(\text{CH}_2)_2\text{S-Au}$ ] as a function of X-ray exposure, followed by the F(1s):Au(4f) (●), S(2p):Au(4f) (○), and C(1s):Au(4f) (▼) XPS area ratios. Ratios were normalized to the values obtained for the untreated film to show changes relative to the native semifluorinated SAM.

pictorially in Fig. 3. This carbonaceous, partially fluorinated, cross-linked structure stabilizes the film against additional carbon and sulfur desorption, as shown in Fig. 2 by the invariant C(1s):Au(4f) and S(2p):Au(4f) ratios for prolonged X-ray exposures. The absence of sustained C and S desorption can be explained by fact that once a cross-linked structure has been produced, additional C desorption requires the simultaneous cleavage of two C–C bonds along the same chain, which is an extremely low-probability event.<sup>[30,36]</sup> In contrast, the loss of fluorine is observed continuously because any fluorine is attached to the film through a single C–F bond that can be cleaved by an electron-stimulated process to yield volatile fluorine species. This is shown pictorially in Fig. 3.

As a result of the structural changes that accompany X-ray-induced changes to the CF-SAM, the electron-stimulated loss of fluorine is the only bond-breaking process that contributes to desorption for prolonged X-ray exposures. Indeed, a detailed mechanistic understanding of the processes that lead to fluorine desorption for prolonged X-ray exposures can be derived from the spectral changes in the C(1s) region, as shown in Fig. 4. Initially, the C(1s) XP spectra have three component peaks corresponding to the  $\text{CF}_3$  (292.8 eV),  $\text{CF}_2$  (290.5 eV), and  $\text{CC/CH}_2$  (284.5 eV) functional groups characteristic of CF-SAMs. Upon X-ray exposure, defluorination is evidenced by the decrease in intensity of the  $\text{CF}_3$  and  $\text{CF}_2$  component peaks with the concomitant appearance of  $\text{CFCF}_n$  and  $\text{CFC}$  peaks and the growth of the  $\text{CC/CH}_2$  peak. Fluorine loss for prolonged X-ray exposures is proportional to the concentration of C–F bonds in the film, consistent with a first-order process.<sup>[33]</sup> Indeed, the evolution of the film's chemical composition [based on changes to the C(1s) region] after the film has stabilized toward carbon and sulfur

**Fig. 3** Schematic representation of the X-ray-induced modification of a semi-fluorinated SAM as a function of X-ray exposure time.

desorption can be well fitted by a kinetic model where defluorination is postulated to occur via a series of consecutive C–F bond-breaking processes (i.e.,  $\text{CF}_3 \rightarrow \text{CF}_2 \rightarrow \text{CF} \rightarrow \text{C}$ ).<sup>[33]</sup>

Our results indicate that the chemical modification of CF-SAMs by means of X-ray exposures proceeds with a lack of chemical selectivity, rendering this a relatively poor means for achieving controlled modification of SAMs. However, in the context of surface patterning, it appears that X-rays or low-energy electron beams can be used to create surface features that exhibit hydrophobicity distinct from the<sup>[37]</sup> and highly

hydrophobic CF-SAMs. However, the inability of X-rays and low-energy electrons to completely remove the carbon overlayer is undesirable for most lithographic applications, where there is interest in creating distinct regions that contain native SAM structures and regions where the SAM has been completely removed and the substrate has been exposed.

### CHEMICAL MODIFICATION OF SAMs WITH ATOMIC RADICALS

There is interest in modifying SAMs through the introduction of new chemical functionalities to attain a film with specific chemical and physical properties. Chemically modified SAMs have applications that include the development of functionalized electrodes to achieve selective sensing capabilities<sup>[7]</sup> and the understanding of the specific surface interactions of protein and biological materials.<sup>[8]</sup> Surface selectivity is often a desirable aspect of a chemical modification process because many chemical and physical properties are determined by interfacial characteristics.

Ion beam and plasma treatments represent two popular vacuum-based means of modifying polymeric interfaces. Ion implantation surface modification strategies are derived from the collision of energetic ions (typically >1 keV) with a material, resulting in bond-breaking events and the incorporation of new functional groups.<sup>[38]</sup> Although ion implantation is a well-developed methodology for modifying polymeric substrates, its application to SAMs is limited by the fact that sputtering effects dominate over the incorporation of new chemical functionality for typical ion beam energies. Recently, ion beam-induced modification of SAMs has been accomplished by collisions involving polyatomic ions with low-energy ions (<100 eV).<sup>[39]</sup> However, such ion beam modification

**Fig. 4** Variation in the C(1s) XP spectral region of a semi-fluorinated SAM as a function of X-ray exposure. (A) Shows the native semifluorinated SAM fitted to a combination of  $\text{CC}/\text{CH}_2$ ,  $\text{CF}_2$ , and  $\text{CF}_3$  species. The following spectra show the semifluorinated SAM after X-ray exposure, fitted with additional  $\text{CFCF}_n$  and  $\text{CFC}$  species. Data are shown in filled circles ( $\bullet$ ), whereas fits, backgrounds, and envelopes are shown as solid lines.

of SAMs is limited by the need for dedicated and expensive equipment capable of generating such low-energy ions.<sup>[40]</sup> Plasma treatments are another potential method to achieve the chemical modification of SAMs. Plasmas are highly reactive media that contain ions, neutrals, radicals, electrons, and ionizing radiation.<sup>[41]</sup> Plasma-based surface interactions represent one of the most widely employed means for polymer surface modification.<sup>[41]</sup> However, the competition between film removal with the incorporation of new chemical functionality limits the general applicability of this approach for the chemical modification of SAMs.<sup>[42,43]</sup>

These difficulties, inherent in the use of ion beams and plasmas to modify SAMs can in principle be overcome by the use of free radical species. A wide range of radicals can be formed under vacuum conditions, either by photodissociation or thermal dissociation of a parent molecule, resulting in the formation of species with relatively low kinetic energies (<10 eV). The low kinetic energy of radicals ensures that the modification of a SAM will be dominated by the inherent chemical reactivity of the radical, rather than sputtering. Furthermore, in contrast to ions, the extremely low kinetic energies of radical species limits their effective penetration depth, often facilitating selective reactivity at the vacuum/film interface.<sup>[21,22,26]</sup>

In this section, we detail the modification of semifluorinated and alkanethiolate SAMs with AO and atomic chlorine. AO and chlorine incorporation into organic films often produce opposite effects on interfacial properties (e.g., hydrophobicity). Because of its

relative abundance in low Earth orbit, there is also particular interest in following the reactions of AO ( $O^3P$ ) with well-defined organic films (SAMs) to elucidate the elementary reaction steps responsible for the well-documented weight loss of polymeric coatings used on spacecraft.<sup>[44]</sup>

### Modification of Semifluorinated SAMs with AO

The modification of semifluorinated SAMs by AO was monitored by following the evolution of the C(1s) XP spectral region (Fig. 5A), the integrated area of the C(1s) and F(1s) XPS regions (Fig. 5B), and the oxygen uptake measured from the O(1s) region (Fig. 5C). The native semifluorinated SAM (CF-SAM), derived from  $CF_3(CF_2)_7(CH_2)_2SH$  adsorbed on Au, exhibits the characteristic  $CF_3$ ,  $CF_2$ , and  $CC/CH_2$  peaks in the C(1s) region, as shown in Fig. 5A. During the initial stages of oxygen exposure (<90 min), the C(1s) spectral envelope and the C(1s) and F(1s) XPS areas in Fig. 5B remain unchanged. Taken in conjunction with a lack of oxygen uptake in the CF-SAM during this initial period of AO exposure, these results indicate an initial period of inertness toward AO. This inability of AO to chemically modify the vacuum/film interface can be attributed to the combined effect of the chemical inertness of C–F and C–C bonds toward AO and the limited penetration depth of AO within the well-ordered semifluorinated SAM.

AO-induced modification of the CF-SAM is initiated by the permeation of oxygen to the film/

**Fig. 5** Modification of semifluorinated SAMs [ $CF_3(CF_2)_7(CH_2)_2S-Au$ ] by AO. (A) Shows the variation in the C(1s) XP spectral region of semifluorinated SAMs after (i) 0, (ii) 120, (iii) 250, and (iv) 600 min of AO exposure. (B) Shows the total C(1s) (●) and F(1s) (○) XPS areas as a function of AO exposure. Areas were normalized to the values obtained for the untreated film to reflect changes relative to the native semifluorinated SAM. (C) Shows the production of  $Au_2O_3$  (▲) calculated from the area of the fitted peak in the O(1s) region. The vertical dashed line in (B) and (C) indicates the AO exposure for which  $Au_2O_3$  is produced. (A)–(C) were compiled from the same data set. Each data point represents individual AO exposures to separate semifluorinated SAMs, rather than consecutive exposures to the same semifluorinated SAM.

substrate interface as shown in Fig. 7A. Although the detailed mechanism responsible for the oxygen migration through the semifluorinated SAMs cannot be determined unambiguously from XPS studies, it is reasonable to assume that AO permeation and subsequent reactivity are initiated in proximity to defect sites within the SAM, rather than uniformly throughout the film. AO-induced reactivity at the film/substrate interface is evidenced experimentally by the oxidation of sulfur groups producing  $\text{RSO}_3$ <sup>[22]</sup> and the formation of  $\text{Au}_2\text{O}_3$  (Fig. 5C). AO reactions at the film/substrate interface also lead to the desorption of intact adsorbate chains, as shown in Fig. 7A. This is responsible for the fact that fluorine and carbon are lost from the film at equal rates, evidenced by the nearly constant C(1s) spectral profile observed despite the decrease in the integrated C(1s) XPS area (shown in Fig. 5B) and the fact that the C(1s):F(1s) ratio remains essentially constant during the entire AO exposure. In conclusion, the presence of a fully fluorinated surface does indeed appear to provide limited protection toward the effects of chemical modification by AO, although the long-term stability of the CF-SAM toward the effects of AO is compromised by the instability of the C–H, C–S, and S–Au bonds at the film/substrate interface toward AO.

### Modification of Alkanethiolate SAMs with AO

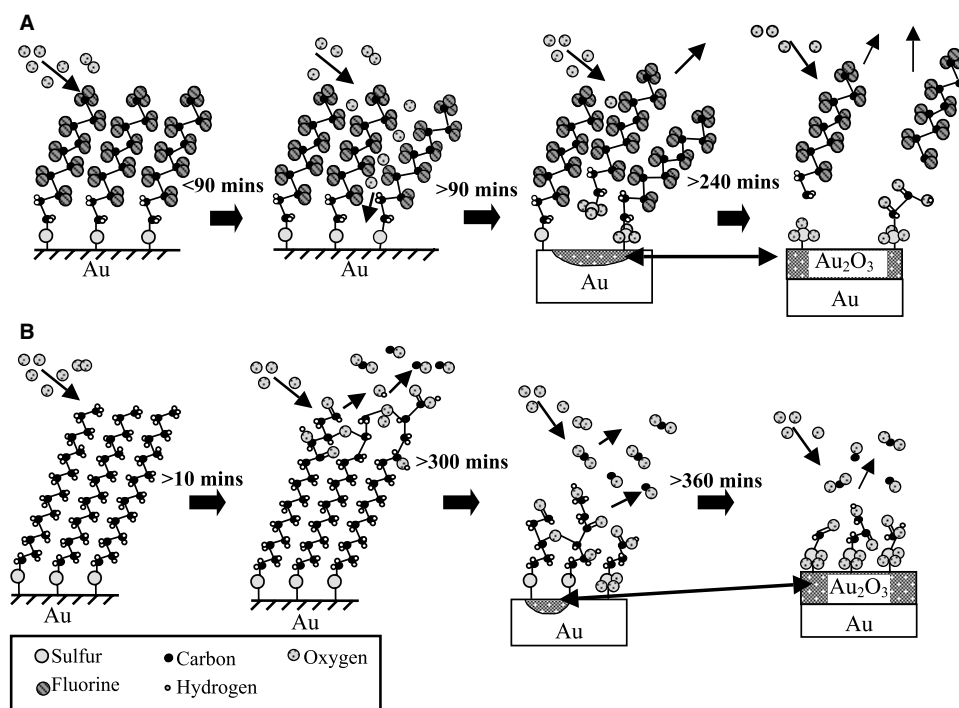

In contrast to semifluorinated SAMs, the modification of alkanethiolate SAMs is initiated exclusively at the

vacuum/film interface because of the facility of AO-mediated H-atom abstraction from C–H bonds. The selective reactivity of alkanethiolate SAM surfaces toward AO is evidenced experimentally by the appearance of spectral intensity in both the C(1s) (Fig. 6A) and O(1s) regions characteristic of oxygen-containing carbon functionality ( $\text{CO}_x$  species) in the absence of  $\text{RSO}_3$  or  $\text{Au}_2\text{O}_3$  production (Fig. 6C).<sup>[22]</sup> Simultaneous changes in the C(1s):Au(4f) area ratio in Fig. 6B indicate that during the early stages of AO-induced modification, the production of new chemical functionality proceeds in the absence of any significant erosion of the native SAM; this is shown schematically in Fig. 7B. Thus it appears that under controlled conditions (corresponding to short AO exposures), the vacuum/film interface of alkanethiolate SAMs can be modified by AO as a means to tailor the physical and chemical properties of the interface (e.g., adhesion and hydrophobicity) while the hydrocarbon backbone of the SAM is retained.

However, prolonged exposures of AO result in etching of the alkanethiolate SAM, as evidenced by the decrease in area of the C(1s) region in Fig. 6A and B. The removal of the hydrocarbon overlayer for prolonged AO exposures can be attributed to the production of volatile species, namely CO and  $\text{CO}_2$ , as presented in Fig. 7B. On AO exposures in excess of 300 min, the hydrocarbon overlayer thickness becomes smaller than the oxygen penetration depth, enabling AO to penetrate to the film/substrate interface, producing  $\text{RSO}_3$  and  $\text{Au}_2\text{O}_3$  (Fig. 6C). Continued AO

**Fig. 6** Modification of alkanethiolate SAMs  $[\text{CH}_3(\text{CH}_2)_{15}\text{S-Au}]$  by AO. (A) Shows the variation in the C(1s) XP spectral region of alkanethiolate SAM after (i) 0, (ii) 120, (iii) 360, and (iv) 540 min of AO exposure. (B) Shows the C(1s):Au(4f) (●) XPS area ratio normalized to the value obtained for the untreated film. (C) Shows the production of  $\text{CO}_x$  ( $\Delta$ ) and  $\text{Au}_2\text{O}_3$  ( $\blacktriangle$ ) species, calculated from the area of the fitted peaks in the O(1s) XPS region. The vertical dashed line in (B) and (C) indicates when  $\text{Au}_2\text{O}_3$  is produced. (A)–(C) were compiled from the same data set. Each data point represents individual AO exposures to separate alkanethiolate SAMs, rather than consecutive exposures to the same alkanethiolate SAM.

**Fig. 7** Schematic representation of the AO modification of (A) semifluorinated and (B) alkanethiolate SAMs as a function of AO exposure time.

exposure results in the complete etching of the film, as illustrated in (Figs. 5A and B and 7B).

A comparison of the reactivity of semifluorinated and hydrocarbon alkanethiolate SAMs reveals that for a patterned surface containing both species, selective modification of the alkanethiolate portion can be accomplished during controlled exposures to AO. Furthermore, the AO modification of hydrocarbon surfaces could also represent a viable alternative to oxygen-based plasma treatments for thin films and coatings where substrate erosion must be minimized. For prolonged AO exposures, etching of both alkanethiolate and semifluorinated SAMs will occur, although film erosion is initiated at the substrate/film interface in the case of semifluorinated SAMs and at the vacuum/film interface for alkanethiolate SAMs.

### Modification of Alkanethiolate SAMs with Atomic Chlorine

The reactions of alkanethiolate SAMs with atomic chlorine lead to the production of mono- (CCl) and dichlorinated (CCl<sub>2</sub>) species (Fig. 8A). Chlorine incorporation is initiated by Cl-mediated hydrogen abstraction from C–H bonds, generating volatile HCl species.<sup>[45]</sup> This process creates alkyl radicals in the film whose subsequent reactions with either atomic or molecular chlorine lead to the production of CCl and

CCl<sub>2</sub> species. In contrast to AO reactions with alkanethiolate SAMs, atomic chlorine-based modification of alkanethiolate SAM occurs in the absence of film erosion. This is evidenced by the invariant C(1s):Au(4f) ratio presented in Fig. 8B and is a reflection of the fact that atomic chlorine species are unable to induce C–C bond cleavage.

Related experiments on polymeric substrates<sup>[26]</sup> revealed that chlorination under these vacuum conditions created a strong depth-dependent concentration of chlorine-containing functional groups in the surface, with a predominance of chlorinated groups near the vacuum interfacial region. The observed concentration gradient is attributed to a combination of cross-linking reactions between alkyl radicals and steric effects because of the presence of bulky CCl and CCl<sub>2</sub> groups, with both effects limiting chlorine incorporation into the film.<sup>[26]</sup> The same reasons are also ascribed to the limited chlorination of alkanethiolate SAMs, indicated by the continued presence of CC/CH<sub>2</sub> species (Fig. 8A) even after chlorine uptake in the film has reached a maximum value (Fig. 8C); this is illustrated in Fig. 9. Evidence for the surface-selective chlorination of SAMs has also been reported during the photochlorination of 1-octadecene SAMs on Si substrates,<sup>[46]</sup> where IR studies reveal the disappearance of methyl groups after photochlorination while methylene groups still remain.

**Fig. 8** Modification of alkanethiolate SAMs [ $\text{CH}_3(\text{CH}_2)_{15}\text{S-Au}$ ] by atomic chlorine. (A) Shows the variation in the C(1s) XP spectral region of alkanethiolate SAMs after (i) 0, (ii) 10 and (iii) 30 min of atomic chlorine exposure. (B) Shows the C(1s):Au(4f) ( $\bullet$ ) XPS area ratio normalized to the value obtained for the untreated alkanethiolate SAM. (C) Shows the incorporation of atomic chlorine into the alkanethiolate SAM measured by the increase in area of the  $\text{CCl}_x$  ( $x = 1, 2$ ) ( $\blacktriangle$ ) fitted doublet peaks in the Cl(2p) XPS region. (A)–(C) were compiled from the same data set. Each data point represents individual atomic chlorine exposures to separate alkanethiolate SAMs, rather than consecutive exposures to the same alkanethiolate SAM.

## VAPOR-PHASE METALLIZATION OF SAMS

The chemical modification of SAMs by means of metal vapor deposition has been proposed as a possible route for the formation of nanometer-scaled micro-electronic components. Employing this approach, molecular-scale capacitors and dielectrics consisting of a molecular-sized organic insulating unit (the SAM)<sup>[47]</sup> located between two conductive metallic surfaces<sup>[48,49]</sup> could be prepared. However, to determine if the fabrication of such devices can be reliably achieved

using vapor-phase metal deposition, a molecular-level understanding of the chemical processes taking place at the metal/organic interfaces during metallization must be developed.<sup>[10]</sup> It is also essential to understand these elementary processes because of the requirement for reliable performance in any discrete metal–organic–metal device, which dictates that the growth of the deposited metal should be restricted to the film/vacuum interface.<sup>[50]</sup>

Previous research has shown that chemical reactivity between end groups of the SAM and incident

**Fig. 9** Schematic representation of the atomic chlorine-induced modification of alkanethiolate SAMs as a function of exposure time.

vapor-phase metal atoms promotes nucleation and metallic growth at the SAM vacuum/film interface.<sup>[9,48,49]</sup> The relationship between the chemical composition of SAMs and metal reactivity is exemplified by recent studies on the vapor-phase aluminum metallization of hydrocarbon-based SAMs on Au substrates, functionalized at the vacuum/film interface with different head groups [methyl ( $-\text{CH}_3$ ), alcohol ( $-\text{OH}$ ), ether ( $-\text{OCH}_3$ ), ester ( $-\text{CO}_2\text{CH}_3$ ), and carboxylic acid ( $-\text{CO}_2\text{H}$ )].<sup>[9,49,51]</sup> Aluminum metal was selected because of its importance in the microelectronics industry.<sup>[9]</sup> Results from these studies revealed that methyl-terminated SAMs were unreactive during Al deposition, allowing Al to penetrate to the film/substrate interface.<sup>[9]</sup> In contrast, for alcohol-, ester-, and carboxylic acid-terminated SAMs, the deposited aluminum reacted at the vacuum/film interface to form Al-O-C complexes, preventing Al penetration to the Au substrate.<sup>[9,49,51]</sup> When ether-terminated SAMs were used, Al also initially reacted with O at the vacuum/film interface. Upon continued deposition, however Al penetrated through the film to the Au substrate, an effect ascribed to the weak interaction of Al with ether functional groups.<sup>[49]</sup> These results illustrate that the chemical reactivity of functional groups at the vacuum/film interface of the SAM with vapor-phase metal atoms plays a crucial role in determining the stability and integrity of a metal/organic interface in any molecular device.

Vapor-phase metallization of model organic interfaces, such as SAMs, has also become an important experimental tool for modeling the chemical interactions occurring at metal/polymer interfaces.<sup>[11,48,52]</sup> Physical vapor deposition (PVD) is widely used to

metallize polymers encountered in microelectronics,<sup>[11]</sup> data, and food storage devices,<sup>[53]</sup> and in the development of biomaterials for implants.<sup>[54]</sup> Because the depth of metal interactions within polymeric substrates is typically limited to the top few nanometers, surface reactions are particularly important in determining overall adhesion properties.<sup>[11]</sup> However, the nature of chemical reactions taking place at the metal/polymer interface is often difficult to assess because of the multifunctional and heterogeneous nature of most polymer surfaces, particularly those that have been pretreated (e.g., with plasmas) prior to PVD of metal overlayers.<sup>[55,56]</sup> These disadvantages can be largely overcome by the application of SAMs as models for polymeric interfaces, allowing us to study reactions on ultrathin, well-ordered organic interfaces that can be prepared with discrete chemical functionality.

We have recently examined the reactivity of a common chemical functional group expressed at the vacuum/film interface of an alkanethiolate SAM with different vapor-deposited metal atoms. In particular, we have explored the reactions of a nitrile-terminated SAM (CN-SAM) with a variety of different metals (Au, Cu, Ni, Fe, and Ti).<sup>[57]</sup> Interest in these systems was motivated, in part, by the reported presence of nitrile groups following  $\text{N}_2$ -based plasma treatments of hydrocarbon-based polymers prior to metallization.<sup>[58,59]</sup> In addition, the 12-mercaptododecanenitrile ( $\text{HS}(\text{CH}_2)_{11}\text{CN}$ ) precursor for the CN-SAM can be readily synthesized and contains the chemically robust nitrile functional group, making it an ideal candidate for more generalized applications.<sup>[60]</sup>

Fig. 10 shows representative N(1s) and C(1s) XP spectral regions of the native CN-SAM following

**Fig. 10** Variation in the N(1s) and C(1s) XP spectral regions of nitrile-terminated SAMs exposed to  $\approx 20\%$  of Au, Cu, Ni, Fe, and Ti measured from the elemental composition of the XPS spectrum.

exposure to vapor-phase Au, Cu, Ni, Fe, and Ti atoms. In addition to the peak at 284.6 eV in the C(1s) region corresponding to the CC/CH<sub>2</sub> groups present in the hydrocarbon backbone of the SAM, Fig. 10 shows spectral characteristics of C≡N functionality, notably a peak in the N(1s) region at 399.6 eV and a corresponding C≡N peak at 286.8 eV in the C(1s) region. Upon Au and Cu metallization, the N(1s) peak broadened, probably as a result of increased physical heterogeneity in the system. However, no evidence of metal–nitrogen bond formation was observed<sup>[57,61]</sup> and based on previous studies,<sup>[11,48,62,63]</sup> it is anticipated that Au and Cu will penetrate through the SAM to the Au substrate.

During the vapor-phase deposition of Ni, Fe, and Ti, Fig. 10 reveals that a lower binding energy peak is observed in the N(1s) spectral region. This new species is indicative of the formation of a metal–nitrogen linkage, possibly a metal nitride.<sup>[57]</sup> It should be noted that the Ni reactivity observed in our study is in contrast to previous investigations by Herdt, Jung, and Czanduha,<sup>[48]</sup> where Ni vapor deposition on CN-SAMs exhibited no reactivity. In the case of Ti metallization, the C(1s) spectral profile also shows the appearance of an additional peak at lower binding energies indicative of titanium carbide formation, which is not observed during Au, Cu, Ni, or Fe deposition.

The relative reactivity of different metals with organic functional groups during vapor-phase metallization has been explained based on differences in heat released during metal condensation ( $\Delta H_{\text{vap}}$ ).<sup>[64]</sup> However, in several studies of polymer metallization, we have found a poor correlation between the reactivity of metal atoms deposited on both functionalized SAMs and polymers and  $\Delta H_{\text{vap}}$ .<sup>[20,24,25,57,65]</sup> For

**Fig. 11** Variation in the concentration of TiN (●) and TiC (○) species as a function of Ti coverage. TiC and TiN peak areas were derived from the fitted peaks in the C(1s) and N(1s) regions, respectively.

example, during the metallization of nylon 6 ( $-\text{NH}(\text{CH}_2)_5\text{CO}-_n$ ), vapor-deposited Fe atoms were found to activate the carbonyl group (forming a Fe–O linkage), whereas Ni was unreactive with this same functional group, despite the fact that Ni has a larger  $\Delta H_{\text{vap}}$  than Fe [ $\Delta H_{\text{vap}}(\text{Fe}) = 415 \text{ kJ mol}^{-1}$ ;  $\Delta H_{\text{vap}}(\text{Ni}) = 425 \text{ kJ mol}^{-1}$ ].<sup>[57]</sup> Similarly, in the context of Fig. 10, Fe exhibits a greater degree of reactivity with the nitrile group compared with Ni for comparable metal exposures. A more reliable guide to metal reactivity has been found based on the strength of new metal-containing bonds (e.g., metal–nitrogen) that can form during metallization. The strength of these bonds decreases from left to right along a transition metal series and also decreases as a given series is descended. From spectral trends shown in Fig. 10,

**Fig. 12** Schematic representation of the Ti deposition on nitrile-terminated SAMs as a function of Ti coverage.

the predicted reactivity from this argument yields  $\text{Ti} > \text{Fe} > \text{Ni} > \text{Cu} > \text{Au}$ , which is in agreement with the results shown here for the nitrile group as well as for other organic functional groups studied in our laboratory.<sup>[25,52,57,65]</sup>

In the case of Ti, reactivity is observed at the vacuum/film interface (titanium nitride formation) as well as within the hydrocarbon backbone of the SAM (titanium carbide formation). Fig. 11 shows the area of the fitted Ti–N peak in the N(1s) region and the Ti–C peak in the C(1s) region as a function of Ti coverage. The fact that TiN is an exclusive product observed for short Ti exposures is indicative of a surface-selective reaction. However, on longer exposures, Ti penetration to the hydrocarbon backbone of the SAM is evidenced by the formation of TiC. These results, summarized schematically in Fig. 12, suggest that surface-selective modification of the CN-SAM can be attained during low Ti coverage. Similarly, we anticipate that Ni and Fe deposition on the CN-SAM will also produce an initially surface-selective process. However, despite the reactivity of initial vapor-deposited Ti atoms with nitrile functionality located at the film/vacuum interface, the resultant structure is permeable, enabling Ti migration through this interfacial region and initiating subsequent reactivity within the hydrocarbon backbone of the film. Thus although Ti exhibits initial surface selectivity in its reaction with the CN-SAM, exposures must be carefully controlled to create a discrete metal/organic interface.

## CONCLUSION

Results have been presented on the vacuum-based physical and chemical modification of SAMs studied with in situ XPS. These studies illustrate that the nature of the physical and chemical modification within the SAM is controlled by the relationship between the reactive gas-phase species (vapor-phase metal atoms, radicals, and electrons) and the chemical composition of the SAM.

The importance of the chemical identity of the reactive species in the modification process is demonstrated in metallization studies on nitrile-terminated alkanethiolate SAMs, where the initial site of reactivity can initially be localized at the film/vacuum interface through an appropriate choice of metal atom. Similarly, in the case of radical reactions with alkanethiolate SAMs, the significance of the radical's chemical identity is evidenced by the observation of film erosion during exposure to AO, whereas reactions with atomic chlorine proceed in the absence of substrate erosion.

The importance of the SAM's chemical composition is illustrated in the reactions of alkanethiolate and semifluorinated SAMs with AO. Thus during the initial stages of AO exposure to alkanethiolate SAMs, the incorporation of O-containing chemical functionalities is restricted to the vacuum/film interface because of the lability of C–H bonds toward H-atom abstraction. In contrast, for semifluorinated SAMs, AO-induced reactivity is initiated exclusively at the film/substrate interface, leading to desorption of intact adsorbate chains because of the inertness of C–F and C–C bonds present at the vacuum/film interface. In contrast to SAM modification by vapor-phase metal atoms or atomic radicals, the X-ray-induced modification of semifluorinated SAMs exemplifies a non-selective modification process because it proceeds through a combination of C–C, C–F, C–S, and S–Au bond-breaking events throughout the SAM, leading to the formation of a largely stabilized, cross-linked carbonaceous overlayer.

## INTRODUCTION

The determination of solid–vapor ( $\gamma_{sv}$ ) and solid–liquid ( $\gamma_{sl}$ ) interfacial tensions is of importance in a wide range of problems in pure and applied sciences. For example, the process of particle adhesion can be modeled by the net free energy change  $\Delta F^{\text{adh}}$  of the system during the adhesion process, which depends explicitly on the solid (particle) surface tensions: The net free energy change per unit surface area for the adhesion process of a square particle is given by:

$$\Delta F^{\text{adh}} = \gamma_{pv} - \gamma_{pl} - \gamma_{sl} \quad (1)$$

where  $\gamma_{pv}$  and  $\gamma_{pl}$  are the particle–vapor and particle–liquid interfacial tensions, respectively. If  $\Delta F^{\text{adh}} < 0$ , the adhesion process is thermodynamically favorable. The work of adhesion  $W^{\text{adh}}$  is simply:

$$W^{\text{adh}} = -\Delta F^{\text{adh}} \quad (2)$$

Because of the difficulties involved in measuring directly the surface tension involving a solid phase, indirect approaches are called for. Several independent approaches have been used to estimate solid surface tensions, including direct force measurements,<sup>[1–9]</sup> contact angles,<sup>[10–17]</sup> capillary penetration into columns of particle powder,<sup>[18–21]</sup> sedimentation of particles,<sup>[22–25]</sup> solidification front interaction with particles,<sup>[25–32]</sup> film flotation,<sup>[33–37]</sup> gradient theory,<sup>[38–41]</sup> the Lifshitz theory of van der Waals forces,<sup>[41–44]</sup> and the theory of molecular interactions.<sup>[45–50]</sup> Among these methods, contact angle measurements are believed to be the simplest.

We report low-rate dynamic contact angle data of various liquids on self-assembled monolayers (SAMs) of octadecanethiol on annealed and non-annealed gold. It was found that the interpretation of solid surface tensions using contact angle data on less well-prepared polycrystalline non-annealed gold surfaces can be misleading. Our findings were supported by

reflectance infrared (IR) spectra and atomic force microscopy (AFM) data indicating that surface nanostructure, defects, and polycrystallinity can be important factors for a systematic study of wettability on SAMs in terms of surface energetics. We found that the contact angle and adhesion patterns of various liquids on SAMs of octadecanethiol adsorbed onto annealed gold substrates are consistent with recent experimental data for the relatively thick polymer-coated surfaces. The variation of surface structure in terms of surface energetics can be estimated only when a fundamental understanding of contact angles and surface tensions is known.

## CONTACT ANGLE MEASUREMENTS

Contact angle measurement is easily performed by establishing the tangent (angle) of a liquid drop with a solid surface at the base. The attractiveness of using contact angles  $\theta$  to estimate the solid–vapor and solid–liquid interfacial tensions is because of the relative ease with which contact angles can be measured on suitably prepared solid surfaces. It is apparent in the literature that this seeming simplicity can be misleading.

The possibility of estimating solid surface tensions from contact angles relies on a relation that was recognized by Young<sup>[51]</sup> in 1805. The contact angle of a liquid drop on an ideal solid surface is defined by the mechanical equilibrium of the drop under the action of three interfacial tensions: solid–vapor  $\gamma_{sv}$ , solid–liquid  $\gamma_{sl}$ , and liquid–vapor  $\gamma_{lv}$ . This equilibrium relation is known as Young's equation:

$$\gamma_{lv} \cos \theta_Y = \gamma_{sv} - \gamma_{sl} \quad (3)$$

where  $\theta_Y$  is the Young contact angle (i.e., a contact angle that can be inserted into Young's equation). The experimentally accessible contact angles may or may not be equal to  $\theta_Y$ , as there exist many metastable contact angles that are not equal to  $\theta_Y$ .

Several contact angle approaches,<sup>[10–17]</sup> of current interest, were largely inspired by the idea of using Young's equation for the determination of surface energetics. Although these approaches are, logically and conceptually, mutually exclusive, nevertheless, they share the following basic assumptions:

1. All approaches rely on the validity and applicability of Young's equation for surface energetics from experimental contact angles.
2. Pure liquids are always used; surfactant solutions or mixtures of liquids should not be used because they would introduce complications because of preferential adsorption.
3. The values of  $\gamma_{lv}$ ,  $\gamma_{sv}$ , and  $\gamma_{sl}$  are assumed to be constant during the experiment (i.e., there should be no physical/chemical reaction between the solid and the liquid).
4. The liquid surface tensions of the test liquids should be higher than the anticipated solid surface tension.
5. The values of  $\gamma_{sv}$  going from liquid to liquid are also assumed to be constant (i.e., independent of the liquids used).

Recent contact angle studies<sup>[52–54]</sup> have shown the complexities of contact angle phenomena, which prevent the use of measurements for surface energetic calculations, by means of low-rate dynamic contact angle measurements using an automated drop shape analysis. It was found that there were three apparent contact angle complexities that violated the basic assumptions made in the interpretation of contact angles for solid surface tensions:

1. Slip/stick of the three-phase contact line.
2. The contact angle increases/decreases as the drop front advances.
3. The liquid surface tension changes as the drop front advances.

These contact angles should not be used for the determination of solid surface tensions. With respect to the first point, slip/stick of the three-phase contact line indicates that Young's equation is not applicable. An increase/decrease in the contact angle and a change in the liquid surface tension as the drop front advances violate the expectation of no physical/chemical reaction. Therefore when the experimental contact angles and liquid surface tensions are not constant, they should be disregarded. After eliminating the meaningless (non-constant) data, experimental contact angles on a large number of polymer surfaces yield smooth curves of  $\gamma_{lv} \cos \theta$  vs.  $\gamma_{lv}$ ,  $\cos \theta$  vs.  $\gamma_{lv}$ , and  $W_{sl}$  vs.  $\gamma_{lv}$  for one and the same solid surface.<sup>[52–63]</sup> Changing the solid surface shifts the curve in a very regular

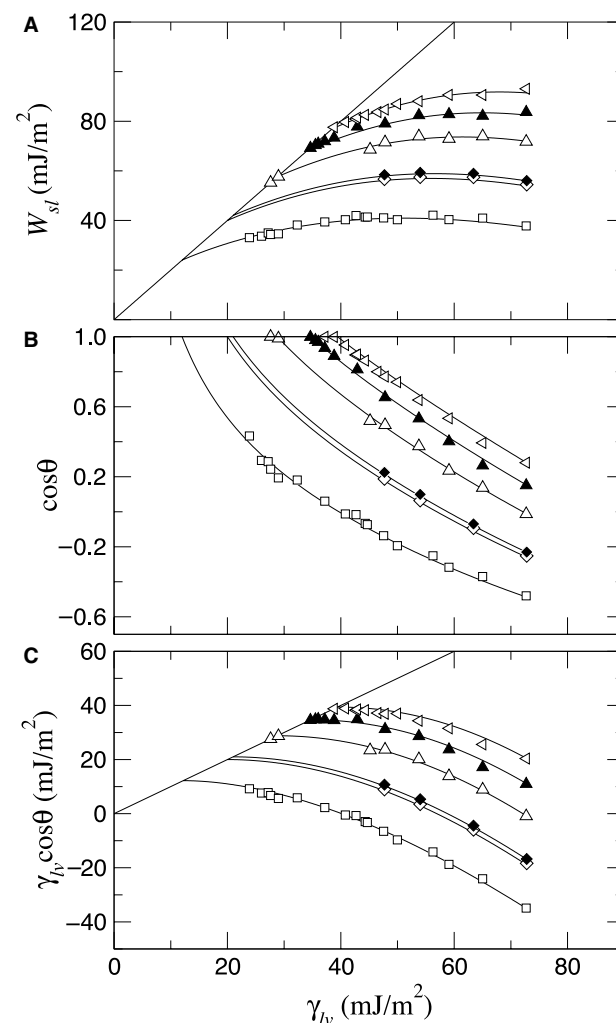

manner, suggesting the following relations:

$$\gamma_{lv} \cos \theta = f_1(\gamma_{lv}, \gamma_{sv}) \quad (4)$$

$$\cos \theta = f_2(\gamma_{lv}, \gamma_{sv}) \quad (5)$$

$$W_{sl} = f_3(\gamma_{lv}, \gamma_{sv}) \quad (6)$$

We reproduce in Fig. 1 the adhesion and contact angle patterns for six surfaces: fluorocarbon FC722,<sup>[52]</sup> hexatriacontane,<sup>[64–67]</sup> cholesteryl acetate,<sup>[64–66]</sup> poly(*n*-butyl methacrylate),<sup>[56]</sup> poly(methyl methacrylate/*n*-butyl methacrylate),<sup>[68]</sup> and poly(methyl methacrylate).<sup>[57]</sup> This and other results suggest the existence

**Fig. 1** (A) The solid–liquid work of adhesion  $W_{sl}$ ; (B) the cosine of the contact angle  $\cos \theta$ ; and (C) the liquid vapor surface tension times the cosine of the contact angle  $\gamma_{lv} \cos \theta$  vs. the liquid–vapor surface tension  $\gamma_{lv}$  for fluorocarbon FC722 ( $\square$ ), hexatriacontane ( $\diamond$ ), cholesteryl acetate ( $\triangle$ ), poly(*n*-butyl methacrylate) ( $\triangle$ ), poly(methyl methacrylate/*n*-butyl methacrylate) ( $\blacktriangle$ ), and poly(methyl methacrylate) ( $\triangleleft$ ) surfaces.

of universal adhesion and contact angle patterns for low-energy solid surfaces. However, a question arises as to whether the low-rate dynamic measurements giving constancy of  $\theta$  and  $\gamma_{lv}$  will always guarantee that the above contact angle assumptions are fulfilled and the patterns in Fig. 1 are unique.

Because these measurements were performed on relatively thick polymer-coated surfaces, it is legitimate to question if the selection of surfaces was biased. In this entry, we purposely selected a thin monomolecular film as our substrate, prepared by SAMs of octadecanethiol adsorbed onto gold. The choice of octadecanethiol SAM is because of its popularity and ease of generating different wettabilities.<sup>[69–74]</sup> To our knowledge, a systematic study of the low-rate dynamic contact angle measurements on SAMs in terms of solid surface tensions has not been performed. A review of literature on contact angle data for octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  SAM on Au suggests that the dependence of  $W_{sl}$ ,  $\gamma_{lv} \cos \theta$ , and  $\cos \theta$  on  $\gamma_{lv}$  is not unique and is different from those shown in Fig. 1. A question arises as to whether the patterns in Fig. 1 do not exist for these monomolecular films, or are there other reasons that complicate our interpretation. The aim of this work is to investigate if the relationships and patterns shown in Fig. 1 exist only for the thick polymer surfaces and not for the relatively thin monolayers by means of low-rate dynamic contact angle measurements. As a second objective, we also study how surface nanostructure and defects of octadecanethiol SAM adsorbed onto gold affect wetting in terms of solid surface tension interpretation.

## EXPERIMENTAL

### Materials

Silicon wafers of test grade were obtained from Wafer World (West Palm Beach, FL) in circular discs of about 10 cm diameter and were cut into rectangular shapes of about  $2.5 \times 5$  cm. Gold shot (99.999%) and titanium shot (99.995%) were obtained from Kurt

J. Lesker (Clairton, PA). Ethanol (100%) was obtained from the Chemistry Department at the University of Alberta (Edmonton, Alberta, Canada). Octadecanethiol [ $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$ ] was obtained from Aldrich and used as received. Six liquids were chosen for contact angle measurements. Selection was based on the following criteria: 1) they should include a wide range of intermolecular forces; 2) they should be non-toxic; and 3) the liquid surface tension should be higher than the anticipated solid surface tension.<sup>[10,14,21,75]</sup> They are listed in Table 1.

### Preparation of Self-Assembled Monolayers

Supported gold films were prepared by sequentially evaporating titanium ( $\sim 10$  nm) and gold ( $\sim 100$  nm) onto small rectangular silicon wafers in a diffusion-pumped vacuum chamber at  $\sim 10^{-6}$  Torr. The chamber was backfilled with air and the substrates were used within 48 hr of preparation. The evaporated surfaces were rinsed with ethanol before SAM formation. Self-assembled monolayers were prepared by immersing into 1 mM  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  in ethanol overnight. The resulting surfaces were rinsed with ethanol and blown dry by nitrogen before use. Evaporated gold substrates were also flame-annealed for  $\sim 30$  sec using a Bunsen burner under ambient laboratory condition. After  $\sim 1$  min, the annealed substrate was then immersed into 1 mM  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  in ethanol overnight.

### Characterization of Self-Assembled Monolayers

Self-assembled monolayers were first characterized by a Sopra GES5 Variable Angle Spectroscopic Ellipsometer. Ellipsometry measurements were performed using a rotating polarizer in the tracking analyzer mode. A broad band of light (300–850 nm) from a 75-W Xe arc lamp is linearly polarized and directed onto the film surface at an incident angle of  $75^\circ$  from the surface normal. The  $\tan \Psi$  and  $\cos \Delta$  for each bare gold substrate were measured as references immediately after evaporation. After immersion into 1 mM

**Table 1** Experimental advancing and receding contact angles on SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto Au

octadecanethiol/ethanol solution overnight, a new set of  $\tan \Psi$  and  $\cos \Delta$  for each substrate was measured again using an ambient film substrate model for regression with known refractive index ( $n$  and  $k$ ) for octadecanethiol adsorbed onto gold. The refractive index for octadecanethiol adsorbed onto gold as a function of wavelength was independently obtained from a Sopra GXR Grazing X-ray Reflectometer, rather than assuming an index of refraction (e.g.,  $n = 1.46$ ) at a given wavelength (e.g.,  $\lambda = 6328 \text{ \AA}$ ) as typically performed in the literature. Such spectroscopic measurements are expected to provide more accurate results in ellipsometer thickness because the optical constants for a range of wavelengths were used simultaneously. The thickness was calculated according to the following equation:

$$(\tan \Psi)e^{(i\Delta)} = f(n_i k_i T_i)$$

where  $n$  and  $k$  are the optical constants of the film, and  $T$  is its thickness; subscript  $i$  represents different wavelengths. The averages of three measurements made at each location on the sample were used to calculate the thickness of each sample.

Reflectance IR spectra of SAMs of octadecanethiol onto Au were obtained by using a Thermo Nicolet Nexus 670 Spectrometer equipped with a VeeMax glazing angle accessory. A p-polarized light was incident at  $70^\circ$  from the surface normal and the reflected light was detected by means of an MCT-A detector cooled with liquid nitrogen. The spectra resolution was  $2 \text{ cm}^{-1}$ . Spectra were referenced to the corresponding bare (anneal and non-annealed) Au substrates and 1024 scans were obtained for good signal-to-noise ratios. An IR gain of two was selected for all reflectance IR measurements to ensure that the input IR signals are constant. Samples were rinsed with ethanol and blown dry by  $\text{N}_2$  prior to characterization.

Atomic force microscopy measurements were performed using a Digital Instruments Nanoscope IIIa atomic force microscope (Digital Instruments, Santa Barbara, CA). Standard silicon nitride cantilevered probes were used with a force/spring constant in the range between 0.06 and 0.58 N/m. The AFM images of annealed and non-annealed Au surfaces were captured by using contact mode under ambient laboratory conditions. The surfaces were cut into  $1 \times 1$ -cm samples to fit onto a  $1.5 \times 1.5$ -cm sample stage.

## Contact Angle Measurements

Contact angle measurements were chosen as the last step for the characterization of SAMs. A Linux version of the axisymmetrical drop shape analysis profile (ADSA-P) was used for sessile drop contact angle measurements. Axisymmetrical drop shape analysis

profile is a technique used to determine liquid–fluid interfacial tensions and contact angles from the shape of axisymmetrical menisci (i.e., from sessile as well as pendant drops).<sup>[76,77]</sup> Assuming that the experimental drop is Laplacian and axisymmetrical, ADSA-P finds a theoretical profile that best matches the drop profile extracted from an image of a real drop, from which the surface tension, contact angle, drop volume, surface area, and three-phase contact radius can be computed. The strategy employed is to fit the shape of an experimental drop to a theoretical drop profile according to the Laplace equation of capillarity, using surface/interfacial tension as an adjustable parameter. The best fit identifies the correct surface/interfacial tension from which the contact angle can be determined by a numerical integration of the Laplace equation. Details of the methodology and experimental setup can be found elsewhere.<sup>[52,53,76–78]</sup>

Sessile drop experiments were performed by ADSA-P to determine the advancing and receding contact angles. Temperature and relative humidity were maintained at  $23.0 \pm 0.5^\circ\text{C}$  and at about 40%, respectively, by means of an independent central air conditioning unit in the laboratory. It was found that because ADSA-P assumes an axisymmetrical drop shape, the values of liquid surface tensions measured from sessile drops are very sensitive to even a very small amount of surface imperfection, such as roughness and heterogeneity, whereas contact angles are less sensitive. Therefore the liquid surface tensions used in this study were independently measured by applying ADSA-P to a pendant drop because the axisymmetry of the drop is enforced by using a circular capillary. Results of the liquid surface tension from previous studies<sup>[52,56,57]</sup> are reproduced in Table 1.

In this study, at least five and up to 15 dynamic contact angle measurements at velocities of the three-phase contact line in the range from 0.1 to 1.0 mm/min were performed for each liquid. The choice of this velocity range was based on previous studies,<sup>[52,53,79,80]</sup> which showed that low-rate dynamic contact angles at these velocities were essentially identical to the static contact angles for these relatively smooth surfaces. Liquids were supplied from below the surface through a hole of  $\sim 1$  mm in diameter on the substrate by means of a motorized syringe system. Details of this setup can be found elsewhere.<sup>[52,53]</sup>

## RESULTS AND DISCUSSION

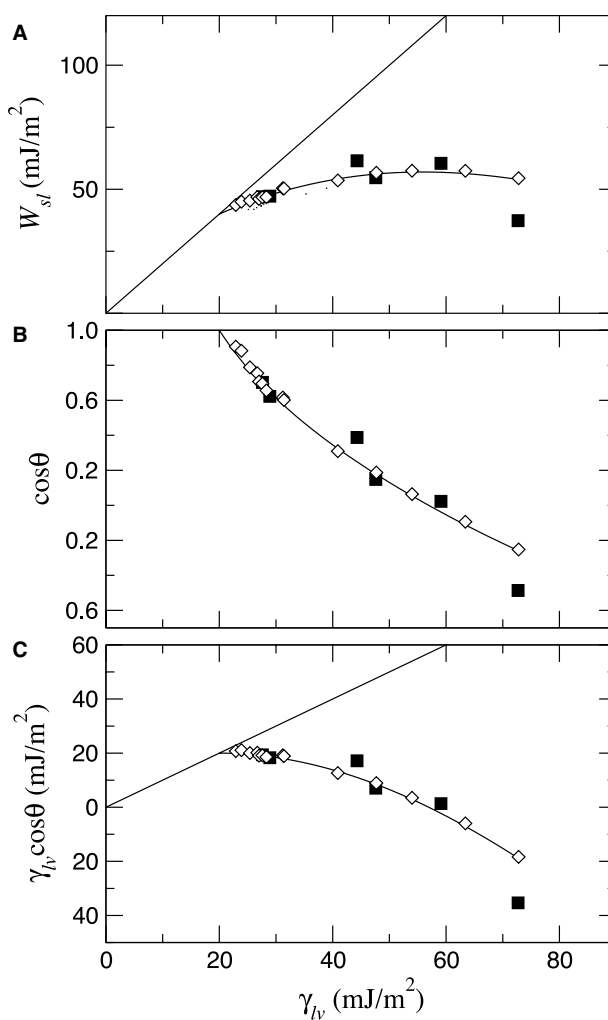

### Formation of Self-Assembled Monolayers on Polycrystalline Gold

Fig. 2 displays a typical low-rate dynamic contact angle of water on SAMs of octadecanethiol

**Fig. 2** Low-rate dynamic contact angles of water on SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_{17})_2\text{SH}$  adsorbed onto Au.

$\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto Au. As can be seen, increasing the drop volume  $V$  linearly from 0.11 to  $0.12\text{ cm}^3$  increases the apparent contact angle  $\theta$  from ca.  $110^\circ$  to  $118^\circ$  at essentially constant three-phase contact radius  $R$ . This is because of the fact that even carefully putting an initial water drop from above on a solid surface can result in a contact angle somewhere between advancing and receding angles. A further increase in the drop volume causes the three-phase contact line to advance, with  $\theta$  essentially constant as  $R$  increases. Increasing the drop volume in this manner ensures the measured  $\theta$  to be an advancing contact angle. Because the contact angles are essentially constant after  $R = 0.37\text{ cm}$  and according to Ref.<sup>[53]</sup>, these contact angles can be used for the determination of solid surface tensions. The averaged contact angle of  $118^\circ$  in Fig. 2 is consistent with the literature values.<sup>[81,82]</sup> The experimental results for the other five liquids also yield essentially constant contact angles; these results, together with the receding angles, are summarized in Table 1. The solid-liquid work of adhesion  $W_{sl}$ ,  $\cos \theta$ , and  $\gamma_{lv} \cos \theta$  vs.  $\gamma_{lv}$  for these liquids is plotted in Fig. 3. However, there are significant scatters in these data even though the procedures of low-rate dynamic contact angles were used to distinguish meaningful angles from meaningless ones. Comparison of this figure with Fig. 1 suggests that the two patterns are different. A question arises as to whether or not the patterns shown in Fig. 1 are unique only for thick polymer surfaces and not for other surfaces such as monolayers.

**Fig. 3** (A) The solid-liquid work of adhesion  $W_{sl}$ ; (B) the cosine of the contact angle  $\cos \theta$ ; (C) the liquid vapor surface tension times the cosine of the contact angle  $\gamma_{lv} \cos \theta$  vs. the liquid-vapor surface tension  $\gamma_{lv}$  for hexatriacontane ( $\diamond$ ) and SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto Au ( $\blacksquare$ ).

From the point of view of surface energetics, we note that a water contact angle of  $119.1^\circ$  (Table 1) for a surface exposing purely methyl groups [ $\text{CH}_3(\text{CH}_2)_{17}\text{S}/\text{Au}$ ] appears to be too high. For example, the experimental advancing contact angles of water on polystyrene, hexatriacontane, Teflon PTFE, and fluorocarbon are expected to be  $90\text{--}92^\circ$ ,  $105\text{--}107^\circ$ ,  $108\text{--}110^\circ$ , and  $118\text{--}120^\circ$ , respectively, as summarized in Table 2. This comparison suggests that SAMs of octadecanethiol adsorbed onto Au, which are supposed to expose mainly methyl groups, should have a solid surface tension similar to that of fluorocarbon ( $118\text{--}120^\circ$ ) and lower than that of Teflon PTFE ( $108\text{--}110^\circ$ ). These interpretations are questionable. From a surface energetic viewpoint, if SAMs of octadecanethiol adsorbed onto Au expose only methyl

**Table 2** Comparison of expected water contact angles on fluorocarbons, PTFE, polystyrene (PS), and poly (methyl methacrylate) (PMMA) with that measured on SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto Au

Surface	Water contact angle (°)
Fluorocarbon	118–120
PTFE	108–110
Hexatriacontane	105–107
PS	90–92
PMMA	73–75
$\text{CH}_3(\text{CH}_2)_{17}\text{S}/\text{Au}$	118–120

groups, we would expect them to behave very much like a hexatriacontane surface (with water advancing angles between  $105^\circ$  and  $107^\circ$ ) because both surfaces have predominately methyl groups exposed to the surface. The only apparent difference is that the former is a monolayer and the latter is a thick crystalline and well-ordered surface. The hexatriacontane surface was prepared by vapor deposition, of which the surface quality was so good that there was no contact angle hysteresis for water.<sup>[66]</sup> Self-assembled monolayers with methyl groups cannot possibly have a solid surface tension as low as that of fluorocarbon. We also superimposed the contact angle data of octadecanethiol SAM/Au onto those of the hexatriacontane in Fig. 3 and found that the monolayer data appear to fluctuate around those of the hexatriacontane. We wish to point out that the conventional thinking regarding contact angles is that they are indicators for surface hydrophobicity in terms of solid surface tensions (e.g., higher contact angle implies lower surface energy and, similarly, lower contact angle suggests higher surface energy). Such an interpretation is not necessarily conclusive for the systems considered here as will be illustrated and discussed later. We speculate that the discrepancy may come from additional and unexpected effects of changing solid–liquid interfacial tensions on the contact angles through the variation of surface structures, even though the solid–vapor surface tension might have been constant. If  $\gamma_{sv}$  and  $\gamma_{lv}$  are constant, changes in  $\theta$  suggest that  $\gamma_{sl}$  is changing. In “Formation of Self-Assembled Monolayers on Annealed Gold,” we will quantify such effects by looking into the surface structures of octadecanethiol SAMs adsorbed onto Au.

It is commonly known in the literature<sup>[83,84]</sup> that thermally evaporated gold yields smoother and better polycrystalline structures than that by sputtering. It has also been found that SAMs on thermally annealed gold have larger terraces with less surface defects.<sup>[85,86]</sup> Thus SAMs on annealed gold are typically used in AFM studies to obtain atomic resolution pictures.

As a matter of fact, most contact angle studies of SAMs on gold were prepared either by sputtering or thermal evaporation because of the relatively simple procedures.<sup>[81,87–89]</sup> To our knowledge, no systematic contact angle study on SAMs has yet been performed and has looked into the details of how surface structures affect wetting in terms of surface energetic interpretation using thermally annealed gold. Thus we will investigate in “Formation of Self-Assembled Monolayers on Annealed Gold” low-rate dynamic contact angles on octadecanethiol monolayers formed on thermally annealed gold, in an attempt to isolate any (possible) effect of surface structures and defects on solid surface tension interpretation.

### Formation of Self-Assembled Monolayers on Annealed Gold

Fig. 4 shows the low-rate dynamic contact angle results of water on SAMs of octadecanethiol adsorbed onto a thermally annealed gold substrate. Similar to the experimental results in Fig. 2, as  $V$  increases at the beginning,  $\theta$  increases at constant  $R$ . This is because of the fact that such contact angles are not truly advancing angles and that it takes time for the drop front to advance. As  $V$  increases further, the three-phase contact radius  $R$  moves and the contact angle remains rather constant. Averaging the contact

**Fig. 4** Low-rate dynamic contact angles of water on SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto annealed gold.

**Table 3** Experimental advancing and receding contact angles on SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto evaporated (non-annealed) and annealed gold

Liquid	$\gamma_{lv}$	Non-annealed		Annealed	
		$\theta_a$ (°)	$\theta_r$ (°)	$\theta_a$ (°)	$\theta_r$ (°)
Water	72.7	$119.1 \pm 0.8$	$100.2 \pm 0.7$	$106.9 \pm 0.5$	$92.3 \pm 0.9$
Formamide	59.1	$88.7 \pm 0.8$	$63.0 \pm 1.4$	$92.4 \pm 1.5$	$69.2 \pm 1.9$
Ethylene glycol	47.6	$81.5 \pm 0.6$	$66.4 \pm 1.1$	$81.6 \pm 2.4$	$68.2 \pm 1.6$
Bromonaphthalene	44.3	$67.2 \pm 0.8$	$44.1 \pm 0.8$	$76.1 \pm 0.9$	$64.3 \pm 1.3$
Decanol	28.9	$50.7 \pm 0.5$	$38.2 \pm 1.1$	$53.2 \pm 0.9$	$45.1 \pm 1.3$
Hexadecane	27.6	$45.4 \pm 0.4$	<20.0	$45.7 \pm 0.8$	$35.4 \pm 2.2$

Error bars are 95% confidence limits.

angle yields a mean value of  $107.0^\circ$ . We see that this water contact angle value ( $107.0^\circ$ ) is significantly lower than that shown in Fig. 2 ( $118.2^\circ$ ) on the evaporated (non-annealed) gold. We also note that the contact

angle obtained here ( $107.0^\circ$ ) for the  $\text{CH}_3(\text{CH}_2)_{17}\text{S}$  or thermally annealed gold is similar to those obtained on the hexatriacontane (cf. Table 2) and paraffin. This result agrees with the expectation that a monolayer surface exposing predominately methyl groups should have a similar solid surface tension, and hence contact angle, as those of hexatriacontane and paraffin surfaces. Low-rate dynamic contact angle measurements for the remaining five liquids were performed and found to be also constant. These angles, together with the receding angles, are summarized in Table 3.

It is of interest to plot these contact angles in Fig. 5 together with those on the hexatriacontane surface. We see that the apparent scatter in Fig. 3 has disappeared in Fig. 5 using the contact angles on the annealed samples. The resulting  $W_{sl}$ ,  $\cos \theta$ , and  $\gamma_{lv} \cos \theta$  vs.  $\gamma_{lv}$  curves are quite smooth and similar to those shown in Fig. 1. We conclude that the experimental results in Fig. 5 are compatible with the functional relationships in Eqs. (4–6). The origin of the difference in experimental patterns between the nonannealed and annealed gold will be discussed below.

### Characterizations by Ellipsometry, Fourier Transform Infrared Spectroscopy, and Atomic Force Microscopy

The ellipsometer thickness for octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto annealed gold was consistently 21 Å, whereas that formed on the non-annealed Au varied between 20 and 21 Å. Although this difference is not statistically significant, we noticed that the experimental  $\tan \Psi$  and  $\cos \Delta$  for the non-annealed Au samples did not always match those of the theoretical curves. Nevertheless, our thicknesses are consistent with those reported in the literature.<sup>[82]</sup>

The reflectance spectra for SAMs derived from octadecanethiol on Au and annealed Au are shown

**Fig. 5** (A) The solid–liquid work of adhesion  $W_{sl}$ ; (B) the cosine of the contact angle  $\cos \theta$ ; and (C) the liquid vapor surface tension times the cosine of the contact angle  $\gamma_{lv} \cos \theta$  vs. the liquid–vapor surface tension  $\gamma_{lv}$  for hexatriacontane ( $\diamond$ ) and SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto thermally annealed Au ( $\bullet$ ).

in Fig. 6. In both spectra of Fig. 6, the asymmetrical methylene peaks appeared at  $\sim 2918\text{ cm}^{-1}$ . This indicates a primarily trans-zigzag extended hydrocarbon chain with few gauche conformers. Both spectra demonstrate that SAMs of octadecanethiol adsorbed onto Au and annealed Au are highly crystalline. However, the intensities of the methylene peaks are larger on Au and smaller on the annealed Au. The difference in the peak intensity could reflect different canted orientations for the polymethylene chains on these surfaces, or different amounts of the polymethylene chains that the IR detected. Because the tilt of the chain on the Au substrate for alkanethiolate SAMs is known to be  $\sim 30^\circ$  and this structural orientation is unlikely to be changed by annealing, we speculate that the difference in the intensity of the asymmetrical methylene peaks appears at  $\sim 2918$  and  $2850\text{ cm}^{-1}$ , indicating different amounts of polymethylene chains that were detected by the IR. The spectrum for the adsorbed layer of octadecanethiol on non-annealed Au exhibits a higher dichroic ratio ( $\sim 2$ ) for the methylene adsorption modes [ $\nu_a(\text{CH}_2)/\nu_s(\text{CH}_2)$ ], and that on the annealed Au exhibits a much lower dichroic ratio ( $\sim 1.3$ ). We also note the lower asymmetrical methyl intensity  $\nu_a(\text{CH}_3)$  at  $2964$  (asym)  $\text{cm}^{-1}$  and the higher symmetrical methyl intensity  $\nu_s(\text{CH}_3)$  at  $2879$  (sym)  $\text{cm}^{-1}$  for SAMs on annealed Au in Fig. 6, suggesting that the methyl groups are oriented more toward the surface normal. These features in the spectra provide evidence that SAMs of octadecanethiol on non-annealed Au have a structure that is not the same as that on the annealed Au. Independent AFM images shown in Fig. 7 suggest that the annealed Au has larger terraces (as much as 200 nm), whereas that of the non-annealed Au has much smaller gold steps.

From the interpretation of the above IR and AFM results, we constructed a model in Fig. 8 that illustrates a possible arrangement of octadecanethiol adsorbed onto non-annealed and annealed Au. From the schematic, it is expected that the reflectance IR would detect more methylenes per unit projected area on the non-annealed Au than that for the annealed Au. This is because of the polycrystallinity nature of non-annealed Au that causes variations of the methyl and methylene groups exposed to water. The schematic also supports the IR results for lower asymmetrical methyl intensity and higher symmetrical methyl intensity for SAMs on the annealed Au, as the methyl groups are oriented more toward the surface normal than those on the non-annealed Au.

### Wetting Interpretation in Terms of Solid Surface Tensions

Contact angle interpretation requires extreme experimental care to ensure that all of the commonly accepted assumptions are not violated. It is apparent in Table 3 that, in general, the contact angle hysteresis  $H = \theta_a - \theta_r$  decreases for the annealed gold substrate, suggesting better surface quality. The slightly larger errors for the contact angle data of octadecanethiol adsorbed onto annealed Au were because of the variation of our annealing procedures. From the AFM results above, we conclude that the non-annealed surface consists of smaller gold steps, whereas that of the annealed Au has larger terraces and less defects, as illustrated schematically in Fig. 8. In the case of the non-annealed samples, water could “see” deeper of the surface layer (the methylenes) under the methyl

**Fig. 6** Grazing incidence polarized infrared spectra for SAMs of octadecanethiol  $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  adsorbed onto evaporated (non-annealed) and annealed gold. The approximate positions of the methylene modes are  $2918$  (asym) and  $2850$  (sym)  $\text{cm}^{-1}$ , and those for the methyl modes are  $2964$  (asym),  $2935$  (sym, Fermi resonance), and  $2879$  (sym)  $\text{cm}^{-1}$ . The spectra have been offset vertically for clarity.

**Fig. 7** Atomic force microscopy images of (A) annealed Au and (B) non-annealed Au for a scan size of 1  $\mu\text{m}$ .

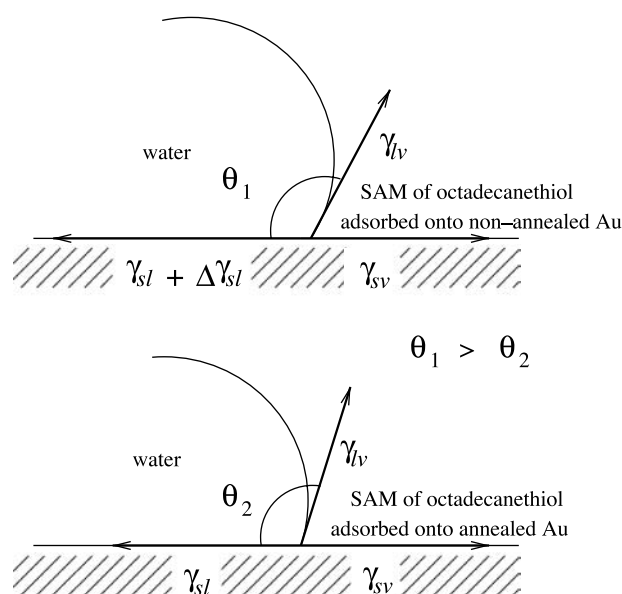

groups because of the relatively less packed monolayers as a result of smaller gold steps or defects. This allows the formation of additional intermolecular interactions between water and the methylenes in the solid–liquid interface. In this case, the surface no longer consists of predominantly methyl groups, but a mixture of methyl and methylene groups in the solid–liquid interfacial region. These molecular interactions with methylenes would result in a higher, additional, interfacial tension between the solid–liquid interface  $\Delta\gamma_{sl}$ , and is illustrated schematically in Fig. 9. This additional effect is believed to have less influence on the solid–vapor interface because of the presence of the relatively less dense water vapor on the solid–vapor interface. Assuming that  $\gamma_{sv}$  is roughly constant for both annealed and non-annealed surfaces, an increase

in  $\gamma_{sl}$  for the latter would cause the contact angle to increase from that of a surface where water can only “see” most of the outer methyl groups and less methylene groups. Thus it appears that the change in the contact angle is a result of additional and unexpected formation of intermolecular interactions in the solid–liquid interface for less packed monolayers. The magnitude would depend, of course, on the intermolecular strength, polarity of the liquid, and structures of the monolayers. In this case, even though we apparently fix our substrate, the intermolecular interactions would not be the same for a given pair of liquid and solid, depending on the surface defect, structure, polycrystallinity, and arrangement of monolayers. In Table 3, we also note that the advancing contact angles for the annealed and non-annealed surfaces are nearly identical

**Fig. 8** Schematic illustration of SAM assembly on two different Au substrates. The upper figure demonstrates the SAM assembly of octadecanethiol adsorbed onto non-annealed Au with smaller gold steps. The lower figure illustrates the SAM assembly of octadecanethiol adsorbed onto annealed Au with larger terraces.

**Fig. 9** Schematic illustration of how the variation of surface structures affects the solid–liquid interfacial tension  $\gamma_{sl}$  for SAMs of octadecanethiol on non-annealed and annealed Au.  $\Delta\gamma_{sl}$  in the upper figure represents the increase in the solid–liquid interfacial tension from that of an annealed Au. Given that the liquid vapor interfacial tension  $\gamma_{lv}$  and the solid–vapor interfacial tension  $\gamma_{sv}$  remain unchanged, an increase in  $\Delta\gamma_s$  results in a higher contact angle  $\theta_1$  than that of the annealed Au,  $\theta_2$ .

and did not change very much for both ethylene glycol and hexadecane. However, the molecular interactions between hexadecane/ $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  and ethylene glycol/ $\text{CH}_3(\text{CH}_2)_{17}\text{SH}$  on two different Au surfaces are not clearly known. We conclude that, whatever these interactions are, they appear to be insensitive to the structural changes and surface defects of the monolayers. If the intermolecular interactions change drastically as we change the substrate's surface preparation for a given liquid, this violates our expectation of constant solid properties along the curves shown in Figs. 1, 3, and 5. Interpretation of such angles on the non-annealed ones would be difficult.<sup>[90–92]</sup> Because the annealed surfaces contain less defects, additional variation of the solid–liquid interfacial interactions  $\Delta\gamma_{sl}$  would be minimal. We conclude that the surface structures of the underlying gold on which the monolayers of octadecanethiol are formed can affect directly the interpretation of contact angles. Only when a fundamental framework (such as that shown in Fig. 1 or Fig. 5) has been established can the variation of the interfacial interactions from liquid to liquid as an additional effect be studied more systematically. With the above stipulation, the variation of  $\gamma_{sl}$  as a result of surface structural change can be estimated if we assume  $\gamma_{sv}$  for the non-annealed and annealed Au to

be the same. Therefore a  $\Delta\gamma_{sl}$  of  $12.9 \text{ mJ/m}^2$  can be estimated by taking the difference in the water advancing angles,  $\Delta\gamma_{sl} = [72.7(\cos 107 - \cos 118)]$ , using Young's equation. This value represents an increase in  $\gamma_{sl}$  because of the variation of surface structures of octadecanethiol SAMs adsorbed onto Au when interacting with water. However, conventional thinking would have interpreted the water contact angle of  $118^\circ$  for octadecanethiol SAMs on Au to have a much lower solid surface tension similar to that of fluorocarbon ( $\gamma_{sv} = \sim 12 \text{ mJ/m}^2$ ), rather than a  $\gamma_{sv}$  of  $19\text{--}20 \text{ mJ/m}^2$  for methyl-terminated surfaces.

## CONCLUSION

We conclude that the surface defect, structure, and crystallinity of SAMs of octadecanethiol adsorbed onto gold can affect the interpretation of contact angles in terms of solid surface tensions. The contact angle and adhesion patterns of various liquids for SAMs of octadecanethiol adsorbed onto annealed gold are consistent with recent experimental findings on the relatively thick polymer-coated surfaces. We also found that interpretation of solid surface tensions using contact angle data on less well-prepared polycrystalline gold surfaces can be misleading. The variation of surface structures in terms of surface energetics can be estimated only when a fundamental understanding of contact angles and surface tensions is achieved.

## ACKNOWLEDGMENTS

This research was supported financially, in part, by the Natural Sciences and Engineering Research Council (NSERC) of Canada, the Canada Research Chair Program (CRCP), and the Canada Foundation for Innovation (CFI). ## Abstract

This entry describes critical challenges, opportunities, approaches, and recent results in the science and technology of heteroepitaxial semiconductor zero-dimensional structures known as quantum dots (QDs). Focus is placed on the controlled fabrication and tight management of the properties of self-assembled QD through design, epitaxial growth, and modification of QD heterostructures using nanoscale engineering techniques, for example, surface kinetics control, shape engineering, and band-structure engineering. Examples of applications are described where the advantageous properties of the engineered QD ensembles have been demonstrated.

## INTRODUCTION

Heteroepitaxial semiconductor zero-dimensional structures known as quantum dots (QDs) are arguably the most developed quantum-type entities. Control of such entities can be achieved in a relatively straightforward manner using current technologies, thus leading to many potentially exciting applications.

In this context, this entry presents a review of the fabrication and properties of self-assembled QDs. Given that self-assembly is controlled by the thermodynamics and kinetics of the specific system under study, the entry begins with a brief overview of the mechanism of self-assembly and the main processes that drive the nucleation and evolution of a QD structure. Typically, the phenomenon of self-assembly is exploited to control the structure laterally, while in the growth direction it is managed directly by growth control (usually through composition control) with atomic-scale precision. The overview is followed by a description of key techniques to improve carrier localization and carrier dynamics in the QD ensemble. Modification of QD heterostructures using nanoscale engineering protocols is then discussed, including pertinent methods for QD shape, strain, and heterostructure band engineering. Examples are provided of applications where the distinctive properties of engineered QD ensembles have been demonstrated.

## HETEROEPITAXIAL QUANTUM DOTS

Manipulation of materials at the atomic scale opens enormous opportunities for the development of novel applications, devices, and processes. Among the many nano-engineered systems proposed over the years, one of the most exciting and probably the most mature is

heteroepitaxial quantum confined semiconductor structures. These structures can be classified as quantum wells (QWs) and QDs. Over two decades of research in both areas have resulted in significant advances, including the demonstration of various electronic devices such as microwave transistors, laser diodes, and photodetectors, just to name a few. These advances are attributed primarily to the development of two semiconductor growth approaches, namely, molecular beam epitaxy (MBE) and metal-organic vapor phase epitaxy (MOVPE). These approaches are capable of producing quantum-confined heterostructures with highly controlled purity, epitaxial quality, and interfacial sharpness.

A QW consists typically of an ultra-thin film with a thickness of a few nanometer (nm) grown usually on gallium arsenide (GaAs) or indium phosphide (InP) substrates. Its main advantages include single-dimension quantization of the electronic spectrum and reasonably strong carrier localization. As a result, single QW and multiple stacked quantum well structures are responsible for a reduction of more than an order of magnitude in the threshold current in semiconductor laser diodes and an increase in mobility in two-dimensional electron gas in field-effect transistors. Quantum wells have also enabled the fabrication of far-infrared quantum cascade lasers.

A QD consists typically of a few nm-size particles of one semiconductor material embedded into a matrix consisting of a wider bandgap semiconductor. Its main advantage is achievement of ultimate zero-dimensional localization. Remarkably, the electronic spectrum of individual QDs is quantized in all three directions, as is the case for atoms and molecules. In this respect, the electronic spectrum of QDs is determined by the type of semiconductor materials used for the QD and matrix, as well as quantum confinement and strain in the QD.

Quantum dot ensembles are more attractive than QWs for electronic and, especially, photonic devices, such as lasers,<sup>[1]</sup> infrared photodetectors,<sup>[2,3]</sup> broad spectrum superluminescent light emitting diodes (LEDs)<sup>[4,5]</sup> due to their enhanced performance. A case in point is the projected performance of QD-based laser diodes. According to theoretical predictions, heterojunction lasers with QD active media will exhibit superior characteristics in comparison with conventional QW lasers,<sup>[1,6]</sup> including higher efficiency at elevated temperatures, higher thermal stability, improved reliability, and faster dynamics. The primary reason for this superiority is the discrete atom-like electronic spectrum of QDs without any thermal spreading of carriers.

The ability to fully exploit the exciting benefits of QD ensembles still presents some challenges, mainly due to (i) inhomogeneous broadening of the QD electronic spectrum resulting from the size dispersion of QDs, (ii) existence of excited states in the dots, (iii) relatively slow relaxation of carriers to the ground level in the QDs, and (iv) poor localization of carriers at room temperature because of escape of carriers from the QDs to the wetting layer and barrier. These problems can be potentially solved through various atomic-scale engineering approaches, as discussed in what follows.

### TEMPLATING VS. SELF-ASSEMBLY

The most common approach for growing heteroepitaxial QDs relies on the phenomenon of self-organization in epitaxial heterostructures with high lattice mismatch between the structures. The most widely explored heterosystem is In(Ga)As/(Al)GaAs structures with up to 7% lattice mismatch (Fig. 1). The growth of InAs QDs on GaAs surface is usually described rather simplistically in terms of a classic Stranski–Krastanov growth mechanism, where the structure attains the lowest total free energy through a trade-off between strain energy in the growing film and the surface free energy of the islands. According to this mechanism, after formation of a thin coherent wetting layer, growth spontaneously becomes three-dimensional through the assembling of islands. In reality, the mechanism of self-assembly is further complicated by the involvement of kinetics in addition to thermodynamics.

To obtain more uniform QD density and enable the formation of periodic arrays of QDs, various types of nanolithographic patterning or templating methods using either e-beam or scanning probe techniques were proposed and evaluated.<sup>[7]</sup> Electron beam lithography accompanied with wet or dry etching<sup>[8,9]</sup> was employed to pattern the QD structures with the lateral dimensions down to 20 nm. Nanolithographic methods

**Fig. 1** (A) Plane-view transmission electron microscopy (TEM) image of InAs quantum dots grown on AlAs surface. The lateral size is about 14 nm and lateral density is about  $10^{11} \text{ cm}^{-2}$ ; (B) high-resolution TEM micrograph of an InAs QD grown on (100) GaAs surface. (111) lattice fringes of GaAs/InAs are visible in the image. InAs QD appears as darker pyramid with 20 nm base and 8 nm height.

involve direct atomic force microscopy (AFM) oxidation of the GaAs surface<sup>[10]</sup> or formation of scanning tunneling microscopy (STM) current-induced deposits<sup>[11]</sup> followed by the MBE growth of self-assembled InGaAs QDs. In situ ultra-high vacuum nanolithography techniques include direct electron-beam writing with subsequent chlorine etching of the GaAs surface to provide arrays of holes serving as nucleation sites for the InAs islands.<sup>[12]</sup> Though QD formation has been successfully demonstrated, these nanoscale methods so far generate a high defect density, which introduces traps and recombination centers in the active medium of the device. These features result in low quality material in comparison with the self-assembly method. In addition, nanolithographic

**Table 1** Properties of self-assembled InAs QD ensemble prepared for laser gain medium and associated optimization trade-offs

QD property	Demonstrated optimum	Trade-offs
Narrow size distribution (small inhomogeneous broadening)	25–35 meV at $h\nu = 1.1$ eV	High density High efficiency
Strong localization	400–500 meV at RT	High density
Large ground-excited states separation	~100 meV	Fast relaxation to GS
High density	$\sim(8-12) \times 10^{10} \text{ cm}^{-2}$ per layer	Strong localization, high efficiency
High efficiency (defects)	Close to 100%	High density
High efficiency (e–h overlap)	Symmetrical shape	High density
Fast carrier transport to GS	~5–10 ps at RT	Thermal stability

patterning or templating methods exhibit very low throughput, making scalability a serious issue.

### BASIC PROPERTIES OF SELF-ASSEMBLED QD ENSEMBLES

Self-assembly is driven by the thermodynamics and kinetics of 2D-to-3D phase transformation, which limit the ability to vary QD properties to a narrow window. Any improvement to one QD parameter results in degradation of other properties. Table 1 lists key parameters and associated trade-offs for a self-assembled InAs QD ensemble used in a laser medium. A narrow QD size distribution, high QD density, and high radiation recombination efficiency are essential for the formation of a QD medium with high optical gain, whereas strong carrier localization and large energy separation between ground and excited states are needed for laser thermal stability. Fast carrier transport to the lasing state (preferably ground state)

results in higher saturation gain and faster modulation properties.

In this respect, the narrowest size distribution is achieved in QD sheets with low areal density, where growth of one island is less affected by other islands in proximity. Self-assembly results in a large QD size distribution, thus giving rise to wide inhomogeneously broadened emission spectra (Fig. 2). A single QD energy level is extremely narrow  $\sim 10 \mu\text{eV}$  (Fig. 3), but the narrowest spectrum for an ensemble of QDs is  $\sim 25-35$  meV. Creating a QD medium with more uniform size distribution is a significant challenge because island size distribution, or more accurately, island volume distribution, is determined by the kinetics of fluctuations in phase transformation. If the island size fluctuations were purely statistical (varying around some equilibrium size), the variation in number of atoms would be on the order of  $N^{-1/2}$  ( $N$  is the number of atoms in the island). A typical InAs QD with  $\langle N \rangle = 3000$  atoms would have fluctuations of  $\sim 50$  atoms, corresponding to an inhomogeneous broadening

**Fig. 2** Schematic diagram of the electron–hole pair energy levels in a QD heterostructure and room-temperature photoluminescence spectrum of QD ensemble. QD luminescence results from transitions between quantum-confined levels of electrons and holes in the QD potential. Width of the spectrum is determined by inhomogeneous broadening due to QD size distribution.

**Fig. 3** Near-field photoluminescence of small QD cluster taken at liquid helium temperature. Each narrow peak corresponds to PL of individual dot. *Source:* J. Merz and A. Mintairov, University of Notre Dame.

of the emission line of  $\sim 3$  meV as can be estimated from Fig. 4.<sup>[13]</sup> Practically, the full-width at half-maximum (FWHM) of QD luminescence band is usually 30–50 meV, and is quite higher than the simple statistics of the number of condensed atoms. Island size distribution is determined by the dynamics of island formation and could be controlled by nanoengineering methods, as described here.

As mentioned earlier, the benefits of QDs are attributed mainly to strong carrier localization. To maintain localization at higher temperatures, the separation between ground and excited levels ( $\Delta_{exc}$ ) and the barrier height in QDs should be made much larger than the thermal energy. This separation is determined by QD barrier height and shape. Barrier height decreases when QD size decreases due to increased quantum confinement energy. Therefore, smaller dots with high density provide lower localization energy than larger dots

**Fig. 4** Emission energies as a function of QD volume, expressed as the total number of atoms in the dot for three different QD heights. *Source:* Reprinted with permission from Pryor.<sup>[13]</sup>

with low density. Additionally, high QD density is essential to achieving higher gain in the laser medium, a feature that is critical to the performance of miniature lasers such as vertical cavity surface-emitting lasers (VCSELs) and short edge-emitting laser diodes. High QD density mediums ( $>10^{11}$  cm<sup>-2</sup>) suffer from poorer localization and lower radiative efficiency, the latter most likely due to higher defect density in the heterostructures with increased InAs/GaAs interface area.

Management of electronic and optical properties of QDs, such as homogeneous and inhomogeneous electronic spectrum and defects that define non-radiative recombination and carrier dynamics, relies on understanding the basic technology–structure–property relationships that control their performance. A set of physical phenomena essential for understanding these relationships is given in Table 2. These phenomena serve as basis for the development of effective management methods (somewhat interrelated), as discussed in the following sections.

**Table 2** Processes involved in QD formation and associated phenomena

Process	Associated phenomena
Nucleation of QDs	Thermodynamics and kinetics of 2D–3D phase transition Adatom diffusion
Evolution of QDs	Tendency towards larger dots with time Evaporation and intermixing of In
Overgrowth of QDs	Segregation of In Lateral redistribution of In
Post-growth control	Diffusion of species Stress-induced redistribution

**Fig. 5** Schematic drawing illustrating QD self-assembly. Two main driving forces for self-assembled growth: (i) strain energy is lower in 3D structure than in the uniform 2D strained layer, and (ii) stress term in surface chemical potential drives adatoms towards the top of the islands.

## QD SELF-ASSEMBLY

### Control of QD Nucleation

The nucleation of InAs QDs utilizes the large ( $\sim 7\%$ ) lattice mismatch between InAs and GaAs to promote the formation of strained 3D InAs islands through the Stranski–Krastanow growth mode. At first, InAs grows pseudomorphically on top of GaAs, forming a strained film (wetting layer) with a thickness on the order of  $\sim 1.5$  ML.<sup>[14]</sup> At this critical thickness, it becomes energetically favorable for InAs to form islands, or QDs, which allows the effective release of strain as shown in Fig. 5.

The main driving force for QD self-assembly is the stress term in surface chemical potential, which drives adatoms towards the top of the islands. Therefore, it is obvious that the characteristics of the developing QDs are strongly affected by the process temperature and underlying surface chemistry. Figure 6 exhibits the dependence of InAs QD density on the growth temperature for GaAs and AlAs underlayers. Though the growth conditions are somewhat different in experiments reported by various investigators, resulting in different absolute values of QD densities, the trend is quite clear. The Arrhenius behavior with

$\sim 2.0$  eV activation energy is evident up to QD densities as high as  $10^{12}$  cm<sup>-2</sup>.<sup>[15,16]</sup> The density of dots is consistently higher by approximately a factor of 2, if formed on AlAs surface. This behavior is attributed to the lower surface diffusion rates of In adatoms on AlAs.

Atomic force microscopy imaging of the QDs allows assessment of QD size and heights (Fig. 7). As expected from transmission electron microscopy (TEM) studies, AFM results indicate that the dots grown on AlAs surface are smaller and have higher densities. When the QDs are grown at 475°C, the aspect ratio is about 6 for the dots on GaAs surface, and slightly higher on AlAs. In both cases, total thickness of deposited InAs was kept identical, 2.4 ML. Hence, there is no noticeable difference in the total volume of the QDs grown on AlAs or GaAs. In this context, further overgrowth, along with cooling down of surface dots, may change the QD resulting size and shape. Accordingly, the ultimate QD heterostructures may contain QDs of varying features and characteristics. In fact, it will be shown in the next section that (volume  $\times$  density) can be controlled through a QD overgrowth process.

Manipulation of the chemistry of the underlying surface at the monolayer (ML) scale can be effective

**Fig. 6** Arrhenius plot of InAs QDs areal density. The solid (black) symbols correspond to GaAs and 2 ML AlAs, as measured by TEM.<sup>[14]</sup> The open (white)-symbols are from Ref.<sup>[53]</sup> (circles) and Ref.<sup>[54]</sup> (squares), with the circles and squares corresponding to growth on, respectively, GaAs and thick AlAs, as measured by AFM. Straight lines correspond to activation energy of 2.0 eV. Source: Reprinted with permission from Ref.<sup>[14]</sup>

**Fig. 7** AFM images of QDs grown on AlAs and GaAs surfaces at 475°C. The QD ensembles have almost identical average lateral size: 31 nm on GaAs, and 27 nm on AlAs), different aspect ratio ( $d/h$ ):  $\sim 6$  on GaAs and  $\sim 11$  on AlAs; lower QD density on GaAs  $\sim 5.2 \times 10^{10} \text{ cm}^{-2}$ , and  $\sim 9.8 \times 10^{10} \text{ cm}^{-2}$  on AlAs.

at fine-tuning QD size, leading to direct changes in the optical properties of QD structures. Figure 8 plots photoluminescence (PL) intensity and linewidth dependence on ground state transition energy of QDs,  $E_g$ . Noticeable degradation in PL intensity and broader size distribution were measured for QDs grown on AlAs surface. The intermediate properties were obtained for QDs grown on 1 ML of GaAs on short period superlattice (SPSL) terminated by AlAs.

### SURFACE EVOLUTION OF QDs AND QDs OVERGROWTH

As mentioned earlier, overgrowth of QDs can lead to significant changes in their overall characteristics. The overgrowth process reveals the following major trends: (i) evolution of QDs on the surface towards larger QDs with lower density; (ii) QD evolution may be preserved by a capping layer deposition; and (iii) redistribution of In from QDs may occur when capping is slow. These trends are discussed in more detail here.

Trend (i) is quite obvious and results from the fact that uncapped dots that exist on a bare surface for the longest time exhibit the largest volume. It is well

**Fig. 8** Normalized room temperature PL intensity and linewidth,  $\text{FWHM}/E_{gr}$ , corresponding to size distribution versus ground state PL energy  $E_{gr}$  for QD ensembles grown on various underlayers *Source*: Reprinted from Ref.<sup>[16]</sup> with permission of Springer Science and Business Media.

understood that if the QD growth process is allowed to progress, surface redistribution of In adatoms will continue and the islands will become larger and larger. This has been shown both experimentally<sup>[17]</sup> and through theoretical modeling.<sup>[18]</sup> This conclusion is very important for understanding QD growth mechanisms because it indicates that there is no thermodynamic equilibrium size for the QDs on the surface, and the QDs will be growing on the surface as long as they are not overgrown.

Of course, some other requirements should be met for this process to continue, such as maintaining the As equilibrium overpressure, confinement (evaporation or solution) of In atoms to the surface, and the absence of plastic strain relaxation. The initial size and density of QDs is determined by the characteristics of critical nuclei at the 2D–3D phase transformation, and after this transformation takes place within a few seconds, the QDs start growing slowly by dissolution of the smaller dots. To prevent QD evolution on the surface, fast capping is essential since it can “freeze” the growing surface.

Processes (ii) and (iii) compete with each other. A few ML thick AlAs layer deposited at a fast rate is a good candidate for the capping layer.<sup>[19]</sup> In fact, a comparison of fast and slow capping with thin GaAs or AlAs layers using AFM, TEM, and PL studies<sup>[16]</sup> has shown that fast AlAs capping results in the ensemble of the highest density. On the other hand, the observed reduction in QD size with other capping procedures is due to a segregation and lateral redistribution of In from the dots to the surrounding matrix.

**Fig. 9** Left: (002) dark field TEM image of InAs QD embedded in a SPSL. Right: (A) Magnified (002) DF image of the frame “A” including two periods of (2 ML-AlAs)/(8 ML-GaAs) SPSL,  $\sim 1$  ML InAs wetting layer (WL), 2 ML AlAs capping layer, 20 ML GaAs QW; (B) multislice image simulation of the image in (A) using a supercell as depicted in (C), with  $\text{In}_{0.5}\text{Al}_{0.5}\text{As}$  alloyed wetting layer and Indium segregation into GaAs; and (C) Supercell used in the image simulation viewed along [110] direction. *Source:* Reprinted from Ref.<sup>[16]</sup> with permission of Springer Science and Business Media.

Indium is known to segregate at the growing surface even at relatively low growth temperatures (450–500°C). The reported values for the In segregation efficiency parameter are high and almost identical for AlAs and GaAs overgrowth:  $R = 0.86$  for both GaAs and AlAs overgrowth at 480°C;<sup>[14]</sup>  $R = 0.82$ <sup>[20]</sup> for GaAs; and  $R = 0.77$  for AlAs<sup>[20,21]</sup> at 530°C. As a result, the InAs redistribution thickness is about 6 ML. An indication of In segregation can be found from analysis of TEM images. Figure 9 shows a (002) dark field image of a QD assembled on GaAs surface and capped with 2 ML AlAs, with arrows pointing to heterostructure features.

The image contrast variations simulated using multislice package (MacTempas<sup>®</sup>) indicated vertical In distribution in the region above the wetting/capping layers within  $\sim 6$  ML and incorporation of Al atoms (alloy formation) into the wetting layer. In segregation alone cannot account for the difference in QD capping by GaAs or AlAs layers. Since the In surface segregations are found to be almost identical for GaAs and AlAs, the difference in QD capping with GaAs or AlAs layers is most likely to be due to lateral redistribution of In resulting from different adatom mobility on the two surfaces.

### SHAPE ENGINEERING OF QDs

All-epitaxial InAs QDs assembled on GaAs or AlAs surfaces typically exhibit pyramidal or close to pyramidal shapes, which is determined by the surface energy of the growing InAs islands. A high-resolution UHV STM image reveals the corresponding QD shape with dominant  $\{137\}$  (or  $\{136\}$ ) and  $\{111\}$  facets, as shown in Fig. 10.<sup>[22–24]</sup> This pyramidal shape is responsible for the quite poor interaction between the electron and hole. More specifically, the electron and hole ground state wave functions have a small overlap integral due to a stress-induced piezoelectric field that separates electrons and holes,<sup>[25]</sup> thus resulting in reduced optical gain in the QD systems.<sup>[26]</sup> QDs with more

symmetric shapes, such as spheres or disks would be preferable to strengthen the electron–hole interaction.

The shape of QDs also determines the energy splitting between the ground state and excited states. In III–V semiconductor QDs, quantum confinement splitting of holes is usually much smaller than that of electrons due to significantly large effective mass of heavy holes. Though the binding energies of the ground states are mainly controlled by QD volume, the splitting between the ground s-like and first excited p-like conduction states ( $\Delta_{\text{exc}}$ ) increases with the increase in height-to-base ratio of the pyramid<sup>[26]</sup> and also with the increase in the barrier height. Quantum dot ensemble with high  $\Delta_{\text{exc}}$  is required for thermally stable lasers. Control of shape and  $\Delta_{\text{exc}}$  allows fabrication of quantum dot infrared photodetectors (QDIPs) in the 3–14  $\mu\text{m}$  range. Large height-to-base QD ratio results in a reduced dependence of IR sensitivity on polarization, and the volume and shape determine the spectral range of the resulting photodetector.<sup>[28,29]</sup>

**Fig. 10** Atomically resolved STM image of uncapped InAs QD grown on GaAs(100) at 450°C. *Source:* Reprinted with permission from Ref.<sup>[22]</sup>.

The height-to-base aspect ratio can be controlled using the “punctuated island growth” method developed by Mukhametzhanov et al.<sup>[30]</sup> It was found that the lateral size remains remarkably unchanged with further InAs deposition, if growth is interrupted after deposition of  $\sim 1.7$  ML. The added material (up to 3 ML) after “punctuation” increased the height and density of the dots, while keeping the lateral size almost unchanged at about 24 nm. This approach resulted in impressive low inhomogeneous linewidth broadening value of 26 meV.

An effective shape-managing method was also proposed by Wasilewski et al.<sup>[31]</sup> It employs heating (flushing) of partially overgrown dots to reduce pyramidal shapes to disk-like shapes. Figure 11 demonstrates a further developed method of shape management of QD ensemble.<sup>[32]</sup> The InAs QDs were embedded into 2 ML-AlAs/8 ML-GaAs SPSL barriers with a GaAs overlayer (up to 25 ML in thickness) on top of the QDs. After capping of the freshly formed QDs with 2 ML-thick AlAs layer to prevent coarsening of the islands and In redistribution, the QDs were overgrown with a GaAs layer with a thickness corresponding approximately to the QD heights

**Fig. 11** (A)–(D) Shape management step-by-step procedure.

( $\sim 6$  nm). Owing to high mobility of Ga adatoms, GaAs layer does not cover the QDs entirely but tends to cover the low stress area between the QDs (Fig. 11B). Then, the sample is rapidly heated by an additional  $100^\circ\text{C}$ , resulting in indium redistribution mainly at the top of QDs. This treatment leads to changes in the shape and volume of QD. Finally, the structure is overgrown by a thin layer of GaAs to form a QW for efficient collection of carriers, and further, by SPSL (Fig. 11D).

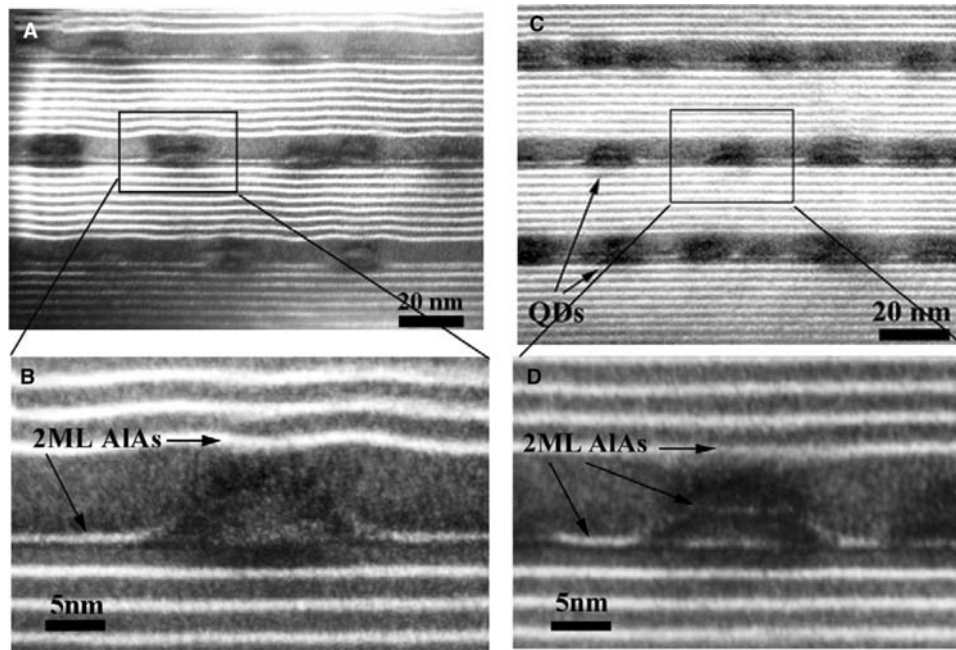

The shape management procedure described results in the QDs with a shape of truncated pyramids with flat tops entirely covered by an AlAs layer, even after subjecting the partially overgrown dots to a heating (truncation) step (Fig. 11D). The shape-engineered QD ensemble has demonstrated better volume uniformity because larger QDs lose more In during the truncation procedure. This reduces the inhomogeneous broadening of the emission spectrum below 30 meV.<sup>[33]</sup> The beneficial (more symmetrical) shape of the QDs was shown to increase the electron–hole coupling, which allowed higher emission efficiency and saturated ground state gain of  $16\text{ cm}^{-1}$  in a triple-layer structure, which is almost doubled when compared with similar non-truncated QD structures.

AlAs capping affected mostly the energy separation between ground and first excited states. In this context, the optimized structures demonstrated a 90–100 meV separation that is considerably higher than the thermal energy. Apart from the increase in electron–hole coupling through shape engineering, a more typical approach to maximum gain increase is through increase in total density of QDs through the addition of further layers. Noticeable advantages of shape-engineered QD ensembles for multilayer QDs are due to reduced roughness for the entire structure with very smooth top SPSL interfaces [as contrasted with wave-shape top SPSL interfaces in non-truncated QDs in Fig. 12(A) and (B)]. It is worth noting that a medium with seven truncated QD layers separated by thin 20 nm interlayer barrier distances (total thickness of  $\sim 125$  nm) with maximum in-plane gain of  $31\text{ cm}^{-1}$  was recently demonstrated.<sup>[34]</sup>

## STRAIN ENGINEERING OF QDs

Given the role of strain as the driving force for QD formation in heteroepitaxial systems, control of strain is a valuable tool for manipulation of QD properties. As reported earlier, tighter 7.2% misfit in InAs/GaAs system typically produces QDs with lateral dimensions of about 20 nm with density in the range of  $10^{10}$ – $10^{11}\text{ cm}^{-2}$ . Lower 3.2% misfit in InAs/InP results in larger dots (30–50 nm lateral size) with low density ( $10^8$ – $10^9\text{ cm}^{-2}$ ).<sup>[34]</sup> The latter can provide significantly

**Fig. 12** TEM images [(200) dark field] of triple-layer InAs QDs embedded in a (2 ML-AIAs)/(8 ML-GaAs) SPSL: (A) non-truncated QDs in SPSL with top AIAs; and (B) magnified image; (C) shape-engineered QDs in SPSL with top AIAs; and (D) magnified image. *Source:* Reprinted from Ref.<sup>[16]</sup> with permission of Springer Science and Business Media.

red-shifted emission in the 1.4–2  $\mu\text{m}$  range, and therefore, is important for telecommunication applications.<sup>[35]</sup>

Epitaxial heterostructures do not provide many options to control strain on any given substrate. In fact, creation of a virtual substrate with a lateral lattice constant different from that of GaAs or InP (i.e., the commercially available high quality III–V substrates) results in the formation of misfit dislocations with inevitable reduction in layer quality. Nevertheless, it is proven possible to control nucleation and growth of QDs via manipulation of the lateral strain field. Quantum dot produce non-uniform lateral strain in the subsequent layers of the structure, which facilitates preferential nucleation of islands directly on top of the existing QDs (Fig. 13). This phenomenon was used by several groups to develop vertically coupled QDs to modify the electronic spectrum, increase the effective density of states in the medium, and enhance the uniformity of dot size and column spacing distributions.<sup>[36–38]</sup>

In addition, the composition and thickness of strained InGaAs underlayers and overlayers were used to control both emission energy and carriers escape energy by means of strain and band structure manipulation.<sup>[39]</sup> This approach is generally believed to be the most promising to red-shift the emission spectrum of GaAs-based structures toward fiber wavelengths of 1.3 and possibly 1.55  $\mu\text{m}$ .

## BAND ENGINEERING OF QD HETEROSTRUCTURES

An important and very useful feature of heteroepitaxial semiconductor structures is the ability to engineer their band structure and to control their electronic spectrum and transport properties. This feature makes group III–V heteroepitaxial QDs unique. For example,

**Fig. 13** Cross-sectional TEM image of 5-layer QD stack in SPSL with the spacing of 12 nm demonstrating vertical alignment of QDs.

free-standing QDs (nanoparticles) or QDs in an insulating matrix, although usually easier to produce and having better uniformity, retain high and uncontrollable energy barriers, and therefore, are of limited use in electronic and optoelectronic applications.

Barrier height around heteroepitaxial InAs QDs is relatively easy to control by varying the composition of the surrounding layers. To increase the bandgap of the QD matrix, it might be beneficial to utilize AlAs/GaAs SPSL as a barrier material instead of an AlGaAs alloy (Figs. 9 and 12). The SPSL or “digital alloy” is a high-quality wide-bandgap material, which can be grown at low temperature (<500°C) required for QD growth. In addition, SPSL provides another variable to control QD growth since both GaAs and AlAs surfaces can be readily used as a starting surface for QD deposition.

Band engineering provides the means to control transport and dynamics of carriers in the structure. A good example is a dots-in-a-well (DWELL) structure where InAs QDs are imbedded into an InGaAs QW. In this structure, if used as a laser gain medium, QW works as an efficient reservoir for capturing carriers, which significantly improve their collection into QDs, and therefore improve modal gain and internal quantum efficiency. As a result, laser diodes with record low threshold current density of 16 A/cm<sup>2</sup> were demonstrated.<sup>[40]</sup> In addition, this DWELL approach was used to red-shift the emission spectrum of QDs down to 1.3 μm by varying the composition of the InGaAs quantum well matrix.<sup>[41]</sup>

The DWELL approach has proved to be very promising for broadening the gain spectrum needed for superluminescent LEDs used, for example, in optical coherence tomography. The shape of the broad emission band can be tailored by varying the composition of InGaAs QWs of a multi-dot-in-well stack.<sup>[5]</sup>

## LOCALIZATION ENERGY

As noted above, strong carrier localization in QDs is responsible for the major advantages in a QD laser medium. Thermal escape of carriers from the QDs negatively impacts the device parameters, such as gain in the laser medium. The same process is responsible for thermal quenching of QD luminescence due to recombination of the carriers outside the dots. Obviously, strong localization requires large barrier for carrier escape, large energy separation between the ground and excited state levels, and lack of intermediate levels with high density of states, such as those in a wetting layer. In general, this set of requirements is good enough to ensure localization.<sup>[42]</sup> It should be emphasized that a wide bandgap barrier, such as AlGaAs, by itself is not enough to guarantee strong localization of the carriers in the dots.

Thermal quenching of photoluminescence of QDs in QW structure fabricated using nanoengineering approaches described in the previous section (Fig. 12) is shown in Fig. 14 with a corresponding band diagram in the inset 2). Within the capture/escape events, carriers are usually considered to behave as excitons or correlated electron–hole pairs, rather than independent electrons and holes. The validity of this approach is justified by the fact that the activation energy for the escape process is typically equal to the sum of the barrier heights for electrons and holes. Le Ru et al.<sup>[43]</sup> have recently argued that more realistic independent capture/escape of electrons and holes will also give a barrier height for thermal escape equal to the sum of the barrier heights for electrons and holes under realistic experimental conditions, such as strong thermal quenching. Therefore, the observed large barrier for escape from QDs (450 meV) simply corresponds to the transitions between ground QDs and the GaAs QW states as in Fig. 14.

The nanoengineered QDs described exhibit over two orders of magnitude higher tolerance to non-radiative defects than QWs at room temperature, as measured by introduction of radiative defects with ion implantation and monitoring the luminescence efficiency.<sup>[42]</sup> There are two reasons for QD defect tolerance. First, a large barrier energy for carrier escape from the QDs results in a high temperature offset (~250 K) for carrier escape from the dots. Second, low non-radiative rate in the barrier material (which is a 7.5 nm-thick GaAs QW in these samples) extends

**Fig. 14** Arrhenius plot of integrated PL intensity in nanoengineered QD structures. Symbols correspond to the experimental data and the line is a fit with the dynamic model,<sup>[42]</sup> which neglects the carrier escape through intermediate levels. Inset: Band structure of electron–hole pairs in nanoengineered QDs in QW.

the high probability of carrier recombination in the QDs to temperatures as high as 320 K and, consequently, shifts the PL thermal quenching offset to higher temperatures. These properties provide a way for significant improvement in reliability and radiation hardness of optoelectronic devices.

## CARRIER DYNAMICS

Many optoelectronic applications, such as lasers (in particular VCSELs) and superluminescent LEDs, require high optical gain, which is difficult to achieve using QD medium due to its low density of states (proportional to the QD density) when compared with QWs. However, this gain can be increased by the nanoengineering approaches described above through reduction of inhomogeneous broadening in the QD ensemble, enhancement of overlap between electrons and holes, and reduction of escape of carriers from the lasing (ground state) QD levels.

Carrier capture and further relaxation to the ground level of a QD is relatively slow ranging from 5 to 50 ps depending on doping, and carrier and QD densities. Shorter relaxation times are usually attributed to electron–hole scattering,<sup>[44]</sup> while longer times are due to slower phonon scattering,<sup>[45]</sup> also known as “phonon bottleneck”.<sup>[46]</sup> An effective way to improve the gain is to increase the capture rate of carriers into QDs using tunnel injection from QWs.<sup>[47–49]</sup> In this case, QW is working as a reservoir for electrons and holes with high density of states and, therefore, with large capture cross-section. Hence, carrier capture in QWs is more efficient than in QDs, and may provide a path for fast carriers transfer into the dots by resonant tunneling. As a result, tunnel-coupled QW-QDs medium exhibited extremely high maximum saturated gain,<sup>[47]</sup> and impressive 23 GHz modulation bandwidth as a result of fast tunneling time into QDs of about 1.7 ps as shown in Fig. 15.<sup>[48]</sup> This fast tunneling rate is comparable with the stimulated emission rate at high injection currents, thus reducing gain suppression and improving saturation gain of the medium.

Fig. 16 shows a (200) dark-field TEM image of tunnel-coupled well-on-dots structure. This multilayer structure has smooth interfaces as a result of the QD shape-engineering (truncation) procedure described above. Immediately after QD truncation, a tunnel barrier consisting of 5 ML(GaAs) + 2 ML-(AlAs) + 4 ML(GaAs) is grown, followed by a 3 nm-thick  $\text{In}_{0.33}\text{Ga}_{0.67}\text{As}$  QW on top of the tunnel structure. Fast carrier transport from QW into QDs is believed to be due to LO phonon-assisted tunneling. It is proved, for example, by photoluminescence measurements of the described tunnel structure where the broad QD band consists of multiple narrow peaks, separated by

**Fig. 15** Pump-probe differential transmission signal from a QW–QD tunnel injection heterostructure taken at different temperatures. The gain (pump) pulse at 800 nm generates carriers in the heterostructure, and the probe pulse at 980 nm monitors population of the QD levels. *Source:* Reprinted with permission from Ref.<sup>[48]</sup>.

energies equal to LO phonon energy of  $\sim 37$  meV.<sup>[49]</sup> In this case, the resonant tunneling process occurs only in those QDs with energy levels shifted by multiple LO phonon energies from the QW level.

**Table 3** summarizes relevant parameters for different QD laser media fabricated using the nanoengineering methods described here. Shape-engineering improves the gain almost by a factor of 2. Another twofold enhancement may be obtained through a

**Fig. 16** TEM (200) dark-field micrographs of QW-on-QDs tunnel structure. The InGaAs QW is separated from the top of the InAs QDs by a GaAs/AlAs barrier. The AlAs layers appear bright, while GaAs appears dark under these conditions.

**Table 3** Comparison of resonant tunnel injection lasers with multilayer QD lasers.  $\lambda_{\text{las}}$  is a lasing wavelength,  $J_{\text{th}}$  is threshold current density,  $L_{\text{min}}$  is minimum cavity length for lasing with cleaved mirrors. All the lasers tested were fabricated using the same waveguide design

MQD lasers	3xQD non-truncated	3xQD	7xQD	3x (QW on QDs)
$\lambda_{\text{las}}$ ( $\mu\text{m}$ )	1.23	1.22	1.12	1.13–1.11
Minimum $J_{\text{th}}$ ( $\text{A}/\text{cm}^2$ )	78	56	155	255
$L_{\text{min}}$ (mm)	1.73	0.87	0.41	0.13
Max. modal gain (per layer) ( $\text{cm}^{-1}$ )	9 (3)	16 (5.3)	31 (4.4)	90 (30)

simple increase in the number of QD layers from 3 to 7. The slight reduction of gain per layer is most likely due to lower injection efficiency in a thicker double heterostructure. A significant fivefold improvement of the modal gain is achieved in the tunnel QW–QD structures shown in Fig. 14. These structures were recently used in an all-epitaxial VCSEL.<sup>[51]</sup>

It is important that the tunnel QW–QD structures have the beneficial properties of QDs even though some lateral transport exists during the operation. For example, frequency chirping and linewidth enhancement factor remain significantly less ( $\sim 5$  times) than that in QW laser.<sup>[50]</sup>

## CONCLUSIONS

Semiconductor quantum dot structures with a discrete atomic-like electronic spectrum have significant physical advantages over those commonly used in optoelectronic devices quantum wells. While growth of semiconductor heterostructures with QDs is relatively easy, it is essential to employ various nanotechnology technologies to maximize projected benefits. A number of methods have been employed recently to improve carrier localization and carrier dynamics in QD ensembles. These methods employ self-assembly to control the structure laterally, and atomically precise component deposition from MBE or MOVPE to achieve the same control in the growth direction. It is reasonable, therefore, to expect major breakthroughs in both the physics and applications of QDs through the development of methods for 3D control of heterostructures via patterning or templating technologies paving a road toward single QD devices.<sup>[52]</sup>

# Self-Assembled Quantum Dots: Electronic Structures and Optical Properties

Andrew Williamson

Lawrence Livermore National Laboratory, Livermore, California, U.S.A.

## INTRODUCTION

As evidenced by many of the entries in this encyclopedia, the past decade has witnessed a series of significant advances in the growth of semiconductor nanostructures. These nanostructures range in size from a few atoms up to several million atoms and have been produced by myriad synthesis techniques.<sup>[1]</sup> In this entry, we describe calculations of the electronic and optical properties of self-assembled (so-called Stranski–Krastanow) quantum dots produced by molecular beam epitaxy.<sup>[2,3]</sup> Even more dramatic than the advances in the growth of these structures has been the development of extremely sophisticated techniques for measuring the optical, electronic, magnetic, and transport properties of these quantum dot systems. The availability of such high-quality measurements for a wide range of properties presents theorists with the formidable challenge of constructing models that can explain the origins of these experimental observations in terms of the underlying energy states of the quantum dots.

Calculating such energy states in self-assembled semiconductor quantum dots is rendered particularly challenging by a number of factors:

1. The quantum dots contain a large number of atoms. A typical self-assembled quantum dot has a base of  $\sim 300 \text{ \AA}$  and a height of  $\sim 50 \text{ \AA}$ . Therefore the dot itself may contain  $\sim 10^5$  atoms. This dot then needs to be surrounded by a barrier material to isolate it from other dots. Therefore a representative system containing both the dot and barrier typically contains  $\sim 10^6$  atoms.
2. By the nature of the growth process, self-assembled quantum dots are highly strained. For example, in the most common InAs/GaAs material combination, the lattice mismatch is 7%. Therefore an accurate solution of the strain profile in the system is required before the electronic structure can be calculated.
3. The valence band maximum (VBM) in III–V semiconductor materials is threefold degenerate (in the absence of strain and spin–orbit splitting),

therefore any realistic approach must describe at least the band mixing between the three valence band edge states.

4. In InAs, the bulk band gap is 0.42 eV and the spin–orbit splitting is 0.38 eV, therefore the mixing between valence and conduction band states and split off states also have to be taken into account.
5. In a zero-dimensional InAs/GaAs quantum dot system, the charge carriers are artificially confined inside the dot, which is typically smaller than the bulk excitonic radius—the “Strong Confinement” regime. This dramatically enhances the Coulomb interaction between charges in the dot and strongly modifies the dielectric screening.

## OVERVIEW

The standard theoretical approach to this problem has been to adapt effective mass-based techniques and their more sophisticated extension, the  $\mathbf{k}\cdot\mathbf{p}$  method, which has been extremely successful in explaining a range of properties of bulk semiconductors. In essence, these methods expand the single-particle wavefunctions of the system in a basis of bulk Bloch orbitals derived from the Brillouin zone center ( $\Gamma$  point). If a sufficient number of basis states are included, this expansion provides an excellent description of the band structure of the bulk material close to the  $\Gamma$  point. However, errors in the predicted energy rapidly increase as one moves away from the zone center. To improve the description of the band structure away from the zone center, one typically includes more and more basis functions in the expansion of the wavefunctions. The successes of this effective mass model in describing spectroscopic and transport properties in both three-dimensional bulk systems and two-dimensional quantum well structures are well documented. This model was also demonstrated to be able to provide at least a qualitative picture of the energy states in zero-dimensional systems. However, some of this success is mitigated by the fact that often, the

parameters in the model have to be refit to the nanostructure system itself. Recently, a direct comparison<sup>[4]</sup> between an eight-band  $\mathbf{k}\cdot\mathbf{p}$  calculation and a full pseudopotential calculation for a pyramidal InAs quantum dot embedded within bulk GaAs showed a generally good agreement between the two techniques. However, the higher symmetry imposed by the  $\mathbf{k}\cdot\mathbf{p}$  approach acts to omit certain energy level splittings and polarization anisotropies. The  $\mathbf{k}\cdot\mathbf{p}$  approach also overconfined both electrons and holes level by  $\sim 50$  meV.

Instead, in this entry, we describe our method of choice, the empirical pseudopotential method (EPM) approach to calculating the energy states in semiconductor quantum dots. This approach has several advantages over the conventional effective mass approach to the problem:

1. Once a pseudopotential has been developed to describe the bulk system, there are no adjustable parameters for describing a heterostructure system.
2. The EPM method has the same accuracy, whether it is describing a three-dimensional bulk system, a two-dimensional quantum well, a one-dimensional quantum wire, or a zero-dimensional quantum dot.
3. The EPM method provides an *atomistic* description of the system. Therefore the correct symmetry of the underlying crystal lattice is reproduced. In addition, an atomistic description of interfaces between materials is also maintained.

We begin with a detailed description of each of the stages required in a typical EPM calculation of the energy states in a semiconductor quantum dot. Then we describe a series of applications of the EPM technique to studying a range of optical and electronic properties of self-assembled quantum dots.

## DESCRIPTION OF PSEUDOPOTENTIAL TECHNIQUES

To calculate the energy states associated with various electronic excitations in self-assembled quantum dots requires three stages of calculation:

1. Assume the shape and composition and compute the strain:  
We first construct a supercell containing both the quantum dot and surrounding barrier material. Sufficient barrier material is used, so that when periodic boundary conditions are applied to the system, the electronic and strain

interactions between dots in neighboring cells is negligible. The atomic positions within the supercell are relaxed by minimizing the strain energy described by an atomistic force field<sup>[5,6]</sup> including bond bending, bond stretching, and bond bending–bond stretching interactions. More details of the atomistic relaxation are given in the section “Calculation of the Strain Profile.”

2. Set up the pseudopotential single-particle equation:

A single-particle Schrödinger equation is set up at the relaxed atomic positions,  $\{\mathbf{R}_{nz}\}$

$$\begin{aligned}\hat{H}\psi_i(\mathbf{r}) &= \left\{ -\frac{\beta}{2}\nabla^2 + \sum_{nz} \hat{v}_z(\mathbf{r} - \mathbf{R}_{nz}) \right\} \psi_i(\mathbf{r}) \\ &= \epsilon_i \psi_i(\mathbf{r})\end{aligned}\quad (1)$$

The potential for the system is written as a sum of strain-dependent, screened atomic pseudopotentials,  $v_z$ , that are fit to bulk properties extracted from experiment and first-principles calculations. For more details of the constructing of the Hamiltonian see the section “[Constructing the Single-Particle Hamiltonian.](#)”

3. Calculate the screened, interparticle many-body interactions:

The calculated single-particle wavefunctions are used to compute the electron–electron, electron–hole, and hole–hole direct,  $J_{ee}$ ,  $J_{eh}$ ,  $J_{hh}$ , and exchange  $K_{ee}$ ,  $K_{eh}$ ,  $K_{hh}$  Coulomb energies. For more details, see the section “[Calculation of ‘Two-Body’ Interactions.](#)”

The main approximations involved in our method are as follows: 1) the fit of the pseudopotential to the experimental data of bulk materials is never perfect; and 2) we neglect self-consistent iterations in that we assume that the screened pseudopotential drawn from a bulk calculation is appropriate for the dot. Our numerical convergence parameters are: 1) the size of the GaAs barrier separating periodic images of the dots; and 2) the number of basis functions used in the expansion of the wavefunctions (see the sections “[Expansion in a Plane Wave Basis](#)” and “[Expansion in a Linear Combination of Bloch Bands](#)” for more details).

## Calculation of the Strain Profile

To obtain an *atomistic* description of the strain profile in a heterostructure system, we construct an expression for the strain energy in terms of few-body potentials

between actual atoms

$$E_{\text{strain}} = \sum_{ij} V_2(\mathbf{R}_i - \mathbf{R}_j) + \sum_{ijk} V_3(\hat{\Theta}_{ijk}) + \dots \quad (2)$$

where  $V_2$  is a two-body term,  $V_3$  is a three-body function of the bond angle,  $\hat{\Theta}_{ijk}$ . The functional form of these terms is taken to be strain-independent. The strain is determined by minimizing  $E_{\text{strain}}$  with respect to atomic positions  $\{\mathbf{R}\}$ .

Our chosen expression for the elastic strain energy, is a generalization (G-VFF) of the original valence force field (VFF)<sup>[5,7]</sup> model. Our implementation of the VFF includes bond stretching, bond angle bending, and bond length/bond angle interaction terms. This enables us to accurately reproduce the  $C_{11}$ ,  $C_{12}$ , and  $C_{44}$  elastic constants in a zincblende bulk material. We have also included higher-order bond stretching terms, which yield the correct dependence of the Young's modulus with pressure. The expression for the G-VFF total energy is:

$$\begin{aligned} E_{\text{G-VFF}} = & \sum_i \sum_j^{n_i} \frac{3}{8} [\alpha_{ij}^{(1)} \Delta d_{ij}^2 + \alpha_{ij}^{(2)} \Delta d_{ij}^3] \\ & + \sum_i \sum_{k>j}^{n_i} \frac{3\beta_{jik}}{8d_{ij}^0 d_{ik}^0} [(\mathbf{R}_j - \mathbf{R}_i) \cdot (\mathbf{R}_k - \mathbf{R}_i)] \\ & - \cos \theta_{jik}^0 [d_{ij}^0 d_{ik}^0]^2 + \sum_i \sum_{k>j}^{n_i} \frac{3\sigma_{ijk}}{d_{ik}^0} \Delta d_{ij} \\ & \times [(\mathbf{R}_j - \mathbf{R}_i) \cdot (\mathbf{R}_k - \mathbf{R}_i) - \cos \theta_{jik}^0 d_{ij}^0 d_{ik}^0] \end{aligned} \quad (3)$$

where  $\Delta d_{ij} = [(\mathbf{R}_i - \mathbf{R}_j)^2 - d_{ij}^{02}]/d_{ij}^0$ . Here,  $\mathbf{R}_i$  is the coordinate of atom  $i$  and  $d_{ij}^0$  is the ideal (unrelaxed) bond distance between atom types of  $i$  and  $j$ . Also,  $\theta_{jik}^0$  is the ideal (unrelaxed) angle of the bond angle  $j$ - $i$ - $k$ .  $\sum^{n_i}$  denotes the summation over the nearest neighbors of atom  $i$ . Example values of  $\alpha$ ,  $\beta$ , and  $\sigma$  can be found in Ref.<sup>[8]</sup>.

For an InGaAs alloy system, the bond angle and bond length/bond angle interaction parameters  $\beta$ ,  $\sigma$  for the mixed cation Ga-As-In bond angle are taken as the algebraic average of the In-As-In and Ga-As-Ga values. In Fig. 1, we show the result of a G-VFF calculation for the strain profile in a lens-shaped InAs quantum dot embedded within GaAs. The trace of the strain is plotted in a (010) plane through the center of the dot. It shows that, to a first approximation, the InAs dot is subjected to a uniform compressive strain and the GaAs barrier is slightly expanded around the interface with the dot.

**Fig. 1** Contour plot of the hydrostatic strain profile in a lens-shaped, self-assembled InAs/GaAs quantum dot with a base of 252 Å and a height of 35 Å.

## Constructing the Single-Particle Hamiltonian

We construct the single-particle Hamiltonian as

$$\hat{H} = -\frac{\beta}{2} \nabla^2 + \sum_{nz} \hat{v}_z(\mathbf{r} - \mathbf{R}_{nz}) \quad (4)$$

where  $\mathbf{R}_{nz}$  is the G-VFF relaxed position of the  $n$ th atom of type  $\alpha$ . Here  $\hat{v}_z(\mathbf{r})$  is a screened empirical pseudopotential for atomic type  $\alpha$ . It contains a local part and a non-local, spin-orbit interaction part.

The local potential part is designed to include dependence on the local hydrostatic strain  $\text{Tr}(\epsilon)$ :

$$v_\alpha^{\text{loc}}(r; \epsilon) = v_\alpha^{\text{eq}}(r; 0) [1 + \gamma_\alpha \text{Tr}(\epsilon)] \quad (5)$$

where the  $\gamma_\alpha$  is a fitting parameter. The zero strain potential  $v_\alpha^{\text{eq}}(r; 0)$  is expressed in reciprocal space  $q$  as

$$v(q) = a_0(q^2 - a_1)/[a_2 e^{a_3 q^2} - 1] \quad (6)$$

where  $a_{0,1,2,3}$  are fitting parameters. The local hydrostatic strain  $\text{Tr}(\epsilon)$  for a given atom at  $\mathbf{R}$  is defined as  $\Omega_R/\Omega_0 - 1$ , where  $\Omega_R$  is the volume of the tetrahedron formed by the four atoms bonded to the atom at  $\mathbf{R}$ .  $\Omega_0$  is the volume of that tetrahedron in the unstrained condition. The need for explicit dependence of the atomic pseudopotential on strain in Eq. (5) results from the following: While the description in Eq. (4) of the total pseudopotential as a superposition of atomic potentials situated at specific sites,  $\{\mathbf{R}_{nz}\}$ , does capture the correct local symmetries in the system, the absence of a self-consistent treatment of the Schrödinger equation deprives the potential from changing in response to strain. In the absence of a strain-dependent term, the volume dependence of the energy of the bulk valence band maximum is incorrect. While self-consistent descriptions show that the volume deformation potential  $a_v = dE_v/d \ln \Omega$  of the valence band maximum is *negative* for GaAs, GaSb, InAs, InSb, and for all II-VI, this qualitative behavior cannot be

obtained by a non-self-consistent calculation that lacks a strain-dependent pseudopotential.

In Eq. (4), the kinetic energy of the electrons has been scaled by a factor of  $\beta$ . The origin of this term is as follows: In an accurate description of the crystal band structure, such as the GW method, a general, spatially non-local potential,  $V(r,r')$ , is needed to describe the self-energy term. In the absence of such a term, the occupied band width of an inhomogeneous electron gas is too large compared to the exact many-body result. However, to a first approximation, the leading effects of this non-local potential,  $V(r,r')$ , can be represented by scaling the kinetic energy. This can be obtained by Fourier transforming  $V(r,r')$  in reciprocal space,  $q$ , then making a Taylor expansion of  $q$  about zero. We find that the introduction of such a kinetic energy scaling,  $\beta$ , permits a simultaneous fit of both the effective masses and energy gaps. In this study, we fit  $\beta = 1.23$  for both GaAs and InAs.

The pseudopotential parameters in Eqs. (5) and (6) were fitted to the bulk band structures, experimental deformation potentials and effective masses, and first-principles calculations of the valence band offsets of GaAs and InAs. The alloy bowing parameter for the GaInAs band gap (0.6 eV) is also fitted. An example of the quality of the pseudopotential fit for GaAs and InAs can be found in Ref.<sup>[9]</sup>.

## Solving the Single-Particle Hamiltonian

We have developed two techniques for solving for the eigenstates of Eq. (4). The choice of technique depends on the size of the heterostructure system being studied, i.e., the number of electrons in the system, and the desired level of accuracy. The two techniques are distinguished by: 1) the choice of the basis set for expanding the single-particle eigenstates of Eq. (4); and 2) the algorithm used to solve for the eigenstates within that particular basis. In our first approach, we expand the eigenstates in a *plane wave* basis and use the folded spectrum method to obtain eigenstates in a given energy window. In the second approach, we expand the eigenstates in a basis of *bulk Bloch orbitals* and use a Lanczos algorithm to obtain eigenstates.

### Expansion in a plane wave basis

The conventional basis set for performing calculations of the electronic band structure of periodic materials, such as bulk semiconductors, is the plane wave basis.

$$\psi_i(\mathbf{r}) = \sum_{\mathbf{G}}^{E_{\text{cut}}} c_{\mathbf{G}}^i e^{i\mathbf{G}\cdot\mathbf{r}} \quad (7)$$

Within this basis, one can easily utilize fast Fourier transforms to convert the wavefunctions from a real-space to reciprocal-space representation. The matrix elements of the Hamiltonian in Eq. (4) in the basis of Eq. (7) can be written as

$$\hat{H}_{\mathbf{G},\mathbf{G}'} = \frac{1}{2} \mathbf{G}^2 \delta_{\mathbf{G},\mathbf{G}'} + V_{\text{local}}(\mathbf{G} - \mathbf{G}') + V_{\text{nonlocal}}(\mathbf{G}, \mathbf{G}') \quad (8)$$

The conventional variation al approach to solving for the eigenstates of Eq. (8) is to minimize the energy  $\langle \psi_0 | \hat{H} | \psi_0 \rangle$ , of the groundstate wavefunction,  $\psi_0$ , by varying its expansion coefficients,  $c_{\mathbf{G},0}$ . To find higher states, one needs to orthogonalize each  $\psi_i$  to all previously converged energy eigenstates below it. This orthogonalization process scales as the third power of the number of states and so only small systems with up to a few hundred electrons can be solved in this manner.

To enable us to study heterostructure systems containing  $10^6$  electrons, we instead “fold” the spectrum of eigenstates about a specified reference energy and hence solve<sup>[10,11]</sup> for the eigenstates of the equation

$$(\hat{H} - \epsilon_{\text{ref}})^2 \psi_i = (\epsilon - \epsilon_{\text{ref}})^2 \psi_i \quad (9)$$

where  $\epsilon_{\text{ref}}$  is a chosen reference energy. By placing  $\epsilon_{\text{ref}}$  within the band gap of the quantum dot system, and close to the valence band maximum (VBM) or conduction band minimum (CBM), one is then able to calculate the top few valence states or the bottom few conduction states, respectively. As quantum confinement effects act to lower (raise) electron (hole) levels in the quantum dot compared to the bulk, one can ensure that  $\epsilon_{\text{ref}}$  falls within the band gap of the dot simply by placing it within the bulk band gap of the dot material. By applying the  $\hat{H}$  operator twice, it is easy to see that the eigenstates of Eq. (9) are also eigenstates of the Hamiltonian in Eq. (4). Therefore, the process of folding the spectrum does not introduce any additional approximations compared to the conventional  $N^3$  scaling algorithms. It simply removes the need to calculate all the low-energy eigensolutions and then orthogonalize to each of these states. By removing the need for this costly orthogonalization, the folded spectrum algorithm is able to scale linearly with the number of electrons in the system. A version of this folded spectrum code was developed<sup>[12]</sup> for parallel supercomputers, which linearly scales up to hundreds of processors and is able to handle systems containing up to  $10^7$  electrons. Typically, a calculation requires 20–50 plane waves per atom in the system and so these parallel calculations are effectively finding selective eigenstates of a matrix of order  $10^8$ .

## Expansion in a linear combination of bloch bands

For larger quantum dot heterostructure systems containing several million atoms, using a plane wave basis set to expand the single-particle eigenstates becomes too computationally demanding, even when the folded spectrum method is employed. Instead, we choose to use a more physically intuitive basis set, namely a linear combination of bulk bands (LCBB).<sup>[13]</sup>

$$\psi_i(\mathbf{r}) = \sum_s \sum_{n,k} c_{s,n,k}^{(i)} u_{s,n,k}(\mathbf{r}) e^{i\mathbf{k}\cdot\mathbf{r}} \quad (10)$$

where  $u_{s,n,k}(\mathbf{r})$  is the cell periodic part of the bulk Bloch wavefunction for structure,  $s$ , at the  $n$ th band and the  $k$ th  $k$ -point. As these states form a physically more intuitive basis than traditional plane waves, the number of bands and  $k$ -points can be significantly reduced to keep only the physically important bands and  $k$ -points. This method was recently generalized to strained semiconductor heterostructure systems<sup>[14]</sup> and to include the spin-orbit interaction. To study an  $\text{In}_x\text{Ga}_{1-x}\text{As}$  quantum dot embedded within a GaAs barrier, we typically use an LCBB basis derived from a set of structures,  $s$ . This allows us to directly include the effects of strain on the basis functions. The structures used are as follows: 1) unstrained, bulk InAs at zero pressure; 2) unstrained, bulk GaAs at zero pressure; 3) bulk InAs subjected to the strain value in the center of the InAs dot; and 4) bulk InAs subjected to the strain value at the tip of the InAs dot. For an  $\text{In}_x\text{Ga}_{1-x}\text{As}$  quantum dot system, where we expect the electron and hole states to be derived from around the bulk  $\Gamma$  point, the wavevectors,  $\{k\}$ , include all allowed values within a given cutoff of the zone center. For calculations of electron states, we find we only need to include the band index,  $n$ , around the  $\Gamma_{1c}$  point. For the hole states, we also include the three bands around the  $\Gamma_{15v}$  point. As the number of  $k$ -points and bands in the LCBB basis is increased, the eigenstates converge to those calculated using a converged basis, such as the above plane wave basis with a large cutoff,  $E_{\text{cut}}$ . Therefore we can use a plane wave, folded spectrum calculation as a reference to judge when our LCBB basis set is sufficient. We find that to study a typical quantum dot system, a basis set containing 10,000 bulk bands produces single-particle energies that are converged with respect to basis size, to within 1 meV.

## Calculation of “Two-Body” Interactions

Using screened Hartree Fock theory, the energy associated with loading  $N$  electrons and  $M$  holes into a

quantum dot can be expressed<sup>[15]</sup> as

$$\begin{aligned} E_{MN} = & \sum_i -\epsilon_{h_i} m_i + \sum_{i<j} (J_{ij}^{\text{hh}} - K_{ij}^{\text{hh}}) m_i m_j \\ & + \sum_i \epsilon_{e_i} n_i + \sum_{i<j} (J_{ij}^{\text{ee}} - K_{ij}^{\text{ee}}) n_i n_j \\ & - \sum_{ij} (J_{ij}^{\text{eh}} - K_{ij}^{\text{eh}}) n_i m_j \end{aligned} \quad (11)$$

where the electron and hole levels are denoted by  $e_0, e_1, e_2, \dots$ , and  $h_0, h_1, h_2, \dots$ , respectively. The  $n_i$  and  $m_i$  are the electron and hole occupation numbers, respectively, such that  $\sum_i n_i = N$  and  $\sum_i m_i = M$ . The  $\epsilon_i$  are the single-particle energies of the  $i$ th state,  $J_{ij}$  and  $K_{ij}$  are the direct and exchange Coulomb integrals between the  $i$ th and  $j$ th electronic states. For example, by using Eq. (11), in the strong confinement regime where kinetic energy effects dominate over the effects of exchange and correlation, an exciton involving an electron excited from hole state  $i$  to electron state  $j$  can be expressed as

$$E_{ij}^{\text{exciton}} = (\epsilon_{e_j} - \epsilon_{h_i}) - J_{ji}^{\text{eh}} + K_{ji}^{\text{eh}} \delta_{S,0} \quad (12)$$

The direct and exchange Coulomb energies are defined<sup>[16]</sup> as

$$\begin{aligned} J_{ijkl} &= \iint \frac{\psi_i^*(\mathbf{r}_1) \psi_j(\mathbf{r}_2) \psi_k^*(\mathbf{r}_1) \psi_l(\mathbf{r}_2)}{\bar{\epsilon}(\mathbf{r}_1 - \mathbf{r}_2) |\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2 \\ K_{ijkl} &= \iint \frac{\psi_i^*(\mathbf{r}_1) \psi_j(\mathbf{r}_2) \psi_k^*(\mathbf{r}_2) \psi_l(\mathbf{r}_1)}{\bar{\epsilon}(\mathbf{r}_1 - \mathbf{r}_2) |\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2 \end{aligned} \quad (13)$$

where  $\bar{\epsilon}$  is connected to a phenomenological, screened dielectric function,<sup>[17]</sup>  $\epsilon(\mathbf{r}, \mathbf{r}', R)$ , by,

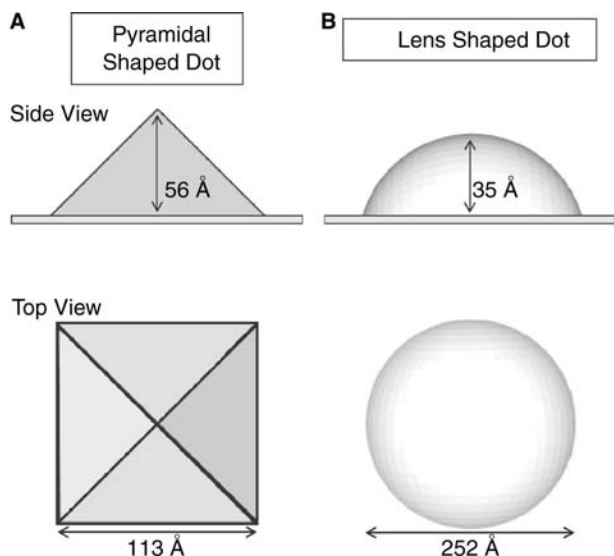

$$\frac{1}{\bar{\epsilon}(\mathbf{r}, \mathbf{r}'') |\mathbf{r} - \mathbf{r}''|} = \int d\mathbf{r}' \epsilon^{-1}(\mathbf{r}, \mathbf{r}'; R) \frac{1}{|\mathbf{r}'' - \mathbf{r}'|} \quad (14)$$

where  $R$  is the diameter of the quantum dot being studied.

## RECENT APPLICATIONS

One of the long-standing problems that has held back the development of accurate models for the energy states in semiconductor quantum dot heterostructures is the need to accurately determine the size, shape, and composition of quantum dot samples. This problem is further compounded by the fact that, while it is possible to determine the shape of dots by using atomic force microscopy (AFM) *before* they have been capped with a GaAs “barrier,” it is believed that the capping process itself induces the diffusion of gallium into the dots and diffusion of indium from the dots into the surrounding matrix. Hence AFM data for

the size and shape of *uncapped* dots is only of limited use in evaluating the quality of theoretical models for *capped* dots. Therefore a major determining factor in our choice of which systems to apply the above EPM techniques to has been the continuing experimental progress in the characterization of self-assembled quantum dots. The earliest quantum dot samples were believed to contain pure InAs, pyramidal structures, with {101} facets (Fig. 2) forming 45° angles between the facets and the base. Following this interpretation of the structure, early calculations were also performed assuming a pyramidal geometry. In the section “Pyramidal Quantum Dots: Single-Particle Electron and Hole States,” we compare the results of our initial calculations for pyramidal InAs quantum dots embedded within GaAs with those from other theoretical techniques. More recent characterization using cross-sectional transmission electron microscopy (TEM) and scanning tunneling microscopy (STM) measurements of *capped* dots has predicted that a more realistic dot geometry and composition is a lens-shaped  $\text{In}_x\text{Ga}_{1-x}$  As quantum dot. In the section “Lens-Shaped Dots: The Effect of Changing the Shape and Composition Profile,” we present results of calculations for the energy states, excitonic band gaps, and Coulomb matrix elements in lens-shaped  $\text{In}_x\text{Ga}_{1-x}$  As quantum dots. These calculations were used in combination with a range of measured properties to help to determine both the geometry and composition of these quantum dots.

**Fig. 2** The assumed geometry of the (A) pyramidal and (B) lens-shaped dots described in the sections “Pyramidal Quantum Dots: Single-Particle Electron and Hole States” and “Lens-Shaped Dots: The Effect of Changing the Shape and Composition Profile.”

### Pyramidal Quantum Dots: Single-Particle Electron and Hole States

The EPM techniques described in the section “Description of Pseudopotential Techniques” have been applied to the study of pyramidal self-assembled quantum dots in several publications.<sup>[17–19]</sup> The assumed pyramidal geometry is illustrated in Fig. 2A. in Fig. 3 we schematically show the single-particle energy levels that are typically calculated. The five lowest energy electron states are labeled in increasing energy from  $e_0$  to  $e_4$  and the three highest energy hole states are labeled in order of decreasing energy from  $h_0$  to  $h_2$ . The single-particle wavefunctions corresponding to each of these electron and hole states are illustrated in Fig. 4. Fig. 4 shows only the square of the envelope function,  $f(\mathbf{r})$ , for each of the single-particle states,  $i$ , defined as

$$f^i(\mathbf{r}) = \sum_{\mathbf{k}} c_{n,\mathbf{k}}^i e^{i\mathbf{k}\cdot\mathbf{r}} \quad (15)$$

where the  $c_{n,\mathbf{k}}^i$  are the coefficients of the  $i$ th single-particle wavefunction,  $\psi_i(\mathbf{r})$ , when expanded in a basis of bulk Bloch orbitals representing a large number of bands,  $N$ , at the Brillouin zone center ( $\Gamma$  point),

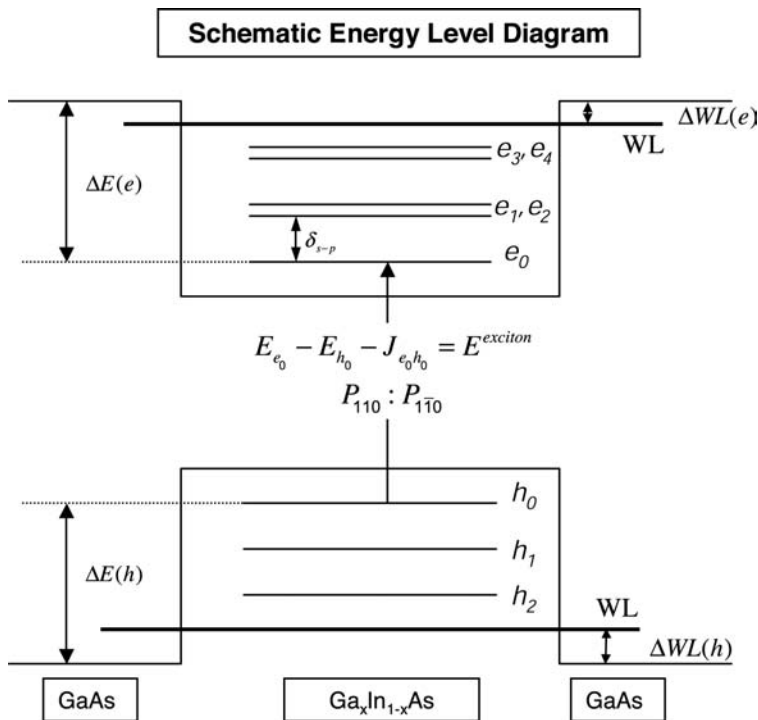

$$\psi_i(\mathbf{r}) = \sum_{n=1}^N \sum_{\mathbf{k}} c_{n,\mathbf{k}}^i u_{n,\Gamma}(\mathbf{r}) e^{i\mathbf{k}\cdot\mathbf{r}} \quad (16)$$

The expansion coefficients,  $c_{n,\mathbf{k}}^i$ , are obtained by projecting each of the calculated single-particle states onto this zone center basis,

$$c_{n,\mathbf{k}}^i = \langle \psi_i(\mathbf{r}) | u_{n,\Gamma}(\mathbf{r}) e^{i\mathbf{k}\cdot\mathbf{r}} \rangle \quad (17)$$

Plotting the envelope function squared,  $f(\mathbf{r})^2$ , instead of the wavefunction squared,  $\psi_i(\mathbf{r})^2$ , has the effect of averaging out the atomic-scale oscillations in the wavefunction, purely for graphical purposes. In all our calculations, the atomistic structure of the EPM technique automatically includes both the envelope,  $f(\mathbf{r})$ , and atomistic,  $u_{n,\Gamma}(\mathbf{r})$ , contributions to the wavefunctions. A useful intuitive guide to interpreting the single-particle electron states is to consider the eigenstates of the  $\hat{L}_z$  operator.<sup>[3]</sup> The first six bound electron states corresponding to  $l_z = 0, \pm 1$ , and  $\pm 2$ . The first state  $e_0$ , has  $l_z = 0$  and is commonly described as *s*-like as it has no nodes. The  $e_1$  and  $e_2$  states have  $l_z = \pm 1$ , and are *p*-like with nodal planes (110) and ( $\bar{1}10$ ). The  $e_3, e_4$ , and  $e_5$  states have  $l_z = \pm 2$  and 0, respectively, and are commonly described as  $d_{x^2 - y^2}$ ,  $d_{xy}$ , and  $2s$ , respectively. Obviously, the square base of the pyramid reduces the symmetry of the dot from  $C_\infty$  to  $C_{4v}$ . In addition, the underlying zincblende atomistic structure further reduces the

**Fig. 3** A schematic representation of the single-particle energy levels in a self-assembled quantum dot. The five lowest energy electron states are labeled in increasing energy from  $e_0$  to  $e_4$ , and the three highest energy hole states are labeled in order of decreasing energy from  $h_0$  to  $h_2$ . The electron and hole binding energies are labeled  $\Delta E(e, h)$ , and the wetting layer energies with respect to the GaAs VBM and CBM are labeled  $\Delta WL(h, e)$ .

symmetry to  $C_{2v}$ . Hence, the  $e_0$  to  $e_5$  states correspond to the  $a_1, b_1, b_2, a_1, a_2,$  and  $a_1$  irreducible representations of the  $C_{2v}$  group, rather than eigenstates of  $\hat{L}_z$ . The alignment of the  $e_1$  and  $e_2p$ -states along the  $[110]$  and  $[1\bar{1}0]$  directions results from the underlying zincblende lattice structure. Note that this simple analysis neglects the effects of the spin-orbit interaction, which further reduces the symmetry from the  $C_{2v}$  group to a double group with the same single representation for all the states. In our calculations, the spin-orbit interaction is included, but it produces no significant effects for the electron states. For the pyramidal dot studied in Fig. 4, the small size of the dot ( $113 \text{ \AA}$  base) and the relatively light effective mass of electrons in InAs ( $0.023 m_0$ ) results in a large quantum confinement of the electron states which, in turn, pushes these states up in energy so that only the five states  $e_0$  to  $e_4$  are bound in the pyramidal dot. Here our definition of a bound electron (hole) state is that its energy is lower (higher) than the bulk GaAs CBM (VBM).

Fig. 4 also shows calculated envelope functions squared for the hole states in the pyramidal InAs/GaAs quantum dot. As there is a strong mixing between the original bulk Bloch states with  $\Gamma_{8v}$  and  $\Gamma_{7v}$  symmetry, the hole states cannot be interpreted as the solutions of a single-band Hamiltonian. The larger effective mass for holes results in a reduced quantum confinement of the hole states and consequently, many more bound hole states. Only the six bound hole states with the highest energy are shown in Fig. 4.

In Fig. 5, we show how the energy of the lowest 4 electron states and highest 4 hole states in a pyramidal InAs quantum dot depends on the size of the dot. It shows that, as the size of the dot increases, the quantum confinement of the electrons and holes in the dot is reduced and therefore the electron levels decrease in energy and the hole levels increase in energy. Reducing the quantum confinement by increasing the size of the dots also acts to increase the number of bound states in the dot. For example, the  $e_3$  state is bound for dots with a base size greater than  $90 \text{ \AA}$ , but is higher than the wetting layer energy for dots with a base less than  $90 \text{ \AA}$ , and is therefore effectively unbound. It is interesting to compare these results with earlier calculations by: 1) Grundman, Stier, and Bimberg<sup>[20]</sup> and Cusak, Briddon, and Jaros<sup>[21]</sup> who applied single band effective techniques to pyramidal InAs dots with base sizes ranging from  $60$  to  $160 \text{ \AA}$  and found only a single bound state; and 2) eight-band  $\mathbf{k}\cdot\mathbf{p}$  calculations by Jiang and Singh<sup>[22]</sup> and Pryor,<sup>[23]</sup> who found three bound electron states over a similar range of sizes. Therefore we conclude that obtaining even qualitative estimates for the quantum confinement energies in these systems requires a multiband technique of at least eight bands.

### Lens-Shaped Dots: The Effect of Changing the Shape and Composition Profile

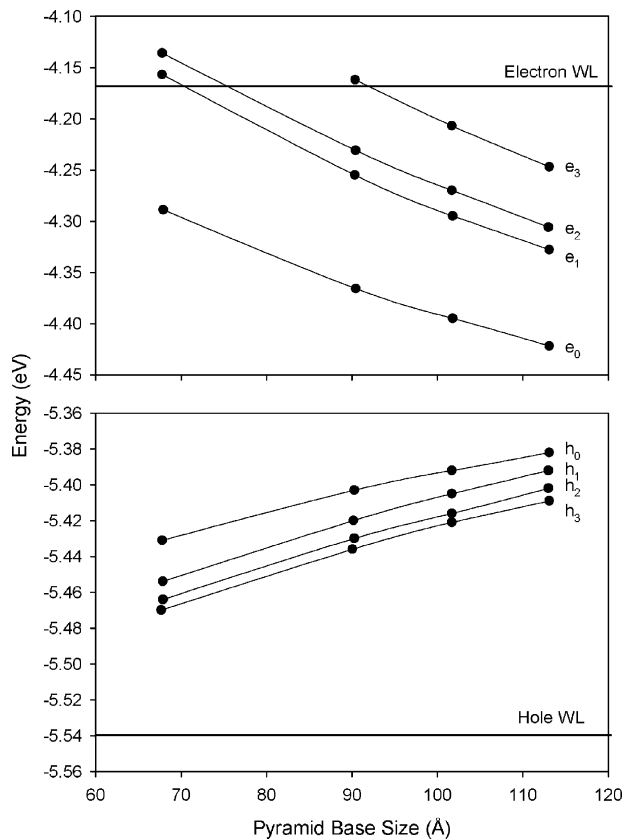

In the section “Pyramidal Quantum Dots: Single-Particle Electron and Hole States,” we discussed the

**Fig. 4** Top view of the calculated electron and hole wavefunctions squared for pyramidal and lens-shaped InAs quantum dots embedded in GaAs, with bases of 252 and 113 Å and heights of 25 and 56 Å. The grey and dark gray isosurfaces represent 20% and 60% of the maximum charge density, respectively.

single-particle electron and hole states in an idealized, pure InAs, pyramidal quantum dot. Recently, considerable evidence has emerged that, in fact, a more realistic geometry for self-assembled InAs/GaAs quantum dots is that of a lens-shaped dot<sup>[24–31]</sup> (see Fig. 2B). In addition to modifying the predicted shape of self-assembled quantum dots, recent measurements<sup>[32–35]</sup> also indicate that the composition of these dots differs from the pure InAs that was originally assumed. In Table 1, we show the results

of calculations for a pure InAs, lens-shaped quantum dot, with a base of 252 Å and a height of 35 Å, embedded within GaAs [column (a)]. Table 1 also shows the experimentally measured of the electron levels, the electron–electron splittings and electron–hole Coulomb energies, the magnetic field dependence, and the excitonic band gap measured in Refs.<sup>[26]</sup> and<sup>[30]</sup>. The agreement between the measured energy level spacings, Coulomb energies and magnetic field response with our theoretical lens-shaped model is

**Fig. 5** The dependence of the energy of the four lowest electron states and four highest hole states on the base size of a pyramidal InAs quantum dot. The horizontal lines show the energy of the groundstate electron and hole energies in a 1-ML-thick InAs WL.

generally good. Both the model and experiment find: 1) a large spacing,  $\delta_{sp}$  ( $\sim 50$ – $60$  meV), between the  $s$ -like  $e_0$  state and the  $p$ -like  $e_1$  state; 2) a small spacing,  $\delta_{pp}$  ( $\sim 3$  meV), between the two  $p$ -like  $e_1$  and  $e_2$  states; and 3) a large spacing ( $\sim 55$  meV) between the  $p$ -like  $e_2$  state and the  $d$ -like  $e_3$  state.

These electron level spacings are similar to those found for pyramidal quantum dots<sup>[18]</sup> [see Table 1, column (g)]. However, because of the lower pyramidal symmetry, the spacings of the two  $p$ -like and  $d$ -like states,  $\delta_{pp}$  and  $\delta_{dd}$ , are larger (26 and 23 meV, respectively). Both the model and experiment also find similar values for the Coulomb energies,  $J(e_0e_0)$  and  $J(e_0h_0)$  ( $\sim 25$  meV).

The calculated hole binding energy of  $\Delta E(h) = 193$  meV is in good agreement with those of Berryman, Lyon, and Segev<sup>[36]</sup> ( $\sim 240$  meV) and Itskevich et al.<sup>[37]</sup> ( $\sim 250$  meV). The calculated electron–electron and electron–hole Coulomb energies are in reasonable agreement with those extracted from Refs.<sup>[26]</sup> and<sup>[30]</sup>. For the integrals  $J_{e_0e_0}^{ee}$ ,  $J_{e_0e_1}^{ee}$ ,  $J_{e_1e_1}^{ee}$ , and  $J_{e_0h_0}^{eh}$ , we calculate values of 31, 25, 25, and 37,

respectively, compared to measured values of 23, 24, 18, and 33.3 meV. The calculated ratios of absorption intensities for light polarized along  $[110]$  and  $[\bar{1}\bar{1}0]$  directions, defined as

$$\lambda = \frac{P_{[110]}}{P_{[\bar{1}\bar{1}0]}} = \frac{\langle \psi_{e_0} | r_{[110]} | \psi_{h_0} \rangle^2}{\langle \psi_{e_0} | r_{[\bar{1}\bar{1}0]} | \psi_{h_0} \rangle^2} \quad (18)$$

are  $\lambda = 1.03$  and 1.2, respectively, for the  $e_0 - h_0$  recombination in lens and pyramidal shaped, pure InAs dots.

In the lens-shaped dot, we find a difference in the average positions of the  $h_0$  and  $e_0$  states,  $d_{h_i, e_j}$ , of around 1 Å. This is smaller than the value that we calculated for a pyramidal quantum dot, where we find the hole approximately 3.1 Å higher than the electron.

In summary, the assumed lens-shaped geometry with a pure InAs composition produces a good agreement with measured level splitting, Coulomb energies, and magnetic field dependence. Detailed inspection of the remaining differences reveals that the calculations systematically *overestimate* the splittings between the single-particle electron levels ( $\delta_{sp}$ : 65 vs. 50 meV,  $\delta_{pd}$ : 68 vs. 48 meV) and *underestimate* the excitonic band gap (1032 vs. 1098 meV).

### Pure InAs dots: The effects of lens shape and size

Focusing only on the lens shape, we examine the effect of changing the height and base of the assumed geometry. Calculations were performed on similar lens-shaped, pure InAs dots where 1) the base of the dot was increased from 252 to 275 Å, while keeping the height fixed at 35 Å, [column (b)] and 2) the height of the dot was decreased from 35 to 25 Å, while keeping the base fixed at 252 Å, [column (c)]. These show that decreasing the height of the dot increases the quantum confinement and hence increases the splittings of the electron and hole levels ( $\delta_{sp}$ : from 65 to 69 meV and  $\delta_{h_0, h_1}$ : from 8 to 16 meV). Decreasing the height of the dot also acts to increase the excitonic band gap from 1032 to 1131 meV by pushing up the energy of the electron levels and pushing down the hole levels. Conversely, increasing the base of the dot decreases both the splittings of the single-particle levels ( $\delta_{sp}$ : from 66 to 61 meV) and the band gap (1032–1016 eV). These small changes in the geometry of the lens-shaped dot have only a small effect on electronic properties that depend on the shape of the wavefunctions. The electron–electron and electron–hole Coulomb energies remain relatively unchanged, the magnetic field induced splitting remain at 20 meV, the polarization anisotropy ( $\lambda$ ) remains close to 1.0, and the excitonic dipole,  $d_{h_i, e_j}$ , remains negligible. In summary, reducing either the height or the base of the

**Table 1** Calculated single particle electron and hole energy level spacings, electron and hole binding energies,  $\Delta E(e,h)$ , electron–electron and electron–hole Coulomb energies, excitonic band gap (all in meV), exciton dipole moment and polarization anisotropy for lens-shaped and pyramidal  $\text{Ga}_x\text{In}_{1-x}\text{As}$  quantum dots embedded within GaAs

dot increases quantum confinement effects and hence increases energy spacings and band gaps, while not significantly effecting the shape of the wavefunctions.

### Interdiffused In(Ga)As/GaAs lens-shaped dots

We next investigate the effect of changing the composition of the quantum dots, while keeping the geometry fixed. Recently, there have been several experiments<sup>[33,34,38]</sup> suggesting that a significant amount of Ga diffuses into the nominally pure InAs quantum dots during the growth process. We investigate two possible mechanisms for this Ga in-diffusion: 1) Ga diffuses into the dots during the growth process from all directions producing a dot with a uniform Ga composition  $\text{Ga}_x\text{In}_{1-x}\text{As}$ ; and 2) Ga diffuses up from the substrate, as suggested in Ref.<sup>[38]</sup>. To investigate the effects of these two methods of Ga in-diffusion on the electronic structure of the dots, we compare pure InAs dots embedded in GaAs with  $\text{Ga}_x\text{In}_{1-x}\text{As}$ , random alloy dots embedded in GaAs, where the Ga composition,  $x$ , 1) is fixed at 0.15, [column (d)] and

2) varies linearly from 0.3 at the base to 0 at the top of the dot, [column (e)].

Table 1 shows that increasing the amount of Ga in the dots acts to decrease the electron level spacings ( $\delta_{\text{sp}}$ : from 65 to 58 for  $x = 0.15$ ). It also acts to increase the excitonic band gap from 1032 to 1080 and 1125 meV, respectively. The electron binding energy,  $\Delta E(e)$ , is decreased by the in diffusion of Ga (from 271 to 209 and 192 meV), while the hole binding energy,  $\Delta E(h)$ , is relatively unaffected. This significant decrease in the electron binding energy considerably improves the agreement with experiments on other dot geometries.<sup>[36,39]</sup>

As with changing the size of the dots, we find that Ga in-diffusion has only a small effect on properties that depend on the shape of the wavefunctions. The calculated electron–electron and electron–hole Coulomb energies are almost unchanged, while the average separation of the electron and hole,  $d_{h,e}$ , increases from 0.16 to 0.5 and 1.2 Å and the polarization ratio,  $\lambda$ , and magnetic field response are also unchanged.

Table 1 shows that the dominant contribution to the increase in the excitonic band gap and reduction in

electron binding energy, results mostly from an increase in the energy of the *electron* levels as the Ga composition is increased. This can be understood by considering the electronic properties of the bulk  $\text{Ga}_x\text{In}_{1-x}\text{As}$  random alloy. The unstrained valence band offset between GaAs and InAs is  $\sim 50$  meV,<sup>[40]</sup> while the conduction band offset is  $\sim 1100$  meV and hence changing the Ga composition,  $x$ , has a large effect on the energy of the electron states and only a small effect on the hole states.

In summary, the effect of Ga in-diffusion is to reduce the spacing of the electron levels while significantly increasing their energy and hence increasing the band gap. We find that only the average Ga composition in the dots is important to their electronic properties. Whether this Ga is uniformly or linearly distributed throughout the dots has a negligible effect.

The effects of changing the *geometry* of the lens-shaped, pure InAs dots on the single-particle energy levels can be qualitatively understood from single-band, effective mass arguments. These predict that decreasing any dimension of the dot increases the quantum confinement and hence, the energy level spacings and the single-particle band gap will increase. Note that as the dominant quantum confinement in these systems arises from the vertical confinement of the electron and hole wavefunctions, changing the height has a stronger effect on the energy levels than changing the base. In this case, decreasing the height by 10 Å has a much stronger effect on the energy spacings and on the band gap than increasing the base by 23 Å.

As increasing (decreasing) the dimensions of the dot acts to decrease (increase) both the level spacings and the gap, it is clear that changing the dot geometry alone will not significantly improve the agreement with experiment as this requires a simultaneous *decrease* in the energy level splittings and *increase* in the band gap. However, Ga in-diffusion into the dots acts to *increase* the band gap of the dot while decreasing the energy level spacings. Table 1 shows that adopting a geometry with a base of 275 Å and a height of 35 Å and a uniform Ga composition of  $\text{Ga}_{0.15}\text{In}_{0.85}\text{As}$  produces the best fit to the measurements in Refs.<sup>[26]</sup> and<sup>[30]</sup>.

## CONCLUSION

In conclusion, we believe we have successfully demonstrated that modern empirical pseudopotential techniques, coupled with atomistic strain calculations, provide a powerful technique for calculating the electronic structure of semiconductor nanostructures containing several million atoms.

Our results strongly suggest that to obtain accurate agreement between theoretical models and

experimental measurements for standard lens-shaped quantum dots, one needs to adopt a model of the quantum dot that includes some Ga in-diffusion within the quantum dot. When 15% Ga in-diffusion is included, we obtain an excellent agreement between state-of-the-art multiband pseudopotential calculations and experiments for a wide range of electronic properties. We are able to fit/predict most observable properties to an accuracy of  $\pm 5$  meV, which is sufficient to make predictions of both the geometry and composition of the dot samples.

The techniques described above have recently been extended to describing the decay of multiple excitons in semiconductor quantum dots. For more details, see Refs.<sup>[9]</sup> and<sup>[41]</sup>.

## INTRODUCTION

In recent years, there has been an increasing interest in the study and development of molecularly thin films such as self-assembled monolayers (SAMs) and Langmuir–Blodgett (LB) films. SAMs provide a unique way of altering just the surface properties of a material, by modifying the terminal functional groups displayed on the surface without altering or affecting the bulk properties of the material. The ability to modify just the surface properties gives rise to several technological applications such as protective coatings,<sup>[1]</sup> lubrication layers,<sup>[2]</sup> membranes for chemical and biochemical sensors,<sup>[3–7]</sup> templates for crystal growth,<sup>[8]</sup> fabrication of nanoparticles,<sup>[9–12]</sup> micropatterning,<sup>[13,14]</sup> and molecularly thin transistors,<sup>[15]</sup> to name a few.

SAMs are molecular assemblies that are formed by spontaneous adsorption of surfactant molecules (amphiphiles), present either in solution or vapor phase, onto the surface of an appropriate substrate. The three classical types of SAMs are: 1) silanes on hydroxylated surfaces;<sup>[16–23]</sup> 2) alkanethiols on gold, copper, or silver surfaces;<sup>[1,18,24–27]</sup> and 3) long-chain carboxylic acids on aluminum oxide surfaces.<sup>[28–30]</sup> The quality of the SAM depends on the head group, the hydrocarbon chain length,<sup>[1,20,31,32]</sup> the terminal functional group, the solvent used,<sup>[33]</sup> the amount of water present in the solvent<sup>[17]</sup> (specifically for silane SAMs), and the preparation temperature.<sup>[21,32,34,35]</sup>

In this entry, we present the results of the modification of the CN terminal functional group of 11-cyanoundecyltrimetjoxysilane (CUTMS) monolayer to the COOH terminal group by a simple hydrolysis reaction. SAMs with a COOH terminal group are technologically interesting, as the ionization state of these groups is sensitive to the pH of the surrounding environment.<sup>[25,26]</sup> By varying the pH of the surface, the terminal groups are transformed from all COOH (at low pH) to all COO<sup>−</sup> (at high pH), or a mixture of COOH and COO<sup>−</sup> (at intermediate pH values).

By controlling the pH, the ratio of the number densities of the COOH group to the COO<sup>−</sup> groups is controlled, which in turn determines the local structure and arrangement of the surface groups. Thus in an indirect way, the structure and arrangement of the COOH and COO<sup>−</sup> groups on the surface are fine-tuned by just controlling the pH of the system. We also demonstrate this interconvertibility of COOH ↔ COO<sup>−</sup> by controlling the pH using both modified CUTMS monolayer and LB film of stearic acid. From quantitative analyses of the infrared spectra of COOH and COO<sup>−</sup> groups, the number densities of these groups present on the surface have been independently determined. This also provides a tool to determine the extent of reaction or conversion of the cyano groups to carboxyl groups.

## FORMATION AND REACTIVITY OF SAMs

The structure and properties of organized thin films have been widely studied. These efforts have focused on understanding the formation mechanism and structural features of these films. Various techniques have been employed such as contact angle measurements,<sup>[24,25]</sup> Fourier transform infrared spectroscopy (FTIR),<sup>[1,26,31,36]</sup> ellipsometry,<sup>[37–40]</sup> X-ray reflectivity,<sup>[41]</sup> X-ray photoelectron spectroscopy (XPS),<sup>[41–45]</sup> and scanning probe microscopy.<sup>[17,34,35,46]</sup>

Researchers now agree that SAMs with long hydrocarbon chains form ordered and densely packed structures, with the methylene groups of the hydrocarbon chain aligned, for the most part, in an all-trans conformation.<sup>[1,31]</sup> It has been also observed that the crystallinity in the structure of the monolayer formed increases with increasing hydrocarbon chain length. It is believed that this increased crystallinity (or packing density) in the structure of the monolayer is a result of the energetically favorable, weak, intermolecular chain–chain interactions. Whereas, it has been observed

that short-chain molecules form disorder structures because of the increase of gauche conformations resulting from decreasing van der Waals interactions between the shorter chains.<sup>[1,31]</sup> Chain length also affects the mechanism of formation of these monolayers.

Iimura, Nakajima, and Kato<sup>[31]</sup> have studied SAMs of trichlorosilanes of varying hydrocarbon chain lengths using FTIR as a function of temperature. In their studies, they found that the silanes with a chain length of 16 methylene groups or less always existed in liquid state (disordered state) for all the temperatures above 0°C. They have attributed that the temperature at which the monolayers were prepared was above the critical phase transition temperature. In analogy with three-dimensional matter, the monolayer existed as crystalline (solid state) for temperatures below the critical transition temperature and existed as disordered liquid state for temperatures above the transition temperature. Independently, Jennings et al.<sup>[1]</sup> in their studies with SAMs of alkanethiols on gold, have noticed that the disorder in the structure increased with a decrease in hydrocarbon chain length, when prepared at the same temperature. As a result, SAMs of long-chain alkyl silanes are formed via a solid–gas phase transition process on the surface, whereas short-chain alkyl silanes form uniform, liquidlike films.<sup>[20]</sup>

When compared with siloxane-based SAMs, alkanethiol SAMs on gold surfaces are widely studied because of the ease by which they can be prepared.<sup>[24–27]</sup> Thiol monolayers are formed via the covalent linkage between the surface gold atom and the sulfur atom of the alkanethiol molecule.<sup>[24–27]</sup> Because of the lack of reactivity between the various terminal functional groups and the sulfur surface binding group, alkanethiol surfactants with different terminal functionalized groups can be prepared a priori to the adsorption process and monolayer formation, thus making it convenient to prepare thiol-based monolayers with varying functionalized groups. Thiol-based monolayers can also be modified by simple synthetic approaches. Several researchers have successfully converted thiols of one functional group to another.<sup>[47,48]</sup> However, these thiol-based SAMs are relatively fragile both thermally and chemically, which restricts the conditions that can be employed for subsequent surface modification.<sup>[49–51]</sup>

Contrary to thiol-based SAMs, silane-based SAMs are thermally and chemically robust. Silane-based SAMs are thermally stable even at temperatures approaching 600 K in an inert nitrogen environment.<sup>[52,53]</sup> However, because of the high reactivity of the electrophilic trifunctional silane group, the functional groups that can be incorporated on silane SAMs are restricted. Because of this limitation, several useful functional groups such as alcohols, carboxylic acids, amines, amides, thiols, phosphines, enamines, enol

ethers, etc. must either be protected in non-nucleophilic form, or introduced subsequent to the monolayer assembly. In addition to this, any functional group present on the alkyl tether must be sterically small enough to allow a close-packed, well-ordered SAM to form on a hydroxylated surface.

Because of the reasons mentioned above, several researchers have been investigating ways of modifying silane-based SAMs to form monolayers of various terminal functional groups. Lee et al.<sup>[54]</sup> Balachander and Sukenik,<sup>[55]</sup> Barness et al.<sup>[56]</sup> Collins and Sukenik,<sup>[57]</sup> and Grisar et al.<sup>[58]</sup> have successfully demonstrated the transformation of Br, CN, SCN, and SCOC<sub>2</sub>H<sub>5</sub> functionalities to N<sub>3</sub>, NH<sub>2</sub>, SH, SO<sub>3</sub>H, SCH<sub>2</sub>CH<sub>2</sub>, and SO<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub> by nucleophilic substitution using various reagents and reacting conditions. Fryxell et al.<sup>[59]</sup> have shown *N,N*-dimethylethylenediamine (DMED) amidation, hydroxylamine amidation, and hydrazine amidation by nucleophilic displacement. Koloski et al.<sup>[60]</sup> have demonstrated nucleophilic displacement reactions on benzyl halide SAMs. Kakkar et al.<sup>[61]</sup> and Yam, Tong, and Kakkar<sup>[62]</sup> have used a simple acid–base hydrolytic chemistry approach to form SAMs of long-chain alcohols terminated with alkyl, phenyl, and acetylene groups. Kim et al.<sup>[63]</sup> have chemically modified SAMs of inert or hydrophobic nature to reactive or hydrophilic state by exposing the monolayers to soft X-rays in air. Wade et al.<sup>[64]</sup> have converted hydroxyl-terminated SAMs to ester, or ether-terminated, by using low-energy collisions of polyatomic cations. Table 1 presents examples of various transformations reported in the literature and of reagents used.

## EXPERIMENTAL

### Materials

11-Cyanoundecyltrimethoxysilane (CUTMS) was purchased from United Chemical Technologies and octadecyltrichlorosilane (OTS; 95% purity) was obtained from Sigma Aldrich Co. Chloroform, toluene, and concentrated sulfuric acid were purchased from Fisher Scientific. Anhydrous grade hexadecane was purchased from Sigma Aldrich Co. Stearic acid was purchased from Fluka. Nochromix crystals used for cleaning purposes were obtained from Godax Laboratories. Silicon wafers used were obtained from Montco Silicon Technologies (Spring City, PA). The silicon wafers used in our experiments have a thickness of 450–500 μm, are double-sided polished, and of orientation (111). Silicon and germanium internal reflection elements [dimensions: 50 × 10 × 3 mm; orientation: (111)] used for infrared spectroscopy were obtained from Harrick Scientific Corp. All chemicals were used as purchased

without any further purification. Deionized water with a resistivity of 18 MΩcm from a Millipore system was used in all our experiments.

### Cleaning Protocols

Silicon crystals were thoroughly cleaned before use. The crystals were first sonicated in a freshly prepared Nochromix solution for 30 min. The Nochromix solution was prepared by dissolving the Nochromix crystals in sulfuric acid and stirring the solution until it became clear. The Nochromix treatment was followed by rinsing with water and subsequent sonication in water for 30 min. Then the crystals were further cleaned using a plasma cleaner (model PDC-32G; Harrick Scientific Corp.). Plasma treatment was performed under an argon environment at low pressure. After the plasma treatment, the crystals were again

cleaned with Nochromix and deionized water. The same procedure was followed for silicon wafers, with the exception of plasma treatment.

### Monolayer Preparation

The cleaned substrates (crystals or wafer) were immersed in a solvent mixture of a known surfactant concentration for a fixed amount of time. After the end of the time period, the substrates were thoroughly rinsed with chloroform to remove physisorbed molecules from the substrate surface.

### CUTMS Monolayer Deposition

For CUTMS monolayers, the concentration of the CUTMS silane solution was maintained between

4 and 5 mM. Chloroform, toluene, and hexadecane were used as solvents. The deposition time was varied from minutes to days. A stable uniform monolayer formed after 24 hr.

### Modification of CUTMS Monolayer

The –CN terminal groups of the CUTMS monolayer prepared as mentioned above were transformed into –COOH groups by a simple hydrolysis reaction. The CUTMS monolayer was kept in a 50:50 (vol/vol) solution mixture of 15% hydrochloric acid and deionized water maintained at 75°C. Before modifying the CUTMS monolayer, the substrates were annealed at 150°C for about 2 hr. The monolayer was not stable for the abovementioned reaction conditions, unless it was annealed. The monolayer molecules desorbed if the substrate was kept for durations of more than 1.5 hr.

### OTS Monolayer Deposition

For the OTS monolayer, a mixture of hexadecane, carbon tetrachloride, and chloroform in the ratio of 30:5:3 by volume, respectively, was used in the OTS solution preparation. The substrate was immersed for 30 min in the above-prepared solution.

### LB Film of Stearic Acid

One hundred microliters of 1.34 mg/mL of a solution of stearic acid in chloroform was spread on a subphase (deionized Millipore water, 18 M $\Omega$ ) maintained at 20°C and at a pH of 2.0 (by adding HCl) in a KSV 2000 dual-compartment LB trough. The solution was allowed to stabilize for about 15 min for the chloroform to evaporate. The trough barriers compressed the surface until the surface pressure reached the desired value of 30 mN/m, at which time the transfer of the LB monolayer onto an OTS-coated (hydrophobic) silicon crystal was performed. At that surface pressure, before transferring, the stearic acid layer was allowed to stabilize for another 30 min to minimize any fluctuations. The transfer speed was maintained at 2.5 mm/min. The structure and orientation information of the transferred film was then obtained from IR measurements.

### Contact Angle Measurements

Contact angle goniometry was used to characterize the prepared monolayers. A 2- $\mu$ L drop of deionized water was placed on the sample surface and the contact angle

was measured within 2 min after the drop was placed to reduce errors caused by evaporation of water drop. The measurements were taken at different locations of the sample. All the values reported are an average of five to six measurements.

### Ellipsometry

The thickness information of the monolayer was obtained using a variable-angle null ellipsometer (Rudolph Instruments). A He–Ne laser beam, corresponding with a wavelength of 632.8 nm, is incident on the substrate. The thickness and refractive index of the monolayer are evaluated from the changes in polarization and the reflectivity of incident parallel and perpendicular polarized light beams. Principally, the ellipsometer is supposed to evaluate both the refractive index and the thickness of the thin film simultaneously, but because of instrument limitations in obtaining data for thin films, the refractive index of the film is assumed and the thickness is calculated. Organic films have a refractive index of approximately 1.46, and we have assumed this value as the refractive index for all our monolayers.

### IR Measurements

IR spectra were measured using a Bio-Rad FTS 175 spectrometer. Spectra were collected as interferograms with a resolution of 4 cm<sup>-1</sup> and Fourier-transformed with triangular apodization. Monolayer spectra were obtained by averaging attenuated total internal reflection (ATR) modes to 100–200 scans. Spectra of liquid samples were obtained in transmission mode using NaCl windows. For quantitative analysis, peaks were fitted with a Lorentzian function. The integrated absorbance value was the area under the appropriate peak. However, the readers have to be cautioned that the absorbance value (or peak area) is very sensitive to the type of fit used and baseline selection. For consistency in results, one has to maintain the same procedures throughout the quantitative analysis.

## RESULTS AND DISCUSSION

### Spectral Features

A typical spectrum of a CUTMS monolayer formed on a silicon substrate after a deposition time of 24 hr is shown in Fig. 1. Some of the important vibrational modes pertaining to methyl and methylene symmetric and asymmetric stretching modes are shown in Table 2. The asymmetric stretching mode of the

Fig. 1 Typical spectrum of CUTMS monolayer formed on a silicon crystal.

methylene group reveals a great deal of information on local molecular order and packing.<sup>[21,65]</sup> How this information is used to get the packing density and coverage is discussed later. The methylene asymmetric stretching modes for the CUTMS monolayer appear at  $\sim 2927\text{ cm}^{-1}$  and those of symmetric stretching modes appear at  $2856\text{ cm}^{-1}$ . These values correspond to a liquidlike structure. The spectrum was compared with the solution spectrum of CUTMS in anhydrous chloroform, obtained independently using NaCl windows in transmission mode. The details of the spectral features are shown in Table 2. The asymmetric and symmetric peaks of  $\text{CH}_2$  of the liquid spectrum match closely those of the CUTMS monolayer. Slight differences in the spectra of molecules at the surface and in the solution are attributed to the small degree of ordering as the molecules are being anchored to the substrate by one end.

**Table 2** Peak positions of important vibrations between CUTMS liquid and monolayer spectra

	$\text{CH}_2$ asymmetric	$\text{CH}_2$ symmetric	CN	COOH
Liquid CUTMS	2930	2857	2250	–
CUTMS monolayer	2927	2856	2248	1725

The difference in spectral values is not considerably different, indicating that the monolayer formed resembles a liquidlike structure.

### Formation and Structure of Silane SAMs

The formation of SAMs of silanes on silicon substrates is a three-step process. First, the trichloro or trimethoxy groups of silanes are hydrolyzed either in the solution, because of the presence of trace amounts of water in the solvent, or near the surface of the substrate, where a thin water film of two to three monolayers is present. The importance of the thin water film on the final structure and formation of the OTS monolayers was largely studied and reported.<sup>[19,22]</sup> Silberzan et al. have reported that for a good, uniform monolayer, a thin water film is necessary. Second, these hydrolyzed silanes react with surface hydroxyl groups and get chemically adsorbed on the surface. Finally, as the monomers adsorb on the surface because of weak van der Waals chain–chain interactions, the molecules order and arrange themselves. In the case of OTS molecules, where the packing density is considerably high, silanols of neighboring molecules form cross-links and a two-dimensional siloxane network. The ability of the molecules to pack depends on several factors such as the chain length of the hydrocarbon chain, the end terminal group, and the head group. Some of these aspects are discussed later.

There is a possibility of these hydrolyzed monomers reacting in the solvent and forming oligomers in the bulk itself, before actually adsorbing onto the surface.<sup>[66,67]</sup> The process of polymerization (oligomerization)

depends on several factors such as the amount of water present in the bulk solution, the incubation time of the silane solution before the deposition process, and the susceptibility of the trichloro or trimethoxy silanes to be converted to hydroxyl groups.<sup>[68–70]</sup> Fig. 1 shows a peak at  $2961.8\text{ cm}^{-1}$  corresponding to the  $\text{CH}_3$  asymmetric stretch of the methoxy group attached to the silicon head group. This clearly indicates that the hydrolysis of CUTMS monomers was not complete. Trichloro silanes are more susceptible to hydrolysis. However, the reaction rate for a methoxy ( $\text{OCH}_3$ ) or ethoxy ( $\text{OC}_2\text{H}_5$ ) is relatively slow when compared with chlorosilanes.<sup>[71]</sup> The  $\text{CH}_3$  peak could be seen even after long deposition times, thus emphasizing the low hydrolysis rates of the methoxy groups. After a uniform layer of CUTMS was formed, the total amount of molecules adsorbed on the surface did not increase even with an increase in deposition time. The total amount adsorbed is qualitatively discerned from the total integrated absorbance value. Details of the actual qualitative analysis are given later. One reason for incomplete methoxy group hydrolysis is the low water content in solvents used in our experiments. Vallant et al.<sup>[67]</sup> in their studies with alkoxy silanes, had to perform the hydrolysis reaction of alkoxy groups in a water-rich tetrahydrofolate (THF) solvent before using the silanes for monolayer formation.

Fig. 1 also shows peaks at  $2248$  and  $1725\text{ cm}^{-1}$  corresponding to the cyano ( $\text{C}\equiv\text{N}$ ) and carbonyl ( $\text{C}=\text{O}$ ) stretching bands, respectively. The peak at  $2248\text{ cm}^{-1}$  is because of the presence of cyano groups in the monomer. However, we believe that the presence of the  $\text{C}=\text{O}$  peak is because of the transformation of some of the CN groups to carboxylic acid ( $\text{COOH}$ ) groups caused by hydrolysis. A similar behavior of acetylchlorides transforming to carboxylic acid groups during monolayer formation was observed by Cheng, Scherson, and Sukenik<sup>[26]</sup> They reported that the rapid hydrolysis of acid chloride to carboxylic acid is likely because of the presence of a thin water film of adsorbed water on the surface of the ATR element and the relatively high local concentration of HCl formed during the growth of the siloxane network. The effect of solvent on monolayer formation was studied. Table 3 shows details of all the important

**Table 3** Peak positions of methylene symmetric and asymmetric vibrations of CUTMS monolayer prepared in different solvents

Solvent used	$\text{CH}_2$ asymmetric	$\text{CH}_2$ symmetric
Chloroform	2927	2856
Hexadecane	2928	2857
Toluene	2927	2856

Data show that there is no considerable effect of solvent on the monolayer structure of CUTMS.

spectral features observed under different solvent conditions. The solvents used were chloroform, toluene, and carbon tetrachloride. As can be seen, there are no considerable differences in spectral features under different solvent environments.

The kinetics of CUTMS monolayer formation was studied from contact angle measurements. Fig. 2 shows the variation of contact angle with deposition time. The solvent used was chloroform. Measurements were taken within 10 min after the removal of the sample from the solution. As can be seen from this figure, the contact angle reaches a constant value of  $55^\circ$  after about 12 hr. However, to guarantee that the monolayer formation process is complete, we have used for all our experiments a deposition time of at least 24 hr. The equilibrium contact angle of  $55^\circ$  is less than the value of  $65^\circ$  reported by Balachander and Sukenik<sup>[55]</sup> for surfaces formed by 1-cyano-16-trichlorosilyl hexadecane. One reason for this contact angle difference is the formation of  $\text{COOH}$  groups as monolayer formation proceeds, as we have described earlier. The other plausible reason for this difference is the difference in packing densities of monolayers formed by two surfactants. We have used an 11-carbon-chain-length surfactant, whereas Balachander and Sukenik have used a 16-carbon-chain-length surfactant. The packing density of molecules depends on hydrocarbon chain length. As the hydrocarbon chain length increases, lateral chain–chain dispersive interactions increase, leading to higher surface coverage and ordering. These chain–chain dispersive interactions are also present in short-chain molecules. However, the energy gain because of these interactions is comparatively less than the equivalent gain for long chains. Thus to minimize the free energy of the system, the molecules decrease entropic penalty by packing less densely. On heating to  $150^\circ\text{C}$  for a few hours, the contact angle reached a steady state value of  $70^\circ$ . The value was very stable and was independent of heating time.

The thickness of the film was found to vary from  $10 \pm 2$  to  $14 \pm 2\text{ \AA}$ . The length of the fully extended CUTMS monomer was calculated to be  $\sim 14\text{ \AA}$  using the CACHE<sup>®</sup> software. The thickness obtained is reasonable because in a disordered structure, the molecules will be inclined at an angle to the surface normal instead of being fully extended. A simple geometrical calculation gives an angle of inclination to the surface normal as large as  $55^\circ$ . The molecules are oriented in all possible angles from  $0^\circ$  to  $55^\circ$  to the surface normal. Even the densely packed monolayers of OTS on hydroxylated surfaces and alkanethiols on gold surfaces are found to be inclined to the surfaces from dichroic measurements. However, the difference in both of them lies in the order and the packing. The schematic in Fig. 3 depicts the idea of molecular order and direction. In densely packed monolayers, all the

Fig. 2 Variation in contact angle of the CUTMS monolayer with increase in deposition time.

molecules are aligned in the same direction, or, in other words, the molecules have a net order parameter value, which is non-zero. However, the molecules in the CUTMS monolayer, although inclined, are not aligned in a particular direction. The order parameter, if one can be defined, will be lesser than that for the densely packed monolayers. Dense packing, caused by weak

van der Waals interactions between chains, brings in a local order of molecules arranged on the surface.

### Modification of Carboxyl-Terminated SAMs

The terminal groups of CUTMS monolayers were modified to COOH groups by a simple hydrolysis reaction, as described in “Experimental.” The kinetics of the reaction was followed by contact angle and IR measurements. The changes in contact angle with reaction time are shown in Fig. 4. The contact angle reached an equilibrium value of  $\sim 32^\circ$  after approximately 45 min. A contact angle of  $30\text{--}40^\circ$  on monolayers with COOH terminal groups is reported by Wasserman, Tao, and Whitesides.<sup>[23]</sup> This clearly indicates that the terminal groups have been converted to COOH groups. The mole fractions of CN and COOH groups present on the surface, as the reaction proceeds, were calculated using the Cassie equation:

$$\cos(\theta_{\text{avg}}) = f_{\text{COOH}} \cos(\theta_{\text{COOH}}) + f_{\text{CN}} \cos(\theta_{\text{CN}})$$

where  $f_{\text{COOH}}$  and  $f_{\text{CN}}$  correspond to the mole fraction of COOH and CN terminal groups, respectively;  $\theta_{\text{COOH}}$  and  $\theta_{\text{CN}}$  correspond to the equilibrium contact angle when the whole monolayer is filled with either COOH or CN groups, respectively; and  $\theta_{\text{avg}}$  is the contact angle on the surface containing a mixture of COOH and CN groups. The variation of  $f_{\text{COOH}}$  and

Fig. 3 Schematic of (A) CUTMS and (B) OTS monolayers. Molecules of the CUTMS monolayer are randomly oriented in all possible directions and are loosely packed. Whereas, molecules of the OTS monolayer are densely packed and are oriented in a particular direction.

Fig. 4 Variation in contact angle as the reaction proceeds.

$f_{CN}$  is shown in Fig. 5. ( $\theta_{COOH}$  was taken as  $32^\circ$  and  $\theta_{CN}$  was taken as  $70^\circ$ .)

The changes in COOH and CN peak intensities were also followed by IR. A typical spectrum is shown

in Fig. 6. The spectrum clearly indicates a decrease in CN peak ( $2253\text{ cm}^{-1}$ ) and an increase in COOH peak ( $1702\text{ cm}^{-1}$ ). The decrease in CN peak intensity is plotted in Fig. 7. As expected, COOH groups are

Fig. 5 Fraction of COOH and CN groups present on surfaces as the reaction proceeds (calculated using the Cassie equation).

**Fig. 6** Spectrum shows an increase in COOH peak at 1702 and a decrease in CN peak at 2253 as the reaction proceeds.

highly sensitive to pH changes, and  $\text{COOH} \leftrightarrow \text{COO}^-$  can be interchangeably converted back and forth by changing the pH. Fig. 8 shows the spectra of the modified COOH surface at different pH values. At a pH value of 2, which is below the  $\text{p}K_a$  value of the surface, the monolayer is terminated with COOH groups.

The peak at  $1718\text{ cm}^{-1}$  confirms that. When the same sample was immersed in a solution with a pH value of 7.5, which was above the  $\text{p}K_a$  value of the surface, the terminal groups were converted to  $\text{COO}^-$ . Spectrum B in Fig. 8 shows a peak split. The peak at  $1590\text{ cm}^{-1}$  corresponds to  $\text{COO}^-$  stretching. The broad

**Fig. 7** Decrease in CN peak intensity as the reaction proceeds.

**Fig. 8** (A) Spectrum of monolayer after reaction at low pH (2.0); only COOH groups are present. (B) Spectrum of monolayer at pH 7.5 after reaction; both COOH and COO<sup>-</sup> exist.

peak between 1650 and 1725 cm<sup>-1</sup> corresponds to the unconverted COOH and the surface-bound water. Cheng, Scherson, and Sukenik<sup>[26]</sup> have calculated the pK<sub>a</sub> value of the monolayer from changes of COOH and COO<sup>-</sup> peaks and found that value to be 5.4.

### Surface Coverage

In this section, we report the results regarding our measurements of the surface coverage by CUTMS surfactants. We have measured the surface coverage of

**Fig. 9** (A) LB film of stearic acid at pH 2.0; (B) LB film immersed in calcium chloride solution of pH 11.5; (C) LB film again immersed in a solution of pH 2.5; and (D) LB film again immersed in a sodium hydroxide solution of pH 10.

**Table 4** Peak positions of methylene symmetric and asymmetric vibrations for OTS SAM and stearic acid LB film

	CH <sub>2</sub> asymmetric	CH <sub>2</sub> symmetric
OTS SAM	2919	2850
Stearic acid LB film	2917	2949.6

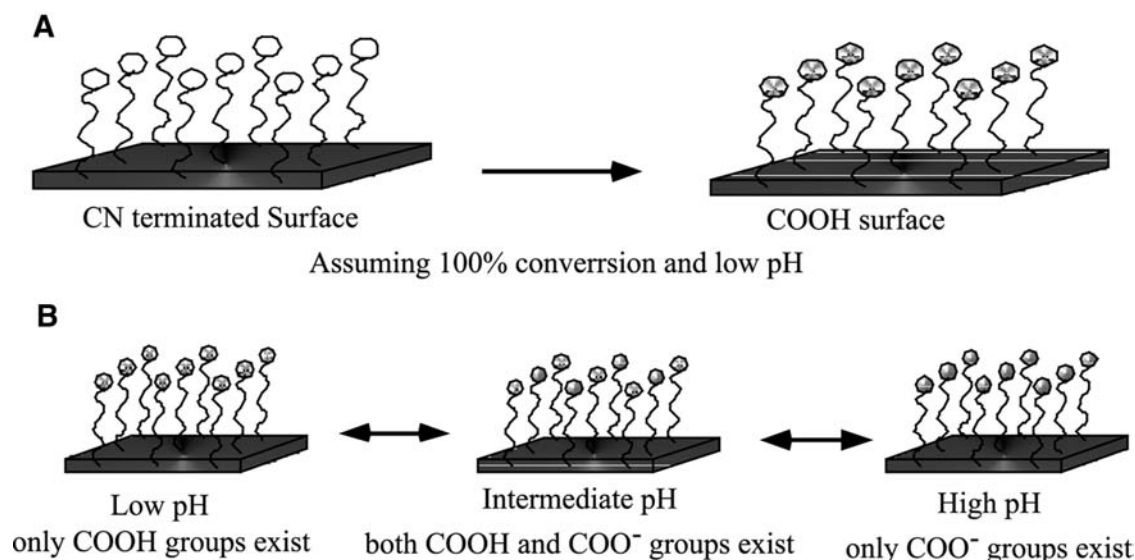

Both of them form a densely packed, crystalline structure.

molecules by the protocol first developed by Kumar et al.<sup>[36]</sup> where the surface coverage  $\Gamma$  is given by  $\Gamma = A/\epsilon$ , where  $A$  is the integrated absorbance and  $\epsilon$  is the molar emissivity. Furthermore, Kumar et al. have also found that the molar emissivity measured for the CH<sub>2</sub> asymmetric peak in monolayers is  $\sim 1.5$  times that obtained from liquid solutions. The difference in  $\epsilon$  values is attributed to the packing and ordering of surfactants onto the solid surface.

In this study, we have used the LB film of stearic acid to estimate  $\epsilon_{\text{CH}_2}$ ,  $\epsilon_{\text{COOH}}$ , and  $\epsilon_{\text{COO}^-}$ . Calculation of these values provides a tool to quantitatively measure the molecular coverage, extent of conversion, and relative coverage of COOH and COO<sup>-</sup>. The LB film of stearic acid was transferred onto a silicon substrate coated with the OTS monolayer using the method described in “Experimental.” The IR spectrum of the transferred stearic acid LB film is shown in Fig. 9. Details of the prominent peaks for the OTS monolayer and the LB film of stearic acid are given in Table 4. The peaks at 2917 and 2850 cm<sup>-1</sup> corresponding to CH<sub>2</sub> asymmetric and symmetric stretch-

ing bands, respectively, indicate that the LB film is crystalline and uniform. The peak at 1702 cm<sup>-1</sup> corresponds to the C=O stretching band of COOH groups. When COOH groups are apart, COOH groups exist as monomers and the peak is seen between 1720 and 1740 cm<sup>-1</sup>. However, when molecules are closely packed, then neighboring COOH molecules interact with one another (hydrogen bonding) and exist as dimers. Crooks, Sun, and Kepley<sup>[72]</sup> have seen a similar phenomenon in carboxylic acid-terminated thiol SAMs. A shoulder at 1692 cm<sup>-1</sup> confirms the strong intermolecular interaction between neighboring molecules.

The sensitivity of COOH groups to pH of the surrounding environment was proven by immersing the substrate coated with the stearic acid LB film in a CaCl<sub>2</sub> solution of pH 11.5 for approximately 30 min. Fig. 9B shows the spectrum of the resulting substrate. As can be seen, the peak at 1702 cm<sup>-1</sup> vanished and a very small peak, corresponding to COOH groups existing as monomers, appeared at 1737 cm<sup>-1</sup>. Two peaks appeared at 1577 and 1541 cm<sup>-1</sup> corresponding to free COO<sup>-</sup> groups and bonded COO<sup>-</sup> groups, respectively. The interchangeability of COOH and COO<sup>-</sup> groups was proven by immersing the above sample in deionized water of pH 2.4 for about 30 min. Fig. 9C shows the spectrum of the same. As can be seen, two distinct peaks appear at 1703 and 1583 cm<sup>-1</sup>. These two peaks correspond to COOH existing as dimers and COO<sup>-</sup> existing as free monomers, respectively. There is also a shoulder at 1735 cm<sup>-1</sup> corresponding to free monomers of COOH groups. If the immersion time is increased, the spec-

**Fig. 10** (A) Schematic of a CN-terminated monolayer modified to COOH terminal groups. Conditions: 1:1 (vol/vol) of 15% HCl and water at a temperature of 75°C. (B) Schematic showing the dependence of COOH terminal groups on the pH of the environment. At low pH, the surface is only covered with COOH groups; at high pH, the surface is covered with COO<sup>-</sup> groups; at intermediate pH values, the surface is covered with both COOH and COO<sup>-</sup> groups.

Integrated absorbance values are also given in the table. No differentiation was drawn between bounded and unbounded COOH and COO<sup>-</sup> in the calculation of integrated absorbance values.

trum looks identical to the spectrum of Fig. 9A. Thus COOH dimers, monomers, and COO<sup>-</sup> monomers coexist on the surface. Fig. 9D shows the spectrum when the sample was immersed again in a solution of high pH (10.5) for about 20 min. The spectral features of Fig. 9B and D are qualitatively very similar. The difference in quantities arises from the difference in deposition times and pH. The schematic in Fig. 10A and B depicts the whole process in short.

For quantitative analysis, the maximum packing density of the stearic acid LB film was set at 18 Å<sup>2</sup> per molecule. This assumption is drawn from the  $\pi$ -A isotherm of the stearic acid LB film obtained on a sub-phase of pH 2. Absorbance values for the CH<sub>2</sub> asymmetric and symmetric stretching bands were obtained by fitting the data with a Lorentzian peak. All the spectra were baseline-corrected before peak fitting analysis was done. For COOH and COO<sup>-</sup> peaks, the peaks were not fitted and the absorbance values were evaluated by calculating the area between two wavenumbers. Details of absorbance values for CH<sub>2</sub>, COOH, and COO<sup>-</sup> and calculated molar absorptivities for the respective groups are given in Table 5. Using  $A_{\text{CH}_2} = N\varepsilon_{\text{CH}_2}(\Gamma)^*\Gamma_{\text{CH}_2}$ , where  $N$  is the number of reflections in the ATR element ( $N$  was geometrically determined to be 18) and  $\Gamma$  is the molecular coverage of the stearic acid monolayer [mol/cm<sup>2</sup>],  $\varepsilon_{\text{CH}_2}$  was found to be  $4.12 \times 10^6$  cm/mol per CH<sub>2</sub> group.

Because the vibrational frequencies for COOH and COO<sup>-</sup> differ by a considerable amount, we have assumed the values of  $\varepsilon_{\text{COOH}}$  and  $\varepsilon_{\text{COO}^-}$  to be different. However, we did not differentiate between the freely existing and bounded COOH and COO<sup>-</sup> groups.

From Fig. 9B, because the total number of COOH and COO<sup>-</sup> should be constant and equal to the molecular coverage of the monolayer, one can write:

$$\begin{aligned} A_{\text{COOH}}/\varepsilon_{\text{COOH}} + A_{\text{COO}^-}/\varepsilon_{\text{COO}^-} &= \Gamma \\ &= A_{\text{COOH}}/\varepsilon_{\text{COOH}} \end{aligned}$$

This allows us to determine the ratio of the molar emissivities of the charged and the uncharged carboxylates  $\varepsilon_{\text{COO}^-}/\varepsilon_{\text{COOH}}$  to be 1.48. The data from Fig. 9C were used for a consistency check and the values agreed.

Similarly,  $\varepsilon_{\text{CH}_2}$ , obtained from stearic acid calculations, was used to evaluate the molecular coverage of the CUTMS monolayer. The molecular coverage of CUTMS monolayers was evaluated to be in the range of 45–60 Å<sup>2</sup> per molecule. The value of 45–60 Å<sup>2</sup> per molecule indicates that the surface monolayer exists in a rather disordered, liquidlike structure, which is further verified by the position of methylene asymmetric and symmetric stretching bands, as discussed earlier.

## CONCLUSION

We have used contact angle measurements, ellipsometry, and IR reflection measurements to characterize the structure of a cyano-terminated monolayer formed by the adsorption of CUTMS on a silicon substrate. We have characterized the structure of the monolayer before and after hydrolysis of the terminal cyano group. CUTMS forms a monolayer film that has a liquidlike, disordered structure. The coverage of CUTMS molecules was found to be approximately between 45 and 60 Å<sup>2</sup> per molecule. The –CN terminal groups of CUTMS monolayer were converted to COOH terminal groups by a simple hydrolysis reaction. The kinetics of the reaction was followed using IR and contact angle measurements. COOH groups are very sensitive to the pH of the surrounding environment and can be reversibly ionized by changing the pH of the wetting solution.

## INTRODUCTION

Spontaneous organization of matter into hierarchical ordered structures is ubiquitous in nature.<sup>[1]</sup> From a single strand of DNA in a biological cell to a colony of king penguins on an Antarctic island, self-assembled structures exist not only on molecular level, but also on a macroscopic length scale. Under a strict definition, self-assembly is a process whereby a large quantity of pre-existing components undergo spontaneous organization to form larger structures driven by internal interactions or external constraints. The assembled structures may retain the properties of their constituent building blocks, but more importantly, can demonstrate new collective phenomena due to the interactions between their components.

Under this definition, crystallization of atoms driven by the formation of covalent or ionic bonds is a self-assembling process. However, it is the self-assembly process driven by noncovalent interaction that has attracted much more attention lately. This is largely because the energy associated with noncovalent bonds is comparable to thermal energy. Thus, a slight variation of interaction or temperature can drive the same system into vastly different structures. This is partly responsible for the existing complexity of nature. Understanding the mechanism for self-assembly is not only of fundamental interest, but may also lead to many technological applications. While the vast majority of self-assembled structures exist in biological systems, this review is from the material's point of view with only a few exceptions. This is largely due to our own research interests as well as the practical consideration that it is impossible to cover every aspect of these research activities in a short review. Nevertheless, we hope to capture the essence of self-assembly, and refer interested readers to several other excellent review articles and monographs published in this encyclopedia and elsewhere.<sup>[2–15]</sup>

## SELF-ASSEMBLY IN MOLECULAR SYSTEMS

The development of synthetic chemistry has led to the construction of many large molecules with well-defined

sizes, functional groups, and chiralities. Most of these molecules such as vitamin B<sub>12</sub> are based on the sequential formation of covalent bonds.<sup>[16]</sup> However, it is becoming increasingly clear that constructing even larger structures would require more efficient synthetic pathways.<sup>[6]</sup> One approach is to mimic nature where covalent bonds are used to construct functional building blocks, and these building blocks are subsequently assembled into well-defined super-structures through non-covalent interactions. Self-assembly of these molecular units has provided a powerful means for designing molecular systems with novel structures and properties.

## Surfactants and Lipids

Amphiphiles, such as surfactants and lipids, are molecules containing both hydrophobic and hydrophilic components. They self-assemble into a variety of structures, such as micelles, bilayers, and vesicles, in both aqueous and organic solvents. The competing interactions that drive this self-assembly arise from the attractive interfacial tension at the hydrocarbon–water interface, the repulsive steric interactions and the electrostatic force between the molecular head groups.

From the thermodynamics point of view, the formation of molecular aggregates is determined by the relative change in chemical potential ( $\mu_N - \mu_1$ ) when the molecules form a finite size aggregate consisting of  $N$  monomers. For simple alkane molecules in water, the change of chemical potential is monotonic with size,  $(\mu_N - \mu_1) \sim (\mu_\infty - \mu_1) + \alpha kT/N^P$ , where  $\mu_\infty$  and  $\mu_1$  are chemical potentials of the infinite solid and single molecule, respectively,  $\alpha kT$  is the binding energy in the aggregate, and the index  $P$  is determined by the dimensionality of the aggregate. Although finite size aggregates do form for simple alkane molecules above the critical micelle concentration (CMC), the population number of these aggregates decreases rapidly with their size. On the other hand, amphiphilic molecules have a minimum in chemical potential at a finite aggregation number. This is because the attractive

**Fig. 1** Amphiphiles can adopt a variety of structures as shown in this figure by simply changing the conditions, such as concentration, pH and temperature. *Source:* From Ref.<sup>[17]</sup>. © 1991, J. Coll. Inter. Sci.

interaction is proportional to the surface area of the molecule's head group whereas the repulsive interaction has an inverse proportionality. So, there is an optimum surface area  $a_0$  for the amphiphilic molecule, and finite size aggregates can form with a large population number.

Self-assembled structures obtained by this competing interaction can be determined by a simple geometrical packing parameter  $v/(a_0l_c)$ , where  $v$  is the volume of the molecule and  $l_c$  is the critical chain length. At low monomer concentrations, spherical micelles form when  $(v/(a_0l_c)) < (1/3)$ , cylindrical micelles form when  $(1/3) < (v/(a_0l_c)) < (1/2)$ , flexible bilayers and vesicles form when  $(1/2) < v/(a_0l_c) < 1$ , planar bilayers form when  $(v/a_0l_c) \sim 1$  and inverted micelles form when  $(v/a_0l_c) > 1$ . Fig. 1 shows some of the most widely studied structures. One interesting phenomenon is that even with the same amphiphile, the packing parameter can change with the environmental conditions, such as the pH of the solvent, the salt concentration and the temperature. As a result, self-organized structures will change correspondingly. This has a significant implication in biological membranes, because biological lipids with different packing parameters can form complex structures with different curvatures while maintaining the flexibility to respond to the changing environment. When the monomer concentration increases, the interaction between the

aggregates becomes more important, which leads to the change of aggregate shape and further organization of aggregates into several liquid crystalline phases (Fig. 1). For instance, the phase diagram of the binary system of water–dodecyltrimethyl ammonium chloride contains a micellar phase at low concentrations, two cubic phases, one hexagonal phase and one lamellar phase at high surfactant concentrations.<sup>[5]</sup> The lamellar phases consist of alternating bilayers that can easily slip relative to each other. Among various liquid crystalline phases, it is more difficult to detect the cubic phase since its isotropic structure cannot be revealed by standard polarized light microscopy. The cubic phase between the micellar and hexagonal phase is made of short rod-like aggregates. The cubic phase in the high amphiphile concentration region has a bicontinuous structure in which a single bilayer of molecules folds its way in space separating the two aqueous compartments.

While the thermodynamic phases created by amphiphile self-assembly have been well characterized, little is known about the kinetics of the phase transition between different structures.<sup>[18]</sup> This is largely because the transitions between different phases exhibit a very broad range of time scales, varying from submicroseconds to many days. Recently, light scattering, small-angle x-ray scattering (SAXS) and small-angle neutron scattering (SANS) have been adopted to investigate the kinetics of phase transitions.<sup>[19]</sup> Time resolved SAXS

experiments on a mixture of a cationic surfactant (tetradecyltrimethyl ammonium hydroxide) and an anionic surfactant (Texapon N<sub>70</sub>-H) show that the transition from micelles to vesicles is a multistep process.<sup>[20]</sup> Globular mixture micelles form very quickly upon mixing. Subsequent bilayer formation has a time scale of 500–1000 msec. The bilayer then closes up in a much slower process (5–100 sec) to form vesicles. Experiments on pentaethylene glycol mono-*n*-dodecyl ether (C<sub>12</sub>E<sub>5</sub>) in D<sub>2</sub>O under increasing pressure show a transformation from cylindrical micelles to ordered hexagonal micellar bundles, possibly due to the pressure induced freezing of the hydrophobic core.<sup>[21]</sup>

### Block Copolymers

This principle of self-assembly, based on combining motifs with different interfacial energies in a single molecule, also applies to polymers.<sup>[22,23]</sup> Copolymers are macromolecules that contain chemically distinct polymer blocks that are linked covalently. Synthetic developments based on living anionic, cationic, and radical polymerization have generated diblock, triblock, and multiblock copolymers that are arranged as linear chains, grafts, or star shapes.<sup>[24]</sup> Diblock copolymers are the most widely studied systems.

At low concentrations in solutions, block copolymers readily form micelles, with a CMC much lower than the typical surfactants or lipids. For diblock copolymers, micelles have a well-defined structure with a core consisting of the insoluble A block and a shell of the soluble B block. The size of the resulting micelles, which is characterized by the aggregation number  $Z$  (i.e., the number of molecules in a micelle), depends on the degree of polymerization of the soluble block  $N_A$  and insoluble block  $N_B$  through a simple relation,  $Z = Z_0 N_A^2 N_B^{-0.8}$ .<sup>[25]</sup> Thus, the diameter of the micelles can be directly tuned by the degree of polymerization of each block. Because of the possibility to tune the aggregate properties by varying either the type, the size, or the relative proportion of the constituting blocks, diblock micellar aggregates are able to provide a much wider range of applications than normal surfactants, including being used as tunable nanoreactors for colloidal synthesis,<sup>[26]</sup> and drug and gene delivery.<sup>[27]</sup>

In bulk materials, block copolymers phase-separate into a variety of mesoscopic structures upon cooling below the glass transition temperature. The sizes of the domains created by microphase separation are typically in the range of 10–100 nm. Electron microscopy<sup>[28]</sup> and SANS<sup>[29]</sup> have been used extensively to investigate the phase separated structures. These studies have shown that the morphologies of segregated diblock copolymer microphases depend upon the degree of polymerization  $N = N_A + N_B$ , the relative composition of the two constituent blocks

**Fig. 2** Phase diagram for a structurally symmetric coil-coil diblock copolymer. $f_A = N_A/N$ , the Flory–Huggins interaction parameter  $\chi$  between the two blocks and the temperature. A predicted stable microstructure, shown in Fig. 2, includes lamellae, hexagonally packed cylinders, body-centered cubic spheres, close-packed spheres, and bicontinuous cubic network phases with  $Ia3d$  symmetry. These structures have been verified experimentally.<sup>[30,31]</sup>

For a thin film of block copolymer, the interfacial energy of polymer/substrate and polymer/air become additional driving forces to affect the morphology of phase separation.<sup>[23,33]</sup> Fig. 3(A) shows the schematic cross-section diagram of polystyrene-*b*-poly(ethylene-*alt*-propylene). Polystyrene (PS) prefers to wet the silicon nitride/polymer interface, whereas the poly(ethylene-*alt*-propylene) (PEP) prefer the polymer/air interface.<sup>[34]</sup> The thickness of these PS-*b*-PEP film are quantized in odd multiples of  $L/2$ , with  $L/2$  being the size of the molecule. Recently, there has been growing effort to control the microdomain orientation and induce long-range lateral ordering in these thin films. So far, this has been achieved through applying an electric field, directional crystallization or confining the polymer on a patterned surface.<sup>[34–37]</sup> Fig. 3(C) and Fig. 3(D) show that cylindrical PS-*b*-PEP domains and spherical Polystyrene(PS)-*b*-polyferrocenyldimethylsilane (PFS) domains can be aligned in the trough lithographically patterned on a substrate.

### Supramolecular Systems

The highly selective and directional nature of the hydrogen bond makes it an ideal candidate for

**Fig. 3** (A) Schematic diagram for a PS-*b*-PEP thin film organized on a silicon nitride substrate. (B) Tapping mode of cylindrical fingerprint structure of PS-*b*-PEP film. constructing large assemblies of molecular building blocks. The strength of hydrogen bonds is relatively weak (3–5 kcal/mol). Furthermore, the enthalpic gain to form such bonds must overcome the entropy loss due to the reduction of molecular translation and conformation. Therefore, multi-hydrogen bond motifs are typically used to construct a stable assembly. Derivatives of 2-ureido-4-pyrimidone have a strong tendency to polymerize with self-complementary DDAA (donor–donor–acceptor–acceptor) hydrogen bonds. Depending on the geometry of this bonding motif in the molecule, linear polymers and reversible networks can be formed (Fig. 4). The network created by hydrogen bonding has a strong temperature dependent rheology. Multicomponent self-assembled structures based on the cyanuric acid–melamine motif were studied by Whitesides.<sup>[38]</sup> It was shown that these molecules form stacked rosettes, which can be further used for the self-assembly of multiporphyrin arrays.

By designing molecules with well-defined chirality, self-enclosed cyclic structures can form instead of straight polymeric chains. Bis-lactam molecules,

designed by Brienne and coworkers, form a ring structure due to the stereochemical arrangement of their hydrogen bonding sites [Fig. 5(A)].<sup>[40]</sup> Two sets of complementary triple hydrogen motifs in molecules such as Fig. 5(B) spontaneously form hexameric aggregates.<sup>[41]</sup> Self-assembled capsules, which contain molecules or ions inside their cavities, are formed using concave building blocks like glycoluril, calixarenes, or resorcinarenes [Fig. 5(C)].<sup>[42]</sup> One example based on complementary hydrogen bonding of glycoluril has created a “molecular tennis ball” [Fig. 5(D)].<sup>[43]</sup> The study of the dynamics of guest exchange in this tennis ball structures leads to the conclusion that optimal binding between the guest molecules and the capsule occurs when approximately 55% of the capsule volume is occupied.

Dendrimers are globular macromolecules in which all bonds emerge radially from a central focal point and with the repeating units converging to a branch point.<sup>[45]</sup> The distinctive features of dendrimers are their layered architecture, globular shape, multifunctional periphery, and radially controlled chemical composition. These features provide a unique oppor-

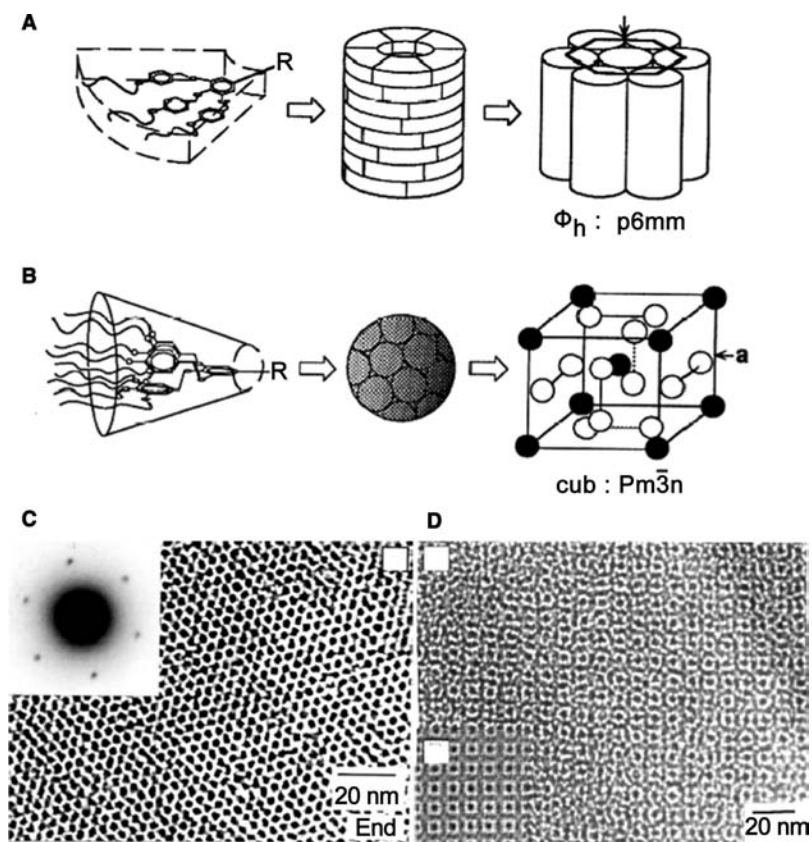

**Fig. 4** Schematic representation of reversible polymer architectures obtained from bifunctional and trifunctional pyrimidone derivatives. *Source:* From Ref.<sup>[39]</sup>. © 1997, Science.

tunity to transform dendritic structures into a variety of supramolecular architectures. Hydrogen-bonding interactions offer an effective route for creating such supramolecular structures. Using this approach, Zimmerman and co-workers prepared a remarkable family of dendrimers, which consisted of six Fréchet-type polyether dendrons, which fitted with two isophthalic acid units at their focal point.<sup>[46]</sup> In this case, six subunits were brought together by hydrogen bonds to construct supramolecular dendritic structures up to four generations. The resulting self-assembled macromolecule was disk-shaped with 9 nm in diameter and 2 nm in thickness. The shape of the first generation monodendron building blocks affects the superstructures they eventually form. Monodendrons with a flat, tapered shape organize into cylindrical dendrimers, which further organize into thermotropic hexagonal columnar phase ( $\Phi_h$ ) (Fig. 6A), whereas the spherical

monodendrons form a homeotropic cubic liquid crystalline (LC) phase of  $Pm\bar{3}n$  symmetry [Fig. 6(B)].<sup>[47,48]</sup> Using a similar approach, Aida and coworkers<sup>[49]</sup> have prepared luminescent superhelical fibers, by exploiting weak metal–metal interactions to create hierarchical self-organization of small dendrimers. Owing to their sizes and unique optical and electronic properties, these supramolecular structures could have great potential applications in display, storage, and electronic devices.

### SELF-ASSEMBLY OF NANOSCALE BUILDING BLOCKS

Building blocks with a nanoscale dimension (typically <100 nm) have different properties compared with their bulk counterparts. For instance, the absorption and photoluminescence of semiconductor quantum dots show a strong size dependence.<sup>[50,51]</sup> Charge injection onto a single quantum dot has to overcome a strong Coulomb charging energy. The magnetic moments of the surface atoms are strongly enhanced due to unquenched orbital moments in transition metal clusters.<sup>[52]</sup> Fundamentally, all these new phenomena can be attributed to two major effects on the nanometer scale, namely, the quantum confinement of charge and spin,<sup>[53]</sup> and the low coordination of surface atoms.<sup>[54]</sup>

Developments in colloidal chemistry during the past two decades have produced a variety of high-quality nanoscale building blocks with many unique properties.<sup>[7,55–58]</sup> Although it is possible to study and utilize the physical properties of nanoparticles on a single particle level, it remains a technically challenging task. On the other hand, experiments on macroscopic 2D and 3D nanocrystal superlattices are more accessible. Self-assembly of nanocrystal building blocks not only provides a way to connect the nanoscale dimension to the macroscopic length scale, but it also creates a revolutionary new class of materials. New collective behavior is expected to emerge if there is a strong coupling between building blocks.<sup>[8,59]</sup>

Self-assembly of nanocrystals upon evaporation of solvents leads to spontaneous organization of particles. Based on this approach, many nanocrystal self-assemblies have been formed, including CdSe, CdS, Au, Ag, Co, FePt, CoO, Fe<sub>2</sub>O<sub>3</sub>.<sup>[60–67]</sup> Such assemblies are driven by interparticle van der Waals interactions. For a polydisperse colloid, this leads to size segregation because the interparticle interaction is size dependent. The balancing force to create a stable structure is provided by either steric repulsion from surface ligands or the electrostatic interactions from the surface charges. X-ray diffraction (XRD) and electron diffraction are typically used to characterize the structure. The

packing structures thus formed are slightly different from the crystal structure formed by atoms, because nanocrystals are typically polyhedral and thus create non-isotropic interactions between the different building blocks. Therefore, the size and shape of nanocrystals can affect the packing structure dramatically. For instance, it was found that truncated octahedral Ag nanocrystals form fcc superlattices, and there is a strong orientational order among particles in the superlattices.<sup>[68]</sup> For quasi-spherical gold nanoparticles, it was found that the crystallographic structure of the self-assembly depends on the ratio between the ligand chain length ( $L$ ) and the size of the metal core  $D_{\text{core}}$ :  $\xi = 2L/D_{\text{core}}$ .<sup>[50]</sup> This relates to a simple property like the “softness” of the particles (relative interaction strength) with the resultant self-assembled structure, with fcc as the hard-sphere limit and bcc in the soft limit. Assembly of building blocks with more anisotropy, such as nanorods, can create nematic and smectic liquid crystal phases.<sup>[69]</sup>

Mixing different nanoparticles with selected size ratio forms binary colloidal crystals with AB, AB<sub>2</sub>, AB<sub>5</sub>, and AB<sub>13</sub> structures, depending on the concentration ratio of the components. Two-dimensional binary lattices were demonstrated using two different sizes of gold nanoparticles.<sup>[71]</sup> Recently, three-dimensional binary lattices consisting of 11 nm  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles and 6 nm PbSe nanocrystals were also demonstrated.<sup>[70]</sup> Fig. 7 shows a TEM image of such a binary lattice. In these multicomponent nanocrystal assemblies, the properties of each component may be engineered individually. By tuning the coupling between different functionalities, it may be possible to obtain new properties that are otherwise difficult to obtain.

Kinetics also plays an important role in nanoscale self-assemblies. For evaporation-induced self-assemblies, percolating networks of nanocrystals are typically obtained because of the highly non-equilibrium process of solvent evaporation.<sup>[72,73]</sup> Despite this, for dodecanethiol ligated gold nanocrystals, it was shown that a highly ordered nanocrystal monolayer with domain sizes up to tens of micrometers can be formed by adding an excess amount of ligand molecules in the solution.<sup>[74]</sup> Recent in situ SAXS experiments (Fig. 8) demonstrated that the presence of excess thiol induces superlattice domain formation at the liquid–air interface rather than at the liquid–substrate interface.<sup>[75]</sup> Evaporation kinetics plays an important role in this process. With a fast evaporation rate, 2D superlattices nucleate and grow into a highly ordered structure. On the other hand, if the evaporation rate is slow enough, the 2D superlattices formed at the liquid–air interface are not stable, and the formation of 3D superlattices occurs in the interior of the droplet.

Nanoparticles functionalized with complementary linker molecules can spontaneously self-assemble into

macroscopic structures due to the chemical recognition ability of the surface ligands. Many such lock-and-key type of linker molecules have been investigated. Triple hydrogen bond motifs were used to assemble nanocrystals.<sup>[76]</sup> Gold nanocrystals ligated with DNA molecules form nanocrystal dimers and trimers when a complementary strand of DNA is added.<sup>[50,77]</sup> Streptavidin ligated gold nanoparticles were shown to form a two-dimensional array on a biotin-labeled glass substrate or form linear chains on biotin-labeled DNA chains.<sup>[78,79]</sup> The antigen–antibody recognition scheme was also used to create bimetallic aggregates.<sup>[80]</sup> Because of their intrinsic diversity, these biological scaffolds have the potential to create a rich family of self-organized structures. Such prospects have been shown recently using DNA scaffolds, where linear chains, ribbons, and branches of nanocrystal arrays were created.<sup>[79–81]</sup>

The self-assembly of nanoscale building blocks can also be induced by a pre-fabricated template. This template can be created by the molecular-scale self-assembly. An example was demonstrated in the evaporation of gold and silver onto a phase-separated polystyrene-*b*-poly(methyl methacrylate) film (Fig. 9).<sup>[82]</sup> Gold and silver particles spontaneously form in the polystyrene domain rather than the poly(methyl methacrylate) domain. This hierarchical self-assembly is driven by the different diffusion rates of metal atoms on the different polymer surfaces. When thiolated gold colloid is mixed with a solution of polystyrene-*b*-poly(4-vinylpyridine), which forms hexagonally ordered micelles upon evaporation, gold nanocrystals preferentially distribute themselves in the polystyrene coronas. If at the same time, the FeCl<sub>3</sub> precursor embedded in the PVP domains is oxidized, Fe<sub>2</sub>O<sub>3</sub> particles form in the PVP cores, thus creating a binary nanocrystal superlattice.<sup>[83]</sup>

## SELF-ASSEMBLY OF SUBMICROMETER TO MILLIMETER PARTICLES

A variety of different systems contain submicrometer particles with sizes ranging from 100 nm to 1  $\mu\text{m}$ . These include common substances such as milk, ink, and smoke. Studies on the self-organization of these particles have not only revealed a myriad of interesting phenomena associated with crystal structures and phase transitions, but have also led to many applications in pharmaceutical and cosmetic industries.<sup>[9]</sup> Most recently, the prospect of using these assemblies for photonic applications became a focus area.<sup>[84]</sup> Particles in an aqueous environment experience a strong, long-range, Hamaker-type van der Waals attraction that is balanced by a repulsive electrostatic double layer. These interactions together create a secondary minimum, well-described by DLVO theory, which

can lead to the assembly of stable supercrystals.<sup>[4]</sup> The range of the interaction is characterized by the Debye length, which can be tuned by changing the ionic strength of the colloidal solution. If the repulsive force is too weak, irreversible fractal aggregation or gel formation occur. The majority of the research has so far concentrated on systems with either hard sphere repulsive interaction or relatively weak attractive interactions.

For hard spheres confined in a finite volume, entropic effects can drive the system to crystallize when the volume fraction ( $\phi$ ) is above the freezing concentration.<sup>[85]</sup> Both the simulations and experiments<sup>[86–88]</sup> have shown that the colloid remains a liquid when  $\phi < 0.494$ , becomes a coexisting mixture of liquid and crystals when  $0.494 < \phi < 0.545$  and finally crystallizes when  $0.545 < \phi < 0.74$ . While the lowest energy crystal structure is still under debate, experiments both on earth

**Fig. 8** In situ SAXS patterns of 2D NCSs formation during droplet evaporation. Time in units of minutes is in reference to the deposition of the colloid droplet. Lett.

and under microgravity both yield random stacking of hexagonal close pack structure (r.h.c.p.).<sup>[89,89]</sup> Face-centered cubic structures only form when the volume fraction is deep into the crystallization region and the sample is maintained undisturbed for a long time. If the volume fraction of the colloid is increased very rapidly into the crystal phase  $\phi > 0.58$ , a glassy state

is obtained. This was first confirmed experimentally by Pusey and van Megen.<sup>[88,91]</sup>

When the range of the interaction or the nature of the interaction between submicrometer particles changes, the formation of the crystal phase occurs at a very different volume fraction, and it can also lead to different crystal structures of the crystal phase. Polystyrene spheres trapped at the liquid–air interface interact through a long-range dipole–dipole interaction, which can also lead to the formation of two-dimensional triangular lattices.<sup>[92]</sup> Large floating particles can also deform the liquid surface enough to create long-range capillary forces due to the curvature of the surface. Smaller particles, however, can only deform the surface enough when they are nearly in contact with the solid substrate.<sup>[93]</sup> These techniques can be used to create extraordinary ordering, and have been recently used to self-assemble photonic band gap crystals of exceptional quality.<sup>[94]</sup> A weak long-range attractive interaction can also be induced by adding nonabsorbing polymers into the colloid.<sup>[95]</sup> Because of the finite radius of gyration ( $r_g$ ) of the added polymer, it will be excluded in the depletion layer surrounding the particles. The osmotic pressure exerted on the particles because of the depletion region will lead to the formation of particle assemblies. Attraction of a sufficiently long range will also introduce a gas phase transition, which depends keenly on the range of the attraction. At a high volume fraction that typically forms a glassy state in hard spheres, tuning the depletion attraction by adding a nonabsorbing polymer can induce transition from a repulsive glass state to a fluid state, followed by a re-entrant transition to

**Fig. 9** (A) Silver and (B) gold atoms selectively decorate polystyrene domains to form nanoscale chains after thermal evaporation of the metals onto the phase separated polystyrene-*b*-poly(methylmethacrylate) film.<sup>[82]</sup> *Source:* Courtesy of Prof. Heinrich Jaeger from University of Chicago.

**Fig. 10** Crystalline aggregates generated by the self-assembly of millimeter-size (A) crosses that have hydrophobic ends and (B) hexagons that have three hydrophobic side faces. *Source:* From Ref.<sup>[100]</sup>. © 1997, Science.

an attractive glass state. This was first predicted by theory and has been recently confirmed by experiment.<sup>[96–98]</sup> Depletion interaction can also drive crystallization at the interface. A patterned surface can induce crystal growth into macroscopic structures that are determined by the symmetry of the surface patterns.<sup>[99]</sup>

Several interesting experiments also exist which examined the self-assembly of tens of micron to millimeter size particles with different shapes and hydrophobicities.<sup>[100]</sup> Hexagons made of polydimethylsiloxane with different hydrophobic surfaces interact selectively to form different 2D structures at the water-perfluorodecalin interface (Fig. 10). Different strengths of attractive interaction caused by capillary forces can also drive phase segregation of different particles. Such an assembly scheme has later been developed for 3D stacking of hexagonal polyurethane rods and 10  $\mu\text{m}$  metal blocks that are functionalized with self-assembled monolayers.<sup>[101]</sup>

## CONCLUSIONS

Compared with the complexity and diversity of biological self-assembled systems, man-made self-assembled systems, some of them outlined in the previous sections, are essentially still very primitive. The size range and the shape of the building blocks are quite limited, and the structures created from these building blocks are rather simple. Nevertheless, studies on many simple model systems have led to a better understanding of the basic energetic driving forces for the self-assembly process.

There are several promising directions in the near future. One area is to develop hierarchical schemes to control self-assembly at all length scales, therefore

creating materials entirely from self-assembly. Such efforts have already yielded some interesting results, with one example being the surfactant mediated crystallization of colloidal crystals.<sup>[102]</sup> In another aspect, much of the understanding of self-assembly has been limited to static systems, with the main focus on equilibrium structures. Dynamic self-assembly, where systems undergo constant energy exchange with their environment and have different phase transitions, will draw more research attention in the future, largely because nature itself is essentially a dynamic and evolving system.<sup>[2]</sup> Therefore, it is crucial to develop new in situ experimental techniques with high spatial and temporal resolutions. Ultimately, creating materials that have the same complexity as biological systems through self-assembly is the holy grail in this research field. It is therefore, not a surprise that there is tremendous interest in developing biomimetic self-assembled systems.

## INTRODUCTION

Many different materials with truly new physical and chemical properties, consisting of controllably deposited colloid particles, are being developed. Particles with a variety of intrinsic properties are used, their sizes varying over at least three orders of magnitude. For photonic band gap materials, particle sizes are in the (sub)micron range, whereas for magnetic applications, such as ultra-high-density storage devices, they are in the low-nanometer range.<sup>[1,2]</sup> A prerequisite for studying colloidal systems is the ability to characterize them unambiguously under relevant conditions. Among the large number of methods available for characterizing colloids and their superstructures, scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are by far the most popular.<sup>[1–7]</sup> For both very small as well as relatively large particles these are the most employed *ex situ* techniques. The use of various scanning probe microscopies—atomic force microscopy (AFM), scanning tunneling microscopy (STM), and magnetic force microscopy (MFM)—among colloid scientists is increasing; with these techniques experiments are also typically performed *ex situ*.<sup>[8,9]</sup> In fact, only optical methods have been employed *in situ*. For larger colloids, imaging techniques such as conventional<sup>[5,10]</sup> or confocal<sup>[11]</sup> microscopy are used. For sizes much smaller than the wavelength of light, such as with gold nanoparticles, only non-imaging (lateral averaging) *in situ* techniques are available. These include primarily ultraviolet/visible (UV/vis) absorption spectroscopy<sup>[1,6,8,9]</sup> and also optical reflection techniques such as reflectometry and ellipsometry.<sup>[12–15]</sup> The major advantage of ellipsometry as compared to reflectometry is its sensitivity to very small perturbations at an interface. Not only the deposition process but also the drying processes of (nano)colloidal particles at a solid–liquid interface can be studied.<sup>[12–14]</sup> However, both the *in situ* and *ex situ* capabilities of the

aforementioned reflection techniques depend on an unambiguous interpretation of recorded optical spectra.

Much work is devoted to the optical characterization of adsorbed proteins.<sup>[15]</sup> The optical contrast between these protein films and other layers is usually small because of the absence of light absorption in the visible and a refractive index of 1.35–1.4, i.e., close to water and glass. The approach developed by de Feijter, Benhamine, and Veer<sup>[16]</sup> gives satisfactory results in such cases. However, for larger colloids and light absorbing particles, such as metal nanocrystals, this approach no longer suffices.

This entry is devoted to the optical characterization of Au nanocolloids (radius  $a = 6.6$  nm) adsorbed from solution onto a naturally oxidized silicon substrate. An unambiguous optical characterization of such a colloidal system is not straightforward. We present an analysis of ellipsometry spectra in the coverage range up to 40%. A comparison of the optically determined coverage with the coverage determined with SEM serves as a benchmark for the quality of the description of the optical response.

The standard approach in the analysis of the optical spectra is to describe the optical properties of a heterogeneous layer, such as an adsorbed layer of colloids, with an effective medium approximation (EMA). In this entry, we will show that commonly used approaches as the Bruggeman and Maxwell-Garnett EMA do not give adequate results. However, the so-called thin film theory developed by Bedeaux and Vlioger<sup>[17]</sup> gives an excellent description of the optical response. In this theory, the incorporation of image dipoles and laterally interacting entities is essential. We will show that an extension which modifies the strength of the image dipole is required. This is necessary for two reasons: 1) there is a large optical contrast between the ambient and the silicon substrate, and 2) the presence of the natural oxide layer also influences the image dipole contribution. This oxide layer has a limited thickness that is three times smaller than

the radius of the colloids, and thus the silicon–silicon oxide interface affects the image dipole contribution. A prerequisite for the description of the optical properties of the colloid layer is the knowledge of the optical characteristics of a single entity. The limited size of the Au colloids results in a different polarizability than that of bulk gold.<sup>[18]</sup> An experimental determination of the absorbance of the Au colloid suspension provides the required modification of the dielectric function of bulk gold in order to incorporate size effects.

## GOLD COLLOID PREPARATION AND DEPOSITION

### Preparation

Colloidal gold suspensions are prepared by standard citrate reduction.<sup>[7,19]</sup> Typically, 100 mL of 1 mM HAuCl<sub>4</sub> (Aldrich) aqueous solution is heated to 100°C under refluxing conditions. While the solution is stirred vigorously, 10 mL of 38.8 mM sodium citrate (Merck) is quickly added, resulting in color changes of the originally yellow solution to transparent, to dark blue/gray, and finally, after approximately 2 min, to burgundy red, which marks the end of the reaction. The mixture is kept at 100°C for 15 min and subsequently cooled to room temperature with continuous stirring.

The particle size was determined by three different methods. (HR)TEM measurements show that the gold particles are spherical multidomain crystallites with a radius of 6.4 nm; the size dispersion amounts to  $\sigma = 8\text{--}10\%$ . Second, the average height of particles in AFM images amounts to a radius of 6.6 nm; laterally, the size of the particles is overestimated because of tip convolution. These AFM images are obtained using a Molecular Imaging PicoSPM system, operated in AAC Mode or MAC Mode, using silicon cantilevers with a typical resonance frequency of 65 kHz (Nanosensors); for MAC Mode, magnetically coated (Molecular Imaging) cantilevers are used. Finally, X-ray fluorescence measurements (XRF 2400 Cr spectrometer with a spot diameter of 10 mm) are performed to determine the number of gold atoms on the surface. This is compared to the number density of gold particles obtained from AFM images on the same samples. The average number of gold atoms per nanocrystal amounts to  $7.62 \times 10^4$ ; using the bulk density of gold (19.32 g/cm<sup>3</sup>), one obtains a particle radius of 6.7 nm.

Assuming that all gold ions in solution are consumed in the formation of the colloids, and with an average particle radius  $a = 6.6$  nm, the number density of particles in suspension amounts to  $N = 7.70 \times 10^{18} \text{ m}^{-3}$ . The tip-colloid convolution is quite large in AFM images, and the lateral dimensions of the colloid double in AFM images. This leads to a rather

cumbersome determination of the surface particle density. Therefore, images obtained from low-voltage SEM are used to determine this. Fractional surface coverages are determined by counting the number of colloids in a particular area and multiplying by  $\pi a^2$ , with  $a = 6.6$  nm the average particle radius.

### Substrates

Polished silicon wafers with a 1.5-nm native oxide are cleaved into  $12 \times 12\text{-mm}^2$  pieces. Before handling, these substrates are cleaned ultrasonically in methanol for at least 15 min. A high surface affinity for the colloidal gold particles is achieved by derivatization of the silicon substrates in a 10% 3-aminopropyltriethoxysilane (APTES) in methanol solution for 60 min, followed by thorough rinsing in methanol. After drying in a nitrogen flow, the samples are immersed in water for 15 min. Deposition of the gold particles is done by immersion of the derivatized substrates in the colloidal suspension, typically for a few hours; underivatized samples do not show any deposition of gold on the surface. After rinsing with water, the samples are dried in a nitrogen gas flow.

### Single-Particle Optical Characterization

An accurate, quantitative optical characterization of thin colloidal gold films is possible only if the dielectric function of the individual particles is known. Owing to their small size the optical properties of nanocrystals is markedly different from those of bulk material. Therefore, we first study the optical properties of single colloidal particles in suspension by means of optical absorbance spectroscopy. Optical extinction spectra are obtained with an HP8452-A UV/vis spectrophotometer. The optical path of the cuvette is  $\ell = 10^{-2}$  m. The extinction coefficient  $\sigma_{\text{ext}}$  of our as-prepared colloidal gold suspension, calculated from absorbance measurements,<sup>a</sup> is shown in Fig. 1 as a function of wavelength. The maximum at 519 nm, often referred to as the surface plasmon resonance, results in a pink color of the suspension, in good agreement with previous work. Upon dilution of the suspension, the entire extinction spectrum scales linearly with the particle concentration. Apparently, the extinction is dominated by absorption (which is proportional to the particle number density), and scattering can be neglected as expected for particles much smaller than the wavelength of the light.<sup>[18]</sup> In this Rayleigh regime ( $a \ll \lambda$ ) the extinction

<sup>a</sup>The extinction coefficient  $\sigma_{\text{ext}}$  defined by  $I/I_0 = \exp(-\sigma_{\text{ext}}z)$ , with  $I/I_0$  the attenuation of the light intensity at depth  $z$  in the suspension, is determined from the optical absorbance  $A$  given by  $A = -\log I/I_0$ , using the known optical path length  $\ell = 10^{-2}$  m.

**Fig. 1** Wavelength-dependent extinction coefficient of an as-prepared colloidal solution, obtained from a measured absorbance spectrum.<sup>1a</sup> Calculated extinction coefficients using bulk (dashed line) and modified (solid line) dielectric functions are also shown.

cross section is due to dipolar absorption only; the scattering cross section and higher multipolar contributions (such as quadrupole extinction and scattering) are strongly suppressed in this size regime.<sup>[20]</sup> The extinction coefficient is thus given by

$$\sigma_{\text{ext}} = \frac{2\pi N \sqrt{\epsilon_1}}{\epsilon_0 \lambda} \text{Im}(\alpha) \quad (1)$$

with  $N$  the particle number density,  $\lambda$  the wavelength of the light, and  $\epsilon_1$  the dielectric function of the medium in which the colloids are suspended. The single-particle polarizability  $\alpha$  is related to the dielectric function through the Clausius–Mosotti relation:

$$\alpha = 3\epsilon_1 \epsilon_0 V \frac{\epsilon - \epsilon_1}{\epsilon + 2\epsilon_1} \quad (2)$$

where  $V = (4/3)\pi a^3$  is the particle volume,  $\epsilon_0 = 8.85 \times 10^{-12}$  F/m is the permittivity of vacuum, and  $\epsilon$  is the complex dielectric function of the particle. The bulk dielectric function for gold<sup>b[21]</sup> is shown in Fig. 2 by the dashed lines. In Fig. 1, the dashed line shows the calculated extinction using the aforementioned bulk optical properties of gold. Qualitatively, the features of the measured spectrum are reproduced. The extinction maxima are at the same wavelength, but the calculated peak is considerably higher and markedly narrower. Nevertheless, the difference between

<sup>b</sup>The bulk dielectric function of gold was determined using spectroscopic ellipsometry on a 1.5- $\mu\text{m}$ -thick gold film on mica.

**Fig. 2** (A) Imaginary and (B) real parts of the complex dielectric function of gold. The dashed lines refer to bulk values<sup>1b[21]</sup> and the solid lines depict the modified dielectric function, as described in the text. The inset shows the wavelength-dependent corrections  $\Delta\epsilon_1$  and  $\Delta\epsilon_2$  of the real and imaginary parts, respectively.

measured and calculated extinction is negligible on the small-wavelength side of the spectrum. A similar decrease of the height and broadening of the peak for gold nanocrystals with a size below approximately 30 nm has been observed.<sup>[22]</sup> However, it is surprising that these spectra are often only compared qualitatively and merely the position of the surface plasmon resonance is considered.

The differences between calculated and measured extinction can be accounted for by considering the limited electron mean free path because of the small particle size.<sup>[20,23]</sup> Within the classical electrical conductivity theory, the overall relaxation frequency for bulk material  $\Gamma_\infty = \sum \Gamma_i$  is composed of contributions  $\Gamma_i$  because of interactions with phonons, electrons, impurities, and lattice defects. Assuming that only electrons near the Fermi surface (with Fermi velocity  $v_F$ ) contribute to the conductivity, the mean free path  $\ell_\infty$  is related to  $\Gamma_\infty$  through  $\Gamma_\infty = v_F/\ell_\infty$ . For gold,  $\ell_\infty$  amounts to 42 nm. As our colloidal particles are markedly smaller than this, the effective mean free path is considerably reduced. Following Matthiessen's rule, the additional scattering of conduction electrons gives rise to an extra term in the relaxation frequency

$$\Gamma(r) = \Gamma_\infty + A \frac{v_F}{a} \quad (3)$$

in which  $A = 4/3$  is a theory-related constant. This size-dependent relaxation frequency leads to an alteration of the dielectric function  $\varepsilon(\lambda, r) = \varepsilon_{\text{bulk}}(\lambda) + \Delta\varepsilon(\lambda, r)$  that now also becomes size dependent. The correction  $\Delta\varepsilon(\lambda, r)$  of the dielectric function because of intrinsic size effects can be expressed in terms of a difference of two Drude expressions:<sup>[23]</sup>

$$\Delta\varepsilon = \frac{\omega_p^2}{\omega} \left( \frac{1}{\omega + i\Gamma_\infty} - \frac{1}{\omega + i\Gamma(a)} \right) \quad (4)$$

where  $\omega = 2\pi c/\lambda$ , with  $c$  the speed of light. As this simple model takes into account only free electron effects, the correction is largest at longer wavelengths.

With the size-dependent dielectric function  $\varepsilon(\lambda, r)$ , we are able to calculate the modified extinction employing Eqs. (1) and (2). The plasma frequency  $\omega_p$  and the Fermi velocity  $v_F$  are not known for these small particles. With the bulk values  $\omega_p = 8.8 \text{ eV}$  and  $v_F = 1.39 \times 10^6 \text{ m/sec}$ , the best fit upon varying  $a$  (shown by the solid line in Fig. 1) yields a particle radius  $a = 4.2 \text{ nm}$ . This value is much lower than the physical nanocrystal radius of  $6.6 \text{ nm}$ . Several reasons for this discrepancy can be envisaged. First, the TEM images reveal that the gold nanoparticles generally consist of multiple crystalline domains. This enhances scattering of electrons and decreases the electron mean free path even further, compared with the bulk value. Furthermore, the radius obtained by fitting is very sensitive to  $\omega_p$  and  $v_F$ , the exact values of which are not known for these small particles. The shift of the surface plasmon resonance of nanocolloidal gold suspensions with varying dielectric constant of the solvent<sup>[24]</sup> yields a plasma frequency  $\omega_p = 9.9 \text{ eV}$ . The best fit with this value inserted into Eq. (4) yields  $a = 5.3 \text{ nm}$ . The sensitivity to the precise value of  $v_F$  is comparable.

The modified dielectric functions are shown in Fig. 2 by the solid lines; the inset depicts the corrections  $\text{Re}(\Delta\varepsilon)$  and  $\text{Im}(\Delta\varepsilon)$  of the real and imaginary parts, respectively. As mentioned above, the correction is largest at longer wavelengths and much more pronounced for  $\text{Im}(\varepsilon)$ . The calculated extinction coefficient using this modified dielectric function yields a broader but also lower peak. At longer wavelengths, between 550 and 800 nm, the tail of the extinction is much higher compared to that calculated using the bulk dielectric function, in agreement with experimental observations.

## OPTICAL CHARACTERIZATION OF COLLOIDAL ASSEMBLIES

### Spectroscopic Ellipsometry on Thin Island Films

Ellipsometry measures the ratio of the reflection coefficient of light polarized parallel,  $r_p$ , and perpendicular,

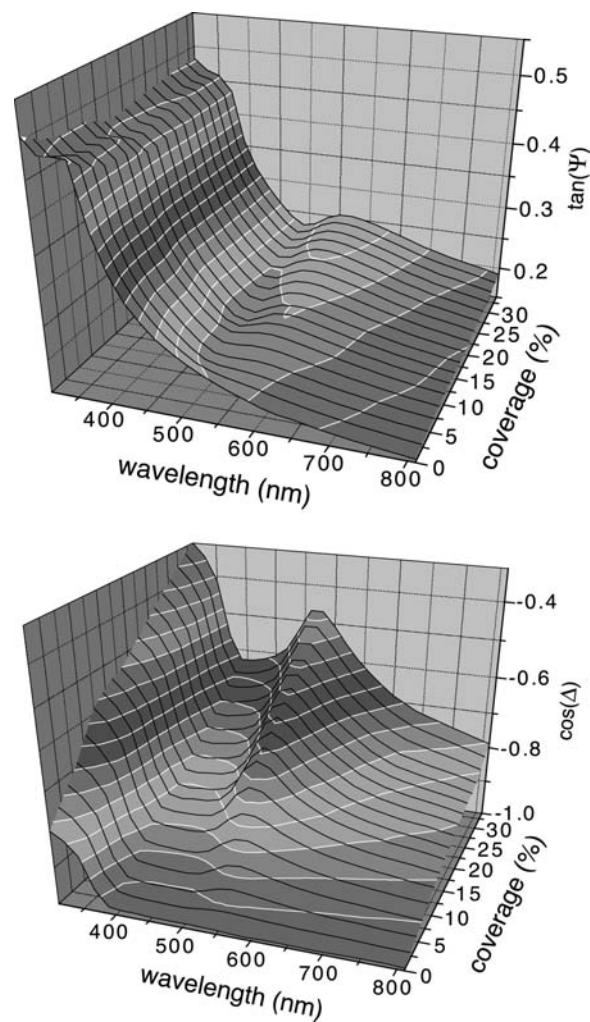

$r_s$ , to the plane of incidence.<sup>[25]</sup> The complex ratio  $\rho$  is defined as

$$\rho \equiv \frac{r_p}{r_s} \equiv \tan(\Psi) \cos(\Delta) \quad (5)$$

For a single interface,  $r_p$  and  $r_s$  represent the Fresnel reflection coefficients. Historically, the complex quantity  $\rho$  is expressed in the two angles  $\Psi$  and  $\Delta$ .

In our experiments, we used a homebuilt rotating polarizer spectroscopic ellipsometer equipped with a Xe lamp and a scanning monochromator.<sup>[26]</sup> Measurements are performed, both in situ during deposition and ex situ after deposition, in the visible region of the spectrum at wavelengths between 300 and 800 nm at a fixed incident angle of  $70^\circ$ .

Fig. 3 shows a 3-D representation of the evolution of ellipsometric spectra with increasing gold colloid coverages in the range from 0% to 35%. Absolute

**Fig. 3** Ellipsometry spectra measured for various coverages up to 40%. The 3-D representation of  $\tan \Psi$  and  $\cos \Delta$  gives a good view of the change in spectra with increasing coverage.

**Fig. 4** SEM images for three coverages as indicated in percent.

surface coverages are determined from SEM images such as those shown in Fig. 4 for three specific coverage values. The deposition of colloidal gold particles has a marked effect on the ellipsometry measurements. As expected for a thin layer of deposited material, the change in  $\cos \Delta$  is much more pronounced than the change in  $\tan \Psi$ . Apart from an increase in  $\cos \Delta$  over the entire wavelength range, a characteristic peak develops with increasing numbers of gold particles on the surface. The position of the peak maximum near 520 nm corresponds to the surface plasmon resonance of the gold colloids (Fig. 1).

### Analysis of Ellipsometric Spectra

Although the actual ellipsometry measurement is relatively simple, the analysis of the results is often complicated.<sup>[25,27]</sup> A model is required for the system under consideration, which can then be used to simulate or fit the results. The optical response of a multilayered structure with known dielectric functions can be simulated using the Abeles matrix algorithm. Details of the original method are described by Azzam and Bashara.<sup>[27]</sup> Two types of matrices are employed. One describes the transition from medium  $m$  to medium  $m + 1$  and is defined as

$$\mathbf{I}_{m,m+1} = \frac{1}{t_{m,m+1}} \begin{pmatrix} 1 & r_{m,m+1} \\ r_{m,m+1} & 1 \end{pmatrix} \quad (6)$$

with  $r_{m,m+1}$  and  $t_{m,m+1}$  the Fresnel reflection and transmission coefficients. Another matrix describes the light passage through the medium and involves the phase

factors

$$\mathbf{L}_m = \begin{pmatrix} e^{-i\Delta_m} & 1 \\ 1 & e^{-i\Delta_m} \end{pmatrix} \quad (7)$$

where  $\Delta_m = (2\pi/\lambda)d_m n_m \cos(\theta_m)$ , with  $\lambda$  the wavelength of the light in vacuum (nm),  $d_m$  the thickness of layer  $m$  (nm),  $\theta_m$  the angle of the light, and  $n_m$  the refractive index of medium  $m$ . The angles in the various media are related through Snell's law:  $n_m \sin(\theta_m) = n_{m+1} \sin(\theta_{m+1})$ .

For our system consisting of a colloidal gold layer ( $m = 2$ ) and a silicon dioxide film ( $m = 3$ ) on a silicon substrate ( $m = 4$ ) in contact with the ambient (air or aqueous solution;  $m = 1$ ), a matrix product is defined

$$\mathbf{A} = \mathbf{I}_{1,2} \mathbf{L}_2 \mathbf{I}_{2,3} \mathbf{L}_3 \mathbf{I}_{3,4} \quad (8)$$

and the overall reflection coefficient is calculated from  $r = A_{21}/A_{11}$ . For both the parallel and perpendicular polarizations the reflection coefficients  $r_p$  and  $r_s$  can be obtained by inserting the appropriate Fresnel coefficients in Eq. (6), and the ellipsometric ratio in Eq. (5) can be calculated.

### Effective Medium Theories

For homogeneous media the wavelength-dependent dielectric function is generally obtained from the literature or by performing an ellipsometric measurement on bulk material. However, determining the dielectric properties of inhomogeneous media consisting of different materials is not straightforward. Effective medium theories have been developed, which provide a relation between the effective dielectric function of the medium and the dielectric functions of its constituents.<sup>[20]</sup> For two types of spherical inclusions with sizes much smaller than the wavelength of light, one can write for the effective dielectric function  $\epsilon_{\text{eff}}$

$$\frac{\epsilon_{\text{eff}} - \epsilon_h}{\epsilon_{\text{eff}} + 2\epsilon_h} = f_a \frac{\epsilon_a - \epsilon_h}{\epsilon_a + 2\epsilon_h} + f_b \frac{\epsilon_b - \epsilon_h}{\epsilon_b + 2\epsilon_h} \quad (9)$$

with  $\epsilon_a$  and  $\epsilon_b$  the dielectric functions of the inclusions in a host matrix with  $\epsilon_h$ . The volume fractions of the materials are given by  $f_a$  and  $f_b$ . Replacing  $f_b$  by  $1 - f_a$  and substituting  $\epsilon_h = \epsilon_{\text{eff}}$  gives the EMA established by Bruggeman,<sup>[28]</sup> whereas inserting  $\epsilon_h = \epsilon_b$  corresponds to the Maxwell-Garnett<sup>[29]</sup> approximation. Both these approximations are commonly used in the description of an ensemble of adsorbed colloidal particles.<sup>[14]</sup>

The dielectric function of the colloidal layer can be mimicked using an EMA in combination with the surface coverage determined from SEM images. The volume fraction  $f$  in Eq. (9) for spherical particles is related to the surface coverage through  $\phi = 1.5f$ .

With the Abeles matrices in Eqs. (6) and (7) the optical response of our multilayered sample can be calculated and compared to the experimental spectra. In Fig. 5, the experimental ellipsometry result of a colloidal gold film with coverage  $\phi = 12\%$  is compared to calculations using the Bruggeman (dashed line) and Maxwell-Garnett (dotted line) EMAs. A thickness of 13.2 nm was used for the colloidal film with a volume fraction  $f = 8.0\%$ . In both simulations, considerable differences are observed in comparison with the experimental data. This is most clearly visible in  $\cos \Delta$ . Apart from being lower, the calculation using the Bruggeman EMA exhibits a shift of the peak maximum in  $\cos \Delta$ . The Maxwell-Garnett approximation yields a peak in  $\cos \Delta$ , which is in qualitative agreement with the experimental result, but is much too low. Increasing the volume fraction  $f$  (corresponding to a higher coverage) results in increasing discrepancy between the

**Fig. 5** Calculated ellipsometry spectra for a silicon/silicon oxide sample with 12% gold coverage. The Bruggeman (dashed lines) and Maxwell-Garnett (dotted lines) EMAs were used to model the dielectric function of the colloidal film with the fill fraction  $f = 8\%$ . The solid lines represent a calculation using the thin island film theory, including image dipoles and lateral interaction with a surface coverage equal to that obtained with SEM. The filled circles represent the ellipsometry data for a film with  $\phi = 12\%$ .

measured spectra and simulations with both the Bruggeman and the Maxwell-Garnett EMA.

### Thin Island Film Theory

The main problem associated with the aforementioned effective medium theories is that in their derivation it was assumed that the effective medium is isotropic in three dimensions. Obviously, this is no longer valid for the monolayer of nanocolloids considered here. A description of the optical properties of particulate films is provided by the thin island film theory as originally described by Bedeaux and Vlieger.<sup>[30,31]</sup> The various extensions of this theory describe the influence of image dipoles and the lateral distribution of the particulates and were also derived for non-spherical particulates. This theory describes the optical response of the constituent entities, which are small compared to the wavelength of the light, in terms of excess optical susceptibilities. Recently, Koper<sup>[14]</sup> and Bedeaux and Vlieger<sup>[17]</sup> published elaborate reviews on this theory. Böhmer, van der Zeeuw, and Kopel described an application of the theory to a reflectometry experiment.<sup>[12]</sup>

The optical response to an electromagnetic field of a particulate is, in a good approximation, described in terms of polarizabilities parallel and perpendicular to the interface, respectively,

$$\begin{aligned}\gamma &= \phi 4a\epsilon_a \frac{\epsilon - \epsilon_a}{\epsilon + 2\epsilon_a} \\ \beta &= \phi \frac{4a}{\epsilon_a} \frac{\epsilon - \epsilon_a}{\epsilon + 2\epsilon_a}\end{aligned}\quad (10)$$

where  $\epsilon$  and  $\epsilon_a$  represent the dielectric functions of the spheres (gold in this case) and the suspending medium (air/water) and  $\phi = n\pi a^2$  is the surface coverage with  $a$  the particle radius and  $n$  the particle density. The reflection and transmission coefficients depend on the polarization of the light and are given by

$$\begin{aligned}r_1^s &= \frac{X^s}{1 - X^s} \\ t_1^s &= \frac{1}{1 - X^s}\end{aligned}\quad (11)$$

for s-polarized light, with

$$X^s = \frac{\pi i \gamma}{\lambda n_1 \cos(\theta_1)}\quad (12)$$

and by

$$\begin{aligned}r_1^p &= \frac{X^p}{1 - X^p} - \frac{Y^p}{1 - Y^p} \\ t_1^s &= 1 + \frac{X^p + Y^p - 2X^p Y^p}{(1 - X^p)(1 - Y^p)}\end{aligned}\quad (13)$$

for p-polarized light with

$$X^p = \frac{\pi i \beta (n_1)^3 \sin^2(\theta_1)}{\lambda \cos(\theta_1)} \quad (14)$$

$$Y^p = \frac{\pi i \gamma \cos(\theta_1)}{\lambda n_1}$$

The Abeles film matrix for such a particulate film in terms of these reflection and transmission coefficients is given by

$$\mathbf{F} = \frac{1}{t_1} \begin{pmatrix} 1 & -r_1 \\ r_1 & t_1^2 - r_1^2 \end{pmatrix} \quad (15)$$

For our system the modified overall matrix becomes

$$\mathbf{A} = \mathbf{F} \mathbf{L}_F \mathbf{I}_{1,3} \mathbf{L}_3 \mathbf{I}_{3,4} \quad (16)$$

The layer matrix  $\mathbf{L}_F$  is identical to  $\mathbf{L}_m$  in Eq. (7), but with a phase factor  $\Delta = (2\pi/\lambda) h n_1 \cos \theta_1$ , where  $h$  is the height of the excess susceptibilities above the Fresnel interface. Often, the distance  $h = a$  between the bare substrate and the particle centers is used. Note that the film matrix  $\mathbf{F}$  is different from the interface matrix  $\mathbf{I}_{m,m+1}$  as for an interface  $r_{m,m+1} = -r_{m+1,m}$ , which is obviously not true for the reflection coefficients  $r_1^s$  and  $r_1^p$  of a thin particulate film.

The solid lines in Fig. 5 show  $\cos \Delta$  and  $\tan \Psi$ , calculated with the thin island film theory for a particulate film using a coverage  $\phi = 12\%$  in Eq. (10). Clearly, the measured features both in  $\cos \Delta$  and  $\tan \Psi$  are reproduced much better than with the Bruggeman or Maxwell-Garnett EMAs (dashed and dotted lines, respectively). Note that as mentioned in a previous section, we used a modified dielectric function for the gold. With the bulk values, a much higher peak in  $\cos \Delta$  is calculated, and the agreement between experiment and simulation is considerably worse.

Not only should the spectra be reproduced, but the coverage determined optically must also correspond to that measured by counting the particle density in SEM images such as those in Fig. 4. This comparison is shown in Fig. 6. The difference between the two ways of determining the coverage is enhanced in the bottom panel, which depicts the ratio of the optically determined coverage and the coverage determined with SEM. From these images, it is clear that for coverages below approximately 15%, the coverage is overestimated in ellipsometry, whereas above 15% it is underestimated. The latter arises because we neglected lateral interaction of neighboring particles, whereas the overestimation at low coverage arises because we neglected image dipole effects, i.e., the perpendicular interaction. The polarizabilities defined by Eq. (10) are thus regarded as due to noninteracting particles, i.e., the bare dipole.

Fig. 7 shows the measured ellipsometry spectrum of two comparable coverages. One of these spectra (filled

**Fig. 6** Comparison of the coverage determined with SEM and the one obtained from the thin island film theory, considering the colloids as noninteracting bare dipoles (top). The solid line indicates a one-to-one correspondence, whereas the dotted line serves as a guide to the eye. Also shown is the ratio of the optically determined coverage and the SEM coverage (bottom).

circles) shows a marked broadening of the plasmon feature in both  $\cos \Delta$  and  $\tan \Psi$ . This broadening is due to coagulation of the particles on the surface as is also observed with AFM and SEM. Coagulation of two or more particles leads to a shift in the plasmon energy<sup>[20]</sup> and is thus directly observed in the ellipsometry spectra. In the analysis presented in this entry, only spectra that do not show this broadening are considered. Coagulation can occur for various reasons such as an unstable solution because of a high salt concentration or an excess amount of APTES on the sample surface. The latter occurs if the substrate is not properly rinsed in methanol after immersion in APTES.

#### Image dipoles and lateral interaction

Yamaguchi, Yoshida, and Kinbara<sup>[32]</sup> and Bedeaux and Vlieger<sup>[30]</sup> considered the influence of image dipoles on the optical response of small particulates

**Fig. 7** Ellipsometric spectra measured with (filled circles) and without (open circles) coagulation. The best fit obtained with the thin island film theory for both cases is shown.

on a surface. Haarmans and Bedeaux considered the influence of the lateral distribution on the optical response.<sup>[33]</sup> The incorporation of image dipole effects and lateral interaction with neighboring particles leads to a modification of the one particle polarizabilities. Haarmans and Bedeaux<sup>[17,34]</sup> have shown that these changes are adequately described by an expansion of the potential distribution up to quadrupole order. The optical response is thus described as the response of an ensemble of non-interacting particles with effective polarizabilities  $\gamma$  and  $\beta$  given by:

$$\begin{aligned} \gamma_{qu} &= \phi \frac{4a\epsilon_a}{3} \\ &\times \frac{(\epsilon - \epsilon_a)(\epsilon_a + L1_p(\epsilon - \epsilon_a))}{(\epsilon_a + L_p(\epsilon - \epsilon_a))(\epsilon_a + L1_p(\epsilon - \epsilon_a)) + \Lambda_p(\epsilon - \epsilon_a)^2} \\ \beta_{qu} &= \phi \frac{4a}{3\epsilon_a} \\ &\times \frac{(\epsilon - \epsilon_a)(\epsilon_a + L1_z(\epsilon - \epsilon_a))}{(\epsilon_a + L_z(\epsilon - \epsilon_a))(\epsilon_a + L1_z(\epsilon - \epsilon_a)) + \Lambda_z(\epsilon - \epsilon_a)^2} \end{aligned} \quad (17)$$

Here,  $L_p$  and  $L_z$  represent the dipolar correction terms and  $L1_p$  and  $L1_z$ ,  $\Lambda_p$  and  $\Lambda_z$  are the quadrupole depolarization factors. Using

$$B_{sa} = \frac{\epsilon_a - \epsilon_s}{\epsilon_a + \epsilon_s} \quad (18)$$

with  $\epsilon_a$  the dielectric function of the substrate, these correction terms are given by:

$$\begin{aligned} L_p &= \frac{1}{3} \left( 1 + 2\sqrt{\frac{\pi}{5}} I_2(\phi) + 2\sqrt{\frac{\pi}{5}} B_{sa} I_{2r}(\phi) \right) \\ L_z &= \frac{1}{3} \left( 1 - 4\sqrt{\frac{\pi}{5}} I_2(\phi) + 4\sqrt{\frac{\pi}{5}} B_{sa} I_{2r}(\phi) \right) \\ L1_p &= \frac{2}{5} \left( 1 - \frac{8}{3}\sqrt{\pi} I_4(\phi) + \frac{8}{3}\sqrt{\pi} B_{sa} I_{4r}(\phi) \right) \\ L1_z &= \frac{2}{5} \left( 1 + 4\sqrt{\pi} I_4(\phi) + 4\sqrt{\pi} B_{sa} I_{4r}(\phi) \right) \\ \Lambda_p &= \frac{8}{35}\pi \left( I_3(\phi)^2 - B_{sa}^2 I_{3r}(\phi)^2 \right) \\ \Lambda_z &= \frac{24}{35}\pi \left( I_3(\phi)^2 - B_{sa}^2 I_{3r}(\phi)^2 \right) \end{aligned} \quad (19)$$

The integral quantities  $I_l$  and  $I_{lr}$ , with  $l = 2,3,4$ , take into account the spatial distribution of the nanoparticles on the surface in terms of the correlation function  $g(r)$ . Haarmans and Bedeaux<sup>[34]</sup> showed that up to 40% surface coverage, the specific lateral distribution has no influence on the optical response. This implies that the isotropic distribution can be used for the integral quantities providing analytical expressions for the quantities in Eq. (19):

$$\begin{aligned} I_2(\phi) &= -\sqrt{\frac{5}{4\pi}} \frac{\phi}{2} \\ I_{2r}(\phi) &= \sqrt{\frac{5}{4\pi}} \left( \frac{1}{8} - \frac{\phi}{4\sqrt{2}} \right) \\ I_3(\phi) &= 0 \\ I_{3r}(\phi) &= \sqrt{\frac{7}{4\pi}} \frac{1}{16} \left( -1 + \frac{\phi}{\sqrt{2}} \right) \\ I_4(\phi) &= \frac{3}{64\sqrt{\pi}} \phi \\ I_{4r}(\phi) &= \sqrt{\frac{9}{4\pi}} \frac{1}{32} \left( 1 - \phi \frac{3}{8\sqrt{2}} \right) \end{aligned} \quad (20)$$

In Fig. 8,  $\gamma$  and  $\beta$  are shown for both the bare dipoles and the modified values with up to quadrupole interactions taken into account. The strength of the image dipoles was evaluated by inserting the silicon dielectric function in Eq. 16. In the limit of zero coverage, because of the incorporation of the image dipole effect the slopes of the curves are different from those obtained using the bare dipole approximation. Above

**Fig. 8** Real and imaginary part of  $\gamma$  and  $\beta$  at 517 nm for the bare dipole approximation (dashed line) and after taking into account the influence of an isotropic distribution of colloids and their image dipole up to quadrupole order (solid line).

20%,  $\beta$  shows an overestimation in the bare dipole model, whereas for  $\gamma$  an underestimation is noted for all coverages. These two effects cancel each other for a coverage of about 20% and results in good correspondence between the optical and AFM-determined coverage. The image dipole effect is especially noteworthy because Si has a relative high dielectric function compared to many oxide materials commonly used as substrates. In this case,  $B_{sa}$  is  $-0.89$  at a wavelength of 517 nm, whereas for instance the value of  $B_{sa}$  for quartz is almost three times smaller. Fig. 9 shows the relation between the optical and SEM-determined coverages with and without the influence of the image dipoles and lateral interaction. The incorporation of these two effects leads to a significant improvement of the one-to-one relation that should exist between the coverage determinations.

#### Modified image dipole contribution

The Au colloids with radius  $a = 6.6$  nm are deposited on the 1.5-nm natural oxide layer of the silicon substrates. The silicon oxide interface is covered with an approximately 0.3-nm-thick layer of APTES, which gives a total layer thickness  $d = 1.8$  nm. This layer is only a fraction of the particle radius  $a$ , and gives rise to the question of where the image dipole is located, i.e., in the silicon oxide layer, in the silicon substrate, or in a combination of the two. The influence of the substrate choice for the image dipole contribution is also shown in Fig. 9. Assuming a pure silicon substrate gives rise to an underestimation of the optical coverage, whereas a pure  $\text{SiO}_2$  layer leads to an overestimation, a modification of the image dipole strength is thus required.

**Fig. 9** The coverage as determined with spectroscopic ellipsometry, analyzed by taking into account the lateral distribution and image dipole effects as a function of the coverage determined with SEM. The lateral distribution was evaluated for an isotropic distribution with silicon as the substrate for the image dipole (triangles), silicon oxide as the substrate for the image dipole (full star), a modified image dipole strength (open circle), and for the bare dipole approximation (full squares). The dotted line is a guide to the eye, whereas the full line reflects a one-to-one relation between the two coverages.

The strength of the image dipole contribution  $B(d)$  for a dipole placed at distance  $a + d$  above a homogeneous substrate falls off with  $[a/(a + d)]^3$ ,

$$\begin{aligned} B(d) &= -\frac{\varepsilon_s - \varepsilon_a}{\varepsilon_s + \varepsilon_a} \left( \frac{a}{a + d} \right)^3 \\ &= B_{sa} \left( \frac{a}{a + d} \right)^3 \end{aligned} \quad (21)$$

with  $\varepsilon_s$  and  $\varepsilon_a$  the dielectric functions of the substrate and ambient, respectively.<sup>[17]</sup> The strength of the image dipole contribution for our system is thus expected to be bound between values for the image dipole contribution given by a silicon substrate and that of a silicon oxide substrate, i.e., between  $B = -0.89$  and  $B = -0.365$ , respectively. For image dipoles, the value  $B$  is treated as a reflection coefficient.<sup>[35]</sup> An expansion with reflection and transmission coefficients of both interfaces combined with the attenuation factor given by the thickness  $d$  of the layer yields an effective image dipole strength

$$B^{\text{eff}}(d) = \frac{B_{la} + B_{sl} \left( \frac{a}{a + d} \right)^3}{1 + B_{la} B_{sl} \left( \frac{a}{a + d} \right)^3} \quad (22)$$

where  $B_{la}$  and  $B_{sl}$  represent the image dipole strengths for the thin layer–ambient and substrate thin layer, respectively. The value of  $B^{eff}$  is plotted as a function of the thickness of the  $\text{SiO}_2$  layer in Fig. 10. Only the real part of  $B^{eff}$  is considered because the imaginary part is negligible at a wavelength of 517 nm. The rapid change of  $B^{eff}$  with thickness leads to a considerably reduced value of the image dipole contribution already for thin oxide layers.

The influence of a thin silicon oxide layer on the polarizabilities  $\gamma$  and  $\beta$  is shown in Fig. 11. Especially for  $\beta$ , a marked difference is observed in both the real and imaginary parts. The most substantial difference is observed in the imaginary part of  $\beta$  in the 10–30% coverage range.

Fig. 9 shows the influence of the modified image dipole on the comparison of optical coverage and SEM coverage. The correction made by incorporating  $B^{eff}$ , yields a one-to-one correspondence between the optically and SEM-determined coverages.

## CONCLUSIONS

We have presented a detailed study of the optical properties of colloidal gold films assembled on naturally oxidized silicon derivatized with APTES. Knowledge of both the single-particle diameter and its polarizability is a prerequisite for a quantitative analysis of the surface coverage for in situ and ex situ

**Fig. 10** The value of the real part of  $B^{eff}$  at 517 nm as a function of thickness  $d$  of the  $\text{SiO}_2$  layer, normalized to the colloid radius  $a$ . The limit for  $d = 0$  is equal to the value for an air–Si interface and the limiting value for a large oxide thickness is equivalent to an air– $\text{SiO}_2$  interface. The dashed line indicates the value of  $d/a$  for a system considered here with  $d = 1.8$  nm and  $a = 6.6$  nm.

**Fig. 11** The influence of different substrates on the image dipole contribution for  $\gamma$  and  $\beta$ . Depicted are the results obtained assuming a Si substrate (solid line),  $\text{SiO}_2$  (dashed line), and the effective substrate for a  $d = 1.8$ -nm oxide layer (dotted line) as described in the text.

characterization with ellipsometry. The diameter of the particle is usually determined from TEM, although AFM or a combination of AFM and XRF provides useful alternatives. An absorbance measurement of the colloid solution gives an excellent basis for the determination of the one-particle polarizability. The polarizability of the Au nanocolloids used in this entry is influenced by the finite size of the colloid. This reduces the effective mean free path of the electrons. Using Mathiessen's rule, a relation between the bulk dielectric function and optical properties of a single Au nanocolloid can be established.

The standard analysis procedure of ellipsometric spectra of samples, such as our gold nanocrystal-on-silicon assemblies, involves an EMA for the dielectric function of the adsorbed colloid layer. However, both the commonly used Maxwell-Garnet and Bruggeman approaches lead to highly inaccurate results.

The thin island film theory developed by Bedeaux and Vlieger, which treats the deposited colloids as excess polarizabilities, allows an accurate calculation of the optical properties. The image dipole and the lateral interaction between the dipoles have to be taken into account. However, up to 40% coverage the details of the lateral distribution of the particles are of little importance. This allows the use of an isotropic distribution. The Au colloids were deposited on naturally oxidized silicon substrates. This implies that the radius of the colloid is three times larger than the thickness of the silicon oxide layer. A modification of the strength of the image dipole contribution is required to take into account the limited thickness of the oxide layer. Such a modification gives a one-to-one relation between

the optically determined and the SEM-determined coverage. This results in an excellent capability of optical techniques for both in situ and ex situ unambiguous characterization of colloid nanocrystal assemblies.

Self-Assembly –  
Self-Organized

## INTRODUCTION

Chirality is a subtle molecular property that has a profound impact in nature. A chiral object or enantiomer is defined as one that has a nonsuperimposable mirror image, in the same way that a left hand is related to a right hand. Although this geometric distinction may seem trivial, it plays a very significant role in a molecule's functionality and has especially important consequences for many biological molecules and pharmaceutical drugs. One of the more infamous and tragic examples of the role chirality plays in a molecule's functionality is the drug thalidomide, administered in the 1950s to pregnant women to alleviate nausea: It was discovered that only one enantiomer of thalidomide was safe whereas the other enantiomer caused severe birth defects. Pharmaceutical companies invest tremendous resources into synthesizing enantiomerically pure compounds or separating racemic compounds (where equal amounts of left- and right-handed molecules are present) into enantiomerically pure forms. Not only are enantiomers extremely difficult to separate, but they are also difficult to identify because all of their chemical properties—except for the direction in which they rotate plane-polarized light—are identical. Therefore classical chemical techniques such as nuclear magnetic resonance (NMR), circular dichroism (CD), and other forms of spectroscopy cannot identify the absolute chirality of a given molecule, and many techniques require some sort of chemical modification of the enantiomer (e.g., forming a diastereomer) to achieve even a relative differentiation between enantiomers.

Scanning tunneling microscopy (STM) has become an obvious and highly relevant technique with which to study chiral systems. The ability of the scanning tunneling microscope to observe molecules on an atom-by-atom basis with angstrom-level resolution makes it a natural choice for detailed, high-resolution studies of chiral molecules and chiral surface structures. The scope of STM studies on chiral systems is too large to be covered in a single article, and so here we focus on surface studies of physisorbed self-assembled monolayers at the liquid–solid interface (i.e., ambient conditions).

## OVERVIEW

This entry aims to explore the many different ways in which chirality affects surface structures. This discussion includes examples of chiral molecules forming interfacial domains that can be chiral or achiral, achiral molecules forming surface structures that possess 2-D chirality, and finally mixtures of chiral and achiral molecules that lead to interesting and often unexpected surface formations. The organization of this article is described below. In “Direct Determination of Chirality of Individual Molecules: 2-Br-Hexadecanoic Acid on Graphite,” we discuss the recent achievement of direct determination of chirality of individual molecules initially achieved by both Fang, Giancarlo, and Flynn<sup>[1]</sup> and Lopinski et al.,<sup>[2]</sup> and we focus on Fang et al.'s study of self-assembly of racemic 2-Br-hexadecanoic acid at the liquid–solid interface. This achievement was critical to the progress of using STM to study chiral systems and serves as a basis for much of the ensuing work described here. In “Self-Assembly of Chiral Molecules at the Interface,” we examine the wide variety of surface structures formed by chiral molecules (both enantiomers and racemates). We continue in “Self-Assembly of Achiral Molecules into Enantiomorphous Domains at the Interface” by discussing the fascinating topic of chiral surface structures formed by *achiral* molecules, and we focus on the specific example of self-assembly of hexadecanoic acid. Although this topic may seem peculiar at first, the imposition of two-dimensional order by the surface onto three-dimensional molecules has many symmetry-breaking properties that lead to a wealth of such systems. In “Achiral Molecules Mixed with Chiral Molecules and Their Effect on Self-Assembly,” we combine achiral molecules with chiral molecules to examine the effect of the former on self-assembly of chiral molecules. The case study explored mixtures of different-length unsubstituted fatty acids with racemic 2-Br-hexadecanoic acid at the liquid–solid interface.

Many of the studies described take advantage of molecules with chemical marker groups. Marker groups are chemical functional groups contained within

a molecular adsorbate that exhibit unusually high or low contrast in the STM topograph relative to the rest of the molecule. This unusual contrast can be used to locate particular functionalities within a given molecule. A number of physisorbed molecular systems that contain such markers have been successfully explored on graphite, and the unusual image contrast arises from both the functional group's topographic positioning and its electronic coupling to the surface. Finally, several of the investigations discussed here involve long-chain functionalized hydrocarbons, popular molecules for STM investigations of self-assembled monolayers physisorbed on graphite and MoS<sub>2</sub> surfaces. In general, these molecules lie flat on the substrate, and the hydrocarbon chains are in a *trans* orientation.

### DIRECT DETERMINATION OF CHIRALITY OF INDIVIDUAL MOLECULES: 2-BR-HEXADECANOIC ACID ON GRAPHITE

Individual molecules in a physisorbed self-assembled monolayer of racemic 2-Br-hexadecanoic acid [CH<sub>3</sub>(CH<sub>2</sub>)<sub>13</sub>CHBrCOOH] dissolved in phenyloctane solution were imaged at the graphite-liquid interface with an STM.<sup>[1]</sup> Previous studies on long-chain *n*-carboxylic acids have shown that these molecules physisorb on graphite with the hydrocarbons flat on the substrate and the carboxyl end groups oriented toward each other to facilitate hydrogen bonding. These studies also reveal that the carboxyl end group always appears with “darker” contrast compared to the rest of hydrocarbon chain, thus making the carboxylic acid functionality a *dark* chemical marker group.<sup>[1,3]</sup> Similarly, bromine atoms at a nonterminal position along the hydrocarbon chain or at a terminal position in the *gauche* conformation appear with bright contrast and are positioned “up” pointing away from the graphite surface,<sup>[4-6]</sup> making the bromine a *bright* chemical marker group.

An STM topograph of a pair of 2-Br-hexadecanoic acid molecules is shown in Fig. 1 accompanied by a schematic of the arrangement of the molecules.<sup>[1]</sup> The dark circles (found between the bright white spots) are unambiguously ascribed to the carboxylic acid groups marked as -COOH. The large “bright” spot (marked as Br in the figure) is attributed to the location of the bromine atom. Given the relative position of the bromine atom and the carboxyl group, the orientation of the rest of the alkyl chain is determined, as the bromine atom lies between the carboxyl group and the rest of the alkyl chain. Thus the alkyl chain associated with the lower of the two labeled bromine atoms (marked as Br in the figure) is represented by the lower set of numbers 1 to 14, where the numbers correspond to small topographic protrusions along the alkyl tail. These

**Fig. 1** Enlarged portion of a constant current image of *R*-2-bromohexadecanoic acid at the interface of a phenyloctane solution and the graphite basal plane. *Source:* From Ref. <sup>[1]</sup>. © 1998 by the American Chemical Society.

small spots are ascribed to the positions of those hydrogen atoms of the adsorbed hydrocarbon molecules protruding farthest out of the molecular plane.<sup>[7]</sup>

Based on the above assignment with bright bromine atoms sticking up,<sup>[4]</sup> the molecule can be easily identified as the *R*-2-Br-hexadecanoic acid because the relative positions of three of the four groups attached to the chiral carbon have been directly determined (Br, COOH, alkyl tail) and the fourth (hydrogen atom) is right beneath the bromine atom, as shown in Fig. 1. The atomic resolution obtained in this STM image has enabled us to determine the absolute configuration of a single organic molecule directly, i.e., without the help of any compound of known chirality. Similarly, Lopinski et al.<sup>[2]</sup> conducted a study of short-chain alkenes on silicon in ultrahigh vacuum and were also able to directly determine the chirality of the *SS* and *RR* enantiomers of adsorbed *trans*-2-butene on an Si(100) surface.

### SELF-ASSEMBLY OF CHIRAL MOLECULES AT THE INTERFACE

The resolution of a racemic mixture of chiral molecules into enantiomers was first observed by Louis Pasteur

in his famous experiment in 1848 on a solution of racemic sodium ammonium tartrate, which he resolved into enantiomorphic crystals.<sup>[8]</sup> This phenomenon translates to the 2-D interface where numerous examples exist of spontaneous resolution of racemic molecules into enantiomorphous domains possessing 2-D chirality, where an enantiomorphous domain is described as one possessing nonsuperimposable mirror-image morphology. Racemic 2-Br-hexadecanoic acid spontaneously resolves into domains that are mirror images of each other.<sup>[1]</sup> A racemic mixture of a binaphthalene dithiol compound on gold was also found to form domains of enantiomeric purity,<sup>[9]</sup> where the study of a self-assembled monolayer of a racemic mixture of 1,2-dihydroxyoctadecane revealed a lamellar-like alternation of enantiomeric purity.<sup>[10]</sup> Clusters of nitronaphthalene were enantiomorphic on the Au(111) image and the STM tip was used to manipulate and separate the enantiomorphic clusters in a molecular analog to Pasteur's experiment.<sup>[11]</sup> An extension of this study explored a coverage-driven, chiral-phase transition of nitronaphthalene clusters on gold.<sup>[12]</sup> An experiment that investigated the effects of the impact of different substrate structures on the packing of chiral molecules revealed that a racemic mixture of thiaheterohelicene on Au(111) resolved into chiral structures only on the steps and not on the terraces. However, many racemic mixtures do not resolve into enantiomorphous domains on a surface as shown for a racemic mixture of physisorbed secondary alcohol molecules<sup>[13]</sup> and formamide molecules at the interface.<sup>[14]</sup>

With the increasing synthetic ability to separate racemic molecules into pure enantiomers, a formidable challenge for chemists as so many properties of chiral isomers are identical, STM studies of chiral systems are not limited to racemic mixtures but also include investigations of enantiomerically pure substances. Enantiomerically pure formamide molecules are found to form enantiomorphous domains.<sup>[14]</sup> Similarly, chiral terephthalic acid derivatives<sup>[15]</sup> and their polymorphs<sup>[16]</sup> have been found to form enantiomorphous self-assembled monolayers. Many chiral liquid crystals also form enantiomorphous domains.<sup>[17]</sup> Conformations of chiral dendrimers have also been explored with STM.<sup>[18]</sup>

A discussion of self-assembly of chiral molecules should also include, at least briefly, the study of chiral surfaces. An elegant approach to formation of a chiral surface is described by Lopinski et al.<sup>[19]</sup> where the sterically hindered 1*S*(+)-3-carene molecule is demonstrated to enantiospecifically chemisorb onto Si(100) surface in a bonding arrangement that is predicted to be very stable. Although many other chiral surface structures formed by adsorbed molecules are described in this article, for the most part they are *physisorbed*, which makes them stable only in the specified liquid–solid

environment in which the experiments were conducted. A different approach to chiral surfaces is to form high Miller index surfaces of single metal crystals; such surfaces have been demonstrated to be chiral.<sup>[20]</sup> Enantiospecific chemical reactions of chiral molecules have also been explored on such chiral surfaces.<sup>[20–22]</sup>

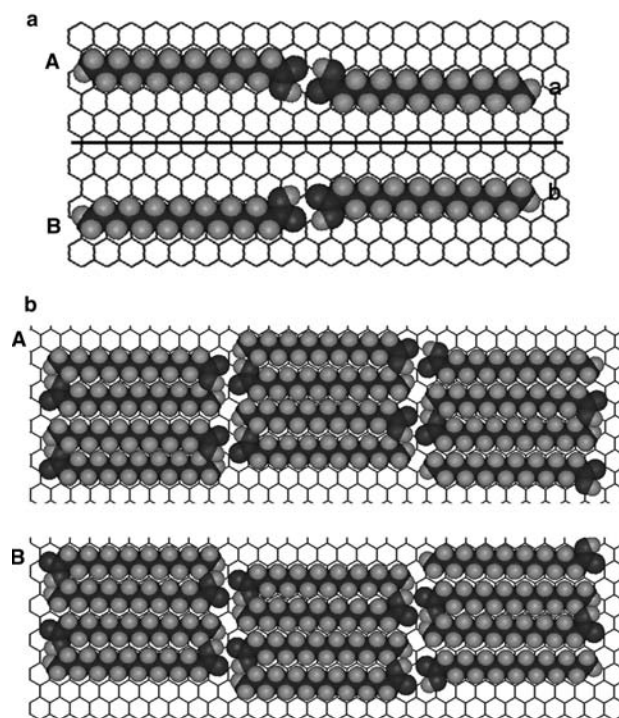

## SELF-ASSEMBLY OF ACHIRAL MOLECULES INTO ENANTIOMORPHOUS DOMAINS AT THE INTERFACE

Surfaces possess symmetry-breaking properties that affect the resultant surface structures formed by *achiral* molecules. Molecules that are achiral in three dimensions can form arrays on the surface that result in a 2-D chiral surface structure. A 2-D chiral surface structure is one in which the adsorbed molecule has a non-superimposable mirror image when the adsorbed molecule is *confined* to motion (i.e., rotation/translation) within the surface plane. This concept is illustrated further below as we examine the specific case of self-assembly of hexadecanoic acid at the graphite–liquid interface.<sup>[23,24]</sup>

Free hexadecanoic acid [ $\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$ ] is an achiral molecule that is always superimposable with its mirror image in three dimensions. This property dramatically changes when hexadecanoic acid is adsorbed onto a graphite surface, for now the molecule is fixed in a plane instead of being able to freely rotate in three dimensions. Two hexadecanoic acid molecules will adsorb onto a graphite surface in a manner that allows the carboxylic acid functional groups to hydrogen-bond together; Fig. 2a depicts a model with two such molecules whose conformations have been labeled “A”. When this pair is reflected through a mirror plane demarcated by the black line, the resultant molecules on graphite adopt the configuration labeled “B”, which (in the restricted two-dimensional world of the interface) is a nonsuperimposable mirror image of the “A” molecules on the surface. The surface ultimately drives hexadecanoic acid to self-assemble in two distinct enantiomorphous domains that possess 2-D chirality. Such 2-D chiral films are generally formed on a graphite surface for fatty acids with an even number of carbon atoms, but not for fatty acids with an odd number of carbon atoms. Two-dimensional arrays arising from the assembly of molecules configured in the “A” or “B” arrangements are presented in Fig. 2b.

Achiral molecules forming enantiomorphous domains on the surface is not an uncommon phenomenon and has been documented via high-resolution SPM studies. Other examples have been observed for discotic liquid crystals,<sup>[25]</sup> for a liquid crystal phase of achiral molecules investigated via optical microscopy,<sup>[26]</sup>

**Fig. 2** The two-dimensional chiral nature of achiral hexadecanoic acid physisorbed onto a graphite surface is shown in (a). The “B” molecules on graphite are the mirror image of the “A” molecules on the surface, reflected through the mirror plane indicated by a black bar. Hexadecanoic acid self-assembles into the two distinct enantiomorphous (possessing mirror-image morphology) domains depicted in (b). Source: From Ref. [24]. © 2000 by the American Chemical Society.

for calcium arachidate assembled on mica probed by atomic force microscopy (AFM),<sup>[27]</sup> for achiral formamide,<sup>[14]</sup> and for adenine molecules adsorbed onto molybdenum disulfide observed via STM.<sup>[28]</sup> Like fatty acids, 1-nitronaphthalene adopts a pseudochirality when adsorbed onto gold, which influences the formation of supramolecular clusters and chains.<sup>[29]</sup> Achiral diamide molecules form supramolecular lamellae that express chirality as observed by STM.<sup>[30]</sup>

### ACHIRAL MOLECULES MIXED WITH CHIRAL MOLECULES AND THEIR EFFECT ON SELF-ASSEMBLY

As discussed in the last three sections, chiral and achiral molecules can form a wide variety of surface structures that range from the formation of achiral surface domains by chiral molecules to enantiomorphous domains created by achiral molecules. This leads us to address the question of what happens when achiral molecules are mixed with chiral molecules? Such

studies have a vastly increased complexity because interadsorbate interactions play a role in determining the surface structure in addition to other adsorbate–adsorbate and adsorbate–surface interactions. Nevertheless, to date, several interesting studies have been undertaken to explore the effects of achiral molecules on self-assembly of chiral molecules. In some instances, the achiral molecules are simply represented as solvent that coadsorbs with the solute as in the work on isophthalic acid derivatives dissolved in 1-heptanol,<sup>[31]</sup> where the achiral molecules were found to express the chirality of the overall monolayer formed by the chiral solute. A similar phenomenon occurred in the study of substituted acids dissolved in alcoholic solvents.<sup>[32]</sup>

A particularly interesting study described below examines an odd/even effect of achiral unsubstituted fatty acids on the self-assembly of chiral 2-Br-hexadecanoic acid at the liquid–solid interface. The achiral molecules form a template that directs the chiral molecules to form interfacial domains either with enantiomeric purity<sup>[24]</sup> or domains with both enantiomers simultaneously present.<sup>[33]</sup> In the latter case, different templates can be chosen to create alternating lamellae of *R*- and *S*-2-Br-hexadecanoic acid or patterns with *R*- and *S*-2-Br-hexadecanoic acid stripes on the surface, thus allowing for the simultaneous detection of both enantiomers within one interfacial domain.

### Hexadecanoic Acid with Racemic 2-Br-Hexadecanoic Acid

Mixtures of the chiral molecule, 2-Br-hexadecanoic, with the achiral molecule, hexadecanoic acid, exhibit long-range order when physisorbed onto a graphite substrate. Multiple domains are formed extending in width from 30 nm to over 100 nm. Fig. 3A,C shows representative STM topograph for two different domains of a mixture of hexadecanoic acid with racemic 2-Br-hexadecanoic acid imaged at the phenyloctane–graphite interface. This image depicts well-ordered lamella separated by dark troughs. The troughs in Fig. 3A,C primarily contain dark circular regions that are sporadically accompanied by bright spots. The individual dark regions (topographical depressions) are assigned to the positions of pairs of hydrogen-bonding carboxylic acid groups<sup>[1,3]</sup> whereas the bright spots (topographical protrusions) correspond to bromine atoms, which appear bright when they are located at a nonterminal position along the hydrocarbon chain.<sup>[4,6]</sup> The presence or absence of the chemical marker bromine (bright) near the COOH (dark) group provides a straightforward and facile differentiation of the two chemical species in this mixture despite their similar lengths.

**Fig. 3** (A) An enlarged portion of a domain of racemic 2-Br-hexadecanoic acid with hexadecanoic acid imaged at the liquid–solid interface where all the brominated molecules are *R*-2-Br-hexadecanoic acid, accompanied by a corresponding model in (B). (C) A second domain of racemic 2-Br-hexadecanoic acid with hexadecanoic acid is shown where all the 2-Br-hexadecanoic acid molecules are identified as the *S* chiral conformers of the molecule with a corresponding model shown in (D). *Source:* From Ref. [24]. © 2000 by the American Chemical Society.

Note that unlike the 45° angle between the lamella direction and molecular axis present in pure 2-Br-hexadecanoic acid from Fang et al.'s work,<sup>[1]</sup> images of the 2-Br-hexadecanoic acid/hexadecanoic acid mixture display a 90° angle (marked by the arrows) between these two axes. Pure hexadecanoic acid self-assembles with a 90° lamellar–molecular axis angle. The 45° molecular–lamellar structure in racemic 2-Br-hexadecanoic acid is driven by favorable Br–Br attractive interactions, which here are effectively shut down in mixtures where the probability that two Br-containing molecules will be found adjacent to each other is low.

Two different domains are found on the surface, represented by STM images in Fig. 3A,C. The relative orientation of the bromine atoms to the carboxylic acid groups remains consistent throughout a single domain. All of the bromine atoms in Fig. 3a lie either above and to the left of the carboxyl group or below and to the right of the carboxyl group. Black lines have been superimposed on some of the individual carboxyl/bromine combinations to denote this arrangement. Fig. 3B presents a molecular model representation of this surface organization.

A different marker group positioning is found in the STM image of a second domain shown in Fig. 3C, where the bromine/carboxyl group orientation is the mirror image of that presented in Fig. 3A,B. Fig. 3D provides a molecular model representation of Fig. 3C where the orientation of the bromine/COOH orientation is marked by a black line.

Determination of the absolute chirality of individual 2-Br-hexadecanoic acid molecules has been described in detail elsewhere<sup>[1,4]</sup> and can be assigned from the relative orientations of the three dissimilar groups on the chiral carbon center that are all clearly present in the STM image—the bromine atom, carboxylic acid group, and the remainder of the alkyl chain. Thus the brominated molecules in Fig. 3A,B

are assigned as *R*-2-Br-hexadecanoic acid, and the brominated molecules in Fig. 3C,D are *S*-2-Br-hexadecanoic acid.

In summary, two phenomena clearly stand out in the self-assembled monolayer of a mixture of two coadsorbates, achiral hexadecanoic acid and chiral 2-Br-hexadecanoic acid. First, the ability to effect a specific self-assembly of 2-Br-hexadecanoic by introducing hexadecanoic acid into the solution has been demonstrated. The element of control for this feature is the “forced” opening of the angle between the molecular axis and the lamellar direction from 45° to 90° in the mixed self-assembly. Second, racemic 2-Br-hexadecanoic acid coadsorbed with hexadecanoic acid segregates into separate chiral domains when the solution is applied to a graphite surface. This phenomenon is attributed to a curious effect of the two-dimensional graphite surface on one element in the mixture, the achiral hexadecanoic acid molecules. In fact, physisorption of hexadecanoic acid on a graphite surface causes it to separate into two distinct domains that exhibit nonsuperimposable mirror-image morphology (enantiomorphous domains) as discussed in “Self-Assembly of Achiral Molecules into Enantiomorphous Domains at the Interface.” These enantiomorphous domains necessarily lead to a resolution of *R*- or *S*-2-bromohexadecanoic acid in the self-assembled monolayer when the mixture is physisorbed onto a graphite surface.

### Heptadecanoic Acid with 2-Br-Hexadecanoic Acid

Another example of the templating effect of achiral molecules on chiral molecules is observed in the mixture of heptadecanoic acid [ $\text{CH}_3(\text{CH}_2)_{15}\text{COOH}$ ] with racemic 2-Br-hexadecanoic acid. A mixture of heptadecanoic

**Fig. 4** (A) An  $18 \times 18 \text{ nm}^2$  STM constant-current topograph of a mixture of heptadecanoic acid with racemic 2-Br-hexadecanoic acid [ $\text{CH}_3(\text{CH}_2)_{13}\text{CHBrCOOH}$ ]. The brominated molecules in the (\*) troughs are identified as *R*-2-Br-hexadecanoic acid while those in the (-) troughs are *S*-2-Br-hexadecanoic acid. (B) A molecular model depicts a typical domain of a heptadecanoic acid/racemic 2-Br-hexadecanoic acid mixture. *Source:* From Ref. [33]. © 2002 by the American Chemical Society.

acid with racemic 2-Br-hexadecanoic acid forms well-ordered domains when physisorbed onto a graphite surface at the liquid–solid interface. A representative STM topograph is shown in Fig. 4A, where a single molecular length of heptadecanoic acid is depicted by a black bar and a single molecular length of 2-BrHA is marked by a gray bar. The chemical marker fatty acid groups (dark) and bromine atoms (bright) are again used to differentiate the two molecules on the surface.

The relative orientation of the bromine atoms to the carboxylic acid groups is identical in *alternating* troughs of this self-assembly pattern; black bars have been superimposed over the COOH/bromine orientation to highlight this configuration. For example, the bromine atoms (bright spots) in the troughs arbitrarily marked by (\*) are either below and to the right or above and to the left of the carboxylic acid group (dark round region). In contrast, the bromine atoms in the troughs arbitrarily marked by (-) are all either below and to the left or above and to the right of the

carboxylic acid groups. The relative positioning of the bromine atoms to the carboxylic acid groups in the (\*) troughs in Fig. 4A is the mirror image of the positioning of the bromine atoms to the carboxylic acid groups in the (-) troughs. Fig. 4B provides a molecular model based on a typical region of the self-assembled monolayer where the orientation of the carboxylic acid group with respect to the accompanying bromine in the alternating troughs is accordingly reflected. Thus, in these mixtures, each lamella is composed of alternating *R*- and *S*-2-Br-hexadecanoic acid molecules giving rise to the enantiomeric alternation along the starred (\*) and minus (-) troughs.

Determination of the absolute chirality of individual 2-Br-hexadecanoic acid molecules has been described in detail elsewhere.<sup>[1,4]</sup> Thus the brominated molecules that appear in those troughs arbitrarily marked by a (\*) are identified as *R*-2-Br-hexadecanoic acid, while the brominated molecules in the troughs arbitrarily marked by a (-) are readily recognizable as *S*-2-Br-hexadecanoic acid. In addition, a mixture of heptadecanoic acid with enantiomerically pure *R*-2-Br-hexadecanoic acid revealed a self-assembled structure where the bright spots (corresponding to brominated molecules) appear in every other trough.

### Longer-Chain Fatty Acid Templates with 2-Br-Hexadecanoic Acid

Self-assembled monolayers of mixtures of 2-Br-hexadecanoic acid with longer-chain fatty acids such as nonadecanoic acid and eicosanoic acid have also been studied with high-resolution scanning tunneling microscopy.<sup>[34]</sup> These mixtures reveal quasi phase segregation, as the length of the unsubstituted achiral fatty acid chain becomes significantly different from that of 2-bromohexadecanoic acid, resulting in a surface structure containing microdomains of brominated molecules and fatty acids. This is in contrast to mixtures of 2-Br-hexadecanoic acid with either hexadecanoic acid or heptadecanoic acid where these mixtures formed fully miscible surface structures.

An STM topograph of a mixture of 2-Br-hexadecanoic acid with nonadecanoic acid on graphite is shown in Fig. 5. Mixtures of 2-Br-hexadecanoic acid with both eicosanoic acid and nonadecanoic acid induce the formation of brominated “stripes” or bands within the greater domain of pure fatty acid; these bands are marked by a black arrow in Fig. 5. These bands are homochiral (meaning each band contains only one enantiomer), but which enantiomers are present depends on the length of the fatty acid template. So mixtures of 2-Br-hexadecanoic acid with eicosanoic acid form surface domains that will contain both *R*- and *S*-2-Br-hexadecanoic acid, while

80 nm

**Fig. 5** An  $80 \times 80$  nm constant-height topograph of a mixture of racemic 2-Br-hexadecanoic acid with nonadecanoic acid. The surface structure is dominated by dark troughs, which are composed of carboxylic acid groups of nonadecanoic acid. Bright spots appear in illuminated bands (highlighted by a black arrow), which are composed of single enantiomers of 2-Br-hexadecanoic acid (i.e., bands are homochiral).

mixtures with nonadecanoic acid form surface structures that contain either *R*- or *S*-2-Br-hexadecanoic acid. This quasi phase segregation is similar to the study of various coadsorbed fluorinated isophthalic acid derivatives where a difference in chain length of three carbon atoms induced formation of microdomains but coadsorbates with a difference in chain length of one carbon atom formed a miscible surface structure.<sup>[35]</sup>

## CONCLUSION

Scanning tunneling microscopy (STM) is a powerful and uniquely suited technique to study chiral surface structures with atomic resolution. In this article, we focus on 2-D chiral self-assembled monolayers formed at the liquid–solid interface. Systems composed of chiral molecules, achiral molecules, mixtures of chiral and achiral molecules, and inherently chiral surfaces have been discussed to reveal a part of the rich and diverse role chirality plays in influencing surface formations and self-assembled monolayers at the liquid–solid interface. Ongoing work in the area of STM investigations of chiral systems include expanding the pool of candidates that can be studied, useful applications of symmetry-breaking properties of surfaces, and a more complete understanding of the subtle effects

that chiral molecules and surfaces have on the self-assembly process.

# Self-Assembly of Coordination Cages

Laura Pirondini  
Enrico Dalcanale

Dipartimento di Chimica Organica e Industriale, Università di Parma, Parma, Italy

## INTRODUCTION

Why is self-assembly so appealing to nanoscience in general and nanotechnology in particular? One answer is, in Whitesides's words: "Self-assembly is one of the few practical strategies for making ensembles of nanostructures."<sup>[1]</sup>

The key issue in self-assembly is that the desired structures are quantitatively formed by simply mixing the programmed components under thermodynamic control. Unlike covalent synthesis, self-assembly is a reversible process. This is a very attractive feature because it allows the system to self-repair possible structural deficiencies.

## OVERVIEW

Of the self-assembly protocols developed so far, metal-directed self-assembly is particularly appealing as a result of the large number of structural motifs and bond energies that are available through coordination chemistry. The most important feature is the great directionality offered by metal–ligand coordinative bonds compared to weak electrostatic and  $\pi$ – $\pi$  stacking interactions or even hydrogen bonding. Moreover, coordinative metal bond offers great versatility due to different transition-metal complexes and multidentate ligands available as building blocks and to bond energies that are between the range of the strong covalent bond in carbon-based molecules and the weak interactions in biological systems. The final shape of the self-assembled entity is not only defined through the metal-complex coordination geometry, but also through the orientation of the ligand interaction sites.

Molecules with a wide variety of topologies and shapes have been constructed in this way, including boxes, cages, catenanes, dendrimers, grids, helicates, rotaxanes, and others. (For recent reviews on this topic, see Refs.<sup>[2–7]</sup>.)

Container molecules are unique among synthetic molecular receptors because of their peculiar encapsulation properties.<sup>[8,9]</sup> Guests of different sizes, shapes, and charges have been trapped within their interior in a timescale that can span from microseconds to

infinity. Desired features of container molecules comprise selectivity in guest encapsulation, control of guest orientation and dynamics within the cage, and reversibility, which allows guest uptake and release under controlled conditions. The ability of such container molecules to confine<sup>[10]</sup> and stabilize<sup>[11]</sup> their guests makes them particularly attractive for many potential applications, ranging from specific drug release to catalysis<sup>[12–14]</sup> and memory-storage devices.<sup>[15]</sup>

Metal-directed self-assembly has been employed to construct container molecules presenting internal cavities of molecular dimensions, capable of trapping ions and neutral molecules.<sup>[16]</sup> The need of highly preorganized, multidentate ligands presenting concave surfaces has led some researchers to resort to calixarenes (for the first report on calixarene-based coordination cages, see Refs.<sup>[17]</sup>; see also Ref.<sup>[18]</sup>) and cavitands (for the first report on cavitand-based coordination cages, see Ref.<sup>[19]</sup>) as source of rigid molecular scaffolds. The present account will focus on the design and self-assembly of cavitand-based coordination cages.

After a comprehensive survey of the literature in the field, the evolution of coordination cages in our group in terms of size, structure, and adaptability to different self-assembly conditions will be presented. Besides our own efforts, three other groups have engaged in the preparation, characterization, and complexation studies of cavitand-based coordination cages. They have in common the synthetic strategy adopted for the introduction of the ligands, which relies on functionalizing the apical positions of methylene-bridged cavitands.

Harrison and coworkers introduced four iminodiacetate moieties as chelating ligands (cavitand **I**, Fig. 1). Treatment with  $\text{CoCl}_2$  under basic conditions led to the formation of cage **IIa**, with the four octahedrally coordinated  $\text{Co(II)}$  connecting two cavitand **I** scaffolds.<sup>[20]</sup> Cage **IIa**, which has been structurally characterized, presents two very interesting features: 1) it is water-soluble; 2) the self-assembly process is pH dependent: At pH values below 2, the carboxyl groups and amine nitrogen atoms are protonated and do not coordinate  $\text{Co(II)}$  ions; upon addition of base at pH 5, cage **IIa** is formed. Taking advantage of the hydrophobic effect, they have been able to include several small lipophilic guests within the cage such

Fig. 1 Harrison's approach to cavitand-based coordination cages.

as aromatic molecules, alkanes, haloalkanes, and alcohols.<sup>[21]</sup> Large upfield shifts in the proton resonances (30–40 ppm) of the encapsulated guest are observed: Thus the cage behaves as a NMR (nuclear magnetic resonance) shift reagent for the included guest. Using the same cavitand ligand, the corresponding Fe<sub>4</sub> cage **IIb** has been prepared and structurally characterized.<sup>[22]</sup> These cages also form grids in the solid state.<sup>[23]</sup> The carboxylate groups bind cations such as Ca<sup>2+</sup>, Sr<sup>2+</sup>, and Ba<sup>2+</sup>, connecting the cages among them in the solid state. The resulting three-dimensional network formed presents channels and pores, whose size can be controlled by varying the cation size.<sup>[24]</sup>

Beer and coworkers have reported the metal-assembled synthesis of trimeric and tetrameric host

architectures **III** and **IV** assembled from dithiocarbamate (dtc) cavitand ligands and zinc or copper ions (Fig. 2).<sup>[25]</sup> In the case of **III**, the three cavitand cups provide the corners for an equilateral molecular triangle with two zinc ions positioned at the midpoints of each side. The Zn(II) ions coordinate two bidentate dtc moieties and a pyridine molecule. Treatment of the same cavitand ligand with Cu(II) acetate provided an intermediate Cu(II) complex that was oxidized to the octanuclear Cu(III) cages **IV**[I<sub>3</sub>]<sub>7</sub>[I]·6H<sub>2</sub>O by treatment with iodine. In this case, four cavitands lie at the apices of a distorted tetrahedron, and are connected to each other by eight Cu(III) ions. The novelty of this approach is in the formation of higher stoichiometric species with respect to the other cases, leading to wider

Fig. 2 (A) Hexanuclear Zn(II) complex **III**; (B) octanuclear Cu(III) complex **IV**.

Fig. 3 Solvent-driven equilibrium between cage VI and metalated cavitand V.

cavities and larger portals. The complexation properties in organic solvents of the trimeric cage III have been explored, using fullerene as guest.<sup>[26]</sup> The selectivity in binding C<sub>60</sub> has been attributed to the presence of 16 sulfur atoms that interact with the electron-deficient guest.

A third approach has been carried out by Hong and collaborators, connecting four pyridine ligands to the apical positions of a cavitand through methyleneoxy spacers. When the pyridyl nitrogen is *para* with respect to the spacer, coordination cages VI are formed upon exposure to square-planar metal precursors such as Pd(en)(NO<sub>3</sub>)<sub>2</sub>.<sup>[27]</sup> Evidences of cage formation come from vapor pressure osmometry <sup>1</sup>H NMR, and electrospray ionization mass spectrometry (ESI-MS) experiments, but these cages have not been structurally characterized yet. Cage VI binds positively charged *N*-alkylpyridinium derivatives in acetone solution as a result of strong cation- $\pi$  interactions. In this particular case, the self-assembly is solvent-dependent (Fig. 3): Cage VI formation is favored by apolar solvents, while cavitand complex V is formed as unique product in water solution.<sup>[28]</sup> This result seems to imply that the solvation of the inner space of cavitand-based coordination cages is pivotal for cage self-assembly.

## SELF-ASSEMBLY OF COORDINATION CAGES IN SOLUTION

### Nitrile-Based Coordination Cages

Among the coordination cages studied in our group, the archetype is cage of general structure 2, which is

composed of two tetracyanocavitand derivatives connected through four Pd(II) or Pt(II) square-planar complexes (Scheme 1).<sup>[19,29]</sup> Such cages were assembled by simply mixing cavitand 1 with different metal precursors MLX<sub>2</sub> [M = Pd, Pt; L = dppp, dppb, (PEt<sub>3</sub>)<sub>2</sub>;<sup>a</sup> X = CF<sub>3</sub>SO<sub>3</sub> (= OTf), BF<sub>4</sub>, PF<sub>6</sub>] in a 1:2 molar ratio. Multinuclear NMR spectroscopy (<sup>13</sup>C, <sup>31</sup>P, and <sup>19</sup>F), ESI-MS, matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry, and vapor phase osmometry (VPO) confirmed the dimeric structure of the cage with respect to the cavitand ligands. Their <sup>1</sup>H NMR spectra showed the complete absence of absorptions belonging to both precursors and the formation of a new set of signals, indicative of the presence of a single highly symmetric compound (*D*<sub>4h</sub> symmetry). The triflate counterions of all cages experience two different environments: Their <sup>19</sup>F NMR spectra exhibited two singlets in a 7:1 integral ratio, the bigger one at about -78 ppm, typical of non-coordinated ionic triflates, and a smaller one shifted upfield at about -82 ppm, indicative of the encapsulation of one triflate anion inside the cage.

Additional evidences for the self-assembly of the cages were obtained by using electrospray mass spectrometry (ESI-MS). (For studies of non-covalent aggregation by ESI-MS, see Refs.<sup>[30]</sup>.) Electrospray ionization mass spectrometry proved to be a powerful technique for the investigation of coordination cages in terms of 1) characterization; 2) individuation of

<sup>a</sup>Ligand abbreviations: dppp = 1,3-bis(diphenylphosphino)-propane; dppb = 1,3-bis(diphenylphosphino)-butane; dppe = 1,3-bis(diphenylphosphino)-ethane, dppm = 1,3-bis(diphenylphosphino)-methane; en = ethylenediamine.

**Scheme 1** Self-assembly of Pd and Pt cage molecules. *Source:* From Ref.<sup>[29]</sup>. © 2001 by the American Chemical Society.

competitive oligomeric species; and 3) presence of solvent molecules trapped within the cages. For **2a–e**, ESI-MS showed prominent [M-2CF<sub>3</sub>SO<sub>3</sub>]<sup>2+</sup> and [M-3CF<sub>3</sub>SO<sub>3</sub>]<sup>3+</sup> peaks.

Suitable crystals of **2d** for X-ray analysis were obtained from a dichloromethane–benzene solvent mixture (Fig. 4). The cage is filled with a single triflate anion, without any ancillary solvent molecule present.

The internal cavity resembles an oblate sphere: The long axis, defined as the distance between opposite Pt atoms, is 13.5(1) Å, the short axis is 12.1(1) Å and is defined as the distance between the centroids of the four resorcinarene methine carbons. These distances are in agreement with the dimensions of the cavity calculated using the Graphical Representation and Analysis of Structural Properties (GRASP)

**Fig. 4** X-ray crystal structure of cage **2d**. *Source:* From Ref.<sup>[29]</sup>. © 2001 by the American Chemical Society.

program.<sup>[31]</sup> The included triflate cannot escape from the lateral portals without breaking a coordinative bond.

### Control of the self-assembly process

The self-assembly process leads to coordination cages via formation of four square-planar transition metal complexes. The *cis* coordination geometry, a necessary condition for cage self-assembly (CSA), is imposed using dppp as chelating ligand. Therefore the following structural parameters have been examined as the key factors controlling the self-assembly process: (1) choice of chelating ligand, transition metal, and counterions of the metal precursor; (2) preorganization and stiffness of the tetradentate cavita nd ligand.

(1) The influences of the chelating ligand and of the type of metal have been analyzed by mixing cavita nd **1b** with organometallic triflate precursors **3a–h** and **4a**, under standard self-assembly conditions. The results are reported in Table 1. All the chosen complexes assume square-planar coordination geometry in solution, except for Ni(dppp)(OTf)<sub>2</sub>**3e**, which in solution is in equilibrium between the tetrahedral and square-planar forms.

The effect of varying the chelate ring size has been examined in the Pd series (entries 1,3,6,8). The results clearly indicate that the CSA is highly sensitive to distortion from the optimal square-planar arrangement of the four ligands provided by dppp, particularly when the P–M–P angle is smaller than 90°. In fact, in the case of dppb (**3h**, entry 8) partial cage formation was observed at 300 K, which became complete at 373 K. In the other two cases (entries 1 and 3), the CSA was completely suppressed at any temperature. The X-ray crystal structure of **2d** supports these results, showing almost no strain in the coordination sphere of the four Pt complexes. Likewise, exchange of dppp with dppe in the Pt complexes (compare entries 4 and 7) destabilizes

the cage with respect to open oligomers. The partial CSA observed in the case of **4a** to give cage **2g** (entry 9) at room temperature demonstrates that the absence of a chelating ligand destabilizes the cage with respect to alternative open species. The influence of the transition metal has been highlighted in the M(dppe)(OTf)<sub>2</sub> and M(dppp)(OTf)<sub>2</sub> series (entries 2–7). The observed trend in cavita nd nitriles coordination is Pt > Pd > Ni in accordance with the relative strength of the CN–M dative bonds.

Another basic factor to be considered for CSA is the selection of the counterions, which must be weakly coordinated to the metal precursor to allow the exchange with the nitriles of the cavita nd ligands. Cage self-assembly proceeded with noncoordinating counterions such as triflate, BF<sub>4</sub><sup>–</sup>, and PF<sub>6</sub><sup>–</sup>, but failed with the acetate, trifluoroacetate, and tosylate anions, which are too strongly coordinated to the metal to undergo ligand exchange with the nitriles.

(2) The preorganization of the cavita nd ligand is another essential ingredient of the self-assembly recipe. The influence of the rigidity of the tetradentate cavita nd ligand and the relative orientation of the four cyano substituents on the cage self-assembly have been evaluated introducing conformationally mobile ethylene-bridged cavita nds. In this case, CSA is possible only with Pt complexes, which provide sufficient coordinative strength toward nitriles to freeze the cavita nd in the required cone conformation. Their Pd analogs failed to give CSA under the same conditions (Table 2).

Also, in this case, inclusion of a single anion has been detected by <sup>19</sup>F NMR. A second interesting feature connected to the use of ethylene-bridged cavita nds is the temperature effect on CSA: In all cases, the process is partial at 300 K and complete only above 350 K. This different behavior points out that, in terms of preorganization of the cavita nd ligands, conformational rigidity is more important than optimal coordination

**Table 1** Cage self-assembly (CSA) using cavita nd **1b** as tetradentate ligand and organometallic precursors **3a–h**, **4a**

Entry	Organometallic precursor	Outcome
1	Pd(dppm)(OTf) <sub>2</sub> ( <b>3a</b> ) (72.7°) <sup>a</sup>	No CSA

geometry; in fact, ethylene-bridged cavitand ligands, despite having the perfect biting angle for CSA, require an entropic price to be frozen in the cone conformation necessary for CSA.

#### Thermodynamics and kinetics of the cage self-assembly

Calorimetric experiments were conducted in tetrachloroethane as solvent at different temperatures to quantify the enthalpic contribution to the self-assembly. In the case of cage **2d** at 298 K, the CSA process is strongly endothermic ( $\Delta H^0 = +57.7 \pm 0.7 \text{ kJ mol}^{-1}$ ); therefore cage formation is *entropy driven*. (For the thermodynamics of self-assembly, see Refs.<sup>[32,33]</sup>). The endothermic nature of CSA can be rationalized in terms of desolvation of the cage components and particularly of the included anion in the self-assembly process, which leads to the entropic overriding of the unfavorable positive  $\Delta H^0$  of formation. The enthalpic opposition has been explained by taking in account the large enthalpic costs associated with ion desolvation.

As the anion exchange experiments require dissociation/recombination of the coordination cages, the kinetic stability of Pd and Pt cages deserves special attention. A rough estimate of the dissociation/recombination timescale can be obtained by monitoring the ligand exchange between a preformed cage and a competitive ligand. This estimate, although not

accurate, is sufficient for the purpose of choosing the optimal anion exchange conditions. (For a detailed NMR study of the exchange process in hydrogen-bonded cal[4]arenes capsules, see Ref.<sup>[34]</sup>). Two set of experiments were directly performed in the NMR tube. Addition of cavitand **1c** to a CDCl<sub>3</sub> solution of cage **2b** at 300 K led to the immediate formation of three new species in solution, identified as cavitand **1b**, Pd heterocage [**1b**(Pdcomplex)<sub>4</sub>**1c**], and Pd homocage [**1c**(Pdcomplex)<sub>4</sub>**1c**], respectively, and to the decrease of **2b**. In the same experiment performed on Pt cage **2d**, the ligand exchange is negligible immediately after the addition, with an equilibration time of over 4 hr at 300 K. The same experiment, repeated at 330 K, led to immediate ligand exchange. Therefore the dynamics of dissociation/recombination, slow on the NMR timescale in both cages, is fast on the human timescale at ambient temperature only for **2b**, a further evidence of the greater strength of the Pt–NC dative bond compared to that of Pd–NC.

Control of the self-assembly process was achieved through metal–ligand exchange (Scheme 2). Addition of eight equivalents of a competing ligand such as triethylamine to preformed **2d** led to complete and clean disassembly of the cage into its cavitand components and [Pt(dppp)(NEt<sub>3</sub>)<sub>2</sub>(OTf)<sub>2</sub>]. Subsequent addition of eight equivalents of triflic acid restored the original Pt complex, which immediately quantitatively reassembled the cage.

### Selectivity in anion encapsulation

The Born equation<sup>[35]</sup> allows to estimate the free energy of solvation of an ion of radius  $r$  (Å)<sup>b</sup> and charge  $z$  in a given solvent. For monovalent anions such as  $BF_4^-$ ,  $PF_6^-$ , and  $CF_3SO_3^-$  in chloroform, we have  $\Delta G_{m,solv}^\circ = -550 r^{-1} \text{ kJ mol}^{-1}$ . Because encapsulation requires desolvation of the anion, our expectation was that inclusion selectivity in a given cage would have been dictated by the relative enthalpy of solvation of the anions, thus favoring the larger, less-solvated ones. Accordingly, in our case, the predicted selectivity should have been  $CF_3SO_3^- > PF_6^- > BF_4^-$ . Two trends are observed: 1) at 300 K in the presence of stoichiometric amounts of the competing ion, the encapsulation preference is in the order  $BF_4^- > CF_3SO_3^- \gg PF_6^-$ , which becomes complete for  $BF_4^-$  in the presence of an excess of  $(NBu_4^+)$  ( $BF_4^-$ ); 2) at 333 K under stoichiometric conditions, the slight prevalence of  $BF_4^-$  vs.  $CF_3SO_3^-$  is reversed in favor of the latter. The discrepancy between observed and expected selectivity in anion encapsulation led us to further investigate the matter both experimentally and via computer modeling. Once again, ESI-MS turned out to be a very valuable investigation tool, enabling to detect the presence of solvent molecules trapped within the cages.<sup>[36]</sup> For all cages having  $CF_3SO_3^-$  and  $PF_6^-$  as counterions, ESI-MS gave  $[M-2X]^{2+}$  and  $[M-3X]^{3+}$  as prominent ions, both in chloroform and acetone as solvents, while in the case of  $BF_4^-$  the base peaks correspond to the  $m/z$  values expected for  $[CHCl_3@M-2BF_4]^{2+}$ ,  $[CHCl_3@M-3BF_4]^{3+}$ ,  $[acetone@M-2BF_4]^{2+}$ , and  $[acetone@M-3BF_4]^{3+}$ , respectively.

<sup>b</sup>Even if the Born equation is strictly valid only for spherical ions, it also gives a good approximation of  $\Delta G_{m,solv}^\circ$  for non-spherical ones.

These results imply that there is enough room in the cavity for one molecule of solvent only in the case of encapsulated  $BF_4^-$ , while in the other two cases the anion is included alone, as proven in the case of  $CF_3SO_3^-$  by the crystal structure. These findings were confirmed by molecular modeling carried out using the GRASP program. Only for  $BF_4^-$  is the cavity sufficiently wide to accommodate an ancillary solvent molecule, thus reducing the enthalpic cost required for the desolvation of  $BF_4^-$ . This renders  $BF_4^-$  the preferred encapsulated anion at 300 K. The change in selectivity observed upon increasing the temperature to 333 K is the result of the higher-cage occupancy factor of  $BF_4^- \cdot CHCl_3$  with respect to  $CF_3SO_3^-$ . At higher temperatures, the entropic term favors  $CF_3SO_3^-$ , as its movements are less restricted in the confined space of the cavity with respect to the couple  $BF_4^- \cdot CHCl_3$ . This additional entropic cost for  $BF_4^- \cdot CHCl_3$  is sufficient to reverse the selectivity pattern observed at 300 K.

This first class of coordination cages gave us the possibility of exploring and understanding the main factors driving CSA. The following structural parameters have been found to be the key elements controlling CSA: 1) a P–M–P angle close to 90° between the chelating ligand and the metal precursor; 2) square planar Pd and Pt as metal centers; 3) a weakly coordinated counterion; 4) preorganization of the tetradentate cavitated ligand.

On the other side, this CSA protocol has some limitations. The major ones are:

1. The internal volume of this first type of cages is only  $250 \text{ \AA}^3$ , which is not sufficient to include guests of nanosize dimensions.
2. Cage self-assembly is highly sensitive to distortion from the optimal square-planar arrangement: Chelating ligands in the metal precursors with

L–M–L angle close to 90° are required. For this reason, dppp ligands are favored with respect to dppb; no self-assembly has been observed in the case of dppe, dppm, and ethylenediamine.

- The nitrile ligands require weakly coordinating counterions to enter the coordination sphere of the metal; for example,  $\text{CF}_3\text{SO}_3^-$ ,  $\text{PF}_6^-$ ,  $\text{BF}_4^-$  worked, whereas  $\text{CH}_3\text{CO}_2^-$ ,  $\text{PhCOO}^-$ , and  $\text{CF}_3\text{CO}_2^-$  did not.
- Only a limited pool of solvents is compatible with CSA: Many solvents such as  $\text{CH}_3\text{CN}$  and dimethyl sulfoxide (DMSO) compete with nitriles for coordination to the metal centers, reducing the applicability of this methodology.

### Enlarged Nitrile-Based Coordination Cages

The demand for cages with internal cavities of nanoscopic dimensions, able to encapsulate large guests or be used as reaction chambers, can be fulfilled either by increasing the number of self-assembled components<sup>[37,38]</sup> or by enlarging the size of the reacting ligands. Following this second approach, self-assembly of nanosize coordination cages **7a–b** using tetradentate cavitand ligands **6a–b** is reported. Phenyl groups were chosen as spacers introduced at the upper rim of **6** to extend the cavity size<sup>[39]</sup> while retaining the relative orientation of the cyano groups and the rigidity of the cavitand framework, both essential for cage formation. Tetracyanophenyl cavitands **6a,b** were synthesized by a known procedure from the corresponding

tetrabromophenyl cavitands<sup>[40]</sup> through reaction with  $\text{CuCN}$  in 1-methyl-2-pyrrolidinone (NMP).

As in the previous case, cages **7a–b** were obtained in quantitative yield mixing **6a–b** with  $\text{Pt}(\text{dppp})$  ( $\text{CF}_3\text{SO}_3^-$ )<sub>2</sub> in a 1:2 molar ratio in dichloromethane at room temperature (Scheme 3). The less-soluble cage **7a** precipitated out of the solution and was collected in pure form by filtration.

No permanent inclusion of the  $\text{CF}_3\text{SO}_3^-$  counterions was observed by <sup>19</sup>F-NMR even at low temperature. Rapid exchange with solvent molecules occurs as a result of the large dimensions of the lateral portals. Their dimensions as well as the internal cavity volume were evaluated by modeling the cage structure. The internal volume is ca. 1100 Å<sup>3</sup>, over four times that of its short analog.

Deepening the cavitand precursor while retaining the relative orientation of the cyano groups and the rigidity of the cavitand framework has proved to be a viable strategy for the preparation of large coordination cages. The drawback of such approach lies in the reduced stability of these larger cages as a result of the lability of the CN–M coordinative bond.

### Pyridine-Based Coordination Cages

To overcome this limit, a strong metal–ligand interaction is necessary to operate cage self-assembly in a wide range of solvents. To this purpose, we designed and synthesized new cavitands bearing pyridines (for references on cages derived from multidentate pyridine

**Scheme 3** Self-assembly of cages **7a,b**. Source: From Ref.<sup>[39]</sup>. © 2001 by Elsevier Science Ltd.

**Fig. 5** X-ray crystal structure of the phenethyl cavitand **8b**. Source: From Ref.<sup>[44]</sup>. © 2002 by the National Academy of Sciences.

ligands, see Refs.<sup>[41–43]</sup>) instead of nitriles as ligands for the coordination to the metal centers.<sup>[44]</sup> The pyridyl groups are positioned on the bridging units and not on the apical positions of the resorcinarene.

The synthesis of these deep-cavity cavitands,<sup>[45]</sup> of general structure **8a–b**, was performed by bridging the corresponding resorcinarenes with 4-( $\alpha,\alpha'$ -dibromo-methyl)pyridine.

In all cases, the low yields (10–12%) of the desired (oooo) isomer with the four pyridyl groups pointing outward (o) the cavity are due to the competitive formation of useless isomers having one (iooo) or two (iioo, ioio) pyridyl groups pointing inward (i). The correct stereochemical assignment of the oooo isomer has been confirmed by the X-ray crystal structure of cavitand **8b** (Fig. 5). From the crystal structure of the tetradentate cavitand, it is possible to evaluate the  $\alpha$  angle of the pyridyl ligands relative to the  $C_{4v}$  symmetry axis: The estimated value is  $42^\circ$ , close to the ideal value of  $45^\circ$  required for the formation of strainless square-planar complexes. Therefore the cavitand ligand is correctly preorganized for CSA.

The typical procedure for cage formation is shown in the case of cavitands **8a** and **8b** and various metal precursors  $MLX_2$  ( $M = Pd, Pt; L = dppp, en; X = CF_3SO_3, NO_3$ ) (Scheme 4): By mixing the two components in a 1:2 molar ratio at room temperature in solvents such as  $CH_2Cl_2, CHCl_3, acetone, or DMSO$ , cages **9a–h** were obtained in quantitative yields. In all cases,  $^1H$  NMR spectra showed the formation of a

**Scheme 4** Self-assembly of cages **9a–h**. Source: From Ref.<sup>[44]</sup>. © 2002 by the National Academy of Sciences.

new set of signals, indicative of the presence of a single highly symmetric compound ( $D_{4h}$  symmetry).

The intramolecular CSA process is the only one detected via  $^1\text{H}$  NMR (Fig. 6): Adding slightly less than 1 eq. of  $\text{Pd}(\text{en})(\text{NO}_3)_2$  to a solution of cavitant **8b** led to the formation of a mixture of Pd-cage and free cavitant. After the addition of the second equivalent of metal precursor, the  $^1\text{H}$  NMR spectrum showed the signals of cage **9h** as the only product.

**Fig. 9** (A) Cage **9b** in the presence of an excess of  $\text{NEt}_3$  at 300 K; (B) partial disassembly of the cage (C) into its cavitand component (L) after heating at 323 K for few minutes. Source: From Ref.<sup>[44]</sup>. © 2002 by the National Academy of Sciences.

The robustness of the M–Py coordination allowed to perform CSA in polar and competitive solvents such as DMSO or acetonitrile, where the nitrile-based coordination cages immediately decompose. The solubility properties of cages **9a–h** can be tuned by appropriately choosing the counterion, chelating ligand, and R substituents at the lower rim of the cavitand ligand. In particular, the solubility of the cages in DMSO or even in DMSO/ $\text{H}_2\text{O}$  mixtures (up to 3:1 ratio) has been achieved by introducing the highly hydrophilic  $\text{NO}_3^-$  counterion as in the case of **9d** and **9h**. The different solubility properties of the cage components have been exploited to perform CSA in a liquid–liquid two-phase system. In a typical experiment, cavitand **8b** (1 eq.) dissolved in 1,1,2,2-tetrachloroethane was exposed to an aqueous solution of  $\text{Pd}(\text{en})(\text{NO}_3)_2$  (2.5 eq.) in a test tube (Fig. 7). A solid immediately formed at the interface, which became more abundant over time.  $^1\text{H}$  NMR analysis of the recovered solid indicated the formation of cage **9h** in pure form. A MALDI-TOF experiment directly performed on the solid sample confirmed the attribution, ruling out the possibility of the formation of a sheet-like network at the interface.<sup>c</sup> This last result is particularly interesting because

<sup>c</sup>In principle, a sheet-like network that contains both components in a 2:1 ratio could also form at the interface and subsequently rearrange into cage **9h** upon dissolution in DMSO.

liquid–liquid interfaces represent another potentially useful field of action for self-assembly protocols, which has barely been explored so far.<sup>[46]</sup>

We were able to obtain good crystals of the  $\text{Pd}(\text{dppp})(\text{OTf})_2$ -cage **9f** from an acetone solution of the cage (Fig. 8). A preliminary X-ray crystal structure of the cage shows the formation of four square-planar complexes. The cavity can be accessed through the four large lateral portals, of 12.3 Å (close Pd–Pd distance)  $\times$  10.8 Å (apical Ar–Ar distance), large enough to allow the entrance/egress of solvent molecules as well as triflate anions, in accordance with  $^{19}\text{F}$  NMR experiments. The dimensions of the internal cavity turned out to be 17.2  $\times$  15.7 Å. Calculations by GRASP highlight the larger dimensions of these pyridine-based cages with an internal volume of 840 Å<sup>3</sup>, which are over three times bigger with respect to the corresponding nitrile-based ones (250 Å<sup>3</sup>).

Several attempts to disassemble Pt and Pd cages were performed. Pd cage **9b** was disassembled into its cavitand component and  $[\text{Pd}(\text{dppp})(\text{NEt}_3)_2(\text{CF}_3\text{SO}_3)_2]$  in the presence of an excess of  $\text{NEt}_3$  as competitive ligand (32 eq.) at 323 K (Fig. 9), whereas, under the same conditions, the  $^1\text{H}$  NMR spectrum of the corresponding Pt cage **9a** remained unchanged. This is consistent with the greater Pt–N bond strength with respect to that of Pd–N.

The kinetic stability of the Pt cages<sup>d</sup> has been assessed via ESI-MS. A ligand-exchange experiment was performed starting from two Pt cages, **9a** and **9e**, different for the chains at the lower rim (R =  $\text{C}_{11}\text{H}_{23}$  and  $\text{CH}_2\text{CH}_2\text{Ph}$ ): Both cages were separately analyzed via ESI-MS, showing  $[\text{M}-2\text{CF}_3\text{SO}_3]^{2+}$ ,  $[\text{M}-3\text{CF}_3\text{SO}_3]^{3+}$ , and  $[\text{M}-4\text{CF}_3\text{SO}_3]^{4+}$  ions. Then they were mixed in a 1:1 molar ratio at room temperature, giving a spectrum resulting from the simple addition of the signals owing to the two homocages. Upon heating the mixture, the ESI-MS spectrum exhibited a third set of peaks belonging to the heterocage in a statistic 1:2:1 ratio with the signals of the homocages.

### Suppressing cage self-assembly

Introduction of methyl groups at the apical position of the resorcinarene completely switched off the CSA process. Addition of three different precursor complexes, such as  $\text{Pt}(\text{dppp})(\text{CF}_3\text{SO}_3)_2$ ,  $\text{Pd}(\text{dppp})(\text{CF}_3\text{SO}_3)_2$ , and  $\text{Pt}(\text{PET}_3)_2(\text{CF}_3\text{SO}_3)_2$ , to a solution of **10** resulted in the precipitation of stone-like oligomeric species only slightly soluble in most organic solvents (Scheme 5). The

<sup>d</sup>Dynamic interconversion of similar square-planar Pd(II) complexes with pyridyl cycloveratrylenes has been shown by Shinkai et al. to occur at room temperature.<sup>[47]</sup>

$R=C_3H_{11}$ ;  $MLX_2=Pt(dppp)(CF_3SO_3)_2$ ,  $Pd(dppp)(CF_3SO_3)_2$ ,  $Pt(PEt_3)_2(CF_3SO_3)_2$ .

**Scheme 5** Oligomeric self-assembly with cavitand **10**.

experiment has been followed by  $^1H$  NMR: The solution became heterogeneous as soon as the first equivalent of metal precursor was added and the spectrum showed a broadening of all the peaks, indicative of oligomer formation. No significant changes were observed by adding the second equivalent of precursor complexes or after heating. This is an evidence of how sensitive CSA is to the preorganization of the molecular components: In fact, a further requirement for efficient CSA is the conformational freedom of the four diverging pyridine ligands, to allow the formation of strainless square-planar connecting units. The presence of the methyl groups at the apical position forces the pyridine ligands to

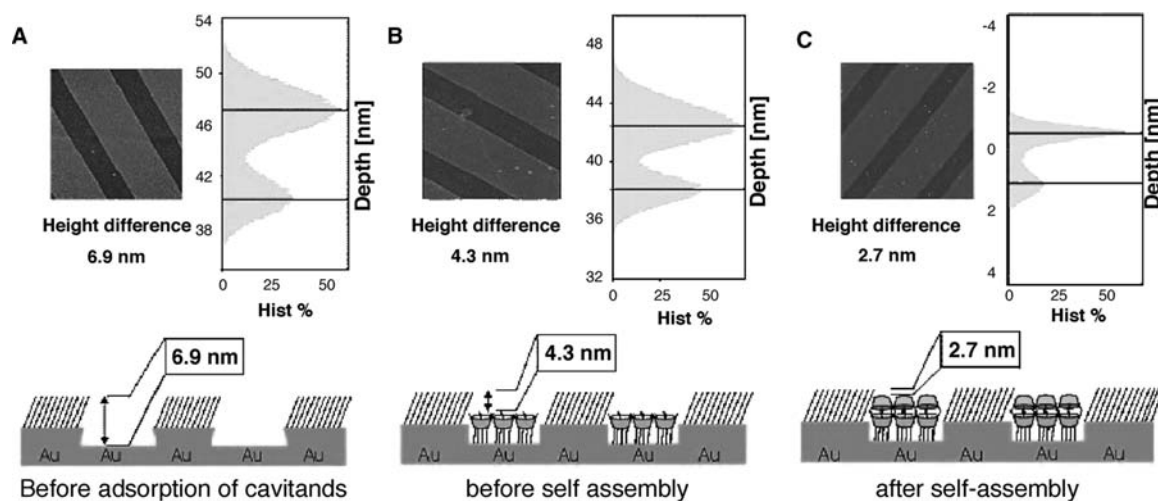

preferentially assume a tilted orientation with respect to the cavity, hampering cage self-assembly, and instead favoring oligomerization via the formation of square-planar complexes among several cavitand ligands.

### SURFACE-DIRECTED SELF-ASSEMBLY OF COORDINATION CAGES

The idea behind this approach is to exploit the thermodynamic control and reversibility of CSA for the generation of three-dimensional architectures directly on surfaces, which is one of the key requirements for the

**Fig. 10** Representation of the self-assembly reaction that leads to the formation of cages on a SAM.

**Fig. 11** Self-assembly of coordination cages on  $\mu$ -CP substrates. The AFM picture, the corresponding histogram, and a schematic representation of the surface is shown for each. *Source:* From Ref.<sup>[49]</sup>. © 2001 by Wiley-VCH.

development of nanotechnology and molecular electronics.<sup>[48]</sup> The clean, precise, and reversible modification of surfaces represents an important opportunity to expand the application range of self-assembly.

Our group, in collaboration with Reinhoudt et al.,<sup>[49]</sup> have recently reported an intriguing example of generation of coordination cages directly on surfaces by using self-assembled monolayers (SAMs) as molecular platforms. At first, monolayers of **11** were prepared by adsorption of the thioether chains on gold surface; then, self-assembly of the cages occurred directly on the SAMs through the addition of a solution of **1a**, and of Pd(dppp)(OTf)<sub>2</sub> (cage **12a**) in one case and Pt(dppp)(OTf)<sub>2</sub> (cage **12b**) in the other (Fig. 10). The formation of these cages on SAMs of **11** was proven by contact angle measurements, electrochemistry, X-ray photoelectron spectroscopy (XPS), and atomic force microscopy (AFM).

A series of control experiments were performed to prove that self-assembly of the cages occurs on the surface of the SAMs via metal coordination. Treatment of the SAM of **12a** with triethylamine shifts the equilibrium toward the formation of M(dppp)(NEt<sub>3</sub>)<sub>2</sub>(OTf)<sub>2</sub> plus uncomplexed cavitand **11**. Complete disassembly of the cages on the SAM was monitored by electrochemistry, in full agreement with the expectations.

The formation of the molecular cages was directly monitored by atomic force microscopy (AFM). For this purpose, microcontact-printed templates were created using standard soft lithography methods.<sup>[50]</sup> These templates showed the presence of very regular features over large areas (Fig. 11). Stripes with a lower height correspond to areas exposing bare gold, while stripes with a higher topographic profile are covered by the SAM of 11-mercaptoundecanol. After deposition of a monolayer of cavitand **11** on the bare gold

**Fig. 12** Atomic force microscopy image and height profiles of individual cages.

grooves, AFM was used to directly measure the differences in the height profile.

The height difference of 2.6 nm (Fig. 11A,B) is consistent with the formation of a monolayer of **11**. The formation of the molecular cages on the printed layers was performed using the same procedure as for the full monolayers. A difference of 4.2 nm was measured after assembly of the cages (Fig. 11C), a value that is consistent with the calculated dimensions of the assembly. The self-assembly of the cages was monitored by comparing the relative height differences.

Moreover, the insertion of sulfides into SAMs of thiols has been recently investigated by Reinhoudt's group.<sup>[51]</sup> A SAM was prepared where single cavitands could be detected far apart from each other by AFM to individually study the formation of the coordination cages. Insertion of cavitand **11** into a monolayer of mercaptoundecanol was achieved by soaking SAMs of thiol into a 0.1 mM solution of **11** in ethanol. Under this experimental conditions, an average of 20–25 molecules per square micron were inserted into the SAM.<sup>c</sup> Extensive washing with large amounts of solvents ensured the removal of all physisorbed material. Atomic force microscopy experiments and profile analysis showed the presence of individual round entities that were protruding from the flat monolayer. A height-profile analysis revealed that these entities all had the expected size of approximately 2 nm. As for the full SAMs, formation of the cages **12a** and **12b** was performed on these samples as described above for the full monolayers. Atomic force microscopy analysis on the new samples proved the presence of two different types of features: 1) individual dots with heights of about 4 nm; and 2) individual dots with heights of about 2 nm (Fig. 12). The two different entities were attributed to the two different species, the cavitand and the coordination cages adsorbed on Au, respectively.

## CONCLUSION

Cage self-assembly represents a successful strategy for the construction of three-dimensional objects having inner cavities of molecular dimensions. The driving force behind this research effort can be attributed to the following factors: 1) precise control of the CSA process via rational design of the molecular components; 2) the reversibility of the process that conveys

self-repairing properties and responsiveness to external stimuli; and 3) extension of the CSA process to interfaces and surfaces.

This last feature in particular opens new avenues to the metal-directed self-assembly of supramolecular species. In the specific case of cavitand-based coordination cages, single-molecule addressing on surfaces of confined molecules having peculiar electric, magnetic, or optical properties can be envisioned.

# Self-Assembly Directed by NH-O Hydrogen Bonding

Katrina A. Jolliffe  
Leonard F. Lindoy

*Department of Chemistry, University of Sydney, Sydney, New South Wales, Australia*

## INTRODUCTION

Following comments on the nature of hydrogen bonding as well as on self-assembly as it applies to supramolecular systems, the role of N–H...O hydrogen bonding in the formation and properties of a variety of supramolecular structures obtained by self-assembly from their molecular components is reviewed. The structures, which range from simple host–guest systems to complex entities such as nanotubes and hydrogen-bonded polymers, serve to exemplify the manner by which hydrogen bonds of the above type may be utilized in achieving particular molecular architectures.

Emphasis in the treatment is given to structure–function relationships underlying the various architectures described.

## MOLECULAR SELF-ASSEMBLY

The self-assembly of molecular or ionic components to form nanometer-scale structures held together by (generally) weak intermolecular interactions is a phenomenon of fundamental importance to the expanding field of supramolecular chemistry.<sup>[1,2]</sup> The latter is driven, in part, by a generally increased appreciation of the latent steric and electronic information inherent in the wide diversity of molecular building blocks that are either already available or that are capable of being synthesized. The self-assembly process requires that molecular recognition between the assembling components initially occurs and this in turn implies that such components be designed such that steric and electronic complementarity occurs between their respective binding sites.

Supramolecular assemblies have been constructed that exhibit novel properties that include unusual redox and/or electron transfer properties, photoactivity, conductivity, as well as non-linear optical behavior. Interest in such behavior for application in new supramolecular “devices” has remained a further motivation for the continuing interest in the synthesis of new assemblies of the above type.

An important outcome of employing weak non-covalent interactions for the construction of

supramolecular assemblies is that their formation is normally readily reversible because the final assembly remains in thermodynamic equilibrium with its components. As a consequence, supramolecular systems of this type have an inherent capacity for assembly “error correction” that is not normally available to systems that are fully covalently bound. In the present context, the “preorganization effect,” first proposed by Cram,<sup>[3]</sup> is also worth mentioning. This concept can provide a useful aid for rationalizing the strength of binding between the components in particular supramolecular systems. In essence, Cram proposed that the more closely the binding sites of a host molecule are structurally preorganized for binding to a guest, the greater will be the binding strength between host and guest in the resulting assembled species.

## HYDROGEN BONDING

Hydrogen bonding is the most directional of all the intermolecular interactions and is also the most widely used interaction in forming supramolecular structures.<sup>[4]</sup> Hydrogen bond formation has been studied for around a century and is now recognized to cover a wide variety of interaction types involving a bound hydrogen atom (X–H, the donor) and one or more acceptors, which may be an atom or an unsaturated molecule. In view of the diversity, it is not easy to offer a precise definition covering all aspects of hydrogen bonding.<sup>[1]</sup> In a recent review of hydrogen bonds, Steiner<sup>[5]</sup> offered the following description: An X–H...A interaction is called a “hydrogen bond,” if 1) it constitutes a local bond, and 2) X–H acts as proton donor to A. Some common hydrogen bond donor groups are C–H, N–H, O–H, S–H, P–H, F–H, Cl–H, Br–H, and I–H, while acceptor groups include N, O, P, S, F, Cl, Br, and I as well as a range of unsaturated aliphatic and aromatic compounds; the degree of directionality in the resulting hydrogen bond is quite dependent on the polarity of the donor. The strength of such bonds can range from very weak to substantial, typically falling in the approximate range of 3–40 kcal mol<sup>−1</sup>. In this entry, we are concerned with the use of hydrogen bonds of the type N–H...O for

the construction of supramolecular assemblies exhibiting a range of architectures. Hydrogen bonds of this latter type typically fall into the “moderate” strength category, with X...A distances in the range 2.5–3.3 Å and bond angles greater than 130°. [6] Although individual hydrogen bonds may be quite weak, in supramolecular systems (as is often also the case in most hydrogen-bonded biological systems), a number of hydrogen bonds may act in unison resulting in, overall, strong forces operating between the individual molecular components. [7] Similarly, hydrogen bonds tend to cooperatively act with other intermolecular interactions, such as van der Waals forces, such that the overall free energy of the assembled system is minimized.

Self-assembly processes involving NH–O hydrogen bonds have now been reported to generate an impressive range of different supramolecular architectures. Examples include simple (1:1) host–guest systems, molecular tweezers, zippers, boxes, large cyclic assemblies, grids, capsules, rotaxanes, catenanes, helices, knots, tubes, dendrimers, and other polymeric systems. Representative examples of selected systems chosen from this list are now discussed.

## SIMPLE SYSTEMS

The simplest type of “self-assembly” is the 1:1 complexation of two molecules, often described as host–guest complexation. Numerous simple host–guest complexes have been investigated and an understanding of the factors affecting their formation has provided a solid platform for the preparation of larger self-assembled aggregates.

Some of the earliest examples of host–guest complexes involving NH–O hydrogen bonding are the complexes formed between 18-C-6 crown ethers and ammonium ions. In these complexes, three of the ether oxygens form hydrogen bonds with the ammonium NH groups. [8,9] This recognition motif has been utilized to prepare more complicated structures (see below).

Hamilton et al. [10,11] have designed a series of receptors containing six inwardly facing hydrogen bonding sites in a cleft, such that they perfectly complement the six available hydrogen bonding groups in 5,5-disubstituted barbiturates. The formation of 1:1 complexes with high association constants [e.g.,  $1.37 \times 10^6 \text{ M}^{-1}$  for the complex **1:2** (Fig. 1)] was established by <sup>1</sup>H NMR experiments, including titrations and by UV–visible and fluorescence spectroscopy titration experiments.

Molecular receptors for nucleic acids have also been designed. For example, Rebek et al. [12–14] have prepared a number of receptors that form complexes with adenine using a combination of hydrogen bonding and  $\pi$ – $\pi$  stacking interactions. A receptor utilizing a similar

Fig. 1 Structure of the complex **1:2**.

combination of hydrogen bonding and  $\pi$ – $\pi$  stacking interactions has also been designed to complex thymine. [15]

Molecules containing self-complementary hydrogen bonding sites can self-assemble to form dimers or polymers. For example, the rigid dipyrindone **3** forms discrete dimers **4** (Fig. 2) in both dilute CHCl<sub>3</sub> solution (as determined by vapor pressure osmometry, VPO) and in the solid state. In contrast, the dipyrindone **5**, which can not dimerize, forms linear polymeric aggregates **6** (Fig. 2). [16] A less rigid analog of **3** was found to dimerize in solution, but X-ray crystallographic analysis showed that linear polymeric aggregates formed in the solid state. [17]

Recently, the dimerization of a guanidiniocarbonyl pyrrole carboxylate zwitterion **7** (Fig. 3) was described. The dimer is held together by two bifurcated hydrogen bonds and two NH–O hydrogen bonds, which are strengthened by ionic attraction. Dimerization constants of the order of  $10^{10} \text{ M}^{-1}$  in DMSO and  $170 \text{ M}^{-1}$  in water were estimated by <sup>1</sup>H NMR dilution studies. A neutral analog with an essentially identical hydrogen bonding pattern but lacking the ionic interactions was found to dimerize in CDCl<sub>3</sub>; however, addition of small amounts of DMSO resulted in virtually complete dissociation of the complex. [18]

## MORE COMPLEX SYSTEMS

Numerous “polytopic” receptors have been designed for molecules with more than one functional group capable of forming NH–O hydrogen bonds. An early example of a ditopic receptor, comprising a crown ether linked to a macrocyclic polyamine, was studied by Kimura, Fujioka, and Kodama [19] This molecule complexes dopamine in aqueous solution through the formation of ion-pair-reinforced NH–O hydrogen

Fig. 2 Dipyridones **3** and **5** and the hydrogen-bonded dimer **4** and polymer **6**.

bonds between the crown ether and the ammonium ion and between the partially protonated azacrown and the electron-donating phenolic oxygens of dopamine.

Schrader et al.<sup>[20,21]</sup> have developed a number of receptors for biologically relevant molecules. The adrenaline host **8** was designed such that the phosphonates bind the ammonium functional group of adrenaline **9** through an ion-pair-reinforced NH-O hydrogen bond and the amide NH's provide hydrogen bonding sites for the catechol oxygen substituents (Fig. 4). Additional interactions are provided by  $\pi$ - $\pi$  stacking of the catechol between the two nitroarene units. <sup>1</sup>H NMR studies indicated that a 1:1 complex is formed between **8** and adrenaline **9** with a binding constant of  $153 \text{ M}^{-1}$  in  $\text{D}_2\text{O}$ -MeOD (1:1).

A series of oligoamides prepared from isophthalic acid and a bisaniline derivative undergo self-assembly via a combination of NH-O hydrogen bonds and edge-to-face aromatic interactions to form double-stranded "zipper" complexes in solution (Fig. 5).<sup>[22]</sup> Evidence for the association comes from <sup>1</sup>H NMR dilution and titration experiments in  $\text{CDCl}_3$  and  $\text{CDCl}_3$ - $\text{CD}_3\text{OD}$  (95:5) together with X-ray crystal structure analysis. The stability of the dimers was found to increase as the length of the oligomer

Fig. 3 Hydrogen-bonded dimer formed upon dissolution of **7** in DMSO or  $\text{H}_2\text{O}$ .

increased, indicating significant cooperativity in the intermolecular interactions along the chain.

## CYCLIC ASSEMBLIES

Whilst it is relatively simple to control the self-assembly of two components, the self-assembly of multiple components into a single aggregate is more difficult to engineer. One technique that has been successfully employed in the self-assembly of multiple components is hydrogen-bond-mediated cyclic aggregation, using either self-complementary molecules or mixtures of molecules with complementary hydrogen bonding sites.

An example of the above strategy is the self-assembly of the pyrido[4,3-g]quinoline **10** to form the cyclic trimer **11** held together by six NH-O hydrogen

Fig. 4 Structure of the complex **8:9**.

Fig. 5 Double stranded “zipper.”

bonds (Fig. 6). The formation of a cyclic trimer was confirmed by a combination of VPO and  $^1\text{H}$  NMR studies and the cyclic assembly was found to be very stable in  $\text{CDCl}_3$  solution ( $K_{\text{ass}} = 20,000 \text{ M}^{-2}$ ).<sup>[23]</sup>

The self-assembly of two-faced, “Janus-type” molecules, which incorporate the AAD hydrogen bonding sequence of cytosine and the DDA sequence of guanine, has been observed by both Lehn, Silvestri, and Lehn<sup>[24]</sup> and Mascal et al.<sup>[25]</sup> The  $60^\circ$  angle between the hydrogen bonding faces of these molecules dictates the formation of cyclic hexamers, both in solution and the solid state.

Using a similar array of hydrogen bonding donor and acceptor sites, Zimmerman and coworkers have found that cyclic hexamers assemble upon dissolution of **12** in  $\text{CDCl}_3$ ,  $d_8$ -toluene and  $d_8$ -THF (Fig. 7).<sup>[26]</sup> In this case, six secondary hydrogen bonds may serve to further stabilize the aggregate, which remains the predominant species in solution in both DMSO–chloroform (1:9) and 8% aqueous THF mixtures. This and similar recognition motifs have been employed in the formation of self-assembled dendrimers.<sup>[27,28]</sup>

Upon crystallization of a 1:1 mixture of cyanuric acid (CA) and melamine (M), a hydrogen-bonded lattice with several recognizable motifs, including a cyclic rosette **13** (Fig. 8), is observed.<sup>[29]</sup> Using appropriately substituted M and CA derivatives, the self-assembly of cyclic aggregates based on this rosette motif has been explored by the groups of Whitesides and Reinhoudt.

A series of hydrogen-bonded cyclic aggregates have been prepared by Whitesides et al., who employed both peripheral crowding and preorganization strategies to favor the formation of cyclic over linear aggregates. The first of these systems contains three M units attached to a central “hub” by semirigid spokes to produce a “tritopic” receptor ( $\text{HubM}_3$ ).<sup>[30,31]</sup>  $\text{HubM}_3$  forms a complex with three molecules of neohexylisocyanurate **14** to form the cyclic rosette **15** (Fig. 9). Double and triple rosette aggregates have been prepared using a similar strategy and aggregates incorporating both linked melamine and linked isocyanurate components have also been prepared. These aggregates have been

Fig. 6 Self-assembly of a cyclic trimer.

**Fig. 7** Cyclic hexamer formed upon self-assembly of six molecules of **12**.

characterized using a combination of  $^1\text{H}$  NMR spectroscopy (including titrations), VPO, and gel phase chromatography (GPC).

Reinhoudt and coworkers have used a similar pre-organization strategy to prepare aggregates comprising multiple-stacked rosettes. In these systems, a number of calix[4]arene derivatives, diametrically substituted with two melamine substituents on the upper rim, are connected with various linker units. Three of these melamine “strings” then complex the appropriate number of isocyanurate or barbiturate derivatives to give aggregates comprising multiple rosettes. Recently, this strategy has been employed in the self-assembly of 27 molecules, via 144 hydrogen bonds, to form an aggregate with eight stacked rosette motifs, which

was characterized using a combination of MALDI-TOF mass spectrometry,  $^1\text{H}$  NMR, and GPC.<sup>[32,33]</sup> The use of either chiral melamine or chiral cyanurate components in the formation of these aggregates has been found to result in the formation of homochiral self-assembled structures.<sup>[34–38]</sup>

## MOLECULAR CAPSULES AND BOXES

A considerable number of self-assembling capsules have now been reported, many of which incorporate arrays of  $\text{N-H}\cdots\text{O}$  hydrogen bonds.<sup>[39]</sup> The resulting three-dimensional structures incorporate enclosed cavities that are frequently occupied by included solvent or other molecules. Shimizu and Rebek<sup>[40]</sup> have prepared a number of systems of this type. For example, the group has reported the synthesis and assembly of self-complementary calix[4]arenes derivatives, which, on dimerization, yield discrete capsules. One system of this type was based on the cone-conformer of tetrabenzylcalixarene **16** that had been further functionalized by the appending of four urea groups to the periphery of the large aperture of the cone (Fig. 10). Individual urea groups from two such half capsules intermesh in an alternate fashion such that they interlink in a head to tail manner to provide the “glue” for connecting the two half capsules; a total of sixteen  $\text{NH}\cdots\text{O}$  contacts are involved in this arrangement (Fig. 10). The resulting cavity in this case is sufficiently large to encapsulate guests such as ethyl benzene and *p*-xylene.

Schall and Gokel<sup>[41]</sup> have described the formation of the molecular “box” given by **17** (Fig. 11).  $^1\text{H}$  NMR chemical shift data were used to assign the nature of the hydrogen bond patterns for this species in  $\text{CDCl}_3$ . Signal broadening was observed in the spectrum and this was interpreted as suggesting the likely presence of more than one aggregate type under the conditions used for the experiment.

**Fig. 8** Cyclic rosette motif observed in the crystal lattice of a 1:1 mixture of melamine and cyanuric acid.

**Fig. 9** Formation of a cyclic rosette by self-assembly of four components.

**Fig. 10** Self-assembly of a molecular capsule.

**Fig. 11** A self-assembled molecular box.

## ROTAXANES AND CATENANES

The use of NH-O hydrogen bonding to promote the threading process in the formation of a range of catenanes, pseudorotaxanes, and rotaxanes has been reported.<sup>[42,43]</sup>

In a typical reaction of this type, a cationic dialkylammonium-containing moiety interacts with a suitable crown ether, e.g., dibenzo-24-crown-8, in a solvent such as chloroform or dichloromethane.<sup>[44]</sup> The success of this procedure relies on the strong tendency for the  $\text{-NH}^{2+}$ -group to be encircled by the macrocycle such that hydrogen bonds form between the NH groups of the cation and the ring polyether oxygens, with the alkyl substituents protruding on either side of the ring. The resulting pseudorotaxane may then be converted into a rotaxane by appending bulky stopper groups to the termini of each alkyl portion of the threaded component to sterically block dissociation of the assembled product.

Ashton et al.<sup>[45]</sup> have been successful in producing a range of  $[n]$ -rotaxanes using the “threading followed by stoppering” strategy discussed above. For example, using the bis-azidomethyl-substituted *p*-xylene- $\alpha,\alpha'$ -dibenzylammonium dicationic salt **18**·**2PF<sub>6</sub><sup>-</sup>** and dibenzo-24-crown-8, both the corresponding [2]-catenane and [3]-catenane were prepared. The structure of the latter dication is illustrated by **19** (Fig. 12). In each case, the bulky “stoppers” were attached by means of two dipolar cycloadditions involving reaction of the azido groups with acetylene-dicarboxylate. The X-ray structure of **19**·**2PF<sub>6</sub><sup>-</sup>** shows that this [3]-rotaxane is stabilized by a combination of  $[\text{N-H}\cdots\text{O}]$ ,  $[\text{C-H}\cdots\text{O}]$ , and  $\pi$ - $\pi$  stacking interactions. Not surprisingly, the X-ray structure of the corresponding intermediate

**Fig. 13** Amide macrocycle **20**. Two molecules of **20** intertwine to form a catenane during the macrocyclization reaction.

[3]-pseudorotaxane shows a very similar (supramolecular) structure to that found for the above rotaxane product.

Different groups<sup>[46–48]</sup> have reported the formation of a series of uncharged [2]-catenanes incorporating amide linkages that are intimately associated with the “interlinking” self-assembly of these species. For example, the [2]-catenane consisting of two interlinked rings of type **20** (Fig. 13) was isolated from a one-pot, double macrocyclization reaction from the required precursors in 34% yield.<sup>[42]</sup> The X-ray structure of the product was subsequently determined<sup>[49]</sup> and shows that the two macrocycles are locked together by a total of six hydrogen bonds that include bifurcated hydrogen bonds from the amide groups of an isophthaloyl subunit in each ring to a carbonyl oxygen belonging to the other ring. For this system, as well as for the related derivatives referred to above, the intermolecular

**Fig. 12** Diammonium “thread” **18** and a [3]-rotaxane.

interactions (which may also involve  $\pi$  interactions in particular cases) clearly play an additional role in acting as templates during the crucial interlinking step.

## HELICAL STRUCTURES

The helical structures found throughout nature (e.g.,  $\alpha$ -helical polypeptides) have inspired the design of synthetic oligomers that fold into helices. Numerous interactions are available to hold such “foldamers” in a well-defined conformation and NH–O hydrogen bonding has been employed in many cases.

Oligoamides that incorporate aromatic rings in their backbones are more rigid than their aliphatic counterparts and can be directed to adopt helical structures using hydrogen bonding between backbone substituents. Oligoanthranilides form intramolecular hydrogen bonds between adjacent amide NH and CO groups. Linking these units with either pyridine-2,6-carboxamide or 4,6-dimethoxy-1,3-diamino benzene derivatives introduces turns into the H-bonded oligomers **21** (Fig. 14), resulting in the formation of extended helical structures.<sup>[50,51]</sup> Similarly, helices have been formed from oligomers of 5-amino-2,4-dimethoxybenzoic acids **22** (Fig. 14) (or analogs in which longer alkyl ethers are present at the 2- and 4-positions).<sup>[52,53]</sup> In this case, hydrogen bonds between the amide NH and the ether substituents together with the *meta*-substitution pattern of the aromatic rings results in the backbone adopting a helical conformation which has a 10 Å cavity. Substitution of some of the *m*-substituted aromatic rings with *p*-substituted analogs permits the formation of helices with larger internal cavities (>30 Å).<sup>[54]</sup> Evidence for the helical nature of these molecules comes from 2-D <sup>1</sup>H NMR experiments, which show end-to-end NOE contacts in CDCl<sub>3</sub> or mixtures of CDCl<sub>3</sub> and DMSO, together with X-ray crystal structure data for a number of compounds that clearly show that these molecules adopt a helical conformation in the solid state.

Berl et al.<sup>[55]</sup> have found that a “heptamer” formed from alternating 2,6-diaminopyridine and 1,3-benzenedicarboxylate units forms helices around a central cyanurate template that has complementary hydrogen bonding sites. In the absence of the template, multiple conformers are present in solution as a result of free rotation about the aryl–CO bonds. Introduction of the cyanurate template results in a single conformer that exhibited end-to-end NOE contacts in the <sup>1</sup>H NMR spectrum, indicating the stabilization of a helical structure.

## SELF-ASSEMBLY OF NANOTUBES

The self-assembly of tubular structures is of great interest because of the large number of potential applications for these nanotubes. Two major classes of nanotubes have been assembled using NH–O hydrogen bonding: those formed by the stacking of macrocycles to form continuous tubes and those formed by interdigitating peptidic side chains attached to rigid rod scaffolds to form  $\beta$ -barrels.

Ghadiri et al.<sup>[56,57]</sup> observed that the controlled acidification of a solution of the cyclic octapeptide cyclo-[-(L-Gln-D-Ala-L-Glu-D-Ala)<sub>2</sub>-] **23** resulted in the self-assembly of hollow tubular structures with an internal diameter of approximately 7 Å **24** (Fig. 15). A number of other cyclic D,L  $\alpha$ -peptides have been found to form self-assembled nanotubes under the appropriate conditions.<sup>[58,59]</sup> Both the exterior surface properties and the internal diameters of the nanotubes may easily be altered upon changing the amino acid side chains and the number of amino acids in the cycle, respectively; thereby providing self-assembled structures that can be tailored for specific applications. It has also been found that cyclic  $\beta^3$ -peptides can form similar tubular structures with an internal pore.<sup>[60,61]</sup> The formation of cylindrical assemblies using macrocycles composed of cystine-bridged bisamides or bisureas has also been reported.<sup>[62]</sup>

Fig. 14 Oligomers that adopt helical structures.

Fig. 15 Self-assembly of nanotubes from stacked cyclic peptides.

Fig. 16 Self-assembly of  $\beta$ -barrels.

Fig. 17 Self-assembled hydrogen-bonded polymers.

Nanotubes composed of either cyclic D,L  $\alpha$ -peptides or cyclic  $\beta$ -peptides have been found to act as transmembrane ion channels, transporting small ions, e.g., K<sup>+</sup> and Na<sup>+</sup>, or, in the case of nanotubes with larger internal diameters, larger molecules, e.g., glucose and glutamate, across lipid bilayers.<sup>[63–65]</sup> More recently, it has been found that nanotubes of cyclic D,L  $\alpha$ -peptides act as selective antibacterial agents by increasing cell membrane permeability.<sup>[66]</sup>

Sakai, Majumadar, and Matile<sup>[67]</sup> have found that suitably functionalized peptide chains attached to rigid *p*-oligophenyl scaffolds **25** self-assemble to form cylindrical “barrels” as a result of intermolecular hydrogen bonding between the NH and carbonyl functionalities of interdigitating peptide strands (Fig. 16). These artificial  $\beta$ -barrels have a fixed length and may be designed to have either a hydrophilic interior and hydrophobic exterior surface or vice versa. The internal diameter of the barrel is flexible, and can be increased by either increasing the steric demands of the interior amino acid side chains or by using electrostatic repulsion between charged side chains on the interior surface.<sup>[68]</sup>

Artificial  $\beta$ -barrels having a hydrophobic interior have been found to encapsulate carotenoids,<sup>[69]</sup> while those with a hydrophilic interior were found to exhibit

substantial ion channel, esterase, RNAase, and fibrillogenetic activity.<sup>[70–72]</sup>

## HYDROGEN-BONDED POLYMERS

The self-assembly of multiple components can lead either to the formation of discrete aggregates, as described above, or to the formation of “supramolecular polymers.” Hydrogen-bonded polymers have been prepared using many of the recognition motifs described above and the field has been recently reviewed.<sup>[73–75]</sup> Recent examples include the reversible polymerization of self-complementary bisureidopyrimidones **26**<sup>[76]</sup> and the copolymerization of biscyanurate **27** and bisdiaminopyridine **28** monomers (Fig. 17).<sup>[77]</sup>

## CONCLUSION

Hydrogen bonds of the type N–H...O have been utilized for the construction of a wide range of supramolecular architectures. These hydrogen bonds are individually weak, but often a number of such bonds

will act in unison, or cooperatively with other intermolecular interactions (e.g., NH–N hydrogen bonds,  $\pi$ – $\pi$  stacking, or ionic interactions), resulting in, overall, strong attraction between the individual molecular components of an assembly. In this entry, we have presented a selection of representative examples of the large number of such assemblies now reported.<sup>[1,7,78–80]</sup>

## ACKNOWLEDGMENT

We thank the Australian Research Council for support.

## INTRODUCTION

There are various methods for the fabrication of quantum dots (QD).<sup>[1,2]</sup> Among them, the self-formation method is one of the most useful methods, because it causes little damage, creates dots of high density, and the fabrication process is rather simple. In this entry, two fabrication methods, i.e., the S–K mode growth method and the composition modulation of short-period superlattices, are introduced. For samples fabricated by these methods, structural characterization with atomic force microscopy (AFM), scanning tunneling microscopy/spectroscopy (STM/STS), magnetic force microscopy (MFM), and transmission electron microscopy (TEM) are described. Furthermore, as optical characterization methods, photoluminescence (PL), time-resolved photoluminescence (TRPL), and electroluminescence (EL) are mentioned and the several results are shown.

## FABRICATION METHODS

Prior to the description of the characterization,<sup>[3,4]</sup> we briefly describe the fabrication methods for self-formed QDs. A frequently used method is the so-called “Stranski–Krastanov (S–K) mode growth method.” In this method, a small amount of materials having a lattice constant different from that of the substrate are supplied at appropriate temperatures on a substrate (e.g., GaAs). Because of the difference of surface energy and the strain, projecting dots of supplied materials are formed on the substrate. A characteristic feature of this method is dot formation on the flat surfaces, shown schematically in Fig. 1A. The typical density of dots made by the S–K mode growth is around  $10^9$ – $10^{10}$  cm<sup>-2</sup>. Examples of materials combination are InAs on GaAs, InGaAs on GaAs,<sup>[5–8]</sup> and InGaN on GaN.<sup>[9]</sup>

As an example, our growth process of InAs dots on GaAs using metal organic molecular beam epitaxy

(MOMBE) is as follows:<sup>[10]</sup> After the growth of GaAs buffer layer, triethylgallium (TEGa) and trisdimethylaminoarsenic (TDMAAS) are supplied at an appropriate substrate temperature. The formation of InAs dots can be monitored by observing the reflection high-energy electron diffraction (RHEED) pattern changes from streaky to spotty. Other growth processes are shown in Refs.<sup>[5–9]</sup>

Another method is the “composition modulation of short-period superlattices.” In this method,<sup>[11]</sup> e.g., short-period GaP/InP superlattice layers are grown on GaAs substrate. The state of grown layers depends on the orientation of GaAs substrates. With this method, wire structures are grown on (100) GaAs substrates<sup>[11]</sup> and CuPt-type GaP/InP superlattices are grown on (111) GaAs.<sup>[12]</sup> On (N11) GaAs substrate, dot structures are self-formed.<sup>[12]</sup> In this case, dots are formed in the grown layer. Therefore the surface is flat, as shown in Fig. 1B. The density of dots is around  $10^{11}$  cm<sup>-2</sup>. Examples of material combination are InP/GaP on GaAs and GaAs/InAs on InP.

Here the fabrication procedure of dots by the above method is described in more detail. Two types of superlattices are grown on Si-doped GaAs(311)A substrates by gas source molecular beam epitaxy. One is (GaP)<sub>n</sub>-(InP)<sub>m</sub>, where *n* and *m* represent the number of the monolayer of each compound. (GaP)(InP) means that the GaP layer was grown first on the substrate and the InP layer was grown next. The other type of sample (InP)<sub>n</sub>(GaP)<sub>m</sub> was formed in the reverse order. Elemental Ga, In, Si, and thermally cracked arsine (AsH<sub>3</sub>) and phosphine (PH<sub>3</sub>) were used as sources.

## STRUCTURAL CHARACTERIZATION

Structure of self-formed quantum dots can be characterized by various methods such as atomic force microscopy (AFM), scanning tunneling microscopy (STM), electron microscopy, and electron diffraction.

**Fig. 1** Schematic view of (A) QDs fabricated by the S–K mode growth method and (B) QDs fabricated by the composition modulation method.

### AFM, STM, and STS

AFM utilizes the atomic force between a sample surface and a probe.<sup>[13]</sup> Therefore the obtained image is almost independent of the electric properties of

materials. In STM, the height position of the probe is controlled to keep the tunnel current between sample and probe constant, and the variation of probe is displayed.<sup>[14]</sup> Hence the obtained image reflects the electrical properties of materials. In scanning tunneling spectroscopy (STS), the position of the probe is fixed and the current–voltage characteristics are measured. These characteristics reflect the electronic structures of materials.

The shape and position of QDs fabricated by the S–K mode growth method are well characterized by AFM. Fig. 2 shows AFM image for (A) InAs dots as grown and for (B) the surface where smaller dots are eliminated by etching.<sup>[15]</sup> The diameter, height, density, and distribution of dots can be measured. The dependence of dot structures on the growth conditions is investigated via AFM.<sup>[16,17]</sup> On the other hand, in the case of QDs made by composition modulation, AFM shows that the surface is flat, and information on the size and distribution of dots are not obtained.

In some special cases, such as InAs dots including Mn atoms, magnetic force microscopy (MFM) can

**Fig. 2** AFM images for (A) the InAs dots as grown by S–K mode growth and for (B) the surface where smaller dots are eliminated by etching. *Source:* From Ref.<sup>[15]</sup>.

**Fig. 3** (A) AFM and (B) MFM images for the InAs dots including Mn atoms. *Source:* From Ref.<sup>[19]</sup>.

be used.<sup>[18]</sup> For MFM, batch-microfabricated silicon probes were magnetically sensitized by sputter coating with ferromagnetic materials. The tip is scanned tens or hundreds of nanometers above the sample, thus avoiding contact. Magnetic field gradients exert a force on the tip's magnetic moment, and monitoring the tip/cantilever response gives a magnetic force image. Fig. 3 shows AFM and MFM images of the InAs dots including Mn atoms.<sup>[19]</sup>

In the case of QDs by composition modulation, STM is a powerful tool for characterization. The STM image of the sample  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  on GaAs(311)A substrate is shown in Fig. 4A.<sup>[20]</sup> In the STM image reflecting the electrical properties, shape and distribution can be observed. The self-formed dots are aligned along two perpendicular directions, [0-11] and [233], and distributed side by side. The lateral period (size) of dots (bottom to bottom in the STM image) is about 20 nm ( $\sim 20$  nm along the [0-11] direction,  $\sim 19$  nm along the [233] direction). The distribution (size fluctuation) is about  $\pm 10\%$ . The dot density is of the order  $10^{11} \text{ cm}^{-2}$ . The bright and dark areas correspond to the InP-rich and GaP-rich regions, respectively, based on STS measurement.

Fig. 4B shows a  $dI/dV$  vs. bias voltage curve at points A, B, and C in the STS measurement. The voltage width for  $dI/dV = 0$  corresponds to the potential change, i.e., the band gap change of the materials. The periodic structure of the voltage width shown in Fig. 4C is not attributable to the geometrical height change, but to the band gap change, because the surface is almost flat as described before.

In the case of the  $(\text{InP})_{1.88}(\text{GaP})_{1.5}$  sample, nearly the same dot structures are observed in the STM measurement. The difference is that the lateral period is about 22 nm ( $\sim 22$  nm along the [0-11] direction,  $\sim 20$  nm along the [233] direction). This is 10% larger than that of the  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  sample. The size distribution is also about  $\pm 10\%$ , which is nearly the same as  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  sample. The difference in the lateral period (size) between these two types of QDs was confirmed for several samples.

STM can be also utilized for the characterization of QDs made by the S-K mode growth. (Please see Refs. <sup>[21,22]</sup>.)

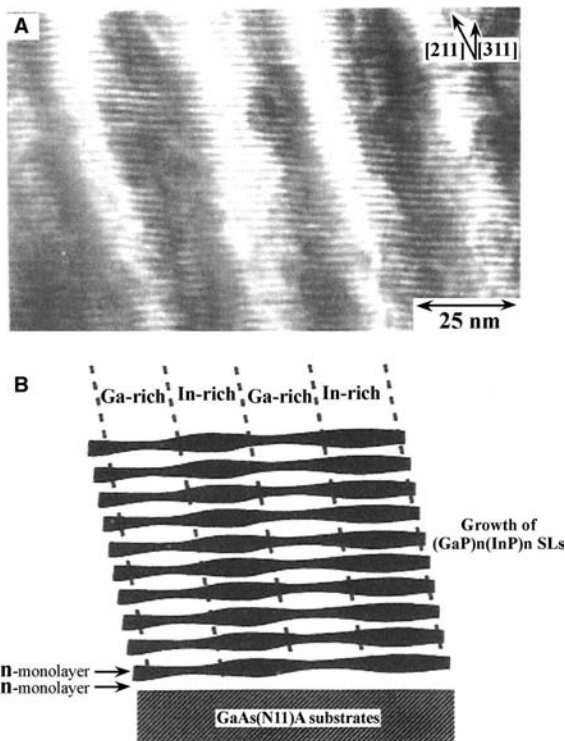

## Electron Microscopy

Inner structures of dots can be observed by using cross-sectional transmission electron microscope (TEM). It is important to carefully prepare specimens without causing damage. First, the sample is sliced or cleaved into bars. The bars, the backside of which is supported with Ti holder, are mounted on glass or metal with carbon epoxy so as to make the cross section

**Fig. 4** (A) STM images for QD structures self-formed  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  SLs grown on the GaAs (311)A substrate, (B)  $dI/dV$  vs.  $V$  curves at different points, and (C) variation of the voltage width for  $dI/dV = 0$  in (B) along the [0 - 11] direction. The left ordinate is related to  $X$  if the dot mean composition is represented by  $\text{In}_{1-x}\text{Ga}_x\text{P}$ . Source: From Ref.<sup>[20]</sup>.

upside. The bars are thinned by polishing and Ar milling to less than 10 nm. Fig. 5A shows a cross-sectional TEM lattice image of the  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  sample grown on (311)A GaAs substrate by composition modulation method.<sup>[3]</sup> This shows the lateral periodic thickness undulation, as shown schematically in

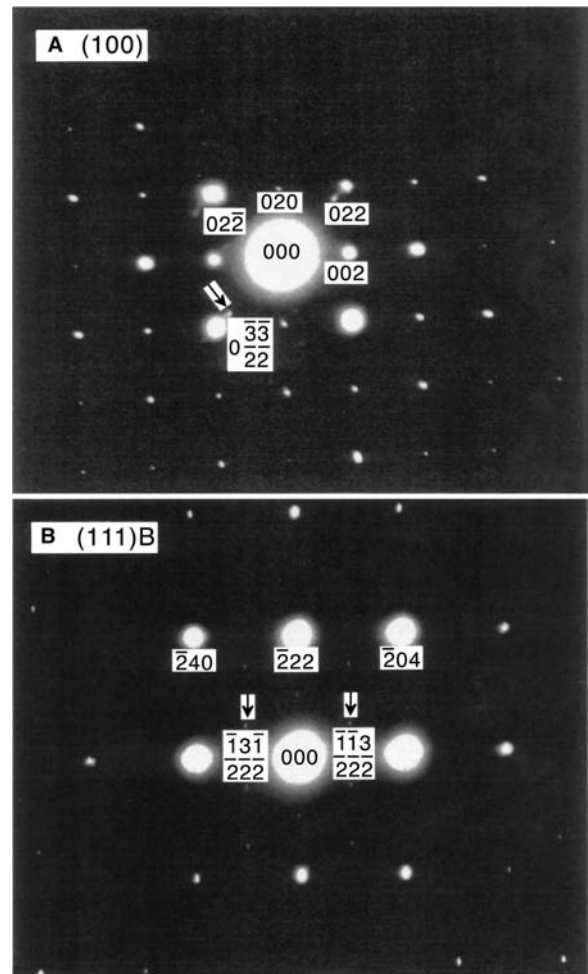

**Fig. 5** (A) Cross-sectional TEM lattice image for the  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  sample grown on GaAs (311)A substrate, (B) schematic drawing illustrating the lateral composition modulation induced by the lateral thickness modulation. *Source:* From Ref.<sup>[3]</sup>.

Fig. 5B, although GaP/InP superlattice structures are essentially preserved.

Characterizations of QDs made by the S–K mode growth with cross-sectional TEM images are reported.<sup>[23,24]</sup>

### Electron Diffraction

TEM diffraction is also used for the structural characterization. Fig. 6 shows TEM diffraction patterns for the  $(\text{GaP})_1(\text{InP})_1$  superlattices grown on (A) GaAs(100) and (B) GaAs(111)B. Incident electron beam is parallel to the [111] direction in the case of Fig. 6A and to the [211] direction in Fig. 6B.<sup>[25]</sup> The sharp spots  $(0 \ 1/2 \ 1/2)$  and  $(0 \ -1/2 \ -1/2)$  were clearly observed in Fig. 6A. This indicates that the superstructure with a period of twice the usual lattice constant is formed in the  $[0 \ 1 \ 1]$  direction. On the other hand, the sharp superstructure spots  $(1/2 \ 1/2 \ 1/2)$  were observed in Fig. 6B. This indicates that the CuPt-type long-range ordering, i.e.,  $(\text{GaP})_1(\text{InP})_1$  superlattices, is formed in the [111] direction. These observations show that the growth on the (100) and (111) substrates does not form quantum dots by the composition modulation method.

**Fig. 6** TEM diffraction pattern for the  $(\text{GaP})(\text{InP})$  SLs grown on (A) GaAs (100) and (B) GaAs (111)B substrates. *Source:* From Ref.<sup>[25]</sup>.

### X-ray Scattering and Diffraction

Grazing incidence small-angle X-ray scattering<sup>[26]</sup> and grazing incidence X-ray diffraction were used for structural characterization of InAs QDs. The grazing incidence technique probes the crystal surface up to depths of only a few nanometers. This strongly enhances the scattering intensity from the InAs QDs. It is revealed through this method that the lateral distribution of InAs QDs is anisotropic, and the most pronounced ordering of dot distribution is in the [110] direction and that the dot shape is an octagonal-based truncated pyramid with  $\{111\}$  and  $\{101\}$  facet families.<sup>[27]</sup>

### OPTICAL CHARACTERIZATION

In QDs, the electronic structures such as the energy level and the density of state greatly differ from those

of bulk crystal. Therefore it is possible to characterize quantum dots by measuring QDs' optical properties, which reflect the electronic structures.

### Photoluminescence (PL)

Ordinary PL peaks at low temperatures correspond to the energy difference between the lowest energy level in the conduction band of dots and the highest level in the valence band of the dots. Because these levels are a function of the size or radius of the dots, the peak position reflects the size of dots and the peak width reflects the size fluctuation of dots.

Fig. 7 shows an example of room-temperature PL spectra obtained by Songmuang et al.<sup>[28]</sup> for InAs dots fabricated through the S-K mode growth. The peak energy around 1 eV for InAs dots is very high, compared with the energy gap (0.36 eV) for InAs at room temperature. This shows the energy increase between the energy levels by dot formation. In this work, GaAs overgrowth on InAs dots was induced at two different temperatures. One is grown at the same level as the QD growth temperature [500°C; conventionally capped (CC)] and another at a lower temperature [470°C; low-temperature capped (LTC)]. In the lower spectra, the full-width at half maximum (FWHM) of the PL peak of CC dots is 51 meV, and that of LTC dots decreases to 26 meV. This implies that the size

**Fig. 7** PL spectra at room temperature for low-temperature capped (LTC) InAs data and conventionally capped (CC) InAs dots by the S-K mode growth method. *Source:* From Ref.<sup>[28]</sup>.

**Fig. 8** Schematic drawing of five cycle multilayer QDs (MQD) formed in the  $(\text{GaP})_n(\text{InP})_m$  SL/InGaP multilayer. *Source:* From Ref.<sup>[29]</sup>.

fluctuations decrease with decreasing overgrowth temperature.

In the PL measurement of QDs fabricated by composition modulation, multilayer QDs, shown in Fig. 8, are used.<sup>[29]</sup> PL spectra at 77 K for  $(\text{InP})_{1.88}(\text{GaP})_{1.5}$  and  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  samples are shown in Fig. 9.<sup>[3]</sup> PL peak energy of the  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  sample is higher than that of the  $(\text{InP})_{1.88}(\text{GaP})_{1.5}$  sample by about 10%. This tendency corresponds to the difference in the lateral period of dots of two samples. The FWHM of PL peak of the  $(\text{InP})_{1.88}(\text{GaP})_{1.5}$  sample is wider than that of the  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  sample by about 10%, as shown in Fig. 9. The FWHM of the  $(\text{InP})_{1.88}(\text{GaP})_{1.5}$  sample decreased nearly monotonically from 100 to 50 meV, when the temperature

**Fig. 9** PL spectra at 77 K for  $(\text{InP})_{1.5}(\text{GaP})_{1.88}$  and  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  samples. *Source:* From Ref.<sup>[3]</sup>.

**Fig. 10** Time-integrated PL spectrum and PL decay time as a function of monitored emission energy at 26 K for MQD5/20. *Source:* From Ref.<sup>[29]</sup>.

is lowered from 350 to 10 K. The FWHM of  $(\text{GaP})_{1.5}\text{-(InP)}_{1.88}$  sample also decreases nearly monotonically down to 100 K, but it shows a maximum at  $\sim 50$  K. In this case, fluctuation of dot size is not to be related to the larger FWHM of the  $(\text{InP})_{1.88}(\text{GaP})_{1.5}$  sample, because the deviation of period is nearly the same within the experimental error in both samples. The difference is probably a result of the difference in crystalline quality or the state of strain in the dot layers.

Optical properties of multilayer QDs made by composition modulation are investigated by changing the superlattice period and the InGaP barrier thickness. By decreasing the period, PL peak energy shifts toward higher energy because of the quantum size effect along the growth direction. The PL line width broadening with temperature is reduced by decreasing the period and the barrier thickness. This is attributed to the

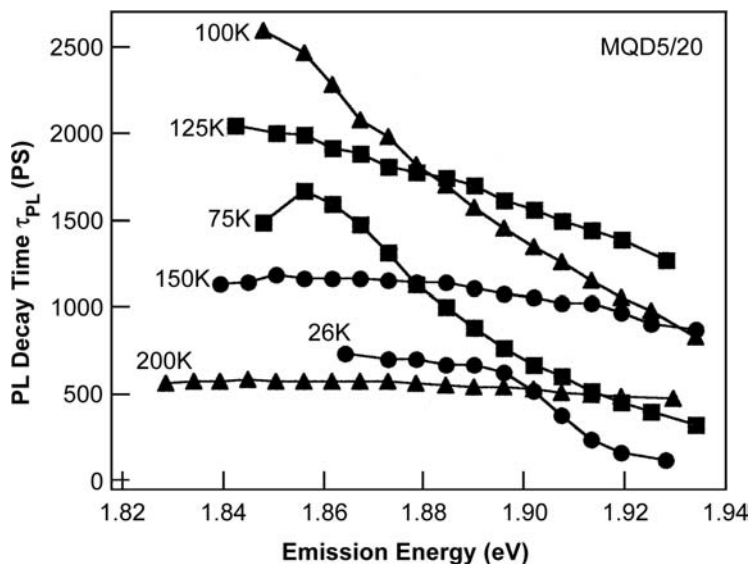

reduction of potential distribution among QDs and the enhancement of quantum confinement as a result of the vertical coupling effect between QDs. Very small temperature variation of PL peak energy is observed in multilayer QDs, which is attributed to the existence of the mutual strains in the multilayer QDs. A detailed discussion is given in another work.<sup>[30]</sup>

### Time-Resolved Photoluminescence (TRPL)

TRPL is effective for the investigation of the nature of emission in quantum dots. TRPL measurements are performed with a fast streak camera in conjunction with a monochromator. Pulsed excitation is provided the frequency doubled beam of a mode-locked  $\text{Al}_2\text{O}_3\text{:Ti}$  laser.

An example of the result for multilayer QDs MQD5/20 (5 is the period of  $(\text{GaP})_{1.5}(\text{InP})_{1.88}$  SL and 20 is the barrier thickness in nm) is shown in Fig. 10.<sup>[29]</sup> PL decay time strongly depends on emission energy. Fig. 11 shows the dependence of PL decay time on emission energy and temperature.<sup>[29]</sup> It ranges between 0.1 and 2.5 nsec. The decay time is shorter for higher energies. This dependence implies the existence of a tunneling process between QDs. In QDs, carriers in the higher energy levels of the smaller QDs can transfer to the lower energy levels in the adjacent larger QDs. Because carriers in the higher energy level have a large number of lower energy levels into which they can relax, the decay time becomes shorter for higher energies. Hence Fig. 11 reflects a variety of sizes of QDs and distances between QDs.

TRPL is also used to measure the tunneling time of carriers in coupled QDs. Takeuchi, Kuroda, and Mase<sup>[24]</sup> measured carrier tunneling times between vertically aligned double QDs using TRPL. The vertically

**Fig. 11** Monitored emission energy dependence of PL decay time as a function of measured temperature. *Source:* From Ref.<sup>[29]</sup>.

Fig. 12 EL spectra at room temperature. Source: From Ref.<sup>[31]</sup>.

aligned double QD structure consists of  $\text{In}_{0.9}\text{Ga}_{0.1}\text{As}$  QDs, a GaAs barrier layer, and InAs QDs, which is made via the S–K mode growth. They revealed the dependence of the tunneling time on the barrier thickness.

### Electroluminescence (EL)

EL shows another feature of the optical properties of QDs. We fabricated two types of light-emitting diodes (LED) using the composition modulation method. One is the sample MMQDs1, which has  $(\text{InGaP})_{40}(\text{InAlP})_{40}$  cladding layers and  $\text{In}_{0.49}\text{Ga}_{0.51}\text{P}$  barrier layers, and another is the sample MMQDs2, which has  $(\text{InGaP})_5(\text{InAlP})_5$  cladding and  $(\text{InGaP})_4(\text{InAlP})_2$  barrier. EL spectra at room temperature for both samples

Fig. 13 Temperature variation of normalized EL and PL intensities. Source: From Ref.<sup>[31]</sup>.

are shown in Fig. 12.<sup>[31]</sup> MMQDs2 exhibits a narrower FWHM (48 meV) than that of MMQDs1. The integrated EL intensity of MMQDs2 is about 30 times higher than that of MMQDs1. This improvement results from the introduction of  $(\text{InGaP})_5(\text{InAlP})_5$  as cladding and  $(\text{InGaP})_4(\text{InAlP})_2$  SL as barrier layers. Fig. 13 shows the temperature variations of integrated EL and PL intensities.<sup>[31]</sup> The temperature quenching of EL intensity is smaller for MMQDs2 than for MMQDs1. Because the effective band gap of the  $(\text{InGaP})_5(\text{InAlP})_5$  SL is larger than that of  $(\text{InGaP})_{40}(\text{InAlP})_{40}$  SL, the reason for these temperature variations is considered to be a result of the suppression of carrier flow from the QD region by the use of higher band gap cladding layers.

If the QDs are applied to devices, characterization via device performance is one of the very severe characterizations. The most popular application of self-formed QDs is semiconductor lasers. An example of InAs/InGaAs/GaAs QD lasers is introduced here. Kovsh et al.<sup>[32]</sup> made QDs via the S–K mode growth and fabricated 1.3- $\mu\text{m}$  edge-emitting lasers. They simultaneously obtained threshold current density of  $100 \text{ A/cm}^2$  and differential efficiency of 80% in the same device.

### CONCLUSION

Structural and optical characterization of self-formed quantum dots was described, based mainly from our experience. Structures such as size, position, and distribution are well characterized by AFM, STM, STS, and TEM, and optical characterizations, capable of obtaining information on carriers and their energy states, are well carried out by PL measurements.

Most of the samples treated here were quantum dots fabricated via the composition modulation methods, and samples made by the S–K mode growth method are a little bit smaller in number. There are numerous reports concerning quantum dots produced by the S–K mode growth. For example, reports on In(Ga)As quantum dots are introduced in detail in Ref.<sup>[2]</sup>. For quantum dots of nitrides, the reader is referred to Ref.<sup>[9]</sup>. For further details on quantum dots using SiGe system, CdSe/ZnSe, and PbSe, please see Refs.<sup>[33–35]</sup> respectively.

The above-mentioned methods for structural and optical characterization are very effective and useful for various semiconductor materials.

# Self-Organized Superstructures: Molecular Design

Makoto Tadokoro

Department of Chemistry, Osaka City University,  
Osaka, Japan

## INTRODUCTION

Molecular arrays with desirable topological networks have recently been realized in crystal by self-organized binding between molecular building blocks with hydrogen-bonding (H-bonding) and metal-coordinating affinities. The coordination bonds and the H-bonds are relatively weak interactions that impart strength, directionality, and complementarity.<sup>[1–6]</sup> Such crystal manipulations, often known as crystal engineering, are performed to yield arrays of controlled superstructures providing new functional molecular solids.<sup>[7,8]</sup> Thus the self-organization of designed molecules containing certain kinds of complementary H-bonding and coordinating units has stimulated new efforts in the material sciences using, for example, controlled molecular arrays adsorbed to a solid surface,<sup>[9–11]</sup> a self-organized molecular assembly with unique cavities,<sup>[12]</sup> and an integrated system of molecular device.<sup>[13]</sup>

## MOLECULAR METAL BUILDING BLOCK

In some molecular systems, it has been possible to control molecular aggregation in the crystal by the di-functional ligands, which bond to metal using coordinate-covalent interactions and to each other using H-bonding interactions.<sup>[14–19]</sup> As 2,2'-biimidazole ( $H_2bim$ ) is a bidentate chelating ligand with multiproton donor sites, it can coordinate to a transition metal with three reversible types of protonated and deprotonated mode: neutral ( $H_2bim$ ), mono-deprotonated (monoanion,  $Hbim^{-1}$ ), and di-deprotonated (dianion,  $bim^{-2}$ ) types.<sup>[20]</sup> The 2,2'-biimidazolate monoanion ( $Hbim^{-1}$ ), recently introduced by us, works as such a di-functional bridging ligand not only to form a stable metal-chelate complex but also a new intermolecular

complementary H-bonding with two sets of NH donors and N acceptors, as shown in Drawing 1.<sup>[21]</sup> Molecular system such as  $Hbim^{-1}$  has not been found in molecular aggregation used for crystal engineering except in our aggregation system.

## CONTROLLED CRYSTAL STRUCTURES WITH ANIONIC $[Ni(Hbim)_3]^{-}$

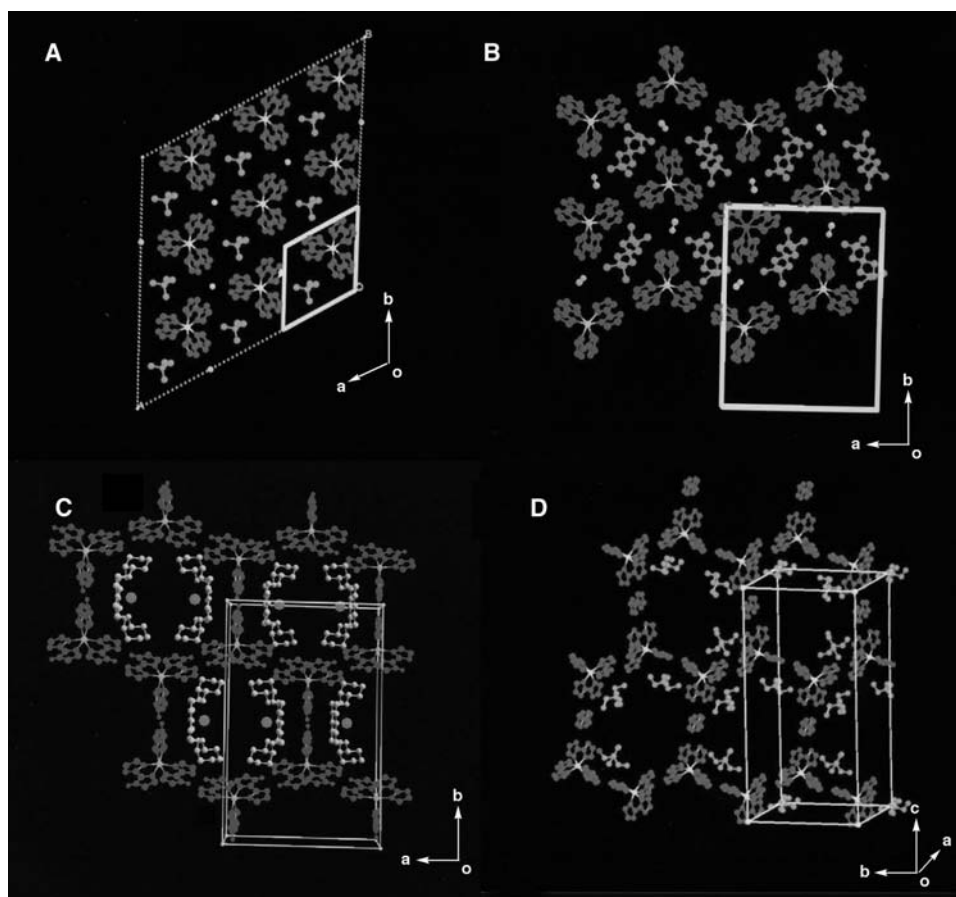

First of all, we have designed a new anionic building block, a tris-biimidazolate nickel (II) complex ( $[Ni(Hbim)_3]^{-}$ ), where the biimidazolate ligand acts as a strong  $\pi$ -conjugated ligand to form three complementary H-bonding sites, which forms a variety of multidimensional superstructures with long-range ordered arrays. The  $[Ni(Hbim)_3]^{-}$  is constructed from the nickel (II) center coordinated by three bidentate  $Hbim^{-}$  ligands through the lone pairs of the imine nitrogen atoms in the imidazole rings. The  $[Ni(Hbim)_3]^{-}$  has an approximate point group  $D_3$  symmetry, whose  $\Delta$  and  $\Lambda$  isomer are illustrated in Fig. 1. In these cases, the nature of metal anion assembly was affected by the nature and size of the counteranion. Interestingly, synthesis of simple one-pot procedures by mixing the nickel (II) ion,  $Hbim^{-}$ , and counteranion produces four types of H-bonded crystals 1–4 based on the arrangement of  $[Ni(Hbim)_3]^{-}$ .<sup>[22]</sup> The production of the four types of molecular architecture by one-pot molecular self-organization of the  $[Ni(Hbim)_3]^{-}$  evolves from three fundamental factors: 1) three complementary binary H-bonding sites; 2)  $\Delta$  and  $\Lambda$  optical isomers in the chiral coordination mode; and 3) the kind of counteranions. Fig. 2 shows crystal structures of the four patterns of molecular arrangement, respectively: A) a zero-dimensional (0-D) dot structure with no complementary H-bonds of  $Hbim^{-}$ , which are blocked by  $H_2O$  molecules; B) a 1-D H-bonded zigzag ribbon formed from alternative linkages of H-bonds between the  $\Delta$  and  $\Lambda$  optical isomers using two of the three  $Hbim^{-}$  of  $[Ni(Hbim)_3]^{-}$ ; C) a 2-D H-bonded honeycomb sheet self-organized by alternative H-bonds using all three  $Hbim^{-}$  between  $\Delta$  and  $\Lambda$  isomers of  $[Ni(Hbim)_3]^{-}$ ; and D) a 3-D supra cross-catenated network formed from expanded 2-D honeycomb sheets. Each crystal has

**Fig. 1**  $\Lambda$  and  $\Delta$  isomers of building blocks  $[\text{Ni}(\text{Hbim})_3]^-$ .

a different kind of counteraction, such as alkyl ammonium [a tetramethyl ammonium ( $\text{NMe}_4^+$ ) ions for 1, a tetra-*n*-propyl ammonium ( $\text{N}^n\text{Pr}_4^+$ ) ion for 2, and a tetraethyl ammonium ( $\text{NEt}_4^+$ ) ion for 4] and

a crown ether derivative [a potassium *cis-syn-cis*-dicyclohexano-18-crown-6 ( $[\text{K-DCH}(18\text{-crown-6})]^+$ ) ion for 3]. Therefore our results suggest that the mode of self-organization can be controlled by varying the kind of counteraction, although at this stage the prediction of the cation specificity is difficult. In the present study, we have succeeded systematically in the organization of the  $[\text{Ni}(\text{Hbim})_3]^-$  for the creation of 3 with double channels as included microporous crystals, such as an organic zeolite<sup>[2,3]</sup> and a modified zeolite with MOF<sup>[2,4]</sup> [Fig. 3A], and 4 with double-interlocking chains as polycatenate structures [Fig. 3B]. The 3 is constructed from all three H-bonding sites of  $[\text{Ni}(\text{Hbim})_3]^-$  with the complementary intermolecular H-bonds. Two of the H-bonding sites in it make a 1-D H-bonded zigzag ribbon like 2. Then the 1-D

**Fig. 2** The crystal structures of the H-bonded building blocks  $[\text{Ni}(\text{Hbim})_3]^-$ . (A) 0-D Dot structures in 1 formed from  $[\text{Ni}(\text{Hbim})_3]^-$  [ball and stick representation of Hbim<sup>-</sup> ligands (red) and nickel ions (magenta) along the *c* axis]. The orange ball-and-stick lines and the green spheres are shown for the  $\text{NMe}_4^+$  and water molecules, respectively. (B) 1-D Zigzag ribbons in 2 formed from  $[\text{Ni}(\text{Hbim})_3]^-$  along the *c* axis. The orange and the green ball-and-stick lines are shown for the  $\text{N}^n\text{Pr}_4^+$  ions and methanol molecules, respectively. (C) Double channel structures built up by 2-D honeycomb sheets in 3 formed from  $[\text{Ni}(\text{Hbim})_3]^-$ . The inner channels in 3 are constructed by  $\text{K}^+$ -crown ether complexes [the ball-and-stick representations of  $\text{K}^+$  ions (orange spheres) and crown ethers (green ball-and-stick lines) and the outer channels are constructed by  $[\text{Ni}(\text{Hbim})_3]^-$  to form a microporous crystal]. (D) 2-D Expanded honeycomb sheet structure in 4 with  $[\text{Ni}(\text{Hbim})_3]^-$  along the *a* axis. The free neutral  $\text{H}_2\text{bim}$  ligands connect 1-D zigzag-ribbon arrays by complementary H-bonding to form an expanded 2-D sheet structure along the *bc* plane. The orange ball-and-stick lines represent  $\text{NEt}_4^+$  ions.

**Fig. 3** (A) A perspective stereo view of a microporous structure with a double channel formed by both  $[\text{Ni}(\text{Hbim})_3]^-$  and  $\text{K}^+$ -crown ether complexes for 3. (B) A portion of the 3-D polycatenate network for 4: red and yellow lines represent the different 2-D expanded honeycomb sheets formed from  $[\text{Ni}(\text{Hbim})_3]^-$ . The stacking honeycomb sheets in red interlock with the other stacking honeycomb sheets with a perpendicular orientation in yellow to generate a double-interlocking polycatenate structure.

zigzag ribbons are connected to each other by the remaining H-bonding site to form the 2-D honeycomb sheets along the  $ab$  plane by the alternate arrangement of  $\Delta$  and  $\Lambda$  optical isomers of the six  $[\text{Ni}(\text{Hbim})_3]^-$ . The 2-D sheet stacks along the  $c$  axis to produce the outer channel structures, which are built up by a sequence of the same optical isomers. While 4 takes an interest in the controlled self-organization of 3-D complicated superstructures for supramolecular chemistry.<sup>[25]</sup> The inner channels are formed by stacking of two  $[\text{K-DCH}(18\text{-crown-6})]^+$  cations facing each other along the  $c$  axis. The channel contains methanol and water molecules with H-bondings. The framework structure of 4 has four structural characteristics. First, this has a 1-D zigzag ribbon structure similar to that with 2. Second, free neutral  $\text{H}_2\text{bim}$  ligands connect 1-D ribbon arrays by complementary H-bondings to form an expanded 2-D honeycomb sheet structure along the  $bc$  plane. Third, the honeycomb sheets interpenetrate the other

honeycomb sheets having the perpendicular orientation to construct a double interlocking catenate structure. Finally, the catenated structure is arranged in 3-D to form an infinite interlocking cross-catenated structure.

### Toward Complicated Crystal Structure

A major goal of the field of crystal engineering is to control rationally the assembly of 3-D arrays using intermolecular interactions and specific molecular topologies. We have found that the  $\text{Cs}^+$  ion can be used as a new tool to manipulate an H-bonded superstructure built with the  $[\text{Ni}(\text{Hbim})_3]^-$ . Two of the three  $\text{Hbim}^-$  in the  $[\text{Ni}(\text{Hbim})_3]^-$  can be bound to a  $\text{Cs}^+$  ion in crystal 5 by an electrostatic  $\pi$ -bonding interaction, which is not possible for other stable alkali metal ions. Furthermore, a more complicated 3-D superstructure of the double-helical racemate was formed in crystal 6 by cooperative application of an organic cation and the  $\text{Cs}^+$  interaction.

Superstructures with many 3-D frameworks have been created in different crystals by a self-assembly process. Most of the 3-D frameworks were developed by employing various topological building blocks as coordination polymers<sup>[26]</sup> and as H-bonding polymers.<sup>[27]</sup> However, the cooperative construction of 3-D arrays using both the weak H-bonding and coordination interactions has rarely been achieved to date.<sup>[28,29]</sup> We explore the effects of alkali metal ions, as well as organic cations, on superstructures formed by  $[\text{Ni}(\text{Hbim})_3]^-$ . Generally, alkali metal ions with a large polarizability can coordinate to aromatic rings in a multi-haptic mode.<sup>[30]</sup> Of all the stable alkali metal cations (i.e.,  $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Rb}^+$ , and  $\text{Cs}^+$ ), only the  $\text{Cs}^+$  ion was found to have a rational electrostatic interaction with  $[\text{Ni}(\text{Hbim})_3]^-$ . We have prepared not only a 3-D double interlocking polycatenate superstructure of interpenetrated 2-D honeycomb sheets by using such a  $\text{Cs}^+$  interaction, but also a double-helical 3-D racemate with (10,3)- $a$  nets by using the cooperative interactions between organic cations and  $\text{Cs}^+$ .<sup>[31]</sup>

Fig. 4A shows a fragment structure of  $\{\text{Cs}[\text{Ni}(\text{Hbim})_3]\}_n$  in 5 formed from the interaction of the  $\Delta$  and  $\Lambda$  optical isomers of  $[\text{Ni}(\text{Hbim})_3]^-$  with  $\text{Cs}^+$  as counterions. The three  $\text{Hbim}^-$  ligands in  $[\text{Ni}(\text{Hbim})_3]^-$  are involved in H-bonding interactions forming a 2-D honeycomb sheet with (6,3) nets. Four  $\text{Cs}^+$  ions are located in each hexagonal cavity of the sheet constructed by six  $[\text{Ni}(\text{Hbim})_3]^-$ , and fix the two interpenetrating rods of the other two sheets at an inclination of  $\sim 70^\circ$  to create a 3-D polycatenate superstructure with a double interlocking interpenetration [Fig. 4B]. Electrostatic interaction between  $\text{Cs}^+$  and

**Fig. 4** (A) The stereo view shows two interlocked honeycomb sheets (red and blue) that are linked to each other by Cs<sup>+</sup> ions. The blue and red sheets were built up by alternate linkage between the optical isomers ( $\Lambda$  and  $\Delta$ ) of  $[\text{Ni}(\text{Hbim})_3]^-$ . Four Cs<sup>+</sup> ions (green spots) are present in each hexagon-cavity formed by the six building blocks. (B) The stereo view shows the whole structure of 4 (red and light blue lines) with the shortest Ni–Ni bonds. The green spots represent Cs<sup>+</sup> ions. The main honeycomb sheet framework forms a twofold interpenetration with (6,3) nets, and as a whole they form a double-interlocking polycatenate structure.

the two different optical isomers of  $[\text{Ni}(\text{Hbim})_3]^-$  forms a 1-D alternative coordination polymer with the general formula  $\{(\Delta)\text{-Cs}[\text{Ni}(\text{Hbim})_3]\text{-}(\Lambda)\text{-Cs}[\text{Ni}(\text{Hbim})_3]\}_n$ . Each  $\Delta$  or  $\Lambda$  optical isomer fixed by two Cs<sup>+</sup> ions participates in the formation of a different interpenetrating sheet, respectively. Such a 3-D double interlocking interpenetration based on  $[\text{Ni}(\text{Hbim})_3]^-$  has already been prepared by 4 using an organic  $\text{NEt}_4^+$  ion. Moreover, an organic cation can work cooperatively with Cs<sup>+</sup> to manipulate the new superstructure formed in the crystal. The addition of  $\text{N}''\text{Pr}_4^+$  ion led 6 with the general formula  $\{\text{Cs}[\text{Ni}(\text{Hbim})_3]_2(\text{N}''\text{Pr}_4^+) \cdot \text{MeOH}\}_n$  to form a 3-D double-helical structure of racemate (10,3)-*a* nets having a 1-D column of Cs<sup>+</sup> in the center (Fig. 5A). The columns of Cs<sup>+</sup> in the 4<sub>1</sub> double helices lie along the *c* axis with Cs–Cs distances of 8.60 and 8.14 Å. The networks of 6 are composed of the  $\Delta$ – $\Delta$  and  $\Lambda$ – $\Lambda$  dimers with the same optical isomer of  $[\text{Ni}(\text{Hbim})_3]^-$  linked by one Cs<sup>+</sup> ion. In other words, each 4<sub>1</sub> strand in the helix is formed by using only one optical isomer of  $[\text{Ni}(\text{Hbim})_3]^-$ . Furthermore, each helix is H-bonded to four other identical optical isomers by using the Hbim<sup>−</sup> moiety. The 3-D H-bonded network forms an 8<sub>7</sub> chiral double helix with large cavities (Fig. 5B). The entire racemate structure is created by combining the 4<sub>1</sub> helices into an opposite-handed 8<sub>7</sub> helical structure. The superstructure formation of 6 can be attributed to the cooperative use of  $\text{N}''\text{Pr}_4^+$  and Cs<sup>+</sup> cations. The  $\text{N}''\text{Pr}_4^+$  ions occupy the void spaces created by the interpenetration of each independent chiral 3-D net with  $\Delta$  or  $\Lambda$  isomers of  $[\text{Ni}(\text{Hbim})_3]^-$ . The use of other alkali metals with  $\text{N}''\text{Pr}_4^+$  produces only 1-D zigzag ribbons within 2.

**Fig. 5** (A) A perspective view along the *c* axis showing the whole network with (10,3)-*a* nets of 5. The shortest Ni–Ni distances of  $\Lambda$  isomers (red and yellow) and  $\Delta$  isomers (blue and light blue) of  $[\text{Ni}(\text{Hbim})_3]^-$  are shown. Green spots represent Cs<sup>+</sup> ions. They are constructed from each homochiral trinuclear unit with two  $\Delta$ -isomers or two  $\Lambda$ -isomers of  $[\text{Ni}(\text{Hbim})_3]^-$  bound by Cs (I) ions. (B) The perspective stereo view along the *c* axis is shown for a larger right-handed 8<sub>7</sub> helix constructed from four smaller right-handed 4<sub>1</sub> helices.

The large ionic radius and high polarizability of  $\text{Cs}^+$  ions are important in the formation of this new, more complicated structure. It is believed that the  $\text{Cs}^+$  ion is bound to the deprotonated imidazole site of the  $\text{Hbim}^-$  ligand by using electrostatic  $\pi$ -interactions in both 5 and 6. The binding distances range from 3.188(10) to 3.62(1) Å for the Cs–C bond and 3.323(10) to 3.607(8) Å for the Cs–N bond for 5, and 3.368(6) to 3.565(7) Å (Cs–C) and 3.342(5) to 3.643(6) Å (Cs–N) for 6. It is also believed that the crystal structures presented are the first where the structure was formed from an interaction between a  $\text{Cs}^+$  ion and an imidazole ring. The bond distances found in 5 and 6 are similar to those in different complexes.<sup>[32–34]</sup> This clearly has shown that an electrostatic  $\pi$ -bonding interaction can form between a  $\text{Cs}^+$  ion and an imidazole ring in  $[\text{Ni}(\text{Hbim})_3]^-$ . Furthermore, when  $\text{Cs}^+$  and  $\text{N}^{\text{Pr}}_4^+$  were used at the same time, an intricate 3-D racemate structure with (10,3)-*a* nets was formed by the  $4_1$  double helices wrapping around a 1-D column of  $\text{Cs}^+$  ions. Finally, the current work may possibly be a general route to the formation of 2-D and helical structures by controlling the assembly of only  $D_3$  symmetric building blocks with different optical activity.

## CONTROLLED CRYSTAL STRUCTURES BY NEUTRAL BIIMIDAZOLATE COMPLEX

We have tried to eliminate the counterion and create a new superstructure with an infinite chain without the effect of counterions on the assembly of metal complexes constructed from H-bonding dimer units such as Drawing 1. In this section, four types of self-organizing superstructures with infinite chains are identified by designing four neutral  $\text{Hbim}^-$  complexes with altered metal coordination spheres. As a result, we can systematically produce five types of preprogramming superstructures of a dimer (A), a linear chain (B), a zigzag ribbon (C), a honeycomb sheet (D), and a helical chain (E), respectively, as shown in Fig. 6.<sup>[35]</sup>

Classification of multidimensional superstructures has already been performed in organic compounds assembled by intermolecular H-bonding of carboxylic acid derivatives<sup>[36]</sup> as well as in coordination polymers by bridging ligands such as oxalate.<sup>[37–40]</sup> Carboxylic acid H-bonding- and oxalate coordination polymers have been rationally synthesized in a linear chain and a zigzag ribbon, a honeycomb sheet, and other 3-D superstructures. These superstructures afford the classification of the multiaggregation compounds that

**Fig. 6** Schematic representations of multidimensional assemblies formed by transition-metal complexes with controlled configurations and regulated numbers of  $\text{Hbim}^-$  ligands: (A) “Zero-dimensional dimer” constructed by complementary intermolecular H-bonds between  $\text{Hbim}^-$  in the metal complexes coordinated by only one  $\text{Hbim}^-$  ligand. (B) “One-dimensional linear chain” assembled by the metal complexes with *trans*-configuration coordinated by at least two  $\text{Hbim}^-$  ligands. (C) “One-dimensional zigzag ribbon” assembled by metal complexes with two  $\text{Hbim}^-$  ligands in *cis*-configuration. (D) “Two-dimensional honeycomb sheet” linked by three intermolecular H-bonds between the metal complexes with three  $\text{Hbim}^-$  ligands. The sheet is constructed by H-bonding with alternate linkage between different optical isomers of  $\Delta$  and  $\Lambda$  types. (E) “Helical chain” assembled by intermolecular H-bonding between the same optical isomers of  $\Delta$  or  $\Lambda$  containing at least two  $\text{Hbim}^-$  ligands. The symbol *n* represents the number of  $\text{Hbim}^-$  ligands coordinated to transition metal ions.

consist only of H-bonds or coordination bonds. Here we have established a new categorical classification of the superstructures generated by the simultaneous use of both complementary intermolecular H-bondings and stable coordination bondings.

The H-bonded dimer unit through the  $\text{Hbim}^{-1}$  ligands has been assembled securely and strongly by using neutral complexes containing  $\text{Hbim}^{-1}$  (Drawing 1). For example, the previously reported neutral  $[\text{Cu}^{\text{II}}(\text{Hbim})(\text{SalenNMe}_2)]$  formed an H-bonded dimer of type A. In contrast, the positively charged  $[\text{Cu}^{\text{II}}(\text{Hbim})(\text{taccn})]^+$  formed an intermolecular H-bonding interaction with  $\text{ClO}_4^-$  counteranion in preference to self-complementary  $\text{NH}\cdots\text{N}$  H-bonding interaction between  $\text{Hbim}^{-1}$  ligands.<sup>[41]</sup> It suggests that the counterions, in particular, the anions with strong H-bonding ability in the ionic complexes, interrupt the formation of the dimer unit. Although counteranions such as alkyl ammonium ions in the crystal with the  $[\text{Ni}(\text{Hbim})_3]$  have an effect on the superstructures, they do not perturb the complementary H-bondings. Thus these facts indicate that there is no chance of interruption of self-complementary ligand–ligand interactions because of sterically demanding bulky cations and the preferential H-bonding between  $\text{Hbim}^{-1}$  ligands of anion complexes. From this point, in order to develop the effective self-organization of superstructures, neutral complexes rather than charged ones should be used.

Fig. 7 shows a superstructure with 1-D linear chains of type B in crystal 7 constructed by neutral  $[\text{Ni}^{\text{II}}(\text{Hbim})_2(\text{tBupy})_2]$  ( $\text{tBupy} = 4\text{-tert-butyl pyridine}$ ) with a *trans* configuration. The blue single crystals of it are obtained from a basic methanol solution by simple one-pot self-organization with  $\text{Ni}^{\text{II}}$  ions,  $\text{Hbim}^{-1}$ , and  $\text{tBupy}$ . The chain in the crystal along the *a* axis is composed of infinite links of intermolecular H-bonds of two  $\text{Hbim}^{-1}$  ligands, located in *equatorial* positions on the distorted octahedron (the range of  $\text{NH}\cdots\text{N}$  distances: 2.80–2.82 Å). The two *axial* positions are occupied by two monodentate  $\text{tBupy}$  ligands. Each

chain is piled along the *b* axis to form stacking sheets in the *ac* plane while fitting each  $\text{tBupy}$  group into the space between the chains. On the other hand, formation of the 1-D linear chains can be altered to that of 1-D zigzag ribbons by changing the direction of intermolecular H-bonding sites in the building blocks. Fig. 8 shows the zigzag ribbon of type C in crystal 8 constructed by  $[\text{Ni}^{\text{II}}(\text{Hbim})_2(\text{bpy})]$  with the bpy (= 2,2'-bipyridine) ligand. The pale orange crystals of  $[\text{Ni}^{\text{II}}(\text{Hbim})_2(\text{bpy})]$  are obtained by the same synthetic method of  $[\text{Ni}^{\text{II}}(\text{Hbim})_2(\text{tBupy})_2]$  except for the use of bidentate bpy instead of  $\text{tBupy}$ . The zigzag ribbon consists of 1-D ordered arrays along the *b* axis formed by alternative H-bondings between different optical isomers of  $\Delta$  and  $\Lambda$  of  $[\text{Ni}^{\text{II}}(\text{Hbim})_2(\text{bpy})]$ . Two  $\text{Hbim}^{-1}$  ligands of  $[\text{Ni}^{\text{II}}(\text{Hbim})_2(\text{bpy})]$  are used to form the H-bonded zigzag-ribbon networks, but a coordinated bpy does not participate in the formation of the networks (the range of  $\text{NH}\cdots\text{N}$  distances: 2.78–2.83 Å). Each bpy residue on the zigzag ribbon is aligned standing alternately parallel to each other and perpendicular to the 1-D main chains. Thus we have demonstrated that we can control linear vs. zigzag 1-D networks by using monodentate and bidentate ligands, respectively.

As shown in Fig. 9A, a neutral racemic complex of  $[\text{Ru}^{\text{III}}(\text{Hbim})_3]$  with  $D_3$  symmetry forms a 2-D honeycomb sheet of type D in crystal 9 with (6,3) nets. Compound  $[\text{Ru}^{\text{III}}(\text{Hbim})_3]$  is prepared from the precursor complex  $[\text{Ru}^{\text{II}}(\text{H}_2\text{bim})_3]^{2+}$  and the desired dark blue single crystals are crystallized from a methanol solution.<sup>[42]</sup> All the three  $\text{Hbim}^{-1}$  sites of  $[\text{Ru}^{\text{III}}(\text{Hbim})_3]$  form the complementary intermolecular H-bonds completely. The honeycomb sheet self-organized by  $[\text{Ru}^{\text{III}}(\text{Hbim})_3]$  is constructed by using alternative H-bondings between optical isomers of  $\Delta$  and  $\Lambda$  types of  $[\text{Ru}^{\text{III}}(\text{Hbim})_3]$  (the range of  $\text{NH}\cdots\text{N}$  distances: 2.79–2.80 Å). Each sheet forms an infinite number of identical sheets and passes each hexagonal cavity created by six  $[\text{Ru}^{\text{III}}(\text{Hbim})_3]$  units through the two interpenetrating rods of the other two sheets at

**Fig. 7** Arrangement of one-dimensional linear chains in a crystal formed by 7. Three  $\text{CH}_3$  groups containing  $\text{tBupy}$  are omitted for clarity. (A) A perspective view of one-dimensional linear chains linked along the *a* axis and piled along the *b* axis (color coding:  $\text{Hbim}^{-1}$  is shown in red,  $\text{Ni}^{2+}$  green, and  $\text{tBupy}$  blue). (B) A perspective stereo view of linear chains, as viewed along the *a* axis.

**Fig. 8** Arrangement of one-dimensional zigzag ribbons in a crystal formed by 8. (A) A zigzag ribbon structure is formed by alternate linkage between different optical isomers of  $\Delta$  (red) and  $\Lambda$  (blue) types along the  $b$  axis (nickel ions shown in green). The zigzag ribbons are stacked along the  $a$  axis. (B) A single chain of a one-dimensional zigzag ribbon is represented along the  $b$  axis.

an inclination of  $\sim 70^\circ$  to give a 3-D polycatenate structure with a double interlocking interpenetration in 9 (Fig. 9B). The two chiral building blocks of  $\Lambda$ -[Co<sup>III</sup>(Hbim)<sub>3</sub>] and  $\Delta$ -[Co<sup>III</sup>(Hbim)<sub>3</sub>] form 1-D helical chains of type E with a right-handed (for crystal 10) (Fig. 10A and C represented by red) and a

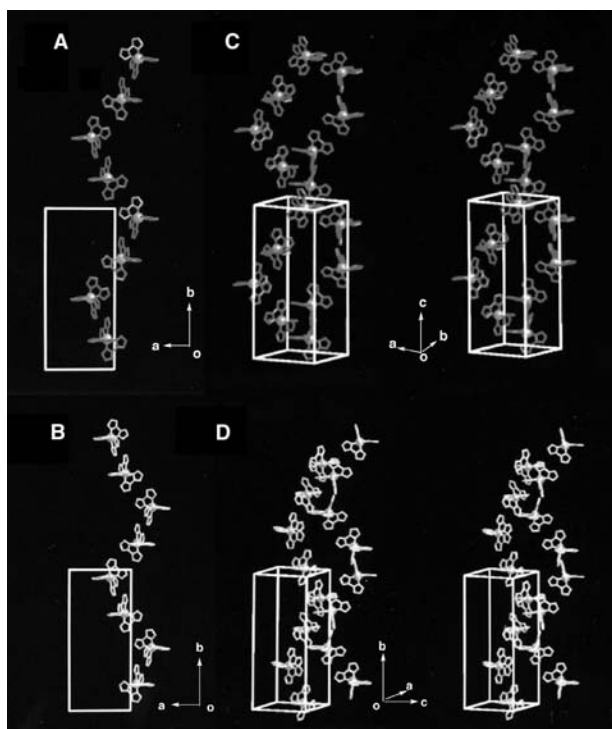

**Fig. 9** Arrangement of two-dimensional honeycomb sheets in a crystal formed by 9 (stereo view). (A) A two-dimensional honeycomb sheet is formed by alternate linkage between different optical isomers of  $\Delta$  (blue) and  $\Lambda$  (red) types (Ru<sup>3+</sup> ions are shown as magenta spheres). The sheet is constructed by complete H-bonds on three Hbim<sup>-1</sup> sites of 9. (B) The crystal structure of the single polycatenate network for the crystal of 9. Double-interlocking interpenetrations with the polycatenate structure are formed by two sets of stacked honeycomb sheets that are nearly perpendicular to each other in three dimensions.

left-handed (for crystal 11) (Fig. 10B and D represented by light blue) orientation, respectively. The red single crystals 10 and 11 of  $\Lambda$ - and  $\Delta$ -[Co<sup>III</sup>(Hbim)<sub>3</sub>] are crystallized from 2-propanol by the deprotonation reaction of the optically resolved  $\Lambda$ - and  $\Delta$ -[Co<sup>III</sup>(H<sub>2</sub>bim)<sub>3</sub>](NO<sub>3</sub>)<sub>3</sub> precursor complexes, respectively.<sup>[43]</sup> Each 1-D helical chain is constructed by employing intermolecular H-bonds between the same optical isomers, which utilize two of three Hbim<sup>-1</sup> sites in  $\Lambda$ - or  $\Delta$ -[Co<sup>III</sup>(Hbim)<sub>3</sub>]. Both helical chains form 4<sub>1</sub> single strands, which have a pitch of ca. 33.4 Å similar to that of the B-DNA double strand. Another residual Hbim<sup>-1</sup> site of  $\Delta$ - and  $\Lambda$ -[Co<sup>III</sup>(Hbim)<sub>3</sub>] is blocked by H-bonds with 2-propanol of crystallization, without using the helical chain construction.

In the case of superstructures on 10 and 11 using all of three sites, a 3-D chiral network with larger porous spaces formed by 8<sub>7</sub> cavities of (10,3)- $a$  nets like 6 would be expected to be constructed as found in the crystal with [Ni(Hbim)<sub>3</sub>]<sup>-1</sup>, which has the structure reinforced by a twofold interpenetration and stable double helical structures. In contrast, 10 and 11 do not have any larger porous networks. It has not been obvious to date why large cavities are not constructed by (10,3)- $a$  single networks, although two factors, solvent effect and the strength of the H-bonds formed, are anticipated. Öhrstrom and Larsson have shown lately the (10,3)- $a$  nets based on single helical H-bonding networks formed from both building blocks of  $\Delta$ - and  $\Lambda$ -[Co<sup>III</sup>(Hbim)<sub>3</sub>] by using a solvent effect with DMF/H<sub>2</sub>O mixed solvent.<sup>[44]</sup> Here the two superstructures of a honeycomb sheet and a helical strand built from tris-2,2'-biimidazolate complexes with  $D_3$  symmetry can be individually prepared by using a racemic compound and an optically resolved ones, respectively.

In summary, we demonstrated the practical structures of A–E in Fig. 6 based on the relationships between specified molecular arrays and molecular building blocks, and identified the four types of new

**Fig. 10** Arrangement of helical chains in a crystal formed by 10 or 11 ( $\text{Co}^{3+}$  ions are shown as yellow spheres): (A) and (B) View of each helical chain is represented by the right-handed helix formed by  $\Lambda$ -isomers of 10 in red and the left-handed helix by  $\Delta$ -isomers of 11 in light-blue along the  $c$  axis. (C) Stereo view of two right-handed single helices made up of  $\Lambda$ -isomers 10 (red). The two single helices do not intersect each other and do not form a double helix. (D) Stereo view of two left-handed single helices made up of  $\Delta$ -isomers of 11 (light blue).

superstructures, B–E, by X-ray analysis. The knowledge from structural data should help provide the preprogramming of new superstructures built from the “neutral”  $\text{Hbim}^{-1}$  complexes. Thus we have recently found that the neutral complexes with some  $\text{Hbim}^{-1}$  ligands can control the preprogramming superstructures in multidimensionality by using configurations around the coordination sphere, as there is no chance of interruption of self-complementary ligand–ligand interactions because of sterically demanding bulky cations and the preferential H-bonding between  $\text{Hbim}^{-1}$  ligands of anion complexes.

## CONCLUSION

Crystal engineering techniques using those functionalized molecular building blocks will be utilized in future studies for the creation of new solid-state materials. Thus the building blocks in Fig. 6 would produce the functionalized preprogramming superstructures

by introducing additive ligands with physical properties such as magnetic and photoactive ones to other coordination sites on the arrays of A, B, C, and E. We are now attempting to develop functional solid-state materials using these techniques. Our further study will be aimed at finding the mutual relationship between H-bonded superstructures of  $[\text{Ni}(\text{Hbim})_3]^-$  and the kinds or shapes of their component counter-cations. Thus cations play an important role in predicting the crystal structures and rationalizing the crystal structure engineering in these systems. In addition, the introduction of paramagnetic metal ions and transition metal chromophores into the system of the H-bonding extended arrays may lead to the creation of a new material with interesting magnetic and electronic properties.

## ACKNOWLEDGMENTS

This work was supported by a Grant-in-Aid for Scientific Research (Nos. 13440201 and 10146103) on Priority Areas from the Ministry of Education, Science, and Culture, Japan. The authors thank the Analytical Center in Osaka City University, for use of a single-crystal X-ray diffractometer and elemental analyses. I would like to thank Prof. Kazuhiro Nakasuji of the Graduate School of Science of Osaka University for the useful discussion of this manuscript.

## INTRODUCTION

This entry briefly reviews preparation and assembly of inorganic semiconductor nanowires and their potential applications in macroelectronics. It is organized into four sections. The first summarizes approaches to generate semiconductor nanowires with controlled dimension, purity, crystallinity, and uniformity. The synthetic, “bottom-up” methods (i.e., growth of nanowires through assembly and crystallization of atoms of precursors) are compared with the complementary “top-down” processes (i.e., preparation of small objects on the nanometer scale by carving, slicing, or etching macroscale material sources). The second section outlines strategies for the formation of ensembles of aligned nanowires, including manipulation of nanowires in solutions with various external forces, in situ growth of aligned nanowires from patterned catalysts, and dry transfer printing of nanowire arrays generated from “top-down” processes. The third section discusses schemes for fabricating high-performance thin-film transistors (TFTs) on plastic substrates using thin films of aligned nanowires. Several examples of devices and their characteristics demonstrate the current state of the technology. The last section concludes with perspectives on the trends for future work related to flexible macroelectronics.

## BACKGROUND

Macroelectronics systems represent a new class of electronics that consist of integrated circuits on flexible substrates that have sizes much larger than those of conventional semiconductor wafers. The most closely related existing electronic technology is based on TFTs on large-area glass substrates of the type that are used to provide power, switching, computation, and communication for large-area displays (e.g., liquid-crystal-based devices), medical X-ray sensors,

and other systems.<sup>[1]</sup> Recent research developments in active sensory skin and electronic textiles, foldable and expandable antennas for military and space applications, etc., require flexible, lightweight, and low-cost substrates to support the associated electronics.<sup>[2]</sup> Polymeric plastics represent ideal classes of materials for these substrates: they are lightweight, rugged, low in cost, and can be processed in the form of continuous rolls. It is extremely challenging, however, to fabricate high-performance transistors using inorganic semiconductor materials on these unusual electronic substrates because they degrade at the high-temperature steps that are present in traditional microelectronics fabrication sequences. One solution of this problem is to perform high-temperature processing (e.g., preparation of semiconductor materials, annealing, implant activation, etc.) on platforms that can withstand high temperatures and then to do subsequent integration with the final plastic device substrates. For example, crystalline Si nanoparticles and quantum dots synthesized from solution-phase reactions at elevated temperatures can be spin cast on plastic sheets to form thin films that can then be used as semiconductor layers for TFTs patterned using traditional photolithography at relatively low temperatures.<sup>[3]</sup> The performance of transistors using nanoparticle-derived films as transport components, however, is relatively low in terms of carrier mobility due to high resistance boundaries between individual nanoparticles. On the other hand, one-dimensional semiconductor nanowires represent potential building blocks in which the transport from source electrode to drain electrode can occur without interruption through the crystalline semiconductor.<sup>[4]</sup> Furthermore, thin films composed of nanowires can survive relatively high strain (i.e., they are mechanically flexible) because of their small thicknesses.<sup>[5]</sup> Conceptually, carbon nanotubes fall into this class of nanowire-based macroelectronics. These materials, which are beginning to show considerable promise for these applications,<sup>[6–9]</sup> will not be covered here.

## PREPARATION OF SEMICONDUCTOR NANOWIRES

Nanowires made of inorganic semiconducting materials are of considerable interest due to their unique properties and potential applications.<sup>[10,11]</sup> For instance, semiconductor nanowires with lateral dimensions less than 15 nm exhibit band gaps in the ultraviolet (UV) and visible regions of light.<sup>[12]</sup> In addition, nanowires of single-crystalline inorganic semiconductors show excellent transport properties of electrons and holes.<sup>[4,13]</sup> As a result, they offer great promise for electronic and optoelectronic devices with interesting properties. A range of approaches have been developed to generate nanowires of various materials (e.g., Si, Ge, III–V compounds, II–VI compounds, and oxides). The techniques can be classified into two general categories, i.e., “bottom-up” and “top-down” approaches.

### “Bottom-Up” Approaches

Atoms of semiconductor materials can crystallize and grow into nanowires in both gaseous and liquid media by controlling reaction conditions. Because a large number of publications have reviewed these techniques for semiconductor materials,<sup>[14–17]</sup> this entry only summarizes the principles of some of these approaches. Among all vapor-based methods, the vapor–liquid–solid (VLS) process, originally developed by Wagner and Ellis, seems to be the most successful and widely used method for generating single crystal nanowires in large quantities.<sup>[18]</sup> The results demonstrated by Lieber, Yang, and many other research groups confirm that the VLS process starts with the dissolution of vapors of target materials into nanosized liquid droplets of a metal catalyst (e.g., Au), followed by nucleation and growth of single-crystalline wires. The liquid droplets are generated from metal nanoparticles at elevated temperatures; their size determines the diameter of wires. The vapor, which can be generated by laser ablation<sup>[19]</sup> or thermal decomposition of organometallic compounds,<sup>[20]</sup> determines the composition of the wires. In a typical setup, target materials (e.g., InP, CdS, and Si) and silicon substrates covered with gold nanoparticles (serving as catalysts) lie at the upstream end and central part of a tube furnace, respectively. The substrate is heated to high temperature of 600–1200°C while the temperature of target material remains room temperature. A pulsed laser ablates the target to generate a vapor, which transports, through a flow of argon, to the surface of the substrate. This vapor dissolves in the droplets of catalyst until the catalyst is supersaturated with material from the target. At this point, the vapor condenses into nanowires through the VLS process.<sup>[21]</sup> This method

has, in principle, the ability to synthesize nanowires of most semiconductor materials that can be evaporated by tuning the parameters (e.g., power, wavelength and pulse width) of the laser. The size of the catalyst droplets controls the diameter of nanowires. The growth time and ablation conditions control the length of the nanowires.<sup>[22]</sup>

By combining nanoparticles of metals (e.g., In, Ga, or Bi) with low melting points as catalysts with thermal decomposition of organometallic precursors, an analog of VLS process can be extended to liquid phase. This process, so-called solution–liquid–solid process, or SLS, has been pioneered by Buhro and coworkers to synthesize nanowires made of III–V compounds.<sup>[23,24]</sup> For example, nanowires of GaAs and InP with small diameters (e.g., 3–17 nm) and relatively narrow diameter distributions were synthesized by refluxing 1,3-diisopropylbenzene solutions of corresponding precursors (i.e.,  $(^t\text{Bu})_3\text{Ga}$  and  $\text{As}(\text{SiMe}_3)_3$  for GaAs, and  $[\text{Me}_2\text{InP}(\text{SiMe}_3)_2]_2$  for InP) in the presence of In nanoparticles. The SLS process is mainly limited by the availability of suitable organometallic precursors. Also, nanowires synthesized via “bottom-up” approaches always have broad distributions in both lateral and longitudinal dimensions. Furthermore, lengths greater than 100  $\mu\text{m}$  are difficult to achieve. Their surface properties, compositional purity, doping uniformity, and concentration, which all strongly influence their electrical properties, are less well defined than those of the single-crystalline wafers used in the semiconductor industry.

### “Top-Down” Approaches

Microwires and nanowires can be fabricated from bulk wafers via “top-down” approaches. These types of nanowires have well-controlled doping levels, dimensions and crystallinity, which, in turn, give them excellent electrical properties for applications in high-performance electronics. The critical step involved in “top-down” approaches is to generate patterned mask lines on the nanometer scale, using simple lithographic techniques such as phase-shift photolithography with soft-phase masks made of poly(dimethylsiloxane) (PDMS) or nanoimprinting.<sup>[25–27]</sup> For example, Si nanowires have been fabricated from multi-layered wafers (i.e., silicon-on-insulator, or SOI wafers) through the near-field optical lithography.<sup>[28]</sup> In this case, exposing photoresist on an SOI wafer through an elastomeric phase mask, which forms a conformal contact with the layer of photoresist, generates patterned lines with widths ranging from 50 to 300 nm. The features patterned in the photoresist film can be transferred onto the underlying wafer using reactive-ion etching or wet-etching of the top Si layer. After

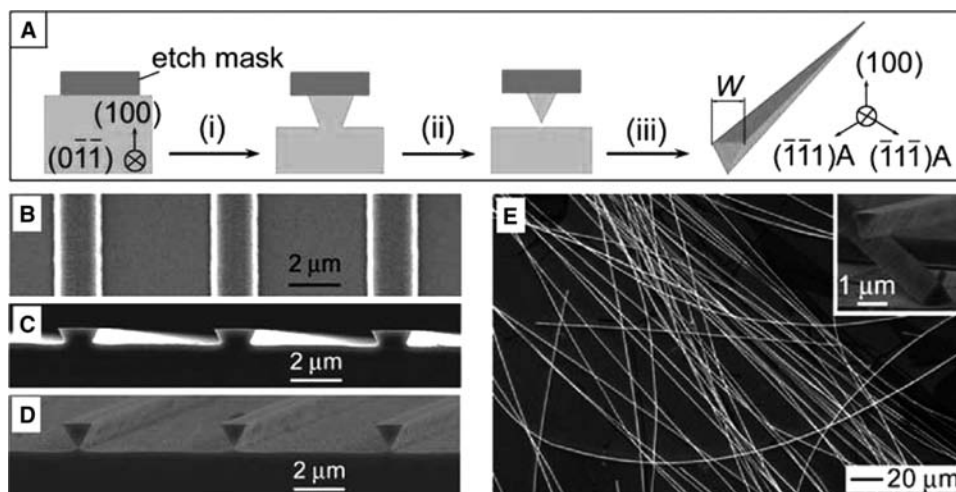

**Fig. 1** Formation of Si wires from a (110) Si wafer. (A) Steps of the fabrication process: (i) anisotropic chemical etching of Si in hot KOH solution using nitride or oxide mask stripes; (ii) removal of mask stripes; (iii) shadow deposition of new mask material on the top and side surfaces of each vertical wall; (iv) isotropic etching to lift off Si wires. (B) SEM image of Si walls with width of  $\sim 1.5 \mu\text{m}$  before lift off. (C) SEM image of Si walls with top surface width of  $\sim 100 \text{ nm}$ .

the buried  $\text{SiO}_2$  layer is selectively dissolved with HF solution, Si nanowires are released from the mother wafer. The resulting wires can be further thinned through oxidation and selective etching of the outer  $\text{SiO}_2$  layer. For many applications, this approach is unsuitable due to the relatively high cost of these kinds of multilayered wafers (e.g.,  $\sim \$500$  for each 6-in. SOI wafer versus  $\sim \$5$  for each 6-in. Si wafer). Developing convenient methods for generating nanowires from inexpensive wafers is therefore crucial to commercialize electronics with large areas, i.e., macroelectronics.

Anisotropic chemical etching of single-crystalline wafers provides a route to fabricate nanowires from inexpensive wafers with uniform compositions. For example, anisotropic etching of a (110) Si wafer with patterned mask lines in a hot aqueous KOH solution can generate trenches with vertical profiles (see Fig. 1A, step i).<sup>[29]</sup> The top surface and partial side surfaces of each wall can be covered with a thin film of inert materials (e.g., Ti/Au and Pd), which can withstand the etchant, through shadow evaporation (step iii).<sup>[30]</sup> Isotropic etching in  $\text{HF-HNO}_3\text{-H}_2\text{O}$  can cut the walls at the edges of mask films on side surfaces to release free-standing wires (step iv). Fig. 1B gives a scanning electron microscopy (SEM) image of the sample before Si wires are released. The width of the top surface of each wall is  $1.5 \mu\text{m}$ ; this dimension can easily be reduced to the nanometer scale by using phase-shift photolithography<sup>[31]</sup> or nanoimprinting.<sup>[32]</sup> Fig. 1C shows an SEM image of the vertical walls with width of  $100 \text{ nm}$  fabricated by phase-shift photolithography. The height of each wire can be easily tuned

by controlling the incident angle ( $\alpha$ ) of the evaporated material. Many other related approaches can generate similar structures.

Anisotropic etching of semiconductor wafer that leads to the formation of reverse mesas (i.e., structures with newly formed sidewalls with an acute angle relative to the original surface of wafer) can be exploited to generate nanowires using only a single etching step. Compound semiconductor materials made of group III and V elements are usually crystallized in the form of zinc blende face-centered cubic (f.c.c.) lattice, whose  $\{111\}$  planes are the most stable.<sup>[33]</sup> The  $\{111\}$  surface terminated by the group III atoms, also called  $\{111\}\text{A}$ , is deficient in electron density compared with the  $\{111\}$  surface terminated by the group V atoms, or  $\{111\}\text{B}$ . This difference makes the  $\{111\}\text{A}$  surface resistant to chemical oxidation and generally difficult to etch. As a result, sidewalls with an acute angle (rather than obtuse angle) relative to top surface can be generated by controlling the orientation of stripes of etching mask. As shown in Fig. 2A, anisotropic etching of (100) wafer patterned with parallel mask lines along  $(0\bar{1}1)$  crystallographic direction in appropriate etchant (e.g.,  $\text{H}_2\text{O}_2\text{-H}_3\text{PO}_4\text{-H}_2\text{O}$  for GaAs and  $\text{Br}_2\text{-methanol}$  for InP) generates reverse mesas with side surfaces terminated by  $(\bar{1}11)\text{A}$  and  $(\bar{1}\bar{1}1)\text{A}$  planes, respectively (step i).<sup>[34,35]</sup> With long etching times, the two side walls of each reverse mesa connect to release a wire with triangular cross section (step ii). Pure wires with single crystallinity, uniform doping concentrations, and well-defined crystalline surfaces are collected after removal of the etching mask (step iii).

**Fig. 2** Fabrication of wires by anisotropic chemical etching of a III-V semiconductor wafer with top surface of (100) plane. (A) Schematic illustration of the steps: (i) anisotropic etching using mask stripes oriented along  $(0\bar{1}\bar{1})$  direction; (ii) continuous etching and release of wire; (iii) removal of etch mask and generation of free-standing, clean wire. (B–E) SEM images of the samples formed by etching a GaAs wafer patterned with photoresist (PR) stripes in an aqueous solution consisting of  $1\text{H}_3\text{PO}_4$  (85 wt.%)– $13\text{H}_2\text{O}_2$  (30 wt.%)– $12\text{H}_2\text{O}$  (v/v/v) at different etching times. (B) PR stripes on GaAs wafer before etching. (C and D) Cross section of reverse mesas. (E) A random assembly of clean GaAs wires. Etching processes were performed in ice-water bath and ambient environment.

Panels B–E of Fig. 2 show a series of SEM images of samples obtained at different etching times. Fig. 2B presents an SEM image of  $2\ \mu\text{m}$  wide photoresist (Shipley® 1805) lines on a (100) GaAs wafer, clearly showing the straight and uniform width along the longitudinal axis. The SEM images shown in Panels C and D display reverse mesas formed at short and long etching times. Comparison of the lateral dimension between reverse mesas and photoresist lines reveals lateral undercutting along with the vertical etching. Fig. 2E shows an SEM image of free-standing GaAs wires randomly assembled on a GaAs substrate. The wires exhibit uniform widths ( $W$ ) of  $840\ \text{nm}$  along their longitudinal axis. The SEM image shown in the inset displays the triangular cross section of each wire, the roughness of the side walls, and the flatness of the top surface. The roughness of the side walls originates mainly from the edge roughness of the mask lines. The formation of curved structures indicates that the wires are flexible. The bendability increases with decreasing lateral dimensions. Wires with widths of  $\sim 400\ \text{nm}$  can form arc shapes with radii as small as  $\sim 20\ \mu\text{m}$ .<sup>[34]</sup> The excellent flexibility of the nanowires allows them to serve as active components in flexible macroelectronic devices.

It is worth noting that the etching generates undercutting and maintains high anisotropy after the wires lift off the substrate.<sup>[34]</sup> As a result, the lateral dimensions of the wires can be easily decreased to tens of nanometers by controlling the etching time even when the mask lines have widths in the micrometer scale.

Figure 3A–D shows SEM images of individual wires obtained by etching a GaAs wafer patterned with  $2\ \mu\text{m}$  wide mask lines. The wires become thinner with increasing etching time, but the triangular cross sections of the wires are preserved. The dependence of wire width ( $W$ ) on etching time is plotted in Fig. 3E, which indicates that GaAs wires with widths down to  $50\ \text{nm}$  can be obtained in this fashion. The minimum width is determined by the roughness on the side walls. The lengths of the GaAs wires can also be easily tuned by controlling the length of mask stripes. Fig. 3F and G shows SEM images of GaAs rods with average lengths of  $6.4$  and  $15.5\ \mu\text{m}$ , respectively. In principle, wires with lengths as long as tens of centimeters, i.e., the diameter of original wafer, can be fabricated. Fig. 4 gives a composition of several SEM images of long GaAs nanowires with lengths of  $1\ \text{cm}$ , which indicates that most wires are continuous in the observed regions.

The physical parameters of nanowires fabricated via “top-down” approaches exhibit good uniformity (comparable to the high-quality wafer precursors) and enable easy control over the processing. The cost of the wires can be greatly decreased if the resultant mother wafers are polished and reused to generate more wires.<sup>[34]</sup> A disadvantage of the “top-down” approach is that the composition of the wires is limited to materials (e.g., Si, Ge, GaAs, InP, etc.) that are already available in wafer or thin film forms. We have demonstrated this approach with Si, GaAs, InP, and GaN.<sup>[34–37]</sup>

**Fig. 3** (A–D) SEM images of GaAs wires that were generated by etching a GaAs wafer patterned with 2 μm wide SiO<sub>2</sub> stripes at different times: (A) 68, (B) 75, (C) 85, and (D) 93 sec. (E) Plot of the dependence of the average width of GaAs wires with etching time. ### GENERATION OF ARRAYS OF ALIGNED NANOWIRES

Hierarchical assembly of nanowires into well-defined architectures is the cornerstone for fabrication of functional devices. In particular, monolayers of aligned nanowires with high density and uniform end-to-end registry are critical to build high-performance TFTs

for macroelectronics. A number of approaches have been demonstrated to organize nanowires dispersed in solutions into parallel arrays by applying various external forces (e.g., microfluidic shear force, electric field, surface compression, and magnetic field) to overcome Brownian motion.<sup>[38–43]</sup> In the VLS process, arrays of aligned nanowires can be in situ grown from metal nanoparticles (i.e., catalysts) patterned on

**Fig. 4** SEM images of long GaAs wires. The arrows indicate the same position of the sample.

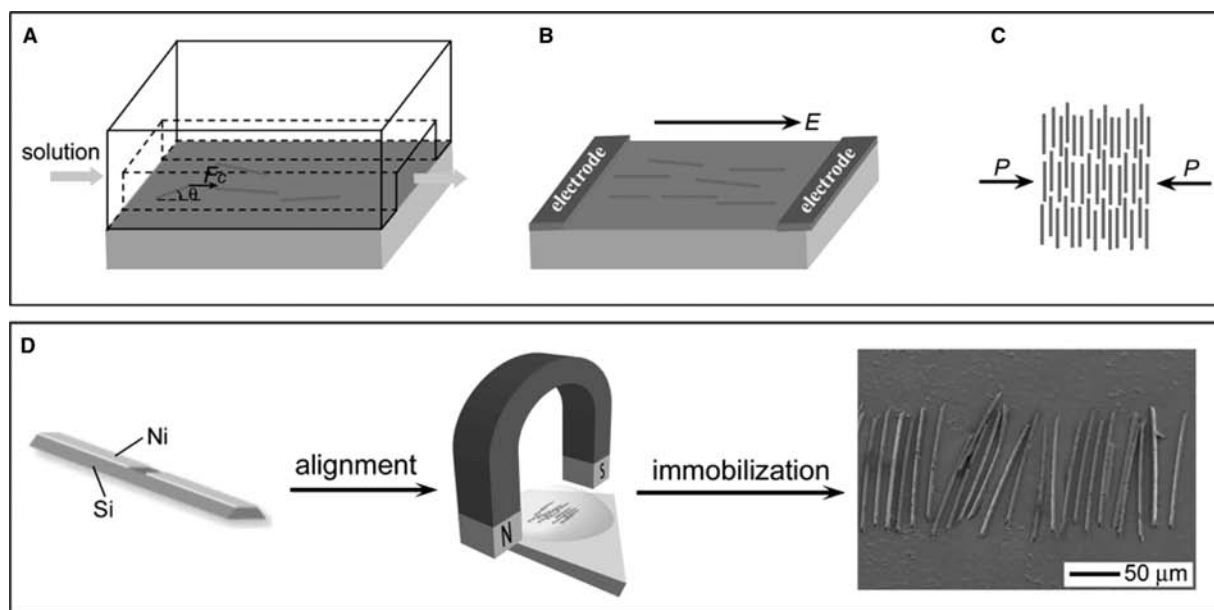

substrates with specific crystallographic planes.<sup>[44–49]</sup> Nanowires fabricated using “top-down” approaches can be designed to maintain the order defined by lithographic process. The resultant wire arrays can be transfer printed onto any desired substrates including plastic sheets.<sup>[34–37]</sup>

### Assembly of Solution-Based Nanowires Using External Forces

Nanowires synthesized through “bottom-up” approaches are often dispersed in solvents and then deposited onto substrates for further applications. Generating organized arrays, which have relatively low entropy, requires external forces to manipulate the nanowires. For example, flow of a nanowire suspension through microfluidic channels formed between a PDMS stamp and substrate has been demonstrated by Lieber and coworkers to align nanowires of various materials.<sup>[38]</sup> In this case, a shear flow formed near the surface of substrate provides a force ( $F_c$ ) to orient the wires parallel to the flow direction before they are immobilized on the substrate (see Fig. 5A). The degree of alignment, which is represented by the angle ( $\theta$ ) of nanowires with respect to the flow direction, can be controlled by the flow rate. Meanwhile, the spacing between individual aligned nanowires can be narrowed by increasing the time for deposition. A disadvantage of this approach is that it is difficult to produce uniform coverage (i.e., the number of tubes per unit area

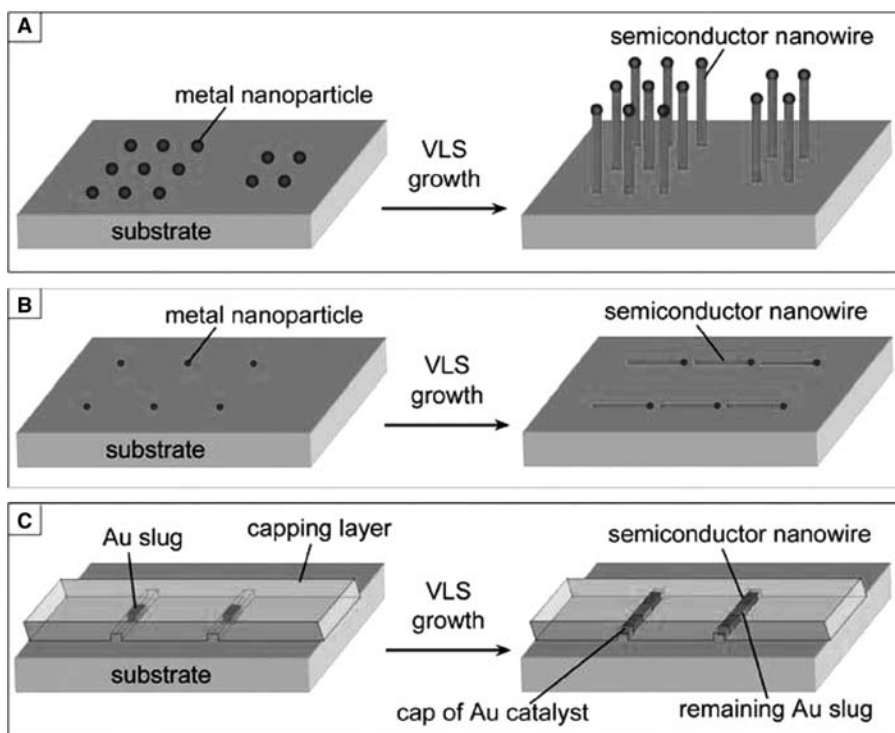

tends to be largest near the place where the nanowire suspension is introduced into the channel). In another approach, nanowires in suspension can be induced to generate polarization when they are exposed to an electric field. The interaction between induced wire polarization and electric field aligns the wires parallel to the field direction (Fig. 5B).<sup>[39,40]</sup> It is difficult, however, with either of these approaches to generate uniform films of aligned nanowires with high-density coverage over large areas.

Langmuir–Blodgett (LB) type techniques can push nanowires floating on the water–air interface into nematic liquid-crystal structures.<sup>[41,42]</sup> In this case, the surfaces of the nanowires are first modified with surfactant molecules that have hydrophobic heads facing the water. The repulsive interaction between these hydrophobic groups and the water molecules lifts the nanowires to the water–air interface. Increasing surface pressure ( $P$ ) forces nanowires to rotate perpendicular to the pressure direction (Fig. 5C) in the LB trough. In this manner, a monolayer of aligned nanowires forms on the surface of the water. These wire arrays can be transferred onto other substrates. The advantage of this approach is that it can achieve high density and large area coverage, both of which are critical requirements for fabrication of high-performance macroelectronics. Nevertheless, the surfactant modification on the surfaces of nanowires can affect their electrical properties and thus their performance in applications. The resultant nanowire arrays also have relatively poor end-to-end registry. Finally, the alignment process can

**Fig. 5** Strategies for assembly of as-synthesized nanowires dispersed in solvents through different external forces: (A) shear flow force formed in microfluidic channels; (B) electric field; (C) surface pressure generated through the Langmuir–Blodgett technique; and (D) magnetic field. The wire array demonstrated in (D) consists of Si wires with Ni stripes sitting on the surface of a thin layer of cured polyurethane spin cast on a glass slide.

**Fig. 6** In situ growth of nanowire arrays on substrates via the VLS process: (A) wire array perpendicular to surface of substrate; (B) wire array in the plane of substrate; (C) wire array grown on substrate in nanochannels.

be slow, and the transfer mechanism can be inconvenient for many applications.

A different approach exploits magnetism to generate, in a high speed and effective manner, concentrated and aligned arrays.<sup>[43]</sup> Here, ribbons or wires are coated with a ferromagnetic material such as Ni. An external magnetic field applied to a solution suspension of such elements aligns and concentrates them in controlled ways. As shown in Fig. 5D, the interaction between a magnetic field and ferromagnetic Ni coatings induces the ribbons to align parallel to the magnetic field. The aligned ribbons can be fixed such that they maintain their order during the drying process by bonding them to the surface of a photo-cured layer of polyurethane (PU) film (see a typical SEM image in Fig. 5D). This method can precisely position nanostructures by controlling the magnetic field. It is possible to integrate this approach with printing technologies to generate patterns over large areas. In addition, the Ni stripes can serve as electrodes in the further TFT fabrication because Ni can form a silicide with Si to generate ohmic contacts.<sup>[50]</sup>

### In Situ Growth of Aligned Nanowires via VLS Process

Nanowires can epitaxially grow vertically to surfaces of appropriate substrates when reaction conditions are precisely controlled. As a result, patterning metal nanoparticle catalysts on a substrate with specific

crystallographic orientation can direct the in situ growth of aligned nanowire arrays via the VLS process (see Fig. 6A).<sup>[44–47]</sup> For example, an array of Si nanowires perpendicular to a (111) Si wafer can grow through catalysis of Au nanoparticles (>20 nm) deposited on the surface of Si wafer because the Si wires prefer to grow along the  $\langle 111 \rangle$  direction.<sup>[44]</sup> ZnO nanowire arrays can vertically grow on an *a*-plane (110) sapphire substrate although ZnO nanowires tend to grow along the  $\langle 001 \rangle$  direction. The epitaxial growth of ZnO nanowires on the (110) plane of sapphire is attributed to the fact that the *a*-axis of wurzite ZnO and the *c*-axis of sapphire are related by a factor of four (i.e.,  $a_{\text{ZnO}} = 3.24 \text{ \AA}$  vs.  $c_{\text{sapphire}} = 12.99 \text{ \AA}$ ) with mismatching less than 0.08% at room temperature.<sup>[45]</sup> Locations of nanowire arrays grown in this way can be easily controlled by precisely manipulating the positions of Au nanoparticles through various lithographic techniques including, for example, soft lithography, e-beam lithography, photolithography, and microcontact printing. It is apparent that the density of wire arrays is determined by the density of Au nanoparticles on substrate. Arrays formed using this method are highly dense and well aligned on the mother substrate, but they might be difficult to transfer to plastic sheets while preserving their order.

Most recently, Stranick et al. reported that the growth orientation of ZnO nanowires on sapphire surface could be altered by controlling the size and spacing of Au nanoparticles.<sup>[48]</sup> The results indicate it is necessary to have Au nanodroplet catalysts with

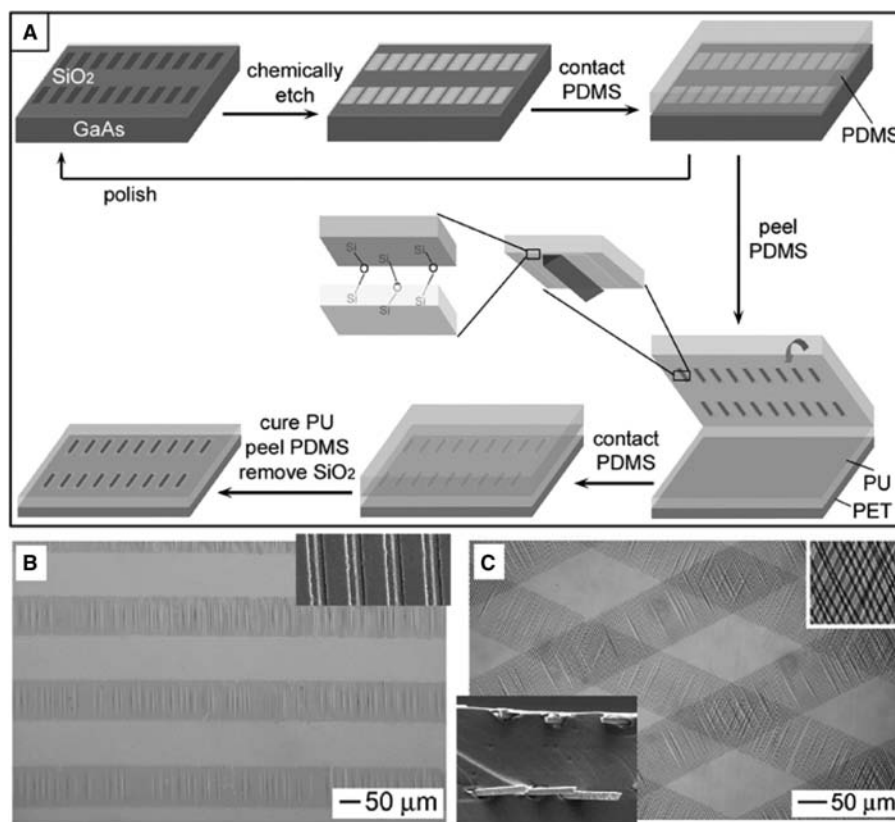

diameters smaller than 20 nm and spacings larger than 100 nm to achieve horizontal growth in the surface plane of substrate (Fig. 6B). Au nanoparticles larger than 20 nm always yield nanowires with off-surface orientations regardless of the interparticle spacing. Aligned ZnO nanowires with diameters less than 10 nm have been grown on the surface of *a*-plane (1120) sapphire substrates through VLS process combined with pre patterning of thin Au lines of very narrow widths. These kinds of wire arrays are suitable for transfer onto plastic substrates for TFTs, but it is difficult to increase the wire density due to relatively large spacing between Au nanoparticles.

The “grow-in-place” approach developed by Fonash and coworkers demonstrates the ability to produce self-assembled, crystalline Si nanowires by combining the VLS growth mechanism with lithographically fabricated nanochannels as growth templates.<sup>[49]</sup> As shown in Fig. 6C, Au lines that have heights and widths on the nanometer scale are first generated on an insulating substrate through e-beam lithography, deposition of metal and lift-off. A capping layer (e.g., silicon nitride) is then deposited over the substrate, followed by photolithographic patterning and selective dry etching. The Au lines under the capping layer are shortened to slugs with lengths of several micrometers by wet etching. In this configuration, the remaining Au in the center of channels serves as

catalyst for the growth of semiconductor nanowires (i.e., Si), while the nanochannels act as templates to confine the dimensions of nanowires. When the Au slug is longer than 10  $\mu\text{m}$ , the silicon cannot saturate the whole slug, but instead locally saturates the ends. The nanodroplet of Au–Si alloy at each end induces the growth of one wire by continuous transfer of  $\text{SiH}_4\text{--H}_2$  gas. As a result, two Si nanowires separated by the remaining Au slug form in the nanochannel. These two wires join together to form a continuous wire when the Au slug is short enough (e.g.,  $<2\ \mu\text{m}$ ). The resultant wires have well-controlled size, shape, orientation, and positioning. On the other hand, the use of e-beam lithography makes it expensive to generate wire arrays with large area.

### “Dry Transfer Printing” of Wire Arrays Formed via “Top-Down” Approaches

Nanowires fabricated via “top-down” approaches can inherit the order of the lithographic patterns used to produce them. Ordered nanowires produced in this manner can be transfer printed onto any desired substrates, such as plastic sheets. For example, Fig. 7A summarizes the steps for generating and transferring nanowire arrays of GaAs to a plastic substrate, i.e., poly(ethylene terephthalate) (PET) sheet.<sup>[34]</sup>

**Fig. 7** Transfer printing wire arrays formed via “top-down” approaches: (A) schematic illustration of steps for transfer printing GaAs wire arrays generated by anisotropic etching; (B and C) optical microscopic images of (B) single and (C) double layers of GaAs wire arrays transfer printed on PET substrates.

If patterned SiO<sub>2</sub> lines (etch masks) surrounded by bulk SiO<sub>2</sub> film are defined on the surface of a (100) wafer, both ends of each GaAs wire generated from anisotropic chemical etching connect to the mother wafer. This connection confines the wires and preserves the spatial orientation defined by the pattern of SiO<sub>2</sub>. GaAs wire arrays can be transfer printed to plastic sheets with retention of their orientation and relative position using a PDMS stamp. In the transfer printing process, the PDMS stamp is slightly oxidized to generate a hydrophilic surface by exposing it to a weak oxygen plasma or ozone. Contacting the oxidized PDMS stamp with SiO<sub>2</sub>-covered GaAs wafer generates strong chemical bonding due to the formation of covalent siloxane (Si–O–Si) linkages between PDMS and SiO<sub>2</sub> via a condensation reaction. This bonding is strong enough to break the crystalline connections at the ends of wires. Peeling the PDMS stamp away from the GaAs substrate transfers all of the wires to the stamp. The remaining GaAs wafer after this transfer step can be polished to regenerate a flat surface for fabrication of more wires. The combination of wafer polishing with wire fabrication has the capability to generate a huge number of GaAs wires from a single piece of wafer, thus significantly decreasing the cost per wire.

In the next step, a photocurable polymer, such as PU, is used as a glue to bind the GaAs wires to a PET substrate. Placing the PDMS stamp (with GaAs wires) against a PET sheet coated with a thin layer of PU (thickness between one and tens of micrometers, determined by spin speed) forms conformal contact by pushing the surfaces of the wires into the liquid PU. Illuminating the sample with a UV lamp crosslinks and solidifies the PU layer, resulting in the formation of a strong bond between the cured PU and the GaAs wires and the underlying PET substrate. Peeling off the PDMS stamp and dissolving the SiO<sub>2</sub> stripes leave the GaAs wire arrays embedded in the matrix of cured PU with order and crystallographic orientation similar to those of the wires prior to transfer. The top flat surfaces of the wires are facing up, and can be exploited for subsequent device fabrication steps.

Fig. 7B gives an optical image of a PU/PET substrate with GaAs wire arrays, indicating that all of GaAs wires were transfer printed onto the PET substrate with preservation of order and spatial orientation. The inset shows an SEM image taken from the same sample, clearly showing that the GaAs wires were well embedded in the cured PU. The flat top surface of each wire is exposed for further applications. The transfer printing process can be repeated to generate multiple layers of GaAs wire arrays on the same PET substrate. Fig. 7C presents an optical image of a sample with two layers of wire arrays formed by rotating the second layer with ~45° relative to the first layer. The bottom left inset is an SEM image of the cross

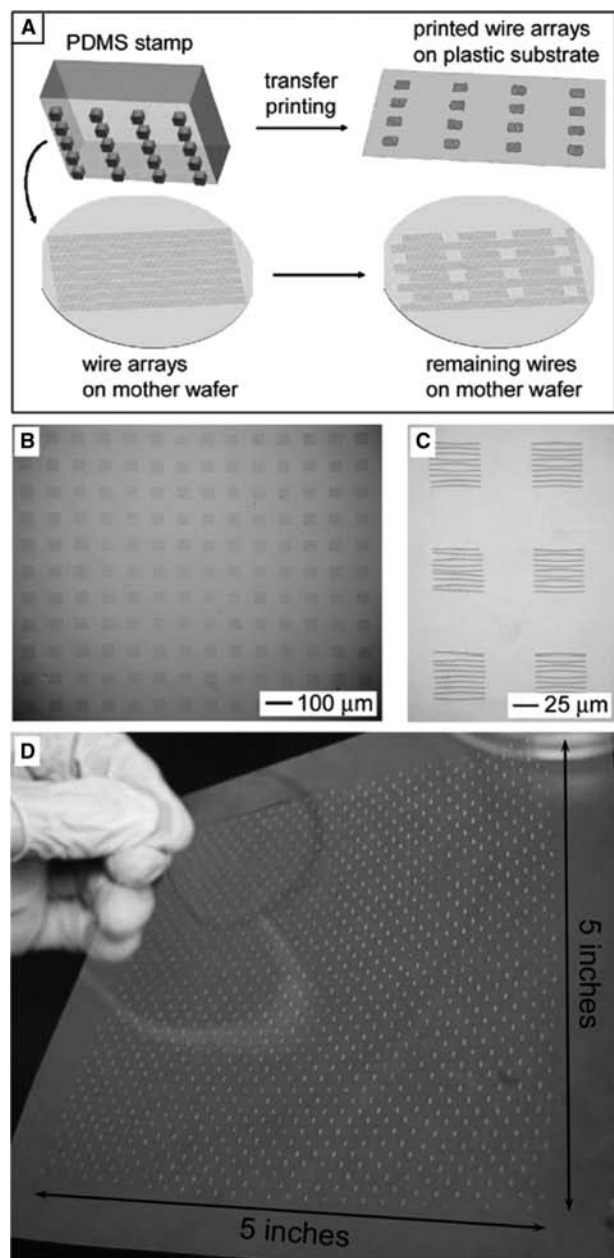

section of this sample, indicating that the two individual layers of GaAs wire arrays are well separated by the cured PU. These PU layers can electrically insulate circuits or devices built on different layers of GaAs wire arrays.

This “dry transfer printing” process combined with the “top-down” fabrication approach is promising for applications related to high-performance macroelectronics. It controls well the crystallographic orientation of transferred wires, with the top (100) surfaces facing up to provide an extremely flat surface (similar to that of original wafer) for device fabrication. The use of SiO<sub>2</sub> stripes as etch mask and buffer layer for the transfer prevents the (100) surfaces of the GaAs wires from becoming contaminated by organics used in the processing. In addition, conformal contact between PDMS stamp and liquid PU generates GaAs wires conformally bound to, and embedded in cured PU, which prevents the wires from moving, especially when the plastic substrates are bent or twisted.

Circuits for macroelectronics are fabricated on substrates with sizes much larger than semiconductor wafers. Active semiconductor films usually occupy only 10–20% area of the whole substrate, and the remaining regions are used to build interconnection between individual device units (e.g., transistors). Therefore, wire arrays generated on a mother wafer can be selectively transferred from certain regions rather than the whole surface, thus further decreasing the cost of fabrication. Fig. 8A shows a diagram for printing nanowire arrays generated from a single wafer over large areas on a plastic substrate. This process uses a PDMS stamp with patterned posts. Placing the stamp against the wafer and peeling it off picks up only the wires that contact with the surface of extrusive posts. The printing process can transfer patches of wire arrays onto plastic substrates. Repeating the steps over the remaining wires on the mother wafer can yield organized arrays of wires over large areas on a plastic substrate. Fig. 8B gives an optical image of patches consisting of GaAs wire arrays that were transfer printed on a PU/PET substrate. The image with relatively high magnification (as shown in Fig. 8C) shows that the wires of each patch are well aligned and have good end-to-end registry. This transfer printing process can be extended to wire arrays of other materials (e.g., InP, Si, etc.) fabricated via “top-down” approaches.<sup>[34,36,51]</sup> For instance, Fig. 8D shows a 5" × 5" PET sheet with patterned patches of Si ribbons.

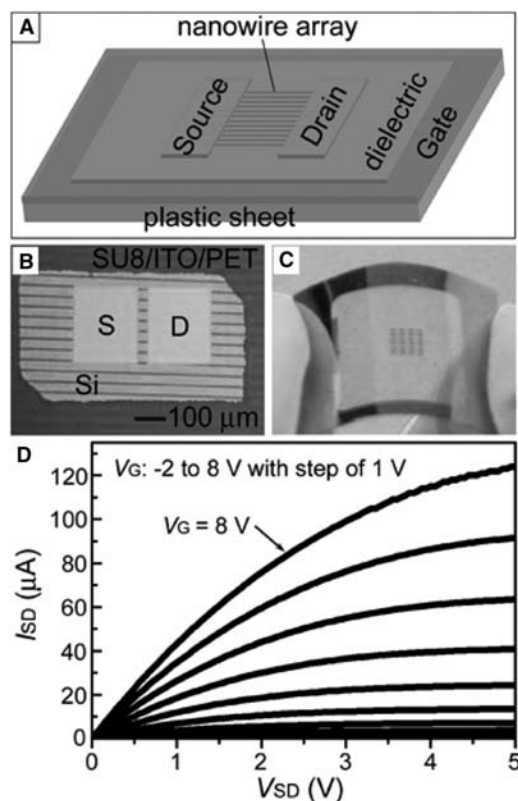

## MACROELECTRONICS APPLICATIONS

Monolayer films of nanowires with aligned orientation on plastic substrates can be used to produce flexible

**Fig. 8** Transfer printing patches of wire arrays on plastic substrates using PDMS stamps with patterned posts: (A) schematic illustration of this process; (B and C) optical images of patches of arrays of 50  $\mu\text{m}$  long GaAs wires; (D) a large-area sample with transfer printed Si ribbons on a PET substrate.

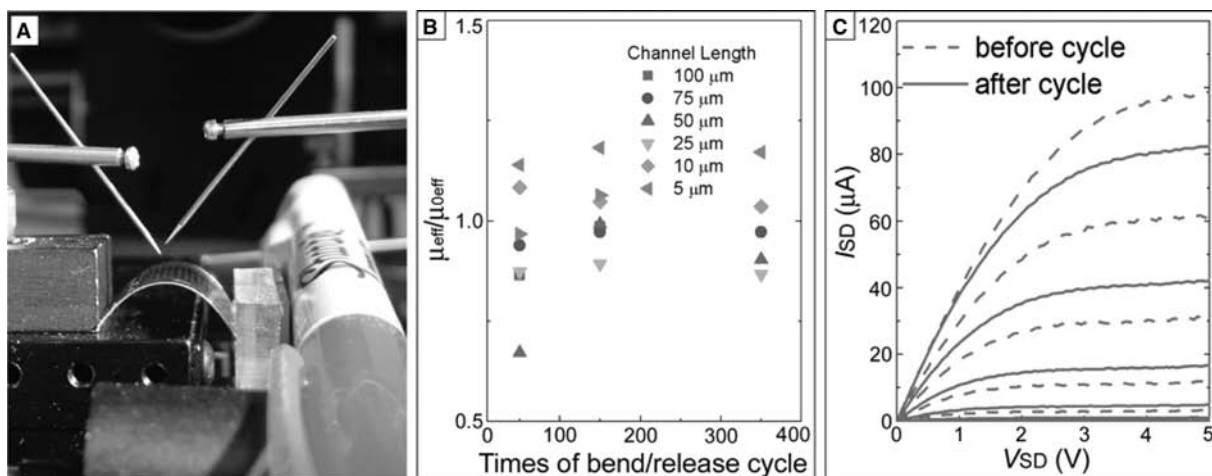

TFTs by traditional lithographic processing steps. Fig. 9A depicts the geometric construction of a typical back-gate TFT using an aligned nanowire array as the semiconductor. A thin conductive layer of metal (e.g., Au) or oxide (e.g., indium-tin-oxide, or ITO) and a thin dielectric layer (e.g., aluminum oxide,  $\text{SiO}_2$ , resin epoxy, etc.) are sequentially deposited on the surface of a plastic sheet. Aligned nanowire films formed using

**Fig. 9** (A) Geometry of a thin film transistor (TFT) fabricated on a plastic substrate using aligned wires as a semiconductor film. (B) Optical image of an individual TFT built using aligned Si ribbons on a 530 nm thick cured SU8 epoxy layer spin cast on an ITO-coated PET sheet. (C) Photograph of a piece of a PET sheet with an array of TFTs, indicating their mechanical flexibility. (D) Typical current–voltage characteristics of a Si ribbon transistor on a PET substrate. From bottom to top,  $V_G$  varies from  $-2$  to  $8$  V with steps of  $1$  V.

the approaches described in the previous section are transferred onto the multilayered plastic substrate with controlled positioning and orientation. Finally, large-area lithographic techniques are used to define the pattern of source–drain electrodes over the thin film of oriented nanowires.<sup>[52]</sup>

Duan and coworkers assembled Si nanowires that were synthesized via the laser-assisted VLS process on a polyetheretherketone (PEEK) sheet (with thickness of  $125 \mu\text{m}$ ) by passing a nanowire suspension through microfluidic channels (detailed description referred to in a previous section).<sup>[53]</sup> Before assembly of nanowires, thin strips of Cr/Au (10/30 nm) and a 30 nm layer of aluminum oxide were deposited on the PEEK sheet to serve as gate electrodes and dielectric. Ti/Au (60/80 nm) patches were defined as source and drain electrodes. The resultant devices show a threshold voltage of  $\sim 3.0$  V, an on-off ratio higher than  $10^5$ , and a subthreshold swing of 500–800 mV per decade. The performance of devices did not significantly

**Fig. 10** Fatigue testing of Si ribbon transistors on a PET substrate: (A) setup for bending test; (B) variation of electron mobility of Si ribbon transistors with different channel lengths after repeated bend/release cycles; (C) comparison of current–voltage curves before and after 350 bending cycles.

change even when the bend radius was  $\sim 55$  mm. In spite of the relatively high per wire mobility ( $\sim 150$  cm<sup>2</sup>/V sec), the device mobilities are low ( $\sim 3$  cm<sup>2</sup>/V sec) due to the low density of these arrays and their random end-to-end registry.

Rogers and coworkers have recently developed a parallel route for fabricating TFTs with high performance on plastic substrates.<sup>[36,51,54]</sup> In their demonstration, Si stripes with thicknesses of 20–100 nm and widths of 1–100  $\mu$ m were fabricated from high-quality SOI wafers via the “top-down” approach. (Note: although the width of Si stripes can be reduced down to 50 nm using phase-shift photolithography, this narrowing is not necessary for macroelectronics applications.) These Si structures, with good order and orientation, were then transferred onto an ITO (100 nm) coated PET (175  $\mu$ m) substrate through the dry transfer printing technique depicted in Figs. 7 and 8A. In this case, a polymeric resin of SU-8 photoresist was used as glue to bind Si film and PET substrate together. This same film served as a gate dielectric. Patterns of 70 nm thick Ti films formed the source and drain electrodes. Fig. 9B shows an optical image of an individual transistor with channel length of 20  $\mu$ m and channel width of 250  $\mu$ m. Fig. 9D presents the  $I$ – $V$  curves of a device at various gate voltages. The electron mobility extracted from the transfer curve is  $\sim 230$  cm<sup>2</sup>/V sec, evaluated in the linear regime. This technique can be easily extended to nanowires of other materials (e.g., GaAs, InP, GaN, Ge, etc.) fabricated from bulk wafers. For example, GaAs nanowire arrays transfer printed onto PET substrates (as shown in Figs. 7 and 8) can serve as active channel for MESFET devices if ohmic contacts are deposited before wires are transferred onto plastic substrates.<sup>[55]</sup>

Because of the flexibility of the thin PET sheet and the nanowires,<sup>[5]</sup> the devices exhibit excellent mechanical bendability. As shown in Fig. 9C, the PET sheet with TFTs can be bent to form curved structures without substantial changes in the electrical properties. The precise degree of flexibility and the fatigue properties have been evaluated using the setup shown in Fig. 10A. The strain generated in the Si ribbons can be determined measuring the geometric parameters of substrate. The data indicate that the electrical properties do not change with 350 bend/release cycles to strains of 0.98%, i.e., bend radii of  $\sim 9$  mm. Fig. 10B shows the variation of the mobilities of transistors with different channel lengths after hundreds of bend/release cycles. Fig. 10C compares the  $I$ – $V$  curves of a device before and after 350 times of bending operation, indicating that this transistor still works well, although with a current drop of  $\sim 25\%$ . These results indicate that the combination of “top-down” fabrication and “dry transfer printing” provides an efficient route to generate substrates for fabrication of large-area, high-performance macroelectronic devices.

## REMARKS AND PERSPECTIVES

Two different paradigms have been demonstrated to have capability for the fabrication of TFTs on plastics using thin film of aligned semiconductor nanowires. In the first strategy, nanowires synthesized via “bottom-up” approaches form aligned arrays through either postassembly or in situ catalyst-positioning growth (i.e., nanowires grow from patterned catalyst nanoparticles into aligned arrays). Chemically synthetic “bottom-up” approaches can produce nanowires with a wide range of materials by controlling

reaction conditions and precursors. The versatility of compositions provides a flexibility to choose suitable nanowires to meet specific applications. However, the moderate quality of nanowires (in terms of dimensional uniformity, purity, dopant concentration, doping uniformity, and surface crystallography) and assembled nanowire film (in terms of density, orientation, and end-to-end registry) might make it difficult to build large arrays of high-performance devices with them. The current lack of effective approaches for assembling high-quality nanowire thin films represents the main challenge for successful technology applications of these systems. In the second strategy, nanowires fabricated from high-quality, single-crystal, bulk wafers via “top-down” approaches adopt the organization and orientation defined by the pattern of mask. The resultant nanowire arrays can be transferred onto plastic substrates through the “dry transfer printing” technique. A drawback of this approach is that it is limited to materials that currently exist in bulk wafer or thin film form.

Although high performance is important, reliable, robust operation of macroelectronic devices is crucial for many of their envisioned applications. In particular, the nature of the interfaces between the plastic sheet (or plastic sheet covered with cured polymer) and the semiconductor, and between the metal and semiconductor are critical from both electronics and mechanical points of view. Appropriate adhesive layer between a semiconductor nanowire film and a plastic sheet is critical for the formation of conformal contact especially when the substrate is bent and relaxed. The long-term reliability of low-temperature dielectrics is also a topic that must be investigated. In spite of these challenges, we believe that printable inorganic semiconductor nanowires represent the most promising approach to building these and other classes of large-area electronic devices.

## INTRODUCTION

A bottom-up approach, in which functional systems are assembled from chemically synthesized, well-defined nanoscale building blocks, has the potential to go far beyond of the limits of top-down technology by defining key nanometer scale metrics through synthesis and subsequent assembly—not by lithography. One-dimensional (1D) nanostructures represent the smallest dimension structure that can efficiently transport electrical carriers and can play an important role as both interconnect and functional device elements in integrated nanosystems. Here, we review recent advances in bottom-up assembly of nanoscale electronics and optoelectronics using semiconductor nanowire (NW) as building blocks. First, we review electrical transport studies on individual NWs, and moreover, examine nanoscale electronic and optoelectronic devices assembled using individual NWs as building blocks. Next, we present approaches for the hierarchical assembly of NWs into well-defined arrays with controlled orientation and spatial location. Third, we address critical issues for integration and demonstrate the assembly of integrated nanoscale devices with logic and computation circuits. Lastly, we describe a unique application enabled by nanoscale NW devices: highly sensitive and selective chemical and biological sensing. We conclude with a brief summary and perspective on future opportunities.

## BACKGROUND

### Top-Down Technology: The Limitations

The rapid miniaturization of electronics to the submicron scale has led to remarkable advances in computing power while at the same time reducing costs. These advances have been made possible by many

scientific and technological innovations associated with “top-down” manufacturing, in which small features are patterned in bulk semiconductor materials by lithography, deposition, and other processing to form functional devices. This now remarkable trend in miniaturization was first pointed out by Gordon Moore, and is now universally referred to as Moore’s Law, which dictates that the number of transistors per chip doubles every 18–24 months (Fig. 1).<sup>[1,2]</sup> The magnitude of what has been accomplished can be recognized by the fact that it is now possible to fabricate a 100 million transistors on a chip of the same size as a single transistor when it was first invented a half century ago. However, as the microelectronic industry advances towards ever smaller devices, it is believed that physical and economic limits of current top-down silicon technology will be soon reached. First, photolithography-based top-down strategies will soon reach a fundamental resolution limit of ca. 70 nm that will limit further reduction in feature sizes using relatively conventional optical sources, although solutions such as extreme ultraviolet lithography are being explored to overcome this limit. Second, the exponentially increasing cost to construct each new generation of fabrication line may limit further miniaturization on the basis of economics alone. These and other limitations of current top-down technology have motivated efforts worldwide to search for new strategies to meet the expected demand for increased computational power as well as for integrating low-cost and flexible computing in unconventional environments in the future.<sup>[3–5]</sup>

### Bottom-Up Technology: Requirements and Promises

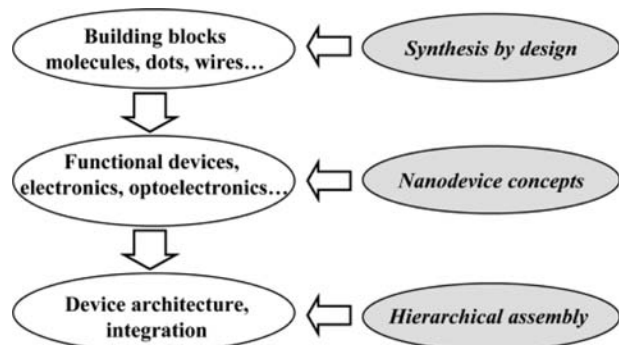

To go beyond the fundamental and economic limitations of top-down technologies will require new

**Fig. 1** Illustration of device scaling in conventional electronics—Moore's law.

methods. A bottom-up approach, in which functional electronic structures are assembled from chemically synthesized, well-defined nanoscale building blocks, much like the way nature uses proteins and other macromolecules to construct complex biological systems, represents a flexible alternative to conventional top-down methods,<sup>[4,6,7]</sup> and moreover, the bottom-up approach has the potential to go far beyond the limits of top-down technology by defining key nanometer scale metrics through synthesis and subsequent assembly—not by lithography.

To enable this bottom-up pathway requires that three key problems, which are at the heart of devices and integration in the broadest terms, be addressed (Fig. 2). First, the bottom-up approach requires nanoscale building blocks with precisely controlled and tunable chemical composition, structure, morphology, and size, since these characteristics determine their corresponding electronic and optical properties. To meet this goal necessitates developing methods that enable rational design and predictable synthesis of the building blocks. Second, it is essential to develop

**Fig. 2** Schematic outlining key challenges (open ellipses) and specific research areas (shaded ellipses) required to enable the bottom-up approach to nanoelectronic systems.

and explore the limits of functional devices based on these building blocks. Nanodevices may behave in ways similar to current electronic and optoelectronic devices, although it is also expected that new and potentially revolutionary device concepts will emerge from these building blocks, for example, due to quantum properties. Third and central to the bottom-up concept is the development of device architectures that enable high-density integration with desired function, and the development of hierarchical assembly methods that can organize building blocks into these architectures.

Addressing and overcoming the hurdles in these three major areas of the bottom-up approach could revolutionize fabrication and manufacturing, make a quantum jump in miniaturization, and lead to reduced power consumption and increased speed in next generation electronics and photonics. Moreover, it is very likely that the bottom-up approach could enable entirely new device concepts and new systems. For example, it is possible to combine seamlessly chemically distinct nanoscale building blocks, which could not be integrated together in top-down processing, into the same device architecture and thereby obtain unique function and/or combinations of function in an integrated system. Small and highly perfect building blocks may also lead to quantum electronic or quantum optical devices that enable quantum computing in an architecture that has many common features with digital systems.

## Nanoscale Building Blocks

Individual molecules<sup>[8–12]</sup> and quantum dots,<sup>[13–15]</sup> which can be classified as zero-dimensional (0D) structures, have been proposed as building blocks for bottom-up assembly of nanoscale electronics. These 0D structures have been intensively pursued over the past decade since they represent the smallest building blocks with corresponding high potential for massive integration. However, the use of individual molecules or quantum dots in nanoelectronics has been limited by challenges in establishing reliable electrical contacts needed to study their fundamental properties and interconnect them. It has thus been difficult to elucidate and understand the intrinsic properties of individual devices, and moreover, to develop and demonstrate realistic schemes for scalable interconnection and integration of 0D devices into functional architectures.

One-dimensional nanostructures have also been the focus of extensive studies worldwide due to their unique physical properties and potential to revolutionize broad areas of nanotechnology. First, 1D nanostructures represent the smallest dimension structure that can efficiently transport electrical carriers, and thus are ideally suited to the critical and ubiquitous

task of moving and routing charges (information) in nanoscale electronics and optoelectronics. Second, 1D nanostructures can also exhibit device function, and thus can be exploited as both the wiring and device elements in architectures for functional nanosystems.<sup>[4,16]</sup> In this regard, two material classes, carbon nanotubes (NTs)<sup>[16–27]</sup> and semiconductor NWs,<sup>[28–35]</sup> have shown particular promise.

Single-walled carbon NTs can exhibit either metallic or semiconducting behavior depending on diameter and helicity.<sup>[17]</sup> The unique electronic properties of NTs open up the possibility of creating a number of different devices that could have potential in nanoelectronics.<sup>[16,18–20]</sup> For example, single-walled NTs have been used to fabricate room-temperature field effect transistors (FETs),<sup>[21,22]</sup> diodes<sup>[23,24]</sup> and recently, logic circuits.<sup>[25,26]</sup> However, the inability to control whether NT building blocks are semiconducting or metallic makes specific device fabrication largely a random event. Hence, moving beyond proof-of-concept single device elements to the integrated arrays required for nanoelectronics poses a serious issue for NT-based approaches. A creative solution to the problem of coexisting metallic and semiconducting NTs involves selective destruction of metallic tubes,<sup>[27]</sup> although such an approach requires extensive top-down lithography and subsequent processing to implement and may not be practical for highly integrated nanoelectronics systems.

Semiconductor NWs<sup>[4,28,29]</sup> represent another important type of nanometer scale wire structure. In contrast to NTs, however, semiconductor NWs can be rationally and predictably synthesized in single crystal form with all key parameters controlled, including chemical composition, diameter and length, and doping/electronic properties.<sup>[30–32]</sup> Semiconductor NWs thus represent one of best-defined and controlled class of nanoscale building blocks, which correspondingly have enabled a wide range of devices and integration strategies to be pursued. For example, semiconductor NWs have been assembled into nanometer scale FETs,<sup>[32,33]</sup> p–n diodes,<sup>[33,34]</sup> light emitting diodes (LEDs),<sup>[33]</sup> bipolar junction transistors,<sup>[34]</sup> complementary inverters,<sup>[34]</sup> complex logic gates, and even computational circuits that have been used to carry out basic digital calculations.<sup>[35]</sup> In contrast to NTs, NW devices can be assembled in a rational and predictable manner because the size, interfacial properties, and electronic properties of the NWs can be precisely controlled during synthesis, and moreover, reliable methods exist for their parallel assembly.<sup>[36]</sup> In addition, it is possible to combine distinct NW building blocks in ways not possible in conventional electronics and to leverage the knowledge base that exists for the chemical modification of inorganic surfaces<sup>[37,38]</sup> to produce semiconductor NW devices that achieve new function and correspondingly could lead to unexpected device and system concepts.

## Overview

In this entry, we describe a broad range of studies addressing nanoelectronics and nanophotonics assembled from semiconducting NW building blocks. First, we review electrical transport studies of individual NWs, and moreover, examine nanoscale electronic and optoelectronic devices assembled using individual NWs as building blocks. Next, we present approaches for the hierarchical assembly of NWs into well-defined arrays with controlled orientation and spatial location. Third, we address critical issues for integration and demonstrate the assembly of integrated nanoscale devices with logic and computation circuits. Lastly, we describe an application enabled today by nanoscale NW devices: highly sensitive and selective chemical and biological sensing. We conclude with a brief summary and perspective on future opportunities.

## NANOWIRE ELECTRONIC DEVICE ELEMENTS

In a previous entry, we have reviewed the rational synthesis of semiconductor NWs. The availability of a wide range of NW materials with controlled chemical composition, physical size, and electronic properties opens up many exciting opportunities ranging from fundamental studies of the role of dimensionality on physical properties to a range of potential applications in areas such as nanoscale electronics and optoelectronics. In the section, we focus on fabrication and electrical transport properties of basic nanoscale device elements fashioned from these NW building blocks, including 1) single NW-FETs, 2) crossed NW p–n diodes, intra-NW p–n diode, 3) bipolar transistors, 4) crossed NW-FETs, and 5) NW quantum interference devices.

### Nanowire Field Effect Transistors

#### Device structure and underlying principles

The basic FET structure fabricated from single semiconducting NWs is illustrated in Fig. 3. The FET is supported on an oxidized silicon substrate with the underlying conducting silicon used as a global back gate electrode to vary the electrostatic potential of the NW. In a typical NW-FET device (Fig. 3, inset), two metal contacts, which correspond to source and drain electrodes, are defined by electron beam lithography followed by evaporation of suitable metal contacts. Current ( $I$ ) vs. source–drain voltage ( $V_{sd}$ ) and  $I$  vs. gate voltage ( $V_g$ ) is then recorded for a NW-FET to characterize its electrical properties.

**Fig. 3** Schematic of a NW-FET. Inset: SEM image of a NW-FET; two metal electrodes, which correspond to source and drain, are visible at the left and right sides of the image.

Variation of  $V_g$  during characterization of the NW-FET enables important qualitative and quantitative properties to be elucidated. For example, changes in  $V_g$  produce variations in the electrostatic potential of the NW, and hence change the carrier concentration and conductance of the NW. As shown in Fig. 4, p- and n-type semiconductor NWs, which are contacted at both ends to metal electrodes, respond in opposite ways to the applied gate. When a positive  $V_g$  is applied, the bands are lowered, which depletes the holes and suppresses conductivity in p-NWs, but leads to an accumulation of electrons and an enhancement in conductivity in n-NWs. Conversely, a negative  $V_g$  will increase the conductivity of p-type NWs and decrease the conductivity of the n-type NWs.

### p-Channel nanowire transistors

Typical  $I$  vs.  $V_{sd}$  data obtained from a single boron-doped Si NW-FET at different  $V_g$ s are shown in Fig. 5. The two-terminal  $I$ - $V_{sd}$  curves are linear, which indicates that the metal electrodes make ohmic contacts to the NW, and moreover, the gate response demonstrates that the NW is p-type; that is, the conductance of the p-Si NW decreases (increases) with increasingly positive (negative)  $V_g$ . The transfer characteristics,  $I$ - $V_g$ , of p-Si NW devices (Fig. 5, inset) exhibit behavior typical of p-channel metal-oxide-semiconductor FETs (MOSFETs).<sup>[39]</sup> Significantly, the conductance modulation of the p-Si NW-FET exceeds  $10^3$ , where the  $V_g$  required for switching ( $-10$  to  $10$  V) could be reduced significantly by reducing the thick (600 nm) oxide dielectric layer in these back-gated devices.

Gate-dependent measurements have also been used to estimate the hole concentration in p-channel NW-FETs. The total NW charge can be expressed as  $Q = C \cdot V_{th}$ , where  $C$  is the NW capacitance and  $V_{th}$  the threshold gate voltage required to deplete completely the NW. The capacitance is given by  $C \cong 2\pi\epsilon\epsilon_0L/\ln(2h/r)$ , where  $\epsilon$  is the effective gate

**Fig. 4** (A,B) Band diagrams illustrating the underlying principle for p- and n-channel NW-FETs. When a positive voltage is applied, the bands are lowered, which depletes the holes in p-NWs and suppresses conductivity, but leads to an accumulation of electrons in n-NWs and enhances the conductivity. Conversely, a negative gate voltage will raise the bands and increase the conductivity of p-type NWs and decrease the conductivity of the n-type NWs.

**Fig. 5** Current vs. voltage for a p-type Si NW-FET. The numbers inside the plot indicate the corresponding gate voltages ( $V_g$ ). The inset shows current vs.  $V_g$  for  $V_{sd}$  of 1 V.

oxide dielectric constant,  $h$  is the thickness of the SiO<sub>2</sub> layer on the substrate,  $L$  is the NW length, and  $r$  is the NW radius. The hole density,  $n_h = Q/(e \cdot \pi r^2 L)$ , is estimated to be  $\sim 10^{18}/\text{cm}^3$  for the device shown in Fig. 5. In addition, it is possible to estimate the carrier mobility of the NW-FETs from the transconductance  $dI/dV_g = \mu(C/L^2) V_{sd}$ , where  $\mu$  is the carrier mobility. Plots of  $dI/dV_g$  vs.  $V_{sd}$  are linear for Si NWs, as expected for this model, yield hole mobilities in the range of 50–800 cm<sup>2</sup>/V sec. Significantly, the p-Si NW-FET mobilities are comparable to or larger than the best p-Si planar devices, 100–300 cm<sup>2</sup>/V sec, at comparable hole densities ( $p \sim 10^{17}$ – $10^{18}/\text{cm}^3$ ).<sup>[40]</sup>

### n-Channel nanowire transistors

It is also possible to assemble n-channel NW-FETs in a similar way from n-type NWs. For example, gate-dependent  $I$ – $V_{sd}$  data recorded from an InP NW-FET exhibits increased conductance for positive  $V_g$  and decreased conductance for negative  $V_g$  (Fig. 6), as expected for an n-channel device. The n-InP NW-FET transfer characteristics ( $I$  –  $V_g$ ) show that the current increases rapidly from below 1 nA at  $V_g = -2$  V to above 400 nA at  $V_g = +2$  V (Fig. 6, inset), and tends to saturate at higher voltages, which can be attributed to contact resistance and other factors. Nevertheless, the conductance changes up three orders of magnitude for only a few volts' change in the gate voltage in these unoptimized devices.

The electron concentration and mobility in the n-channel NW-FETs have been estimated as described above for p-channel devices. For the n-InP NW-FET shown in Fig. 6, the electron mobility is 2200 cm<sup>2</sup>/V sec for an electron concentration of  $\sim 10^{18}/\text{cm}^3$ . Studies of a number of different devices yields mobility values from 400 to 3000 cm<sup>2</sup>/V sec, which is comparable to or larger than bulk InP, 1000–2000 cm<sup>2</sup>/V sec, at similar carrier concentrations.<sup>[40]</sup> These mobilities are

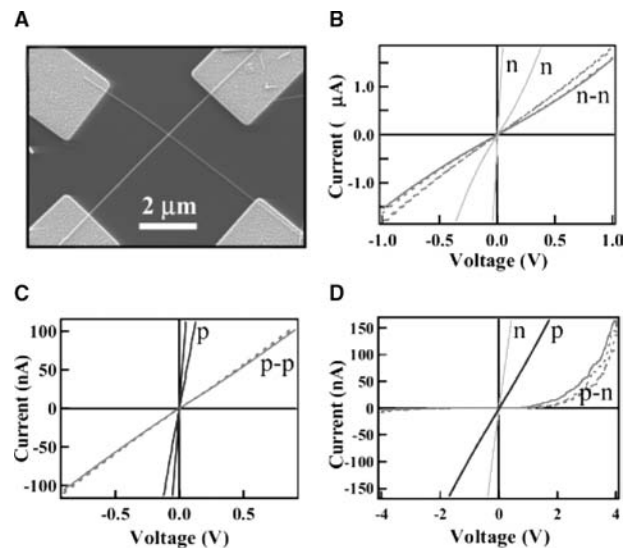

**Fig. 6** Current vs. voltage for an n-type InP NW-FET. The numbers inside the plot indicate the corresponding gate voltages ( $V_g$ ). The inset shows current vs.  $V_g$  for  $V_{sd}$  of 0.1 V.

believed to represent a lower limit in our NW materials since the contact resistance and surface depletion have not been included. Significantly, surface passivation studies suggest that substantially higher carrier mobilities are possible in the NW-FETs. Taken together, these results suggest that the NW-FETs could be essential elements in high performance (e.g., high gain, high speed and low power) nanoelectronics and photonics.

### Crossed Nanowire p–n Diodes

The availability of well-defined n- and p-type NW building blocks opens up the possibility of creating complex functional devices by forming junctions between two or more wires. To explore this exciting opportunity, we have studied the transport behavior of n–n, p–p, and p–n junctions formed by crossing two n-type, two p-type, and one n-type and one p-type NW, respectively (Fig. 7A).<sup>[33]</sup> Significantly, the types of junctions studied in an experiment are reproducible since we can select the specific type of NW used at each of the two stages of device assembly.

First,  $I$ – $V$  data recorded on the individual NWs in n–n and p–p crossed junctions show linear or nearly linear  $I$ – $V$  behavior (Fig. 7B,C), indicating that the metal electrodes used in the experiments make ohmic or nearly ohmic contact to the NWs. This point is

**Fig. 7** Crossed NW junctions. (A) SEM image of a typical crossed InP NW device with four metal electrodes contacted to each of the four arms. (B–D)  $I$ – $V$  behavior of n–n, p–p, and p–n junctions, respectively. The  $I$ – $V$  behavior of individual n- and p-NWs in the junctions is indicated by “n” and “p”, respectively. The  $I$ – $V$  behavior across the junctions is designated by “n–n”, “p–p”, and “p–n”. The solid lines represent transport behavior across one pair of adjacent arms, and the dashed lines represent that of the other three pairs of adjacent arms. *Source:* From Ref.<sup>[33]</sup>.

important since it shows that the NW–metal contacts will not make nonlinear contributions to the  $I$ – $V$  measurements across the nanoscale junctions. In general, transport measurements recorded across the n–n and p–p junctions show linear or nearly linear behavior. These results indicate that interface oxide between individual NWs does not produce a significant tunneling barrier since a tunneling barrier would lead to highly nonlinear  $I$ – $V$  behavior. In addition, the  $I$ – $V$  curves recorded through each pair of adjacent arms show similar current levels, which are smaller than that of the individual NWs themselves, demonstrating that the junction dominates the transport behavior. Taken as a whole, these data show that individual NWs can make good electrical contact with each other, despite the small contact area ( $10^{-12}$ – $10^{-10}$  cm<sup>2</sup>) and simple method of junction fabrication.

Initial studies designed to probe the utility of this new approach for creating functional devices were focused on p–n junctions from crossed p- and n-type NWs. These junctions can be made reproducibly by sequential deposition of dilute solutions of n- and p-type NWs with intermediate drying. Typical  $I$ – $V$  behavior of a crossed InP NW p–n junction is shown in Fig. 20D. The linear  $I$ – $V$  of the individual n- and p-type NWs components indicates ohmic contact between the NWs and metal electrodes, while transport across the p–n junction shows clear current rectification; that is, little current flows in reverse bias, while there is a sharp current onset in forward bias. Significantly, this behavior is similar to conventional semiconductor p–n junctions. In a standard p–n junction, rectification arises from the potential barrier formed at the interface between p- and n-type materials.<sup>[39]</sup> In the case of our crossed NW p–n junctions, this picture is probably modified due to the presence of some interface oxide (Fig. 8), although a thin oxide will not change substantially the overall  $I$ – $V$  response.

The assignment of the observed rectification to the p–n junction formed at the crossing point between p- and n-type InP NWs was further supported by several other pieces of evidence. First, the linear or nearly

**Fig. 8** Band diagrams of the crossed NW p–n junction. (A) Band bending occurs prior to p–n contact due to surface Fermi level pinning; the bands bend further when the p- and n-type NWs come into contact to achieve equilibrium; (B) band bending in a clean p–n junction structure.

linear  $I$ – $V$  behavior of individual p- and n-type NWs shows that ohmic contacts were been made between the NWs and metal electrodes, and thus exclude the possibility that rectification arises from metal–semiconductor Schottky diodes.<sup>[39]</sup> Second, the  $I$ – $V$  behavior of the junction determined through each pair of adjacent electrodes (Fig. 7D) exhibit similar rectification and current level, which is also much smaller than the current through individual NWs, demonstrating that the junction dominates the  $I$ – $V$  behavior. Third, four-terminal measurements in which current is passed through two adjacent electrodes while the junction voltage drop is measured across the two remaining electrodes exhibit similar  $I$ – $V$  and rectification with only a slightly smaller voltage drop (0.1–0.2 V) compared to two-terminal measurements at the same current level. Fourth, measurements made on over 20 independent InP crossed p–n junctions showed similar rectification in the  $I$ – $V$  data. Lastly, the formation of crossed NW p–n junctions is not by any means restricted to InP NWs, and is general to the wide range of materials. For example, p–n junctions have been assembled from p-Si/n-Si,<sup>[34]</sup> p-Si/n-GaN,<sup>[35]</sup> p-Si/n-InP, p-Si/n-CdS, and p-Si/n-CdSe NWs,<sup>[41]</sup> and transport measurements have demonstrated that all of these crossed p–n junctions show consistent current rectification behavior.

## Bipolar Junction Transistors

Since p–n junctions represent a basic element in many functional electronic devices, including amplifiers and switches, we have explored the possibility of assembling such devices at nanometer scale using the well-defined p- and n-type NW materials. As an example, integrated bipolar transistors,<sup>[34]</sup> which are active devices capable of current gain, have been assembled from three distinct types of Si NWs in the form of two crossed junctions (Fig. 9A). A conventional bipolar transistor requires three distinct material types. For example, in  $n^+$ –p–n structure, a highly doped  $n^+$  layer is used as an emitter (E), a p-type layer for the base (B), and an n-type layer for the collector (C).<sup>[39]</sup> Significantly, this  $n^+$ –p–n basic structure can be easily assembled with Si NWs since NWs with controlled doping type and doping concentration are available (Fig. 9C, inset).<sup>[32]</sup>

To characterize the electrical behavior of assembled NW bipolar transistors, the individual Si NW building blocks and p– $n^+$  and p–n junctions were first tested, and found to exhibit ohmic or nearly ohmic metal contacts and rectification, respectively. The bipolar transistor characteristics were then assessed from measurements of the collector current as a function of C–B voltage (Fig. 9B), while the  $n^+$  Si NW emitter

**Fig. 9** Bipolar junction transistors. (A) Schematic illustrating the common base configuration of an  $n^+$ - $p$ - $n$  bipolar transistor built from crossed Si NWs. (B) Collector current vs. collector-base voltage recorded on an  $n^+$ - $p$ - $n$  transistor with emitter and collector Si NWs 15  $\mu\text{m}$  apart. The numbers inside the plot indicate the corresponding emitter-base voltages. (C) The common base current gain vs. collector-base voltage. Inset: Typical SEM image of Si NW bipolar transistors. *Source:* From Ref.<sup>[34]</sup>.

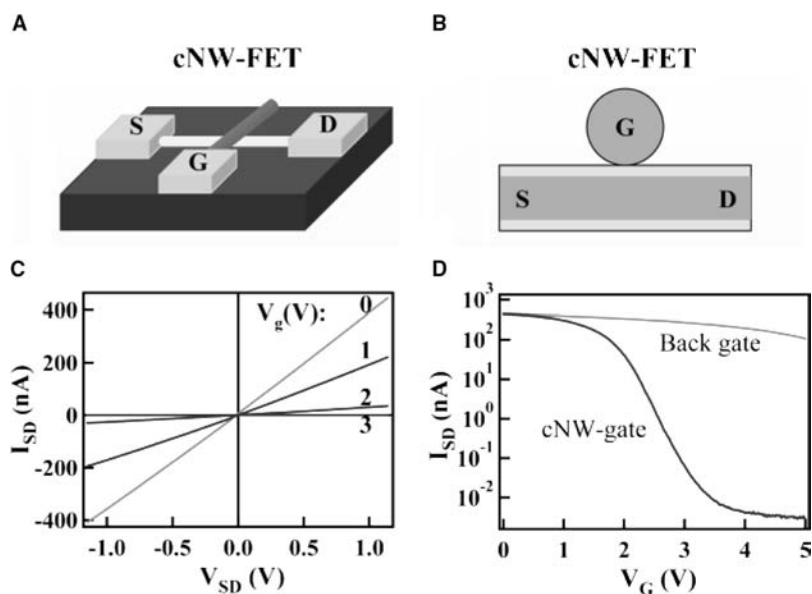

was biased at different values. In general, the collector current is relatively constant (vs. C-B voltage) in the region from 0 to 6 V, which corresponds to the collector in reverse bias with only a very small leakage current, and this current value increases as the emitter forward bias/injected current is increased. The large collector current in reverse bias demonstrates these simple Si NW-based bipolar transistors exhibit behavior similar to that found in standard planar devices,

and moreover, can exhibit very good current gain. The common base current gain, which is defined as the ratio of the collector current to emitter current (Fig. 9C), and the common emitter current gain, which is defined as the ratio of the collector current to base current, were found to be 0.94 and 16, respectively. The relatively large current gain observed in these simple devices suggests several important points. First, the efficiency of electron injection from emitter to base must be quite high, and can be attributed to the controlled NW doping that yields the desired  $n^+$ - $p$  E-B junction. Second, large current gains have been achieved in devices with large (e.g., 15  $\mu\text{m}$ ) base widths. This fact suggests that the mobility of injected electrons can be quite high in the Si NWs and is consistent with the direct mobility studies described above. These observations also indicate clear directions for improving the Si NW bipolar transistors. For example, it will be interesting to study the current gain as a function of base width, because it is easily possible to assemble structures with separations of the  $n^+$  and  $n$ -NWs of the order of 100 nm or less.

### Crossed Nanowire Field Effect Transistors

A major motivation underlying research on nanoscale devices is to achieve integration at densities higher than possible with current technologies. The NW-FETs discussed above represent nanoscale analogs to conventional MOSFETs and have been very useful for testing basic device behavior (e.g., doping type and carrier mobility). However, the basic device structure of the NW-FETs and similar NT FETs<sup>[21,22]</sup> requires lithography to define metallic source-drain electrodes, and use either a global back gate (i.e., the doped silicon substrate) or lithography to define a more local gate. These design and fabrication features pose serious problems for integration. First, lithographically defined metal electrodes (i.e., source, drain, and gate) will limit integration to a level similar to that of conventional silicon technology. Moreover, the use of global back gate electrodes eliminates the possibility of independently addressing individual devices, and thus is incompatible with integration in most architectures.

Direct assembly of highly integrated functional electronic circuits based on NWs requires the development of new device concepts that are amenable to scalable integration. To this end, we recently developed a novel crossed NW-based FET.<sup>[35]</sup> A crossed NW-FET (cNW-FET) is assembled from two NWs where one or both have an oxide coating that serves as the gate dielectric (Fig. 10A,B). This approach is quite flexible since nano-FETs can be readily assembled with  $p$ - or  $n$ -type active channel NWs and the gate NW can also be  $p$ - or  $n$ -type independent of the channel. For

**Fig. 10** Crossed NW-FET (cNW-FET). (A) Schematics illustrating the cNW-FET concept. A nano-FET with both nanoscale conducting channel and nanoscale gate is obtained with one NW used as the gate for the other NW in a crossed configuration. (B) Schematic showing the critical device dimensions of the cNW-FET. Three intrinsic nanometer scale metrics are naturally defined by the structure (see text). (C) Gate-dependent  $I$ - $V_{sd}$  characteristics of a crossed NW-FET. The NW gate voltage for each  $I$ - $V$  curve is indicated (0, 1, 2, and 3 V). (D) The curves showing  $I$  vs.  $V_g$  for n-NW and global back (light gray) gates for  $V_{sd}$  of 1 V. Source: From Ref.<sup>[35]</sup>.

example, using n-type GaN crossed NW as the gate for a p-type Si NW, a p-channel cNW-FET is formed with both a nanoscale channel and a nanoscale gate. Typical  $I$ - $V_{sd}$  data recorded for different NW  $V_g$ s resemble the characteristics of a conventional depletion mode p-channel FET device (Fig. 10C). Notably, the conductance of the Si NW responds very sensitively to the voltage applied to n-NW gate, and can be changed by more than five orders of magnitude with a 1–2 V variation in the NW gate (Fig. 10D). In contrast, the conductance changed less than a factor of 10 for this same device when similar gate voltages were applied to the global back gate (Fig. 23D). The improved sensitivity can be attributed to the intrinsically thin gate dielectric between the two NWs. In addition, there is no leakage current from the n-NW gate when the cNW-FET is operated at low source–drain bias in the depletion mode since the crossed p–n junction is always reverse biased, and in this regard the device is similar to a junction FETs (JFETs).<sup>[39]</sup>

The cNW-FET represents an important new transistor concept for nanoelectronics. With this concept, three critical nanometer scale device metrics are naturally defined in assembled circuits without lithography: 1) a nanoscale channel width determined by the diameter of the active NW; 2) a nanoscale channel length defined by the crossed NW gate diameter; and 3) a nanoscale gate dielectric thickness determined by the NW surface oxide. Significantly, these distinct nanometer scale metrics are determined and can be controlled with near atomic precision during NW synthesis and subsequent assembly, and should enable higher gain, higher speed, and lower power dissipation devices than possible by conventional approaches. Moreover, the cNW-FET concept can be readily

integrated in a parallel manner without lithography, thus enabling one to envision a straightforward way to nanometer scale integrated electronics of the future. Examples of more complex devices—logic gates— assembled from cNW-FET elements are discussed in section “Integrated Nanowire Devices”.

### Summary and Future Directions

Overall, in this section, we have shown that semiconductor NW materials can be doped p- and n-type in a precisely controlled way, and these electronically well-defined NW materials thus enable the assembly of a broad range of nanoscale electronic and optoelectronic devices, including FET, crossed NW p–n diodes, intra-NW p–n diode, bipolar transistors, cNW-FETs. Together, these devices represent a set of critical elements for the bottom-up assembly of more complex electronic circuits. To exploit best, this tool box of elements for building highly integrated electronic circuits will require several issues to be addressed, including: 1) production of device elements in high yield, 2) development of rational methods for assembly of these elements into integrated device arrays, and 3) development of system architectures that best utilize these device element function(s) and assembly capabilities. These important issues are further addressed in sections below.

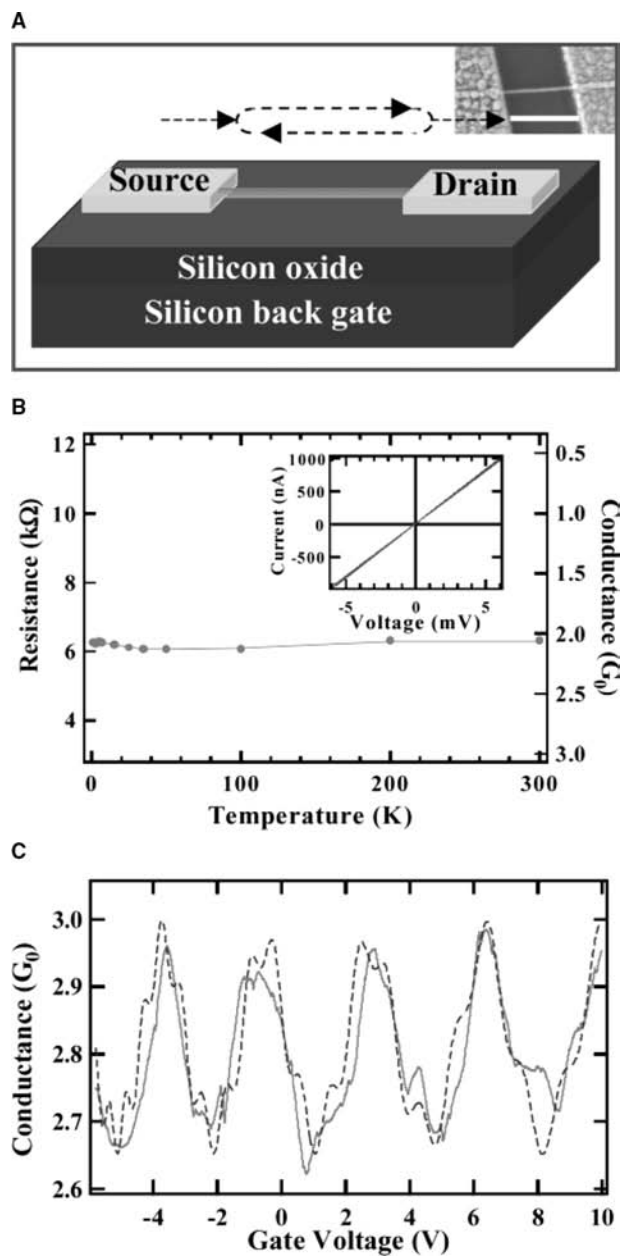

The availability of electronically well-defined NW building blocks, which have enabled to demonstrate a series of nanoscale electronic devices, opens many exciting opportunities in nanoscale science and technology. For example, the nanoscale electronic devices may enable us to construct functional electronic

circuits with integration density far beyond current technologies. The wide range of electronic applications described above are based primarily upon diffusive motion of electrons as in conventional devices—their uniqueness arises from the small size scale and our ability to obtain unique function from combinations of materials that would be incompatible with conventional fabrication processes. In addition, other effects, such as the quantum mechanical or wave-like nature of carriers, will need to be accounted for for sufficiently small structures,<sup>[15,42]</sup> and at the same time could open up entirely new possibilities for electronic manipulation and devices.<sup>[43]</sup>

The intrinsically nanometer scale devices assembled from NWs or NTs represent ideal systems to probe quantum phenomena and exploit devices exhibiting such phenomena for fundamentally new applications such as quantum computation.<sup>[44,45]</sup> The availability of a wide range of NW materials opens up considerable opportunity for exploring these exciting directions since fundamental properties, such as the Fermi wavelength and number of conduction channels, can be systematically varied through choice of NW material (e.g., InAs vs. Si) and diameter, respectively.

As an example of the potential of NWs to enable behavior not readily accessible with conventional planar devices, we consider recent studies of InAs NWs (Fig. 11A). Significantly, temperature dependent three-terminal transport studies show that the conductance of individual InAs NWs remain essentially unchanged over the temperature range from 300 K down to 1.6 K (Fig. 11B). The temperature independent transport suggests strongly that electrons are not inelastically scattered by either impurities or phonons within the NWs, that is, that the electron transport is ballistic. This important conclusion is supported by several other pieces of data, including 1) most of the InAs NWs exhibit conductance values ranging from one quantum conductance ( $G_0 = 2e^2/h$ ) to  $8G_0$  and 2) the conductance shows little or no dependence on NW length. We have also obtained similar results for clean Si NWs, and thus believe that the ballistic transport phenomena can be considered as a general property to exploit in NW-based nanoelectronics.

Transport studies also suggest that InAs and Si NWs can exhibit coherent phenomena. Specifically, low-temperature gate voltage-dependent conductance measurements exhibit reproducible, quasi-periodic conductance oscillations (Fig. 11C). These oscillations can be interpreted as quantum interference between electron waves reflected by two metallic contacts, much like optical waves interfere within a Fabry–Perot cavity. In our NW electron cavities, the gate-voltage modulates the Fermi level, and hence changes the Fermi wavelength and the interference of the electron waves inside the NW. The observed electron–wave

**Fig. 11** Low temperature studies of InAs NWs. (A) Schematic showing an InAs NW device. Electron waves inside the NWs are partially reflected at the two metallic contacts, and the forward and backward reflected waves quantum mechanically interfere with each other. (B) Conductance vs. temperature of an InAs NW device. (C) Conductance vs. gate voltage ( $V_{sd} = 0.5$  mV) at 1.6 K. The dashed line corresponds to a theoretical fit based on multichannel Landauer formalism discussed in the text.

interference has been quantitatively analyzed using a multichannel Landauer formalism,<sup>[42,46]</sup> where the overall conductance is determined from two  $6 \times 6$  scattering matrices representing the NW–metal contacts and one  $6 \times 6$  transmission matrix inside the NWs.<sup>[45]</sup> Significantly, the calculated conductance

behavior accounts for both major and minor oscillatory features in the data, and show that these different features arise from the different sub-band modes of relevance to the InAs NW cavity.

The unique transport properties of these InAs and similar NWs could lead to a number of exciting opportunities for devices and systems integration. For example, ballistic transport will be important to advance interconnects and highly integrated nano-systems since it eliminates power dissipation within the NW. Ballistic and coherent transport should also enable spin-dependent transport and spin-based devices.<sup>[47]</sup> Moreover, the ability of NWs to exhibit coherence over large distances—that is, transmit quantum mechanical information—should also be important in the emerging field of quantum computing.<sup>[44]</sup> In a quantum computer, the usual digital “bits” are replaced by quantum bits (qubits), and these qubits can be manipulated in very different ways by forming superpositions or entangled states, and thereby used to solve computing tasks inaccessible to digital systems. We believe that the availability of high quality NW materials opens up a new pathway for assembling quantum devices and potentially exploiting the potential of quantum computing.

## NANOSCALE OPTOELECTRONICS AND PHOTONICS

In addition to nanoscale electronics, the broad range of optically active III–V and II–VI group compound semiconductor NW materials are attractive as building blocks for miniaturized photonic and optoelectronic devices. In this section, we review exciting progress in this area. First, we discuss results from fundamental photoluminescence (PL) studies of individual NWs. Second, we review assembly and properties of a wide range of photonic devices, including nanoscale LEDs, NW optical cavities, single NW lasers, and photodetectors.

### Photoluminescence Studies of Individual Nanowires

Photoluminescence studies on individual NWs reveal that they exhibit strong PL and can be readily imaged with a liquid nitrogen cooled CCD camera. For example, PL image of an InP NW clearly shows an elongate emission along the wire axis (Fig. 12A). The PL spectrum shows a peak maximum at  $\sim 805$  nm in contrast to bulk value of  $\sim 925$  nm (Fig. 12B). This large blueshift suggests the radial quantum confinement of excitons in the NW, which have been addressed in detail by size-dependence PL studies.<sup>[48]</sup>

In addition to strong quantum confinement caused by the large confining potential for both electrons

**Fig. 12** Photoluminescence studies of individual NWs. (A) Room-temperature PL image and (B) spectrum from single InP NW.

and holes, another unique feature of free-standing NW structures is the large variation in the dielectric constant between the NW and surrounding (air) medium, which could lead to strikingly new phenomena. For example, PL studies of individual InP NWs show that the PL intensity essentially turns from “on” to “off” as the excitation polarization is rotated from parallel to perpendicular (Fig. 13A,B).<sup>[49]</sup> Integration of the emission intensity as a function of excitation angle shows that the PL intensity exhibits a periodic dependence ( $\cos^2 \theta$ ) on the angle. Photoluminescence spectra recorded from NWs of different diameters ranging from 10 to 50 nm show similar large anisotropy in either excitation (Fig. 13C) or emission polarization (Fig. 13D). In both cases, the ratio of parallel to perpendicular emission is greater than an order of magnitude, with a polarization ratio  $\rho = (I_{\parallel} - I_{\perp}) / (I_{\parallel} + I_{\perp})$  of  $0.91 \pm 0.07$ . This large polarization ratio is significantly larger than previously reported (buried) quantum wire samples, where the polarization anisotropy has been attributed to the mixing of valence bands due to quantum confinement. This quantum mechanical effect yields a much smaller polarization ratio of  $\rho < 0.60$ <sup>[50–52]</sup> and cannot be used to explain the large polarization ratio in the free-standing NWs. Rather, the large and unprecedented polarization anisotropy in the free-standing NWs can be accounted for quantitatively by considering the dielectric contrast between a NW and its air or vacuum surroundings; that is, the perpendicular electric field amplitude is attenuated according to  $E_i = [2\epsilon_0 / (\epsilon + \epsilon_0) E_e]$ , where  $E_i$  is the electric field inside the cylinder,  $E_e$  is the excitation field, and  $\epsilon(\epsilon_0)$  is the dielectric constant of the cylinder (vacuum) (Fig. 13E).<sup>[53]</sup> This model yields a theoretical polarization ratio,  $\rho = 0.96$ , in good agreement with the experimental results for InP NWs.

The strong polarized PL emission from individual NWs allows us to explore them for many exciting

**Fig. 13** Polarized PL excitation and emission from individual NWs. (A) Photoluminescence image of a single 20 nm InP NW with the exciting laser polarized along the wire axis. Scale bar, 3 μm. (B) Photoluminescence image of the same NW as in (A) under perpendicular excitation. Inset: Variation of overall PL intensity as a function of excitation polarization angle with respect to the NW axis. (C) Excitation spectra of a 15 nm diameter InP NW. These spectra were recorded with the polarization of the exciting laser aligned parallel (solid line) and perpendicular (dashed line) to the wire axis. (D) Emission spectra of the same wire as in (C). These spectra were taken with the excitation parallel to the wire, while a polarizer was placed in the detection optics. (E) Dielectric contrast model of polarization anisotropy. Source: From Ref.<sup>[49]</sup>.

application in nanophotonics. For example, the previously described GaAs/GaP NW superlattice structures represent an attractive system for applications such as nanobarcodes because GaAs is a direct band gap semiconductor, while GaP has an indirect gap.<sup>[54]</sup> Indeed, PL imaging of individual NWs from the equally spaced (GaP/GaAs)<sub>3</sub> superlattice sample shows that these NWs exhibit an emission pattern of three spots separated by dark regions (Fig. 14A). This

pattern is consistent with emission originating from the three GaAs regions, separated by dark GaP regions that act as optical “spacers.” Control experiments on individual samples of pure GaAs and GaP NWs confirm that strong luminescence is obtained from GaAs but not GaP, as expected. The GaAs regions also exhibit a strong polarization dependence, emitting when the excitation is polarized parallel (||) to the NW axis and appearing dark when the polarization is perpendicular (⊥) to the NW axis (Fig. 14A, inset).

Such superlattice systems can be further extended to more complicated structures. First, the PL image of an 11-layer superlattice in which the length of the GaP regions was doubled each layer while maintaining a constant GaAs period (Fig. 14B) shows clearly that the separation between emitting GaAs regions is doubling along the length of the NW. Second, the PL image of 21-layer GaP/GaAs superlattices (Fig. 14C) consisting of a short 4-period (GaP/GaAs) repeat, followed by three longer GaP spacer repeats, and ending in a relatively short 4-period (GaAs/GaP) repeat shows consistent PL patterns. We consider that, in their present form, these NW superlattice structures could be exploited as optical nanobarcodes, which could be useful as labels for imaging. Moreover, the wide range of group III–V and II–VI NWs that have been demonstrated previously suggests that it should be possible to encode additional information through variations in the color of the emitting region using multicomponent superlattices. Using materials with a large dielectric contrast might also enable the creation of 1D waveguides with built-in photonic band gaps, or of cavities for NW lasers.

### Crossed Nanowire Light Emitting Diodes

The observation of strong PL from individual NWs has stimulated further interest in exploiting such NWs for optoelectronics. We have previously described a wide range of electronic device assembled from NWs including p–n diodes. In direct band gap semiconductors like InP, the p–n diode also forms the basis for the critical optoelectronics devices, including LED and laser diode. To assess whether our nanoscale devices might behave similarly, we have studied the electroluminescence (EL) from crossed NW p–n junctions. Significantly, EL can be readily observed from these nanoscale junctions in forward bias.<sup>[33]</sup> A three-dimensional (3D) plot of the EL intensity taken from a typical NW p–n diode at forward bias (Fig. 15A) shows the emitted light comes from a point-like source, and moreover, comparison of EL and PL images (Fig. 15A, inset) recorded on the same sample shows that the position of the EL maximum corresponds to the crossing point in the PL image.

**Fig. 14** Nanowire nanobarcode. (A) Photoluminescence image ( $\parallel$  excitation) of a NW with a  $(\text{GaAs}/\text{GaP})_3$  superlattice structure. The three bright and dark regions correspond to the three GaAs (direct band gap) and GaP (indirect band gap) regions, respectively. Inset: No PL is observed above background for perpendicular excitation. Scale bar, 5 nm. (B) Photoluminescence image of a 40 nm diameter GaP(5)/GaAs(5)/GaP(5)/GaAs(5)/GaP(10)/GaAs(5)/GaP(20)/GaAs(5)/GaP(40)/GaAs(5)/GaP(5) superlattice; the numbers in parentheses correspond to the growth times in seconds for each layer. Inset: Diagram showing the relative lengths of GaAs (blue) and GaP (red) layers. Scale bar, 5 nm. (C) Photoluminescence image of a 21-layer superlattice  $(\text{GaP}/\text{GaAs})_{10}\text{GaP}$ , showing a group of four equally spaced spots on the left, two in the middle with larger gaps, and another set of four with equal spacing on the end. The superlattice is 25 nm in length. *Source:* From Ref.<sup>[54]</sup>.

These data thus demonstrate that the emitted light indeed comes from the crossed NW p-n junction.

Characterization of the EL intensity as a function of forward bias of the junction shows that significant light can be detected with our system at a voltage as low as 1.7 V (Fig. 15B). Further increases in forward bias beyond this “turn-on” voltage produce rapid increase in the EL intensity. In addition, EL spectra recorded from the cNW-LEDs exhibit blueshifts relative to the bulk band gap of InP (925 nm) (Fig. 15C). The blueshifts are due in part to quantum confinement<sup>[55]</sup> of

excitons, although other factors may also contribute. Furthermore, PL studies have demonstrated that the PL peak can be systematically blueshifted as the NW diameter is decreased,<sup>[48]</sup> and thus these results provide a means for controlling the color of the LEDs in a well-defined way. Indeed, EL results recorded from p-n junctions assembled from smaller (and larger) diameter NWs show larger (smaller) blueshifts. In addition, the emission color from nano-LEDs can be further varied by using chemically distinct semiconductor NWs with different band gaps. Considering the wide range of

**Fig. 15** Crossed NW LED. (A) (Top) Three-dimensional (3D) plot of light intensity of the EL from a crossed NW LED. Light is only observed around the crossing region. (Bottom) Three-dimensional atomic force microscope image of a crossed NW LED. Inset: PL image of the crossed NW junction. (B) Spectrum of the emission shows a peak at ca. 820 nm. (C) Plot of integrated intensity vs. forward bias voltage. *Source:* From Ref.<sup>[33]</sup>.

group IV, III–V, and II–VI semiconductor NW materials available,<sup>[30]</sup> it is possible to assemble a variety of NW-based nano-LEDs for different spectral regimes.<sup>[41]</sup> The ability to tune color with size as well as composition in these nano-LEDs might be especially useful in future nanophotonic applications. Moreover, the nanoscale light emitting device can be flexibly assembled on virtually any substrate and seamlessly integrated together, and allows us to achieve unique optoelectronic function on many technological important substrates, such as silicon substrate, and can open entirely new opportunities in intra-/interchip optical communication, integrated chemical/biological sensing and medical diagnostics on the chip level.

### Single Nanowire Nanolasers

Semiconductor lasers are finding increasing use in technologies ranging from telecommunications and information storage to medical diagnostics and therapeutics. Free-standing semiconductor NWs are attractive building blocks for creating optically and electrically driven lasers since their defect-free structures exhibit the superior optical and electrical transport properties,<sup>[32–35]</sup> and because a single NW can function as a stand-alone optical cavity and gain medium.<sup>[56–58]</sup> In general, a NW will function as a single mode optical waveguide<sup>[59]</sup> (Fig. 16A) when

$1 \sim (\pi D/\lambda) (n_1^2 - n_0^2)^{0.5} < 2.4$ , where  $D$  is the NW diameter,  $\lambda$  is the wavelength, and  $n_1$  and  $n_0$  are the refractive indices of the NW and surrounding medium, respectively. Taking CdS NWs ( $n_1 = 2.5$ ;  $\lambda = 510$  nm, 300 K) as an example, the minimum diameter needed to support a single mode is of the order of 70 nm. If the ends of the NW are cleaved, they can function as two reflecting mirrors that define a Fabry–Perot optical cavity with modes  $m(\lambda/2n_1) = L$ , where  $m$  is an integer and  $L$  is the length of the cavity. Significantly, CdS NWs typically adopt a [001] direction along the axis and can be easily cleaved using solution phase sonication. Transmission and scanning electron microscopy studies show that the cleaved NW end exhibit flat ends (Fig. 16B) indicative of cleavage perpendicular to the [001] NW axis. A luminescence image of a cleaved CdS NW obtained with a fluorescence microscope under uniform illumination from a mercury lamp shows uniform emission along the entire NW body except the end where greatly enhanced emission is observed (Fig. 16C). The uniform emission from the NW body suggests high quality of the NW materials, and the enhanced emission near the NW end suggests that the NW can function as waveguide.

The optical cavity properties of the CdS NWs, which are central to our use of these nanostructures for lasers, were further characterized by PL measurements at the single NW level using a far-field epifluorescence microscope. A typical room-temperature luminescence image (Fig. 17A) of a CdS NW excited with a tightly focused laser ca. 15  $\mu$ m from the NW end shows strong emission at the excitation locus and also prominent emission near the NW end. Studies of a number of NWs show pronounced emission from the NW end in addition to the excitation region and thus confirms waveguide characteristics of the NWs.

To further probe the NW cavity properties, spectroscopy measurements have been made at different regions as a function of excitation power under uniform illumination. At low power, PL spectra recorded from the body exhibit a broad peak with a maximum at 512 nm and full width at half maximum (FWHM) of 24 nm (Fig. 17B). The peak maximum is consistent with room-temperature band edge emission from CdS, and contrasts the deep level emission around 600 nm that usually dominates epitaxial CdS thin films.<sup>[60]</sup> Spectra recorded from the NW end at low excitation power showed a relatively broad peak that was redshifted ca. 30 nm relative to spectra from the body. The observed spectral redshift is consistent with reabsorption of band edge emission within the CdS NW cavity.

Photoluminescence measurements made at higher excitation powers reveal other important features about the CdS NW cavities (Fig. 17C). First, the NW

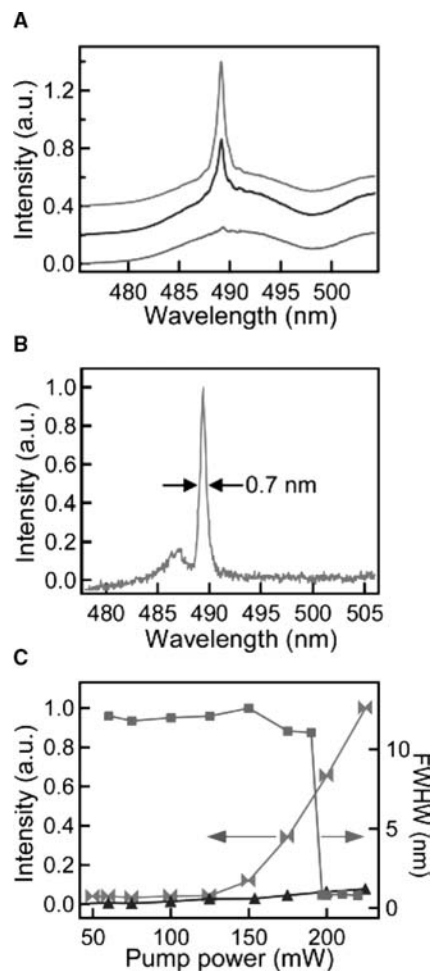

**Fig. 16** Nanowire optical waveguides and cavities. (A) Schematic showing a NW as an optical waveguide; with cleaved ends, it defines a Fabry–Perot cavity. (B) SEM image of a cleaved CdS NW end. **Fig. 17** Nanowire Fabry–Perot optical cavity. (A) Room-temperature PL image of a CdS NW excited ca. 15 μm away from the NW end. The white arrow and dashed line highlight the NW end and axis, respectively. Scale bar, 5 μm. Inset shows an optical image of the NW obtained with white light illumination. (B) Photoluminescence spectra obtained from the body of the NW (left) and the end of the NW (right) at low pump power. (C) Spectrum from the NW end at higher pump power (80 mW) exhibiting periodic intensity modulation, which corresponds to the Fabry–Perot modes of the NW. Inset shows end emission intensity as a function of pump power. (D) Mode spacing vs. inverse NW length. The triangles are experimental point except the origin (0,0) point that corresponding the extrapolation to infinite length; the line is linear fit to these data. *Source:* From Ref.<sup>[58]</sup>.

end emission blueshifts towards the band edge as the reabsorption is partially saturated with increasing excitation power. Second, the end emission intensity increases superlinearly with excitation power, while emission from the NW body exhibits a slight ca. linear increase. Third, periodic variations in the intensity, which are suggestive of the longitudinal modes of a Fabry–Perot cavity, are observed for excitation powers greater than the changeover from linear to superlinear behavior. For a cavity of length  $L$ , the mode spacing,  $\Delta\lambda$ , is given by  $\lambda^2/2L[n_1 - \lambda(dn_1/d\lambda)]^{-1}$ , where  $dn_1/d\lambda$  is the dispersion relation for the refractive index. This expression provides a good description of the observed spacing when the measured NW length is equated with  $L$ , and moreover, analysis of similar data from NWs of varying length demonstrates that the mode spacing is inversely proportional to the wire length (Fig. 17D) as expected. Together these results show that the CdS NWs form a Fabry–Perot cavity with a cavity quality factor of the order of 600 as estimated from the mode line width.

The observation of sharp modes in the uniform CdS NW gain medium above the superlinear threshold is indicative of amplified spontaneous emission. Significantly, excitation at higher powers, which was possible in low-temperature experiments, leads to preferential gain in a single mode and the onset of lasing (Fig. 18A). At low temperatures, the broad emission peak observed at the NW end rapidly evolved to a sharp single mode with the 0.7 nm line width limited by the resolution of our low-temperature instrument (Fig. 18B). The observed line width exhibits a sudden drop in line width to our instrument resolution at an

**Fig. 18** Optically pumped NW laser. (A) Emission spectra from a CdS NW end with a pump power of 190, 197, and 200 mW (from bottom up) recorded at 8 K. (B) Laser emission from a CdS NW end at 8 K with instrument resolution limited line width (FWHM ~ 0.7 nm). A second weaker mode is also resolved. (C) Emission intensity and FWHM of emission peaks vs. laser pump power. The FWHM has a nearly constant value of ca. 12 nm at low power, and abruptly narrows to instrumental resolution when the super-linear threshold is exceeded. The solid symbols correspond to experimental data points and lines serve as guides to eye. *Source:* From Ref.<sup>[58]</sup>.

excitation power coincident with the threshold to superlinear dependence for emission (Fig. 18C). In contrast, emission from the NW body is broad and linearly dependent on excitation further demonstrating that the laser emission is due to the cavity along the NW axis. From this superlinear behavior, we estimate the threshold average pump power to be  $40 \text{ kW cm}^{-2}$ , although the threshold varies from NW to NW with the lowest value to date of  $\sim 10 \text{ kW cm}^{-2}$ .

These optical experiments demonstrate that individual NWs can function as Fabry–Perot cavities and support lasing, although without electrical pumping NW lasers would be of limited technological importance. In general, electrically driven lasing requires efficient electron (n-type) and hole (p-type) injection into the cavity region. In the case of planar CdS structures, this has been difficult due to problems in producing high-mobility p-type CdS or combining n-CdS with other high-mobility p-type materials. A clear advantage of NW-based structures is the ability to combine different high quality materials almost at will to achieve desired device function.

Our initial studies of electrical injection into CdS NW cavities were carried out using an n-type CdS and p-type silicon (p-Si) crossed NW structures (Figs. 19A,B). Transport studies of individual CdS NWs show that they are n-type with doping concentrations of the order of  $10^{18}$ – $10^{19}/\text{cm}^3$  and electron mobilities of ca.  $100 \text{ cm}^2/\text{V sec}$ ; the p-type silicon NWs had a doping concentration of ca.  $10^{18}$ – $10^{19}/\text{cm}^3$  and exhibited mobilities of ca.  $50$ – $300 \text{ cm}^2/\text{V sec}$ . Current–voltage ( $I$ – $V$ ) measurements made on a typical n-CdS/p-Si crossed NW structure (Fig. 19C) show current rectification with a sharp forward bias turn-on at about 2 V, consistent with the formation of a p–n diode. In forward bias, these crossed NW structures exhibit strong EL with several important characteristics. Images of the EL (Fig. 19D) show two points of emission: One corresponding to the n-CdS/p-Si NW cross point and the other to the end of the CdS NW. Significantly, the intensity of the end emission is at least two orders of magnitude larger than the cross point emission, thus demonstrating that the CdS NWs can function as excellent waveguides in this relatively simple device configuration.

The EL spectrum recorded from the cross point (Fig. 19E) is a smooth peak with a maximum at 515 nm, which is consistent with band edge emission. In contrast, EL spectra recorded from the CdS NW end exhibit a prominent modulation in the intensity for injection currents greater than ca.  $1.0 \mu\text{A}$  (Fig. 19E). This current (Fig. 19F, inset) corresponds to a changeover from linear to superlinear intensity–current dependence for emission from the NW end. Significantly, the intensity modulation can be assigned to the longitudinal modes of a Fabry–Perot cavity

**Fig. 19** Electrical injection in NW Fabry–Perot cavities. (A) Device schematic illustrating a p–n diode formed between p-Si and n-CdS NWs, where the CdS NW forms the cavity and active medium. (B) Optical image of a device. Scale bar,  $5 \mu\text{m}$ . (C) Current–voltage ( $I$ – $V$ ) recorded from the diode in (B). (D) The EL image obtained at room temperature with the device forward biased at 5 V. The two bright spots highlighted by blue and green arrows correspond to the emission from the cross point and end, respectively. (E) Electroluminescence spectra obtained from cross (left) and end (right) of the device at an injection current of ca.  $1.5 \mu\text{A}$ . (F) Emission spectrum from the CdS NW end at an injection current of ca.  $2.4 \mu\text{A}$ . Inset shows emission intensity (linear scale) vs. injection current.

having a length consistent with that measured for the CdS NW in this device. In addition, the EL spectra recorded from the CdS NW end exhibits a redshift relative to emission from the cross point, as expected for reabsorption by the NW cavity. As the injection current is increased in the superlinear regime, the overall spectrum shifts to the blue (Fig. 19F), indicating partial saturation of the reabsorption in the NW. These EL results are thus completely consistent with our optically pumped luminescence data recorded from similar CdS NWs, and suggest that at sufficiently high injection currents lasing should be achieved, although the crossed NW injection devices is clearly not optimal for achieving high-density injection into the whole NW cavity and gain medium.

To enable more uniform injection, we have implemented a hybrid structure (Fig. 20A) in which holes are injected along the length of a CdS NW cavity from a p-Si electrode defined in a heavily doped p-Si layer on a planar substrate. Images of the room-temperature EL produced in forward bias from these structures (Fig. 20B) show strong emission from the exposed CdS NW end. At low injection currents, the spectrum of the end emission (Fig. 20C) shows a broad peak with FWHM  $\sim 18$  nm. Significantly, when the injection current is increased further, we found that the emission intensity increased abruptly, and the spectrum quickly collapsed into a limited number of very sharp peaks with a dominant emission line at 509.6 nm (Fig. 20C). The sharp peaks of this device had an average spacing of ca. 1.8 nm, which is consistent with the Fabry–Perot cavity modes for the length

**Fig. 20** Nanowire electrical injection laser. (A) Schematic showing the cross section of the device structure. (B) (Top) Optical image of a device described in (A). The arrow highlights the exposed CdS NW end. Scale bar, 5  $\mu$ m. (Bottom) EL image recorded from this device at room temperature with an injection current of ca. 80  $\mu$ A. The arrow highlights emission from the CdS NW end. The dashed line highlights the NW position. (C) Electroluminescence spectra obtained from the NW end with injection currents of 120  $\mu$ A (lower curve) and 210  $\mu$ A (upper curve). The black arrows highlight Fabry–Perot cavity modes with an average spacing of 1.83 nm. The green spectrum is shifted upward by 0.15 intensity units for clarity. (D) Emission spectra from a CdS NW device with injection currents of 200  $\mu$ A (lower curve) and 280  $\mu$ A (upper curve) recorded at 8 K. The spectra are offset by 0.10 intensity units for clarity. *Source:* From Ref. [58].

of the NW device. Other small, sharp peaks are also observed and their explanation will require more detailed consideration of the NW cavity. Further more, low-temperature measurements (7 K) made on independent CdS injection laser devices. (Fig. 20D) show clearly that the spontaneous emission spectrum can collapse to a single mode, and moreover, these results are very similar to the low-temperature optically pumped results, and thus unambiguously demonstrate the formation of injection NW laser.

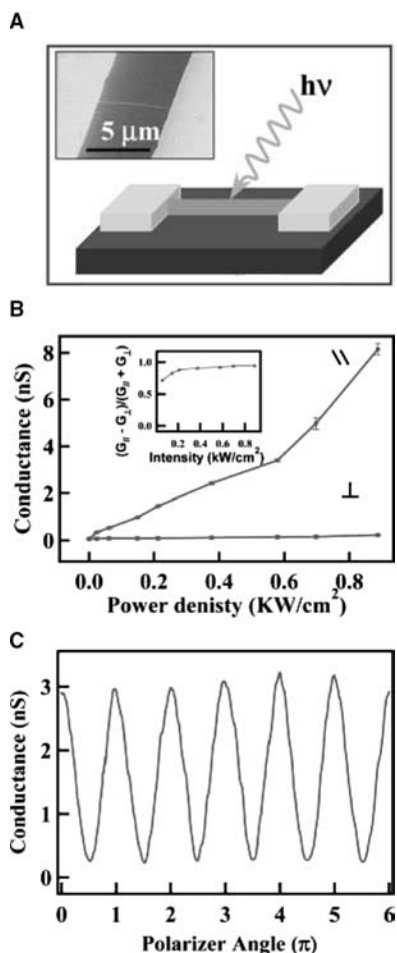

Using individual NWs as the laser cavity and gain medium for laser diodes represents a new and powerful approach for producing integrated electrically driven photonic devices. This basic approach, which relies upon bottom-up assembly of the key laser cavity/medium in a single step, can be extended to other materials, such as GaN and InP NWs, to produce nanoscale lasers that not only cover the ultraviolet through near infrared spectral regions but also can be integrated as single or multicolor laser source arrays in silicon microelectronics and lab-on-a-chip devices. There are also scientific and technical challenges that may need to be addressed to realize this potential, including the development of more efficient cavities and injection schemes. Both issues could be addressed at the NW growth stage prior to device assembly by preparing Bragg gratings at the NW ends through axial composition modulation,<sup>[54]</sup> and using core–shell NW structure<sup>[61]</sup> to enable uniform injection into the active medium/cavity, respectively. By addressing these and other issues, such as quantifying contributions to optical losses within the NW cavity, NW lasers could be developed into systems that impact a number of areas where solid state lasers are used today, including telecommunications and data storage, and may enable new applications in highly integrated chemical/biological sensors, near-field optical lithography, a host of scanning probe microscopies, and perhaps even laser-based surgery with unprecedented resolution.

## Photodetectors

In addition to generating photons via carrier recombination in nanoscale NW devices, absorbed photons can produce electrical carriers, which when measured, serve as the basis for Lilliputian photodetectors.<sup>[49]</sup>

The striking PL polarization anisotropy makes these NWs ideally suited for polarization sensitive photonic devices such photodetectors and optically gated switches. For example, a polarization sensitive photodetector can be easily fabricated by making metallic contacts to both ends of individual NWs (Fig. 21A). The conductance ( $G$ ) of individual NWs was found to increase by 2–3 orders of magnitude with increasing laser intensity (Fig. 21B), and these changes

**Fig. 21** Polarized photodetection using individual InP NWs. (A) Schematic depicting the use of a NW as a photodetector. Inset: SEM image of a 20 nm diameter NW and contact electrodes for photoconductivity (PC) measurements. (B) Conductance,  $G$ , vs. excitation power density for excitation light polarized parallel and perpendicular to the NW axis. Inset: PC anisotropy vs. excitation power. (C) Conductance vs. polarization angle as the polarization was manually rotated while measuring the PC. *Source:* From Ref.<sup>[49]</sup>.

were reproducible and reversible, which indicate that the increases in  $G$  are due to direct carrier collection at the NW–metal contacts.

In addition, a large polarization anisotropy was also observed in the photoconductivity (Fig. 21C). The photoconductivity anisotropy,  $\sigma = (G_{||} - G_{\perp}) / (G_{||} + G_{\perp})$ , values were similar to the PL anisotropy and the theoretical predictions described above. The large anisotropy shows that the conductance of devices is essentially switched on and off while the polarization of the incident light is changed. The overall sensitivity of the photodetector can be gauged by the responsivity, which is the ratio of photocurrent vs. absorbed optical power. For the device shown in Fig. 34, the responsivity is about 3000 A/W, which is an impressive number, considering that this device was not optimized.<sup>[62]</sup>

There are several unique features of these NW-based photodetectors that could enable applications. First, the sensitivity and polarization anisotropy is nearly independent of excitation wavelength for energies larger than band gap. In addition, it is easily possible to make a device that simultaneously measures intensity and polarization by using two crossed NWs and measuring their photoconductivity independently. Second, the active device element in the NW-based photodetector is substantially smaller than other polarization sensitive quantum-well based detectors,<sup>[63,64]</sup> which are not smaller than  $50 \times 50 \mu\text{m}$  and usually only sensitive to a very specific wavelength. Lastly, the extremely small size of these devices may open the possibility of creating ultra high-speed detectors.

## Summary

Overall, we have shown that semiconductor NWs can be used to assemble a wide range of photonic and optoelectronic devices, including LEDs, lasers, and photodetectors. The availability of such nanoscale optoelectronic devices can open many exciting opportunities in nanoscale science and technology. Nanoscale light source and detectors may lead to exciting opportunities in photonics. The nanoscale light sources can be used for ultrahigh resolution imaging, sensing, and analysis in lab-on-a-chip systems as well in telecommunications and information storage. For example, nanoscale emitters can be readily used as the excitation source for a variety of materials. Nanowire photodetectors can be exploited as optically gated switches. When nanoscale light sources and photodetectors are combined together, it is possible to create high-density, high-speed interconnects for electronic and/or photonic circuits, where polarization sensitivity can vastly increase the information bandwidth. Considering the wide range of group IV, III–V, and II–VI semiconductor NW materials available, it should be possible to assemble in the future a variety of NW-based light sources and detector arrays for further into infrared spectral regimes, including the  $1.5 \mu\text{m}$  regime that is critical to current optical communications. In addition, the extremely small size of these structures could also lead to fundamentally new types of device such as single photon sources,<sup>[65,66]</sup> which could enable quantum information encryption and possibly optical schemes for quantum computation.

## HIERARCHICAL ASSEMBLY NANOWIRES

A key motivation underlying research on nanoscale devices is the potential to achieve integration at a level not possible in conventional microelectronics. To achieve this goal in future nanosystems will require

the development and implementation of efficient and scalable strategies for assembly of nanoscale building blocks into increasingly complex architectures. First, methods are needed to assemble NWs into highly integrated arrays with controlled orientation and spatial position. Second, approaches must be devised to assemble NWs on multiple length scales and to make interconnects between nano-, micro-, and macroscopic worlds. To address these critical next levels of organization, we have focused significant effort on developing complementary strategies for hierarchical assembly of NWs on surfaces, and describe two promising approaches below.

### Electrical Field Directed Assembly

Applied electric fields (E-fields) can be used effectively to attract and align NWs due to their highly anisotropic structures and large polarizabilities (Fig. 22).<sup>[33]</sup> This underlying idea of E-field directed assembly can be readily seen in images of NW solutions aligned between parallel electrodes (Fig. 22B), which demonstrate that virtually all of the NWs aligned in parallel along the E-field direction. Electric field directed assembly can also be used to position individual NWs at specific positions with controlled directionality. For example, E-field assembly of NWs between an array of electrodes (Fig. 22C) clearly shows that individual NWs can be positioned to bridge pairs

**Fig. 22** E-field directed assembly of NWs. (A) Schematic view of E-field alignment. (B) Parallel array of NWs aligned between two parallel electrodes. (C) Spatially positioned parallel array of NWs obtained following E-field assembly. The top inset shows 15 pairs of parallel electrodes with individual NWs bridging each diametrically opposed electrode pair. (D) Crossed NW junction obtained using layer-by-layer alignment with the E-field applied in orthogonal directions in the two assembly steps. *Source:* From Ref.<sup>[33]</sup>.

of diametrically opposed electrodes and form a parallel array. In addition, by changing the E-field direction with sequential NW solutions, the alignment can be carried out in a layer-by-layer fashion to produce crossed NW junctions (Fig. 22D). These results demonstrate clearly that E-field directed assembly can be used to align and position individual NWs into parallel and crossed arrays, which correspond to two basic geometries for integration, and thus provide one robust approach for rational and parallel assembly of nanoscale device arrays.

### Fluid Flow Directed Assembly

#### Microchannel fluidic device

Electric field directed assembly, which represents the first approach described for assembly of 1D nanostructures, also has limitations, including 1) the need for substantial conventional lithography to pattern micro-electrode arrays used to produce aligning fields, and 2) the deleterious effect of fringing electric fields at the submicron length scales. To achieve a greater flexibility in rational, parallel assembly of 1D nanostructures into nanosystems, we have developed a powerful new approach called fluidic flow directed assembly.<sup>[36]</sup> In this method, NWs (or NTs) can be easily aligned by passing a suspension of NWs through microfluidic channel structures, for example, formed between a poly(dimethylsiloxane) (PDMS) mold<sup>[67]</sup> and a flat substrate (Fig. 23). Parallel and crossed NW arrays

**Fig. 23** Fluid flow directed assembly NWs. (A) A channel is formed when a trench structure is brought in contact with a flat substrate. Nanowire assembly is carried out by flowing a NW suspension through the channel at a controlled rate and for a set duration. Parallel arrays of NWs are observed in the flow direction on the substrate when the trench structure is removed. (B) Crossed NW arrays can be obtained by changing the flow direction sequentially in a layer-by-layer assembly process. *Source:* From Ref.<sup>[36]</sup>.

can be readily created using single (Fig. 23A) and sequential crossed (Fig. 23B) flows, respectively, for the assembly process.

### Parallel assembly of nanowire

Images of NWs assembled on substrate surfaces (Fig. 24A) within microfluidic flows demonstrate that virtually all of the NWs are aligned along the flow direction. This alignment readily extends over hundreds of micrometers (Fig. 24B). Indeed, alignment of the NWs has been found to extend up to millimeter length scales, and is limited only by the size of the fluidic channels used. The alignment of NWs within the channel flow has been explained within the framework of shear flow.<sup>[68,69]</sup> Specifically, the channel flow near the substrate surface resembles a shear flow and aligns the NWs in the flow direction before they are immobilized on the substrate. This idea readily provides the intellectual underpinning needed for controlling the degree of alignment and average separation of the NWs. First, higher flow rates produce larger shear forces and will lead to better alignment, and thus the flow rate can be used to control the degree of alignment. Indeed, the width of the NW angular distribution with respect to the flow direction significantly narrows with increasing flow rate (Fig. 24C). Studies of the distribution widths measured over a range of flow conditions showed that the width decreased

quickly as flow increased to a nearly constant value at  $\sim 10$  mm/sec (where more than 80% of the NWs are aligned within  $\pm 5^\circ$  of the flow direction (Fig. 24C, inset).

Second, these studies<sup>[36]</sup> demonstrated that the average NW density could be controlled by the flow duration (Fig. 24D). Experiments carried out at constant flow rate show that the NW density increases systematically with flow duration, and can, upon extended deposition time, produce NW arrays with spacings of the order of 100 nm or less. The relationship between average separation and flow duration also depends on and can be further controlled by the chemical functionality on the NW and substrate surfaces; that is, strong complementary interactions will facilitate deposition from the flow.

### Crossed nanowire arrays

The fluidic flow assembly approach can be used to organize NWs into more complex crossed structures, which are critical for building dense nanodevice arrays, using a layer-by-layer deposition process (Fig. 23B). The formation of crossed and more complex structures requires that the nanostructure–substrate interaction is sufficiently strong that sequential flow steps do not affect preceding ones: We find that this condition is readily achieved. For example, alternating the flow in orthogonal directions in a two-step assembly process yields crossbar structures in high yield (Figs. 25A,B). These data demonstrate that crossbars extending over 100 s of microns on a substrate with only 100 s of nanometers separation between individual cross points are obtained through a very straightforward, parallel low cost, and fast process.

Fluidic flow directed assembly of multiple crossed NW arrays offers significant advantages over previous efforts. First, it is intrinsically very parallel and scalable with the alignment readily extending over very large length scales. Second, this approach is general for virtually any elongated nanostructure including carbon NTs and DNA molecules. Third, it allows for the directed assembly of geometrically complex structures by simply controlling the angles between flow directions in sequential assembly steps. For example, equilateral triangles (Fig. 25C) were easily assembled in a three-layer deposition sequence using  $60^\circ$  angles between the three flow directions. The method of flow alignment thus provides a flexible way to meet the requirements of many device configurations in the future. An important feature of this layer-by-layer assembly scheme is that each NW layer can be independent of the preceding one(s), and thus a variety of homo- and hetero-junction configurations can be obtained at each crossed point by simply changing the composition of the NW suspension used for each

**Fig. 24** Parallel assembly of NW arrays. (A) SEM image of a parallel array of InP NWs aligned by flow. (B) Optical microscope image of a parallel array of InP NWs aligned over very large area. (C) NW angular spread with respect to the flow direction vs. flow rate. The inset shows histogram of NW angular distribution at a flow rate of 9.40 mm/sec. (D) Average density of NWs vs. flow time. Source: From Ref.<sup>[36]</sup>.

**Fig. 25** Layer-by-layer assembly of crossed NW arrays. (A, B) Typical optical microscope and SEM images of crossed arrays of InP NWs obtained in a two-step assembly process with orthogonal flow directions for the sequential steps. Arrows indicate the two flow directions. flow step. For example, it should be possible to assemble directly and subsequently address individual nanoscale devices using our approach with n-type and p-type NWs, in which the NWs act as both the wiring and active device elements.

### Control of periodicity

The above results demonstrate clearly the power of the fluidic assembly approach, although to enable systems organization with greatest control requires in many cases that the spatial position also be defined. To realize this additional constraint on the assembly process, we have explored complementary chemical interactions

**Fig. 26** Assembly of periodic NW arrays. (A) Schematic view of NW assembly onto a chemically patterned substrate. (B, C) Parallel arrays of GaP NWs aligned on poly(methylmethacrylate) (PMMA) patterned surface with 5 and 2 μm separation. (D) Parallel arrays of GaP NWs with 500 nm separation obtained with a patterned SAM surface. *Source:* From Ref.<sup>[36]</sup>.

between chemically patterned substrates and NWs (Fig. 26A). Substrates for alignment are first patterned with two different functional groups, with one of the functional groups designed to have a strong attractive interaction with the NW surface, and then, following flow alignment, regular, parallel NW arrays with lateral periods the same as those of the surface patterns are produced (Fig. 26D). These data demonstrate that the NWs are preferentially assembled at positions defined by the chemical pattern, and moreover, show that the periodic patterns can organize the NWs into regular superstructures. In addition, periodic crossed NW arrays can also be envisioned using a substrate with a crossed pattern of chemical functionality.

It is important to recognize that the patterned surface alone does not provide good control of the 1D nanostructure organization. Assembly of NTs<sup>[70,71]</sup> and NWs on patterned substrates shows that 1D nanostructures align with bridging and looping structures over the patterned areas and show little directional control. Our use of fluidic flows avoids these significant problems and enables controlled assembly in one or more directions. By combining this approach with other surface patterning methods, such as phase separation in diblock copolymers<sup>[72]</sup> and spontaneous ordering of molecules,<sup>[73]</sup> it should be possible to generate well-ordered NW arrays without the limitations of conventional lithography.

### Future Directions

The above data demonstrate clearly ordering of NW structures over multiple length scales—organization

of nanometer diameter wires with 100 nm to micrometer scale separations over millimeter scale areas. This hierarchical order can readily bridge the microscopic and macroscopic worlds, although eventual device formation still requires conventional lithography to define metallic contact electrodes to the NWs. It is possible to eliminate this step by direct assembly of NWs onto predefined metallic electrode arrays<sup>[74]</sup> that have been deposited by either via conventional or unconventional (e.g., microcontact printing or imprinting methods) lithography techniques. Lastly, it will also be beneficial to develop further these approaches in the future to enable more complex assembly, such as the selective parallel assembly of two or more electronically distinct NWs and/or NWs with different lengths.

## INTEGRATED NANOWIRE DEVICES

The ability to synthesize rationally NWs with controlled electronic properties, to demonstrate individual functional NW devices, and to assemble NWs into regular arrays has enabled us to explore in unprecedented depth the next level of hierarchy in the bottom-up approach to nanoelectronics—that is, integrated device arrays.

### Integrated Cross Nanowire p–n Junctions and Transistors

To achieve integrated functional device arrays requires high yield and high reproducibility of individual devices with controllable functional properties. In order to assess this issue, we have studied a large number of p–n junctions assembled from p-Si NWs and n-GaN NWs (Fig. 27A).<sup>[35]</sup>  $I$ - $V$  measurements made on over 100 of crossed p-Si/n-GaN NW devices show that over 95% of the junctions exhibit current rectification with turn-on voltages of around 1.0 V. Moreover, the turn on voltage of such crossed p–n junction can be controlled naturally and selectively within the framework of bottom-up approach to fabrication. Specifically, high turn-on voltage junctions can be reproducibly formed by increasing the oxide layer thickness at the junctions by either thermal oxidation of the Si NWs prior to assembly or by Joule heating of specific device elements by passing a high current through a junction in air.

Reproducible assembly of crossed NW structures with predictable electrical properties contrasts sharply with results from NT-based device, and has enabled us also to explore the assembly and properties of integrated p–n junction arrays. Significantly, electrical transport measurements made on a typical  $4 \times 1$

**Fig. 27** Crossed NW nanodevice elements. (A) Turn-on voltage distribution for crossed NW junctions. The top-left inset shows histogram of turn-on voltage for over 70 assembled junctions showing a narrow distribution around 1 V. The top-right inset shows an example  $I$ - $V$  response for low and high turn-on voltage elements. The inset in top-right inset shows a SEM image of a crossed NW device. Scale bar, 1  $\mu$ m. (B)  $I$ - $V$  behavior for a  $4(p) \times 1(n)$  multiple junction array. The four curves represent the  $I$ - $V$  for each of the four junctions and highlight reproducibility of assembled device elements. The inset shows an example of a multiple crossed NW device. (C) Transfer characteristics of four cNW-FET arrays. The inset shows conductance ( $G$ ) vs.  $V_g$  ( $V_{sd} = 1$  V) for one cNW-FET. *Source:* From Ref.<sup>[35]</sup>.

crossed p-Si/n-GaN junction array (Fig. 27B) show that the four nanoscale cross points form independently addressable p–n diodes with clear current rectification and similar turn-on voltages. These data further demonstrate the high yield and reproducibility of our crossed NW p–n devices. In addition, these crossed NW p–n junction arrays can also function as

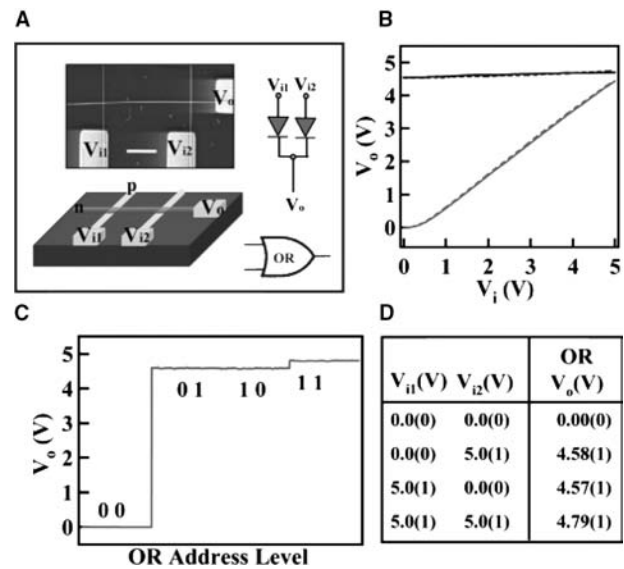

cNW-FET arrays. The transfer characteristics for an array of four cNW-FETs clearly show that each of these four cNW-FET exhibit highly sensitive gate responses with sharp onset voltages at around 2–3 V (Fig. 27C), where the transfer characteristics can be controlled by varying the doping concentration and other characteristics of the NWs used in the assembly process.

### Nanowire Logic Circuits

The controlled high-yield assembly of crossed NW p–n diodes and cNW-FETs with attractive device characteristics, such as high gain, enables the bottom-up approach to be used for assembly of more complex and functional electronic circuits, such as logic gates. Logic gates are critical blocks of hardware in current computing systems that produce a logic-1 and logic-0 output when the input logic requirements are satisfied. Diodes and transistors represent two basic device elements in logic gates.<sup>[75]</sup> Transistors are more typically used in current computing systems because they can exhibit voltage gain. Diodes do not usually exhibit voltage gain, although they may also be desirable in some cases;<sup>[35,75]</sup> for example, the architecture and constraints on the assembly of nanoelectronics might be simplified using diodes since they are two-terminal devices, in contrast to three-terminal transistors. In addition, by combining the diodes and transistors in logic circuits, it is possible to achieve high voltage gain, while simultaneously maintaining a simplified device architecture. To demonstrate the flexibility of these NW device elements, we have investigated both diode- and FET-based logic.

#### Logic OR gate

A two-input logic OR gate output is HIGH if either or both of the inputs are HIGH. This basic OR gate can be realized using a  $2(p) \times 1(n)$  crossed p–n junction array with the two p-Si NWs as inputs and the n-GaN NW as the output (Fig. 28A). The output–input ( $V_o$ – $V_i$ ) voltage response (Fig. 28B) of a typical device shows that  $V_o$  increases linearly with  $V_i$  when one input is set low (0 V) except for the region near 0 V. This low response region is due to the finite turn-on voltage of the p–n diodes, and produces a logic output typically 0.4–0.2 V less than the input voltage. Small reductions in  $V_o$  do not affect the operation of our logic gates because the low turn-on voltage contributions are reproducible and can be readily accounted for in defining the 0 and 1 states. The  $V_o$ – $V_i$  data also show a nearly constant high output when the second input is set high (5 V). For example, the output voltage vs. four possible logic address levels, which are 00, 10, 01 and

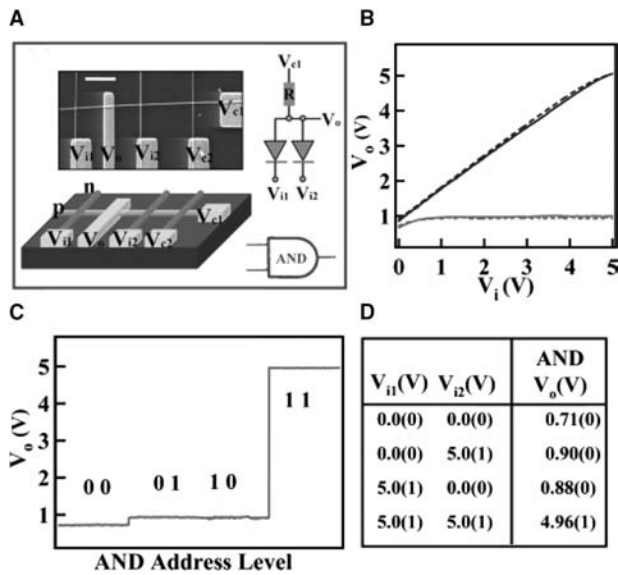

**Fig. 28** Logic OR gate. (A) Schematics of logic OR gate constructed from a  $2 \times 1$  crossed NW p–n junction. The insets show an SEM image of a device (scale bar, 1  $\mu$ m) and the symbolic electronic circuit. (B) Output–input ( $V_o$ – $V_i$ ) relation. (C) The output voltage vs. the four possible logic address level inputs: (0, 0); (0, 1); (1, 0); (1, 1). (D) The experimental truth table for the OR gate. *Source:* From Ref.<sup>[35]</sup>.

11 (Fig. 28C), shows that the output is low (logic-0) when both input voltages are low (0 V), and the output is high (logic-1) when either or both of the input voltages are high (5 V). The experimental truth table for the  $1 \times 2$  crossed NW device (Fig. 28D) summarizes the input–output response and confirms that this NW device behaves as a logic OR gate. We also note that assembly of more p–n diodes would produce in a very straightforward and scalable way multiple input OR gates, that is, a  $1 \times n$  diode array for an  $n$ -input OR gate.

#### Logic AND gate

A two-input logic AND gate output is HIGH only if both inputs are HIGH. We have assembled such two-input AND gates from  $1(p\text{-Si}) \times 3(n\text{-GaN})$  multiple junction arrays (Fig. 29A). In these structures, a p-Si NW is biased at 5 V; two GaN NWs are used as inputs and the third is used as a gate with a constant voltage to create a resistor by depleting a portion of the p-Si NW. The  $V_o$ – $V_i$  data (Fig. 29B) shows constant low  $V_o$  when the other input is low, and nearly linear behavior when the other input is set at high. Correspondingly, logic-0 is observed from this device when either one or both of the inputs are low (Fig. 29C), since  $V_i = 0$  corresponds to a forward biased, low resistance p–n diode that pulls down the output. The logic-1 is observed only when both inputs are high, since this condition corresponds to reverse biased p–n diodes

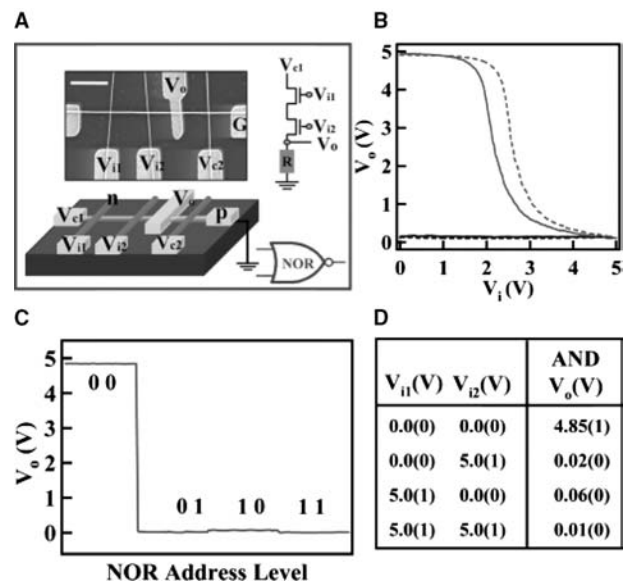

**Fig. 29** Logic AND gate. (A) Schematic of logic AND gate constructed from a  $1 \times 3$  crossed NW junction array. The insets show a typical SEM image (bar,  $1 \mu\text{m}$ ) of the assembled AND gate and symbolic electronic circuit. (B) Output–input ( $V_o$ – $V_i$ ) relation. (C) The output voltage vs. the four possible logic address level inputs: (0, 0); (0, 1); (1, 0); (1, 1). (D) The experimental truth table for the AND gate. *Source:* From Ref.<sup>[35]</sup>.

with resistances much larger than the constant resistor; that is, little voltage drop across the constant resistor and a high voltage is achieved at the output. The experimental truth table for the NW device (Fig. 29D) summarizes the input–output response and confirms that this device functions as a logic AND gate.

### Logic NOR gate

FET-based logic NOR gates have been studied using assembled  $1(\text{p-Si}) \times 3(\text{n-GaN})$  cNW-FET arrays (Fig. 30A). Typically, NOR gates were configured with 2.5 V applied to one cNW-FET to create a constant resistance  $\sim 100$  Mohms, and with the p-Si NW channel biased at 5 V. The two remaining n-GaN NW inputs were used as gates for two cNW-FETs in series. In this way, the output depends on the resistance ratio of the two cNW-FETs and the constant resistor. The  $V_o$ – $V_i$  relation (Fig. 30B) shows constant low  $V_o$  when the other input is high, and a nonlinear response with large change in  $V_o$  when the other input is set low. The logic-0 is observed when either one or both of the inputs is high (Fig. 30C). In this case, one or both of the transistors are off and have resistances much higher than the constant resistor, and thus most of the voltage drops across the transistors. A logic-1 state can only be achieved when both of the transistors are on, that is, both inputs low. Analysis of the  $V_o$ – $V_i$  data demonstrates that these two-input NOR gates

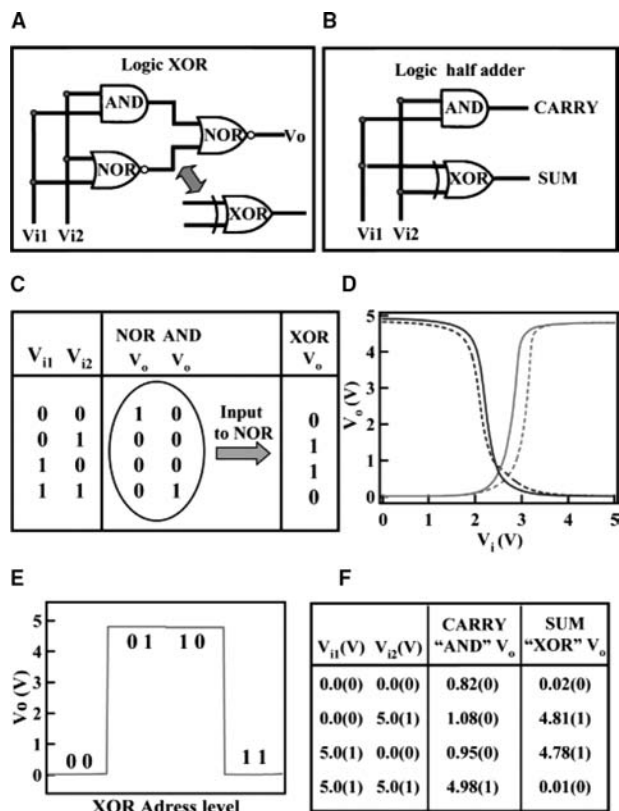

**Fig. 30** Logic NOR gate. (A) Schematic of logic NOR gate constructed from a  $1 \times 3$  crossed NW junction array. The insets show an example SEM image (bar,  $1 \mu\text{m}$ ) and symbolic electronic circuit. (B)  $V_o$ – $V_i$  relation; the slope of the data shows that device voltage gain is larger than 5. (C) The output voltage vs. the four possible logic address level inputs. (D) The measured truth table for the NOR gate. *Source:* From Ref.<sup>[35]</sup>.

routinely exhibit gains in excess of 5, which is substantially larger than the gain reported for complementary inverters based on Si NWs<sup>[34]</sup> and carbon NTs.<sup>[25]</sup> High gain is a critical characteristic of gates since it enables interconnection of arrays of logic gates without signal restoration at each stage. The experimental truth table for this NW device (Fig. 30D) summarizes the  $V_o$ – $V_i$  response and demonstrates that the device behaves as a logic NOR gate. Lastly, these multiple input logic NOR gates can be configured as simple NOT gates (inverters) by eliminating one of the inputs.

### Logic XOR and half adder circuit

Logic OR, AND, and NOR (NOT) gates form a complete set of key logic elements and enable the organization of virtually any logic circuit. To demonstrate the potential for integration of such logic gates, we have interconnected multiple AND and NOR gates to implement basic computation in the form of an XOR gate (Fig. 31A), which corresponds to the binary logic function SUM, and a half adder (Fig. 31B), which corresponds to the addition of two binary bits. The XOR gate is configured by using the output from AND and NOR gates as the input to a second NOR gate, while the logic half adder uses an additional logic AND gate as the CARRY. The truth table for the XOR structure (Fig. 31C) confirms this logic operation. Significantly,

**Fig. 31** Logic XOR gate and half adder. (A) Schematic of logic XOR gate constructed using the output from an AND and NOR as the input to a second NOR gate. (B) Schematic for logic half adder. (C) Truth table for logic XOR gate. (D) XOR output voltage vs. input voltages. The slope of the  $V_o$ - $V_i$  data shows that the gain exceeds 10. The XOR gate was achieved by connecting the output electrodes of an AND and NOR gate to two inputs of another NOR gate. (E) The output voltage vs. the four possible logic address level inputs for the XOR gate. (F) Experimental truth table for the logic half adder. The logic half adder was obtained by using the XOR gate as the SUM and an AND gate as the CARRY. Source: From Ref.<sup>[35]</sup>.

the measured  $V_o$ - $V_i$  transport data for the XOR device (Figs. 31D,E) show 1) that the output is logic-0 or low when the inputs are both low or high, and logic-1 or high when one input is low and the other is high, and 2) that the response is highly nonlinear. The linear response region corresponds to a voltage gain in excess of 10 and is typical of the devices measured to date. We note that this large gain is achieved in an XOR configured from a low gain diode AND gate, and is due to the high gain of the cNW-FET NOR gate. These data are summarized in the experimental truth table (Fig. 31F), which demonstrates that the response is that of the binary logic SUM operation. Significantly, with another AND gate as CARRY, a logic HALF ADDER is formed and can be used to carry out calculations in a manner similar to conventional electronics.

## Summary and Future Directions

In this section, we have demonstrated clearly that our ability to synthesize rationally NWs with controlled electronic properties, to configure them into individual functional NW devices, and to assemble NWs into regular arrays enables the bottom-up approach to move to new levels, including the assembly of devices with an unprecedented level of reproducibility, the integration of these device elements into complex diode and transistor logic gates without resorting to conventional lithography, and the interconnection of logic gates to carry out basic digital computation.

We also note that the OR and AND diode logic gates do not exhibit voltage gain; however, OR and AND logic with substantial gain could be realized if implemented using cNW-FETs. For example, logic OR can be achieved with the NOR gate by reversing the bias and ground connections to the p-Si NW. The AND function could also be implemented using cNW-FETs in parallel (vs. series for OR). In addition, due to finite turn-on voltage of the p-n diodes used in our diode-based OR/AND gates, the overall logic circuits were typically operated at relatively high voltage (5 V). Significantly, it is possible to operate at much lower voltage when all of the logic elements are implemented using cNW-FETs. For example, a logic NOT gate operating at 0.5 V and exhibiting a voltage gain as high as 3 (Fig. 32) was achieved using two cNW-FETs. Such a low operation voltage is a significant improvement over relative high voltage operation of carbon NT circuits (1.5 V) and current commercial circuits (1.2 V), and could be very significant for reducing the power/heat load in highly integrated nanoelectronics logic circuits. In addition, both p- and n-channel transistors could be readily assembled using

**Fig. 32** Low voltage nanoinverter (logic NOT). (A)  $I$ - $V_g$  behavior of a cNW-FET with onset of  $\sim 0.4$  V. The inset shows that the conductance of the FET can be changed over two orders of magnitude with less than 0.1 V change in the NW gate. The transconductance is  $\sim 500$  nS at  $V_{sd} = 0.5$  V. (B) Output-input ( $V_o$ - $V_i$ ) for a nanoinverter configured from two cNW-FETs. The inverter has an operation voltage of about 0.5 V.

NWs, and would enable further reduction in power dissipation.

The assembly of key logic gates and computation circuits represents a substantial advance compared to previous studies of NTs and molecular systems. First, the controllable electronic characteristics of the NW building blocks and reproducible properties of the devices assembled from these blocks contrasts the much lower control achieved to date with NTs. We believe that predictable and reproducible assembly of device elements and arrays is especially important for integration without resorting to extensive top-down lithography to connect to those few devices that function. Second, the use of crossed NW devices defines all nanoscale device metrics without resorting to top-down lithography. For example, the introduction of the new concept of a cNW-FET incorporates three intrinsic nanometer scale metrics (channel width, length, and gate dielectric thickness) into our devices, and thus can potentially enable the whole circuit architecture to be scaled down to the nanometer level in a straightforward way. This achievement and potential is in stark contrast to NT and molecular devices where the critical device dimension reported to date (length for NTs and area for molecules) have been determined by the same top-down lithography used in conventional electronics. Third, these distinct nanometer scale metrics, which are controlled by synthesis and subsequent assembly, lead to and can potentially lead to significantly improved device characteristics such as high gain, high speed, and low power dissipation, which are especially important to future highly integrated nanoelectronics circuits.

Overall, the predictable and reproducible bench-top assembly of nanoscale crossed p–n diode and cNW-FET elements and arrays reviewed in this section, which have enabled the demonstration of all critical logic gates and basic computation, represent a significant step towards integrated nanoelectronics built from primarily bottom-up vs. top-down approaches. Further improvements can be made by assembling NWs directly onto predefined metal electrode arrays<sup>[74]</sup> and by creating more highly integrated circuit elements by feeding the output from NW to NW. Implementing these approaches could eliminate the conventional lithography used to wire-up devices investigated to date. In addition, in a crossbar array with 5 nm diameter NWs, it may be possible to achieve device densities approaching  $10^{12}/\text{cm}^2$ , which is off the present semiconductor road map for top-down manufacturing. To achieve this goal of bottom-up manufacturing in the future will require substantial work—for example, in developing much greater sophistication in assembly and further improving materials synthesis—but are well within the realm of our current understanding and thus suggest a particularly bright and promising future for this approach to integrated nanoelectronics.

## APPLICATION OF NANOSCALE DEVICES IN CHEMICAL AND BIOLOGICAL SENSING

### Underlying Principle

Developments in nanotechnology will not only lead to improved electronics and make quantum jumps in electronics miniaturization, but could also enable significant advances in medicine and healthcare, which benefit mankind as a whole. For example, nanoscale devices could open up fundamentally new ways to probe single molecule properties, and allow in vivo monitoring of diseases, such as cancer, which could lead to detection at the earliest and most treatable stage.

To this end, NW-based FETs have been exploited for highly sensitive and selective detection of chemical and biological species. Planar semiconductors have been used as the basis for many types of chemical and biological sensors in which detection can be monitored electrically and/or optically. For example, planar FETs can be configured as sensors by modifying the gate oxide with molecular receptors or a selective membrane for the analyte of interest.<sup>[76,77]</sup> Binding of a charged species then results in a depletion or accumulation of carriers within the transistor structures. An attractive feature of such chemically sensitive FETs is that binding can be monitored by a direct change in conductance or related electrical property, although the sensitivity and potential for integration are limited. Our nanoscale sensors are based on a similar framework using NW-based FETs (Fig. 33) but have some obvious advantages compared to planar semiconductor sensors. First, the large surface to volume ratio can dramatically increase the sensitivity. Binding of chemical or biological species to the surface of NWs can lead to depletion or accumulation of carriers in the “bulk” of nanometer diameter structures vs. only the surface region in a planar device, and increase the sensitivity to the single-molecule level. Second, high-density arrays of sensors could be readily prepared owing to the extremely small size of the NWs and the rational assembly techniques discussed in earlier sections of this review. Lastly, the small size of these nanosensors could enable minimally invasive in vivo sensors that could be readily coupled to other device functionality, such as telemetry and drug delivery systems. We have used Si NW-based FETs to demonstrate the principle and potential of such a nanoscale sensor approach.

### Chemical Sensors: The Case of pH

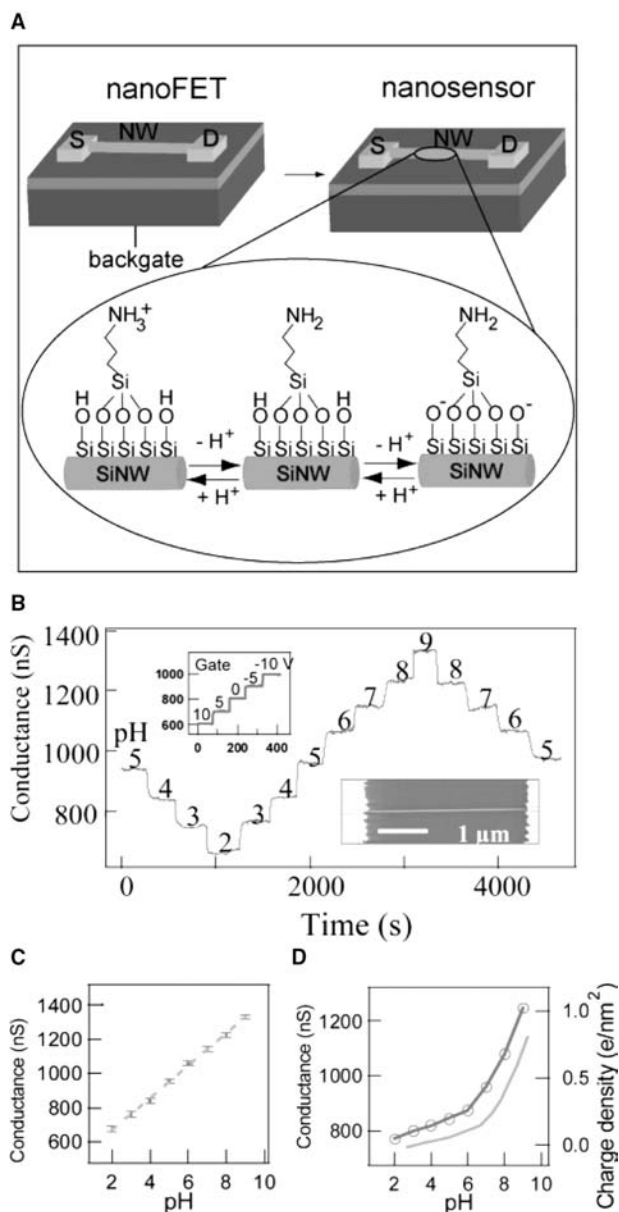

The underlying concept for the NW nanosensor can be illustrated in general for the case of pH sensor

**Fig. 33** Underlying concepts for a nanosensor based on NW-FETs. A solid state NW-FET is transformed into a sensor by modifying the NW surface with molecular receptors. Binding of a charged species (ligand) then results in a depletion or accumulation of carriers within the transistor structures and changes the conductance of the NW-FET.

(Fig. 34).<sup>[78]</sup> Here, a Si NW solid state FET whose conductance is modulated by applied gate, is transformed into a nanosensor by modifying the silicon oxide surface with 3-aminopropyltriethoxysilane (APTES). The APTES provide a surface that can undergo protonation and deprotonation, where changes in surface charge (protonation) chemically gate the Si NW (Fig. 34A). The response of APTES-modified Si NWs to changes in solution pH (Fig. 34B) demonstrate that the NW conductance increases stepwise with discrete changes in pH from 2 to 9 and that the conductance is constant for a given pH. The changes in conductance are also reversible for increasing and/or decreasing pH. A typical plot of the conductance vs. pH (Fig 34C) shows that the pH dependence is linear over the pH 2–9 range and thus suggests that modified Si NWs could function as nanoscale pH sensors.

These results have been explained by considering the mixed surface functionality of the modified Si NWs. Covalently linking APTES to SiNW oxide surface results in a surface terminating in both  $-\text{NH}_2$  and  $-\text{SiOH}$  groups (Fig. 34A), which have different dissociation constants,  $pK_a$ .<sup>[38,79]</sup> At low pH, the  $-\text{NH}_2$  group is protonated to  $-\text{NH}_3^+$  and acts as a

**Fig. 34** NW pH detection. (A) Schematic illustrating the conversion of a NW-FET into a NW pH sensor. (B) Real-time reversible detection of the conductance changes of a modified Si NW as pH is changed from 2 to 9; the pH values are indicated on the conductance plot. Inset: (Top) Plot of the time-dependent conductance of a Si NW-FET as a function of the back-gate voltage. (Bottom) SEM image of a typical device. (C) Plot of the conductance vs. pH; the dashed line is linear fit through this data. (D) The conductance of an unmodified Si NW vs. pH. The dashed curve is a plot of the surface charge density for silica as a function of pH. *Source:* From Ref.<sup>[78]</sup>.

positive gate, which depletes hole carriers in the p-type SiNW and decreases the conductance. At high pH,  $-\text{SiOH}$  is deprotonated to  $-\text{SiO}^-$ , which correspondingly causes an increase in conductance. The observed linear response can be attributed to an approximately

linear change in the total surface charge density (vs. pH) because of the combined acid and base behavior of both surface groups. This point was supported with pH dependent measurements on unmodified (only  $-\text{SiOH}$  functionality) SiNWs, which showed a non-linear pH dependence (Fig. 34D) similar to previous measurements of the pH dependent surface charge density of silica.<sup>[80]</sup>

## Biological Sensors

The above results clearly demonstrate that NW-based FETs can be configured as chemical sensors. Since many biological molecules, such as proteins and DNA, are charged under physiological conditions, it is also possible to detect the binding of these macromolecules to NW surfaces. We have demonstrated detection of biologically relevant species through the detection of proteins, antibodies, and metal ions.<sup>[78]</sup> These critical examples are reviewed briefly below.

Initial investigations of protein detection by Si NW nanosensors were carried out for the well-characterized ligand–receptor binding of biotin–streptavidin (Fig. 35A) using biotin-modified NW surfaces.<sup>[78]</sup> Measurements showed that the conductance of biotin-modified Si NWs increased rapidly to a constant

value upon addition of streptavidin solutions and that this conductance value was unchanged after the addition of pure buffer solution (Fig. 35B). The increase in conductance upon addition of streptavidin is consistent with binding of a negatively charged species to the p-type Si NW surface and the fact that streptavidin ( $pI \sim 5\text{--}6$ )<sup>[81]</sup> is negatively charged at the pH of these measurements. The absence of a conductance decrease with addition of pure buffer also agrees well with the small dissociation constant ( $K_d \sim 10^{-15}$  M) and correspondingly small dissociation rate of biotin–streptavidin.<sup>[81]</sup>

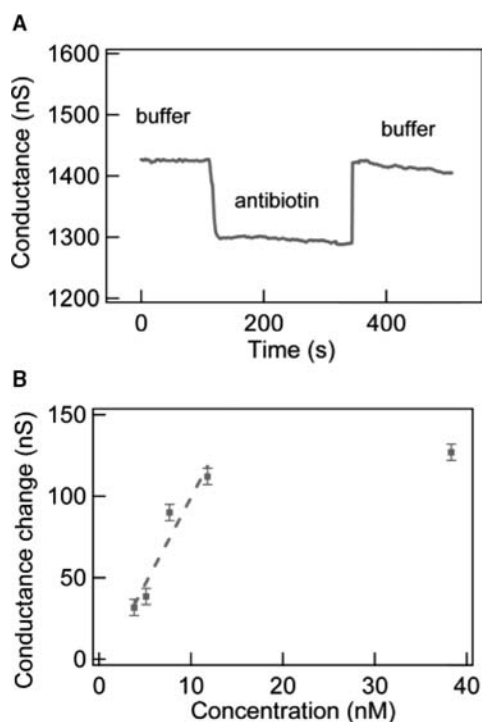

Significantly, the biotin-modified Si NWs nanosensors were also shown to exhibit very high sensitivity. Experiments indicate that it is possible to detect streptavidin binding down to a concentration at least as low as 10 pM (Fig. 35C). This detection level is substantially lower than the nanomolar range demonstrated recently by stochastic sensing of single molecules.<sup>[82]</sup> We note that a time-dependent increase in the conductance can be resolved immediately after streptavidin addition at very low concentrations, which reflects contributions from the forward binding rate and/or diffusion, although future studies will be required to resolve these contributions.

The above studies demonstrate that our NW nanosensors are capable of highly sensitive and selective real-time detection of proteins, although the essentially irreversible biotin–streptavidin binding interaction precludes real-time monitoring of varying protein concentration. To explore this possibility, we studied the reversible binding of monoclonal antibody (m-antibiotin) to biotin.<sup>[83]</sup> Time-dependent conductance measurements made on biotin-modified Si NWs (Fig. 36A) exhibit a well-defined decrease after addition of m-antibiotin solution followed by an increase in the conductance to about the original value upon addition of pure buffer solution. The decrease in conductance upon m-antibiotin addition is consistent with the binding of m-antibiotin, which was positively charged at the pH 7 of these experiments.<sup>[84]</sup> The time scale for the increase in conductance (seconds), which we associate with m-antibiotin dissociation, was also consistent with the reported dissociation rate constant.<sup>[83]</sup>

This reversible, real-time detection of m-antibiotin was further extended to monitor the Si NW sensor conductance as a function of m-antibiotin concentration in these studies.<sup>[78]</sup> These measurements showed a linear change in the conductance as a function of m-antibiotin concentration below  $\sim 10$  nM and saturation at higher values (Fig. 36B) and thus demonstrate several important facts. First, from the linear regime, we estimate that the dissociation constant,  $K_d$ , is of the order of  $10^{-9}$  M, which is in good agreement with the value,  $\sim 10^{-9}$  M, determined previously.<sup>[84]</sup> Second, we can monitor protein concentration in real time,

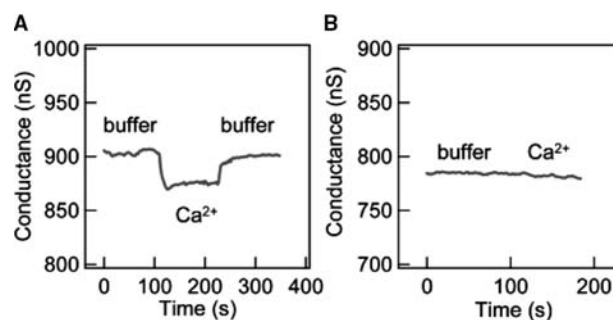

**Fig. 35** Detection of protein binding. (A) Schematic illustrating a biotin-modified Si NW (left) and subsequent binding of streptavidin to the Si NW surface (right). The Si NW and streptavidin are drawn approximately to scale. (B) Plot of conductance vs. time for a biotin-modified Si NW, where first arrow corresponds to the addition of 250 nM streptavidin, and the second arrow corresponds to the addition of pure buffer solution. (C) Conductance vs. time for a biotin-modified Si NW, where the two arrows have the same designation. The streptavidin solution had a concentration of 25 pM. *Source:* From Ref.<sup>[78]</sup>.

**Fig. 36** Real-time detection of reversible protein binding. (A) Plot of conductance vs. time for a biotin-modified Si NW, where “antibiotin” corresponds to the addition of  $\sim 3 \mu\text{M}$  m-antibiotin. (B) Plot of the conductance change of a biotin modified Si NW vs. m-antibiotin concentration; the dashed line is a linear fit to the four low concentration data points. *Source:* From Ref.<sup>[78]</sup>.

which could have important implications in basic research, for example, in monitoring protein expression, as well as in medical diagnostics. Lastly, preliminary experiments also suggest that the linear response dynamic range can be extended by applying a back gate to the NW, where gating can either increase or decrease the intrinsic binding constant.

The concept of using NW-FETs modified with receptors or ligands for specific detection can be extended in many directions. For example, they can also be used to sense calcium ions ( $\text{Ca}^{2+}$ ), which are important for activating biological processes such as muscle contraction, protein secretion, cell death, and development.<sup>[85]</sup> To this end, a  $\text{Ca}^{2+}$  sensor was fabricated by immobilizing the calcium binding protein calmodulin onto Si NW surfaces. Conductance measurements made with such modified Si NW devices (Fig. 37) showed a drop in the conductance upon addition of a  $25 \mu\text{M}$   $\text{Ca}^{2+}$  solution, and a subsequent increase when a  $\text{Ca}^{2+}$ -free buffer was subsequently flowed through the device. The observed conductance decrease is consistent with expected chemical gating by positive  $\text{Ca}^{2+}$ , and the estimated dissociation constant,  $10^{-5}$ – $10^{-6}$  M, is in good agreement with the reported  $K_d$  for calmodulin.

**Fig. 37** Real-time detection of  $\text{Ca}^{2+}$  ions. (A) Plot of conductance vs. time for a calmodulin-terminated Si NW, where “ $\text{Ca}^{2+}$ ” corresponds to the addition of  $25 \mu\text{M}$   $\text{Ca}^{2+}$  solution. (B) Conductance vs. time for an unmodified Si NW. *Source:* From Ref.<sup>[78]</sup>.

### Future Directions

The above studies demonstrate the potential of our NW nanosensors for highly sensitive and selective detection of chemical and biological species. Further development of this new type of nanosensors could also lead to antigen–antibody sensing and/or DNA detection. The availability of NWs with large gate responses should also enable detection down to the single molecule level. More generally, these nanosensors could enable many advances in both basic biological research, such as sensitive detection of many cellular species in real time in an array format to unravel complex signaling pathways, and biotechnology/medicine, where nanosensors might increase the speed of genome sequencing by many orders of magnitude and enable large scale studies designed to unravel the genetic contributions to complex diseases. Moreover, the ability to integrate these electrically monitored nanosensors with other components could facilitate development of multifunctional and minimally invasive implantable devices that enable detection and prevention of diseases at the earliest and most treatable stage.

### SUMMARY AND PERSPECTIVES

In this entry, a brief survey of work drawn primarily from the authors’ laboratory has been presented. Overall, these examples illustrate a series key advances that should ultimately enable nanoelectronics fabrication and manufacturing from the bottom-up. First, we have developed a general approach for the synthesis of NW building blocks with well-controlled chemical compositions, physical dimensions, and electronic properties. Second, we have assembled a wide range of nanoscale electronic and optoelectronic

devices from NW building blocks, and proposed and realized several conceptually new nanodevices, such as crossed NW p–n junctions and cNW-FETs, which are amenable for high-density integration. Third, we have developed methodologies to assemble NWs into integrated device arrays using microchannel fluidics or electrical fields, and have demonstrated integrated functional electronic circuits such as logic gates and carried out basic computations. Lastly, we have developed new types of nanosensors based on NW-FETs that can be used for highly sensitive and selective detection of chemical and biological species.

There is a very bright future for these electronically well-defined NW building blocks both in fundamental science and nanotechnologies. Specifically, we believe that only the very edge of a broad range of ideas has been touched, and that there remain many fascinating fundamental problems in these NW systems, such as the role of finite size and coherent states. Well-defined semiconductor NWs also represent exciting systems to probe fundamental questions about localization or delocalization of electrical carriers and optical excitons in 1D. Further investigations will be not only critical to understanding fundamental issues in 1D systems, but also central to improved device characteristics and possibly conceptually and fundamentally new type of devices, such as single photon emitters and detectors, which could be critical for future quantum communication and computation. Continuing efforts will be required to develop even better control of NW synthesis and more and more sophisticated assembly approaches that can vary device functionality over multilength scales. Lastly, developing new device concepts and integrated architectures will be increasingly essential as we move closer to ultrahigh density integrated nanosystems.

## ACKNOWLEDGMENTS

## INTRODUCTION

Rational design and synthesis of nanoscale materials is critical to work directed towards understanding fundamental properties, creating nanostructured materials, and developing nanotechnologies. One-dimensional (1D) nanostructures [such as nanowire (NW) and nanotubes] have been the focus of considerable interest because they have the potential to answer fundamental questions about role of dimensionality in physical properties and are expected to play a central role in applications ranging from molecular electronics to scanning probe microscopy probes. To explore the diverse and exciting opportunities in 1D system requires materials for which the chemical composition, diameter, length, electronic, and optical properties can be controlled and systematically varied. To meet these requirements, we have focused our efforts on developing a general and predictive approach for the synthesis of 1D structures, much as molecular beam epitaxy has served as an all-purpose method for the growth of two-dimensional (2D) structures. Specifically, it is important to achieve the ability to design and synthesize rationally NWs with predictable control over the key structural, chemical and physical properties, since such control would greatly facilitate studies designed to understand the intrinsic behavior of 1D structures and to explore them as building blocks for nanoscale electronics. Here, in this entry, we review recent advances in rational synthesis of semiconductor NWs. We will first address the key requirement for 1D growth and give a brief overview of various methods towards 1D materials. Subsequently, we will focus our discussion on growth of a broad range of semiconductor NWs via a metal-nanocluster mediated catalytic growth method based on vapor-liquid-solid (VLS) growth mechanism. Next, we further describe growth of NW materials with controlled physical size including diameter and length. Lastly, we discuss growth of NW heterostructures and superlattices with composition/doping modulation along the axial or radial direction.

## SYMMETRY BREAKING: A KEY CONCEPT FOR 1D GROWTH

In general, the growth of 1D nanostructures requires that two dimensions are restricted to the nanometer regime, while the third dimension extends to macroscopic dimensions.<sup>[1-3]</sup> This overall requirement is considerably more difficult to achieve than the corresponding constraints needed for successful growth of 0D and 2D structures.<sup>[4,5]</sup> For example, many important semiconductor materials adopt a cubic zinc-blende (ZB) structure, and thus when growth is stopped at an early stage, the resulting nanoscale structures are nanocrystals with various polyhedron shapes and not 1D NWs (Fig. 1). To achieve 1D growth in systems where atomic bonding is relatively isotropic requires that the growth symmetry be broken rather than simply arresting growth at an early stage.

Over the past decade, considerable effort has been placed on the bulk synthesis of NWs, and various strategies have been developed to break the growth symmetry either “physically” or “chemically.” A common theme in many of these studies has been the use of linear templates, including the edges of surface steps,<sup>[6]</sup> nanofibers,<sup>[7,8]</sup> and porous membranes,<sup>[9]</sup> to direct chemical reactions and material growth in 1D (Fig. 2). This strategy is conceptually simple and has been used to prepare a wide range of NW materials. Despite this simplicity, template-mediated growth is also limited in that the resulting NWs are usually polycrystalline, which could limit their potential for many applications.

Another general strategy that has received increasing focus over that past several years involves exploiting a “catalyst” to confine growth in 1D. Depending on the phases involved in the reaction, this approach is typically defined as VLS,<sup>[10,11]</sup> solution-liquid-solid (SLS),<sup>[12,13]</sup> or vapor-solid (VS)<sup>[14,15]</sup> growth. In VLS growth, a vapor-phase reactant is solubilized by a liquid catalyst particle to form solid wire/rod-like structures. Solution-liquid-solid adopts the same idea with the only change that reactant comes from a

**Fig. 1** Schematic view of key concept for 1D growth. To achieve 1D growth in systems where atomic bonding is relatively isotropic requires that the growth symmetry be broken rather than simply arresting growth at an early stage.

solution rather than vapor phase; in VS, a vapor-phase reactant reacts directly on the solid particle to form a solid wire/tube. Vapor-liquid-solid growth has been used to synthesize a variety of whisker-like structures but with typical diameter much larger than 200 nm.<sup>[10,11]</sup> Solution-liquid-solid has been used to grow NWs of III-V materials but seems to be limited by the availability of low-melting point metal

**Fig. 2** Schematic view of growth of NWs by physically confined chemical reaction. Growth of NWs by (A) Step edge deposition; (B) Pore filling; and (C) Deposition on preexisting 1D fibers such as carbon nanotubes.

catalyst.<sup>[12,13]</sup> Vapor-solid growth has been used to grow carbon nanotubes, and a number of different oxide nanorods,<sup>[14,15]</sup> although it seemed to be limited to the growth of only some particular types of materials and the growth mechanism is yet to be understood.

## CATALYTIC GROWTH: CONCEPTS AND SYNTHETIC DESIGN

Catalytic growth, where the catalyst is used to direct 1D growth of single crystal materials via a VLS mechanism (Fig. 3A), is a powerful concept for NW synthesis.<sup>[1-3]</sup> Here, the catalyst is envisioned as a nanocluster or nanodroplet that defines the diameter of and serves as the site that directs preferentially the addition of reactant to the end of a growing NW much like a living polymerization catalyst directs the addition of monomers to a growing polymer chain.

This synthetic concept is especially important since it readily provides the intellectual underpinning needed

**Fig. 3** Catalytic growth of NWs. (A) Schematics illustrating the underlying concept for catalytic growth of NWs. Liquid catalytic clusters act as the energetically favored site for localized chemical reaction, absorption of vapor-phase reactant, and crystallization of crystalline NWs. (B) Binary A-B phase diagram used as guide for choosing a catalyst for NW growth. The vertical arrow represents a specific composition of catalyst (A) to NW (B) with end point corresponding to the growth temperature. The horizontal arrow defines the composition of the catalyst liquid (L) catalyst-NW (A-B) nanodroplet and shows that pure solid NW (B) is the only solid phase at this temperature.

for the specification of the catalyst and growth conditions required for predictable NW growth. First, equilibrium phase diagrams (Fig. 3B) are used to determine catalyst materials that form a liquid alloy with the NW material of interest. The phase diagram is then used to choose a specific composition and growth temperature such that there is a coexistence of a liquid alloy and solid NW phases. The liquid catalyst alloy cluster serves as the preferential site for absorption of reactant since the sticking coefficient is much higher on liquid vs. solid surfaces and, when supersaturated, the nucleation site for crystallization. Preferential 1D growth occurs in the presence of reactant as long as the catalyst nanodroplet remains in the liquid state. Within this framework, it is straightforward to synthesize NWs with different diameters and composition, if appropriate nanometer scale diameter catalyst clusters are available. Several methods that exploit this general approach are described later with an emphasis on laser-assisted catalytic growth (LCG) and metal-catalyzed chemical vapor deposition (CVD).

## LASER-ASSISTED CATALYTIC GROWTH

A straightforward and general approach for producing the nanometer scale clusters required to nucleate and direct the growth of NWs is laser ablation and condensation.<sup>[16]</sup> In this context, NW growth can be readily achieved by laser ablation of a composite target containing the catalyst and NW material in a heated flow tube (Fig. 4). The background pressure within the flow reactor is used to control condensation of the ablated material and the cluster size, while the temperature is varied to maintain the catalyst cluster in the liquid state. When the laser-generated clusters become supersaturated with the desired NW material, a nucleation event occurs producing a (NW) solid–liquid (NW–catalyst alloy) interface. To minimize the interfacial free energy, subsequent solid growth/crystallization occurs at this initial interface, which thus imposes a highly anisotropic growth constraint that lead to 1D nanoscale wires. We have termed this method “laser-assisted catalytic growth.”<sup>[3]</sup> This approach has proven to be very general for the synthesis of semiconductor NW materials, including group IV elemental,<sup>[17]</sup> group

IV alloys, and group III–V, II–VI, and IV–VI compound semiconductor NW materials.<sup>[3,18–20]</sup> Later we demonstrate the basic principles underlying this approach with the rational and predictable growth of gallium arsenide (GaAs) NWs.

## Laser-Assisted Catalytic Growth of GaAs NWs

A key feature of our catalytic growth approach for NW synthesis is that equilibrium phase diagrams can be used to predict the catalyst material, chemical composition, and growth conditions, thus enabling rational and predictable synthesis of new NW materials. For example, binary phase diagrams have been used to predict the composition and growth temperatures for the synthesis of elemental semiconductor NW materials such as silicon and germanium NWs.<sup>[17]</sup> Predictable catalytic growth of compound NWs is more challenging than that of Si and Ge NWs due to the complexity of ternary and higher order phase diagrams. However, such complexity can be greatly simplified by considering pseudobinary phase diagrams for the catalyst and compound semiconductor of interest. For example, the pseudobinary phase diagram of Au–GaAs (Fig. 5A) shows that Au–Ga–As liquid and GaAs solid are the principle phases above 630°C in the GaAs-rich region of the phase diagram.<sup>[21]</sup> This information implies that Au can serve as a catalyst to grow GaAs NWs by the LCG method, if the target composition and growth temperature are chosen to be within this region of the phase diagram.

Indeed, LCG growth of GaAs NWs using Au as the catalyst produces samples consisting primarily of wire-like structure with diameters on the order of 10 nm, and lengths extending up to tens of micrometers (Fig. 5B). X-ray diffraction (XRD) data from bulk GaAs NW samples can be indexed to the ZB structure with a lattice constant consistent with bulk GaAs, and also show that the material is pure GaAs at least to 1% level. In addition, we note that high yields of GaAs NWs were also obtained using Ag and Cu catalysts. These latter data are consistent with the fact that Ag and Cu exhibit M–Ga–As (M = Ag or Cu) liquid and GaAs solid phases in the GaAs-rich region of the corresponding pseudobinary phase diagrams.<sup>[21]</sup> Taken together, these results demonstrate clearly the power of the LCG approach for predictable NW growth.

Detailed transmission electron microscope (TEM) studies along with electron diffraction (ED) and energy dispersive X-ray (EDX) analysis also revealed important features of the structure and chemical compositions of the produced GaAs NWs. First, diffraction contrast images of individual NWs (Fig. 5C) indicate that NWs are single crystal (uniform contrast) and uniform in diameter. Second, the Ga : As composition

Fig. 4 Schematic of a laser-based NW growth apparatus.

**Fig. 5** Laser-assisted catalytic growth of GaAs NWs. (A) Pseudobinary phase diagram of the GaAs–Au system. (B) Scanning electron microscope (SEM) image of GaAs NWs produced by LCG. (C) Diffraction contrast TEM image of a GaAs NW indicating single crystal structure. The inset shows a convergent beam ED pattern recorded along  $\langle 1\ 1\ 2 \rangle$  zone axis, and demonstrates wire axis (and growth) is along the  $[1\ 1\ 1]$  direction. (D) High-resolution TEM image of the NW. The  $(1\ 1\ 1)$  lattice planes (lattice spacing  $0.32 \pm 0.01$  nm) are clearly seen and perpendicular to the wire axis, further confirming the  $[1\ 1\ 1]$  growth direction. (E) High-resolution TEM image of an NW end showing a catalyst nanocluster. Energy dispersive X-ray analysis indicates that the nanoparticle is composed primarily of Au with trace amounts of Ga and As. *Source:* From Ref.<sup>[3]</sup>.

determined by EDX is consistent with stoichiometric GaAs within limits of instrument sensitivity. Third, the ED pattern recorded perpendicular to the long axis of this NW (Fig. 5C, inset) can be indexed for the  $\langle 1\ 1\ 2 \rangle$  zone axis of the ZB GaAs structure, and thus shows that growth occurs along the  $[1\ 1\ 1]$  direction. Extensive studies of individual GaAs NWs show that growth occurs along the  $\langle 1\ 1\ 1 \rangle$  directions in all cases. This direction and the single crystal structure have been further confirmed by lattice-resolved TEM images (e.g., Fig. 5D) that show clearly the  $(1\ 1\ 1)$  lattice planes perpendicular to the wire axis. Lastly, the TEM studies also revealed that most NWs terminate at one end with a nanoparticle of higher contrast (Fig. 5E). Energy dispersive X-ray analysis indicates that the

nanoparticles are composed largely of Au. The presence of Au nanoparticles at the ends of the NWs is consistent with the pseudobinary phase diagram, and represents strong evidence for a VLS growth mechanism proposed for LCG.

### General Synthesis of Semiconductor Nanowires

The successful synthesis of binary GaAs NWs by LCG is representative of the broad range of binary and more complex NW materials prepared by this method.<sup>[3,18–20]</sup> In a number of cases, phase diagrams could be used to define clearly catalyst, composition and growth

**Table 1** NW materials grown by the LCG approach. All of the NWs were synthesized using gold as the catalyst except for the case of GaN (see text)

Group IV–IV	Group III–V		Group II–VI (Binary)	Group IV–VI (Binary)
	Binary	Ternary		
Si	GaN	Ga(As <sub>(1-x)</sub> P <sub>x</sub> )	ZnS	PbSe
Ge	GaP	In(As <sub>(1-x)</sub> P <sub>x</sub> )	ZnSe	PbTe
Si <sub>(1-x)</sub> Ge <sub>x</sub>	GaAs	(Ga <sub>(1-x)</sub> In <sub>x</sub> )P	CdS	
	InP	(Ga <sub>(1-x)</sub> In <sub>x</sub> )As	CdSe	
	InAs	(Ga <sub>(1-x)</sub> In <sub>x</sub> ) (As <sub>(1-x)</sub> P <sub>x</sub> )		

conditions required for successful NW growth, although appropriate phase diagrams (e.g., pseudobinary and more complex) are not readily available for many compound semiconductor materials and catalytic metals of interest. To extend our synthetic approach to the broadest range of materials, we recognized that catalysts for LCG can be chosen in the absence of detailed phase diagram data by identifying metals in which the NW component elements are soluble in the liquid phase but that do not form solid compounds more stable than the desired NW phase; that is, the ideal metal catalyst should be “physically active” but “chemically stable.” This basic guiding principle suggests that the noble metal Au should represent a good starting point for many semiconductor materials. Indeed, Table 1 summarizes the broad range of NW materials, with different structure types and chemical properties, synthesized as high-quality single crystals using Au as the catalyst. These results demonstrate unambiguously the generality of our approach.

## The Case of GaN Nanowires

Gold nanoclusters are unable to catalyze GaN NW growth due to the low solubility of nitrogen.<sup>[19]</sup> These results are consistent with the basic requirement for a catalyst: physically active and chemically stable. In this context, Au is not physically active. A good catalyst should form a miscible liquid phase with GaN but not lead to a more stable solid phase under the NW growth conditions. This guiding principle suggests that Fe and Ni, which dissolve both gallium and nitrogen, and do not form a more stable compound than GaN, will be good catalysts for GaN NW growth.

Significantly, we found that LCG using either a GaN/Fe or GaN/Ni targets produces a high yield of nanometer diameter wire-like structures.<sup>[19]</sup> Fig. 6A shows a diffraction contrast TEM image of a GaN NW synthesized via an iron catalyst. The uniform contrast of the NW suggests that it has a single crystalline structure. Electron diffraction confirmed that the NWs are single crystals with a wurtzite structure and a [1 0 0] growth direction. Images of the NW ends also exhibited nanoclusters consisting primarily of iron, consistent with a VLS growth mechanism. Lastly, high-resolution TEM images (Fig. 6B,C) confirmed the single crystal structure and growth direction, and moreover, demonstrated that the surfaces of the GaN NWs terminate sharply with only 1–2 atomic layers of amorphous oxide.

## Diameter-, Length-, and Doping-Controlled Synthesis

In the LCG method, laser ablation is used to simultaneously generate nanoscale metal catalyst clusters

**Fig. 6** Laser-assisted catalytic growth of GaN NWs. (A) Diffraction contrast TEM image of a GaN NW that terminates in a faceted nanoparticle of higher (darker) contrast. (Inset) convergent beam ED (CBED) pattern recorded along  $\langle 0\ 0\ 1 \rangle$  zone axis. (B), (C) Lattice resolved TEM images of GaN NW with diameters of ca. 30 and 10 nm, respectively. The image was taken along  $\langle 0\ 0\ 1 \rangle$  zone axis. Source: From Ref.<sup>[19]</sup>.

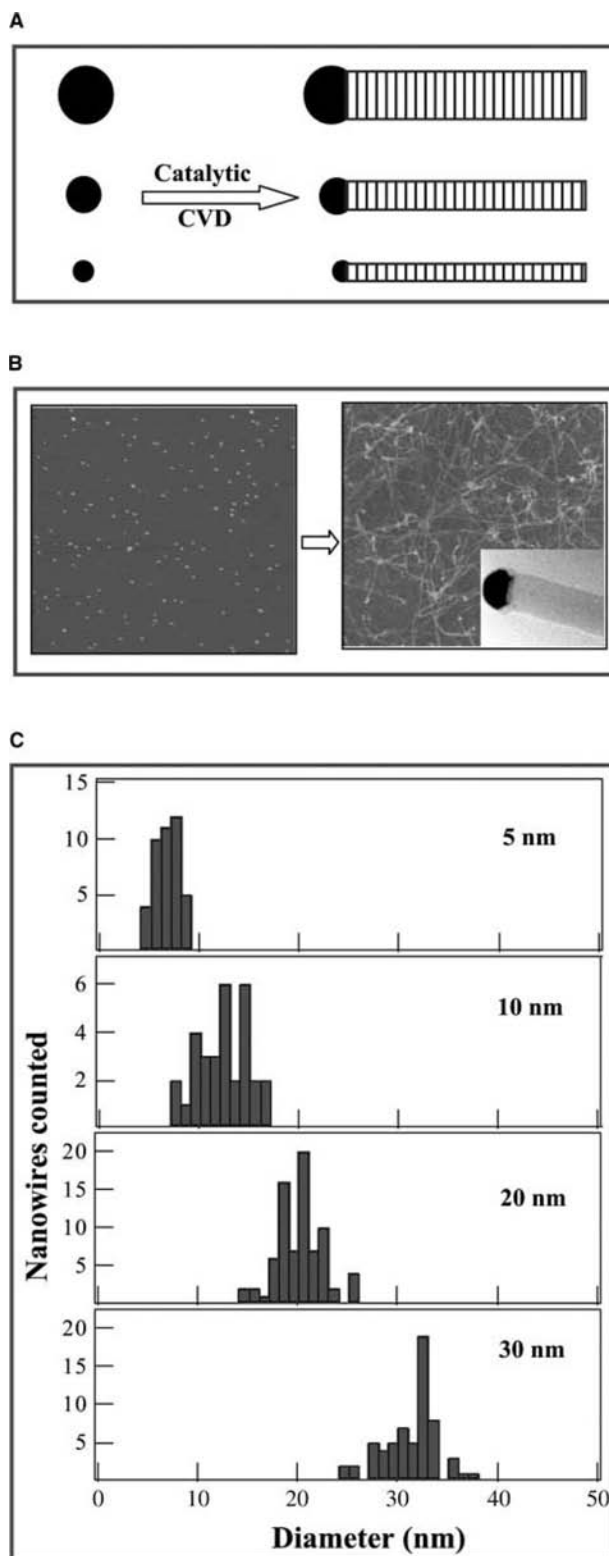

and semiconductor reactant that produce NWs via a VLS growth mechanism. A major advantage of this approach is its flexibility and generality since laser ablation can be used to produce nanoclusters of virtually any material, which has enabled the growth of a very wide range of NWs. To fully exploit the potential of these NW materials also requires control of physical dimensions (i.e., diameter and length) and electronic properties (e.g., doping).

Implicit to our catalytic approach to NW growth is the idea that the size of the metal catalysts determine NW diameter, and thus NWs with a narrow size distribution should be obtained from approximately monodisperse nanocluster catalysts. This important idea was verified recently through the demonstration of diameter-controlled growth of GaP,<sup>[22]</sup> InP,<sup>[23]</sup> and Si NWs<sup>[24]</sup> from monodisperse Au nanocluster catalysts. Significantly, the widths of the NW diameter distributions were essentially the same as those of the starting Au nanoclusters, thus demonstrating that NW diameter can be controlled predictably. The use of well-defined catalyst nanoclusters was also used to show that NWs with a given length can be prepared by controlling the growth time.<sup>[23]</sup> Lastly, studies have shown that controlled p- and n-type doping of these semiconductor NWs, which is critical for most nanoelectronic and many photonic applications, can be readily achieved by simply introducing dopant elements into the reactant.<sup>[25,26]</sup>

### CATALYTIC CHEMICAL VAPOR DEPOSITION GROWTH OF NANOWIRES

An alternative to the LCG implementation of catalytic NW growth is nanocluster-catalyzed CVD, in which the reactants and dopants are well-defined gas sources.<sup>[2]</sup> The catalytic CVD method enables the NW size, composition, and doping level to be controlled in a very precise manner.<sup>[24]</sup>

A clear illustration of the potential of this method is the controlled growth of Si NWs using distinct monodisperse diameter Au nanoclusters as the catalyst and silane as the gaseous reactant source (Fig. 7).<sup>[24]</sup> Field emission scanning electron microscope (FE-SEM) images of the Si NWs grown from Au nanoclusters dispersed on SiO<sub>2</sub> planar surfaces showed a comparable NW density to the starting nanocluster density (Fig. 7B). Qualitatively, these images also show that the Si NWs grown from Au nanoclusters are nearly monodisperse with diameters determined by the nanoclusters. This latter point was confirmed from TEM images (Fig. 7B, inset), which show directly that the Au particles at the NW ends are similar to the NW diameters. Histograms summarizing extensive TEM studies of the NW diameters obtained from different

**Fig. 7** Catalytic CVD growth of Si NWs. (A) Schematic of size-controlled NW synthesis using monodisperse Au nanocluster catalysts. (B) Atomic force microscope (AFM) image of Au nanoclusters deposited on a silicon substrate, and the Si NWs grown by CVD. (C) Distributions of NW diameters obtained from 5, 10, 20, and 30 nm diameter nanoclusters. *Source:* From Ref.<sup>[24]</sup>.

diameter nanoclusters also show that Si NWs grown from 5 ( $4.9 \pm 1.0$ ), 10 ( $9.7 \pm 1.5$ ), 20 ( $19.8 \pm 2.0$ ), and 30 nm ( $30.0 \pm 3.0$  nm) Au nanoclusters have average NW diameters of  $6.4 \pm 1.2$ ,  $12.3 \pm 2.5$ ,  $20 \pm 2.3$ , and  $31.1 \pm 2.7$  nm, respectively. Significantly, the dispersion of the Si NW diameters mirrors that of Au catalysts, suggesting that the NW dispersity is limited only by the dispersity of Au nanocluster catalysts.

These studies also showed that the NW diameters were on average 1–2 nm larger than the catalyst sizes. This observation is consistent with the formation of an (Si, Au) alloy prior to the nucleation of NW growth. In addition, postgrowth oxidation of the Si NWs upon exposure to air could increase observed wire diameters. Overall, these results demonstrate the power of our size-controlled growth approach, and also show that it is possible to produce nearly monodisperse Si NWs with specific core diameters ranging from only 2 to more than 30 nm. In addition, the electronic properties of the Si NWs can be precisely controlled by introducing dopant gases during growth. For example, addition of different ratios of diborane or phosphane to silane reactant during growth produces p- or n-type Si NWs, respectively, with dopant concentration varied in a well-controlled way.<sup>[25]</sup>

## SYNTHESIS OF NANOWIRE HETEROSTRUCTURES AND SUPERLATTICES

Modulated nanostructures in which the composition and/or doping are varied on the nanometer scale represent important targets of synthesis since they could enable new and unique function and potential for integration in functional nanosystems. An initial indication of the significance of this idea was the growth of carbon nanotube–Si NW heterojunctions, which created nanometer scale metal–semiconductor junctions showing current rectification.<sup>[27]</sup> In this section, we will describe the synthesis of both longitudinal and radial NW heterostructures.

### Axial Nanowire Heterostructures

Our approach to axial NW heterostructure growth (Fig. 8)<sup>[28]</sup> exploits metal-catalyzed NW synthesis. We introduce vapor-phase semiconductor reactants required for NW growth by either laser ablation of solid targets or vapor-phase molecular species. To create a single junction within the NW, the addition of the first reactant is stopped during growth, and then a second reactant is introduced for the remainder of the synthesis (Fig. 8B); repeated modulation of the reactants during growth produces NW superlattices

**Fig. 8** Schematics illustrating the synthesis of axial heterostructures: (A) single component NW; (B) heterostructure; and (C) superlattice. *Source:* From Ref.<sup>[28]</sup>.

(Fig. 8C). In principle, this approach can be successfully implemented if a nanocluster catalyst suitable for growth of the different superlattice components under similar conditions is found; our previous studies suggested that Au nanoclusters meet this requirement for a wide range of group III–V and group IV materials.

Gallium arsenide (GaAs) /gallium phosphide (GaP) superlattices have been grown by LCG using GaAs and GaP targets.<sup>[28]</sup> Fig. 9 shows TEM images of the products of this synthesis. It is relatively straightforward to focus on the junction area as the NW lengths can be controlled directly by growth times. High-resolution TEM images of a typical GaAs/GaP junction region (Fig. 9A) exhibit a crystalline NW core without obvious defects, and show that the NW axes lies along the  $\langle 111 \rangle$  direction, in agreement with previous studies of single-component systems. Two-dimensional Fourier transforms calculated from high-resolution images containing the junction region (Fig. 9A, inset) show pairs of reciprocal lattice peaks along the different lattice directions, while such transforms calculated from the regions above and below the junction (not shown) exhibit only single reciprocal lattice peaks. Analysis of these peak data yields lattice constants, indexed to the ZB structures of GaP and GaAs, of  $0.5474 \pm 0.0073$  nm and  $0.5668 \pm 0.0085$  nm, and are in good agreement with the values for both GaP (0.5451 nm) and GaAs (0.5653 nm), respectively.

The TEM structural data suggest that the GaP/GaAs junctions could be abrupt, and thus we have carried out local elemental mapping of the heterojunction by energy dispersive X-ray spectroscopy (EDS) to address composition variation across the junction (Fig. 9E).<sup>[28]</sup> These elemental maps show that Ga is uniformly distributed along the length of the NW, while P (Fig. 9D) and As (Fig. 9E) appear localized in the GaP and GaAs portions of the NW heterostructure, respectively. Quantitative analysis of the P and As composition variation (Fig. 9F) shows, however, that the junction is not atomically abrupt, but rather makes the transition between GaP and GaAs phases over a length scale of 15–20 nm. This length scale is reasonable

**Fig. 9** GaAs/GaP NW junctions. (A) High-resolution TEM of a GaAs/GaP junction grown from a 20-nm gold nanocluster catalyst. Scale bar, 10 nm. Inset, 2D Fourier transforms show splitting of the reciprocal lattice peaks along the  $\langle 111 \rangle$ ,  $\langle \bar{1}00 \rangle$  and  $\langle 200 \rangle$  lattice directions in the  $[022]$  zone axis. considering that the  $\sim 20$  nm diameter Au catalyst must realloy with GaP after initial GaAs growth. The observed composition variation has several potentially important implications. First, composition variation at the interface can relieve strain, and may enable the defect-free junctions and superlattices that we observe in this system—which has a relatively large lattice mismatch. We note, however, that simple estimates of the length between dislocations suggest that defect-free, atomically abrupt interfaces may be possible in wires of diameter less than 20 nm. Second, there are photonic and electronic applications where abrupt interfaces are important. The observed composition variation can be substantially reduced in smaller-diameter NWs; that is, a 5-nm diameter NW superlattice should have variations of  $< 5$  nm across the junction interfaces. Alternatively, it should be possible to use different nanocluster catalysts or variations in the growth temperature when reactants are switched to obtain sharper interfaces.

We find that this approach can produce compositionally modulated NW superlattices in which the

**Fig. 10** Nanowire superlattice structures. (A) Transmission electron microscope image of a  $\sim 20$ -nm diameter  $(\text{GaP}/\text{GaAs})_3$  NW superlattice. Scale bar, 300 nm. (B) Elemental profile of the superlattice along the NW length measured by EDS analysis. The symbols in (A) show the location of each EDS spectrum along the NW and the color of the symbol indicates GaP (red) and GaAs (blue) regions. *Source:* From Ref.<sup>[28]</sup>.

number of periods and repeat spacing can be readily varied during growth.<sup>[28]</sup> Transmission electron microscope images of a six-period structure corresponding to a (GaP/GaAs)<sub>3</sub> superlattice (Fig. 10A) show that the 20 nm diameter NWs are highly uniform over their ~3 μm lengths. Spatially resolved EDS measurements of composition (Fig. 10B) further demonstrate that the P and As regions are distinct from one another, and that there is minimal cross-contamination. Moreover, these data show that each GaP and GaAs NW segment has a length of about 500 nm, and are thus consistent with the equal growth times used for each segment, but also show that growth rates remain relatively constant during the entire NW synthesis.

This methodology for growth of superlattice structures can be generalized in many materials systems. For example, we fabricated p–n junctions within individual Si NWs by Au-nanocluster-catalyzed CVD and dopant modulation.<sup>[28]</sup> Other systems have also demonstrated recently by other groups: Si–Ge<sup>[29]</sup> and InAs–InP.<sup>[30]</sup> These superlattice structures greatly increase the versatility and power of NW building blocks for nanoscale electronic and photonic applications, such as nanobarcodes, injection lasers, and engineered 1D waveguides.

### Radial Nanowire Homo- and Heterostructures

The growth of crystalline overlayers on nanostructure surfaces is important for controlling surface properties

**Fig. 11** Synthesis of core-shell NWs by chemical vapor deposition. (A) Gaseous reactants (red) catalytically decompose on the surface of a gold nanocluster leading to nucleation and axial NW growth. (B) One-dimensional growth is maintained as reactant decomposition on the gold catalyst is strongly preferred. (C) Synthetic conditions are altered to induce homogeneous reactant decomposition on the NW surface, leading to a thin, uniform shell (blue). (D) Multiple shells are grown by repeated modulation of reactants. *Source:* From Ref.<sup>[31]</sup>.

and for enabling new function. We have recently demonstrated this concept with the synthesis of silicon and germanium core-shell and multishell NW homo- and heterostructures using the CVD method applicable to a variety of nanoscale materials.<sup>[31]</sup> The approach to

**Fig. 12** Si–Si homoepitaxial core-shell NWs. (A), (B) Diffraction contrast and high-resolution TEM images, respectively, of an unannealed i-Si core and p-Si shell NW. Scale bars are 50 and 5 nm, respectively. (C), (D) Transmission electron microscope images of an i-Si/p-Si core-shell NW annealed at 600°C for 30 min after core-shell growth at 450°C. Inset, 2D Fourier transforms depicting the [1 1 1] zone axis of the single crystal NW. (E), (F) Transmission electron microscope images of an i-Si/SiO<sub>x</sub>/p-Si NW. Inset, TEM image of p-Si coating the NW and the Au nanocluster tip. Scale bar is 50 nm. *Source:* From Ref.<sup>[31]</sup>.

the synthesis of core-shell NW structures is based upon control of radial vs. axial growth (Fig. 11). Axial growth is achieved when reactant activation and addition occurs at the catalyst site and not on the NW surface (Fig. 11B). Correspondingly, it is possible to drive conformal shell growth by altering conditions to favor homogeneous vapor-phase deposition on the NW surface (Fig. 11C). Subsequent introduction of different reactants and/or dopants produces multiple shell structures of nearly arbitrary composition, although epitaxial growth of these shells requires consideration of lattice structures. This approach to core-shell NW heterostructures is elaborated below for the technologically important silicon (Si) and germanium (Ge) systems.

Homoepitaxial Si-Si core-shell NWs were grown by CVD using silane as the silicon reactant (Fig. 12). Intrinsic silicon (i-Si) NW cores were prepared by gold nanocluster directed axial growth, which yields single crystal structures with diameters controlled by the nanocluster diameter, and then boron-doped p-type silicon (p-Si) shells were grown by homogeneous

CVD, where the shell thickness was directly proportional to the growth time. Radial shell growth can be “turned on” by the addition of diborane, which serves both to lower the decomposition temperature of silane and acts as a p-type dopant. Transmission electron microscope images of the i-Si/p-Si product obtained from constant temperature growth shows a uniform core-shell structure consisting of a crystalline Si core and amorphous Si shell (Fig. 12A), where the core diameter, 19 nm, is consistent with the 20 nm nanocluster used in the initial axial growth step. Transmission electron microscope images show reproducible crystalline faceting at the core-shell interface (Fig. 12B). This faceting suggests that the NW surfaces are sufficiently clean following axial growth to nucleate epitaxial shell growth.

To understand and control Si on Si homoepitaxy in core-shell NW structures, we carried out several distinct experiments. First, i-Si/p-Si core-shell NWs prepared as above were annealed in situ at 600°C. Transmission electron microscope images recorded on the annealed samples exhibited no diffraction

**Fig. 13** Ge-Si core-shell NWs. (A) Bright-field image of an unannealed Ge-Si core-shell NW with an amorphous p-Si shell. Scale bar is 50 nm. (B), (C) Scanning TEM elemental maps of Ge (red) and Si (blue), respectively, in the NW of (A). (D) High-resolution TEM image of an NW similar to those in (A)–(C). Scale bar is 5 nm. (E) Elemental mapping cross-section showing Ge (red circles) and Si (blue circles) concentrations. The solid lines show the theoretical cross-section for a 26-nm diameter core, 15-nm thick shell, and <1 nm interface. (F) High-resolution TEM image of annealed Ge-Si core-shell NW exhibiting a crystalline p-Si shell. Scale bar is 5 nm. (G) Elemental mapping cross-section gives a 5-nm shell thickness with a sharp interface. Source: From Ref.<sup>[31]</sup>.

contrast between the core and shell (Fig. 12C), and lattice resolved images and ED data further show that the shell crystallizes to yield a single crystal structure (Fig. 12D). Second, the importance of the initial nucleation for achieving epitaxy in the shell was probed using in situ oxidation of the silicon core, which produces a thin amorphous silicon oxide layer at the surface of the core, prior to silicon shell growth. Significantly, TEM images of i-Si/SiO<sub>x</sub>/p-Si core-shell-shell structures show a smooth and abrupt interface between the crystalline core and amorphous shell (Fig. 12E,F). The low roughness of the interface is comparable to that observed in NWs after only axial growth, and contrasts sharply with the faceted interface of the low-temperature homoepitaxy (Fig. 12B). These results show that the thin oxide layer completely disrupts homoepitaxy; further annealing and TEM studies show that oxidation inhibits crystallization of the shell under annealing conditions that lead to complete crystallization in samples without the oxide layer.

Radial heteroepitaxy of Si on Ge was also pursued to explore the potential and generality of our approach to core-shell structures in materials of rapidly increasing scientific and technological importance. For example, the energy band offsets in Si-Ge heterostructures produce internal fields that drive charge carrier redistribution, which can enable high mobility devices. Single crystal Ge NWs were defined via gold nanocluster-directed axial growth, and then boron-doped p-Si shells were grown by homogeneous CVD (see “Catalytic Chemical Vapor Deposition Growth of Nanowires”). Bright-field TEM images (Fig. 13A) reveal a core-shell structure that is consistent with Ge-core (dark) and Si-shell (light) structure, and we confirmed this assignment by elemental mapping (Fig. 13B,C), which shows a localized Ge core and Si shell. High-resolution TEM images of i-Ge/p-Si core-shell NWs in which the p-Si shell was deposited at low temperature without annealing show a crystalline Ge core and predominantly amorphous Si shell (Fig. 13D). Analysis of cross-sectional elemental mapping data (Fig. 13E) shows that the Ge core is ~26 nm, the Si shell is ~15 nm, and the Ge-Si interface width is believed to be <1 nm on the basis the electron beam width and modeling.

Significantly, we find that the amorphous Si shell can be completely crystallized following in situ thermal annealing at 600°C.<sup>[31]</sup> Lattice-resolved TEM images of Ge-Si core-shell structures following this thermal treatment exhibit a uniform crystalline Si shell (Fig. 13F), and suggest that thin regions of epitaxially grown Si are present in the unannealed wires. Higher silicon deposition temperatures might make the annealing step unnecessary by improving the surface mobility of adsorbed silicon. Elemental mapping (Fig. 13G) confirms that the contrast in high-resolution TEM

**Fig. 14** Si-Ge and Si-Ge-Si core-shell NWs. (A) Elemental mapping cross-section indicating a 21-nm diameter Si core (blue circles), 10-nm Ge shell (red circles), and <1 nm interface. Inset, TEM image of the Si-Ge core-shell NW. (B) High-resolution TEM image of an NW from the same synthesis as the wire in (A). Scale bar is 5 nm. Inset, 2D Fourier transform of the real-space image. The split lattice reflections perpendicular to the interface can be indexed to the Ge and Si lattice constants (5.657 and 5.431 Å, respectively). (C) Cross-sectional elemental mapping of a double-shell structure with an intrinsic silicon core (diameter, 20 nm), intrinsic germanium inner shell (thickness, 30 nm), and p-type silicon outer shell (4 nm); silicon is blue circles and germanium is red circles. *Source:* From Ref.<sup>[31]</sup>.

images is consistent with an abrupt ( $<1$  nm) Si–Ge interface. Although the present measurements cannot rule out some interface mixing, previous studies of planar growth under similar conditions found no evidence for Si–Ge interdiffusion. Notably, preliminary electrical transport studies of the i-Ge/p-Si core–shell NWs provide good evidence for internal field driven carrier redistribution and we believe these systems will be exciting to investigate in the future.

Synthetic control of Si–Ge core–multishell NW structures could be used to explore a variety of fundamental phenomena and new device concepts, although achieving this goal will require the ability to prepare an essentially arbitrary sequence of Si, Ge, and alloy overlayers on both Si and Ge NW cores. To this end, we also studied Ge deposition on Si NW cores.<sup>[31]</sup> Transmission electron microscope images and composition mapping (Fig. 14A) show the Si–Ge core–shell structure with a sharp ( $<1$  nm) interface, and demonstrate that the Ge shell is fully crystallized for the low-temperature growth (Fig. 14B), presumably due to the higher surface mobility of Ge adatoms. In addition, diffraction data are consistent with coherently strained epitaxial overgrowth (Fig. 14B, inset); that is, a single diffraction peak is observed along the axial direction, which is indicative of compressively strained Ge and tensilely strained Si. Two peaks, which can be indexed to the Ge (5.657 Å) and Si (5.431 Å) lattice constants, are also observed in the radial direction and indicate relaxation normal to the interface. Preliminary transport studies of these structures provide evidence for hole injection from the p-Si core to i-Ge shell as expected from valence band offsets. Finally, we have also explored the growth of more complex multishell structures; composition mapping of a Si–Ge–Si core–double-shell structure (Fig. 14C) demonstrates the ability to make core–multishell structures and suggest that this approach will be viable for introducing complex functionality in the future.

### Summary: Nanocluster Catalyzed NW Growth

To summarize this entry on the controlled and predictable growth of 1D materials, we first review the two crucial points of catalytic NW growth: 1) Nanometer sized catalytic clusters serve as a preferential site for reactant addition and nucleation, and can thereby define the size and direct the growth of crystalline NWs by a VLS mechanism; and (2) equilibrium phase diagrams can be used to predict catalyst material, composition, and growth conditions, and thus enable rational and predictable synthesis of new NW materials. In the absence of detailed phase diagram data, catalysts can be rationally chosen through consideration of the chemical reactivity and physical solubility

of the elements. An ideal catalyst should be physically active—form a miscible liquid phase with elements of the NW—but chemically stable; that is, not form a more stable solid phase than the desired NW phase under the growth conditions.

Two types of catalytic growth method have been developed and have enabled controlled growth of a very wide range of NW materials. First, LCG, where laser ablation is used to produce catalytic nanoclusters and vapor-phase reactants, has been shown to be a general technique for rapidly exploring the growth of new NW materials. Since laser ablation can be used to produce nanoclusters of virtually any material, LCG has perhaps the greatest flexibility and generality for NW synthesis. Second, catalytic CVD, in which gas reactant sources are combined with well-defined nanocluster catalysts, provides exquisite control over NW growth since all of the key parameters, including catalytic nanocluster size, reactant ratios, composition, and doping modulation, can be independently and precisely varied and controlled. In summary, a general approach has been developed for the synthesis of technologically important semiconductor NWs with precisely controlled chemical composition, physical dimension (diameter and length), hierarchical structure (axial or radial heterostructures, superlattices, and core–shell structures), and electronic optical properties. The availability of these broad range of NW materials opens many exciting opportunities in nanoscale science and technology.

### ACKNOWLEDGMENTS

# Semiconductor Quantum Dots: Atomic Ordering over Time

Peter Moeck

Department of Physics, Portland State University, Portland, Oregon, U.S.A.

## INTRODUCTION

This encyclopedia entry consists of two parts. The first part gives a brief overview of epitaxially grown semiconductor quantum dots. This kind of quantum dot is referred to as ordinarily strained random semiconductor alloy quantum dot throughout this review. The objective of the first part is to set the scene for the following part.

The main part of this encyclopedia entry deals with experimental evidence in favor of the existence of long-range atomic order within certain III–V and II–VI compound semiconductor Stranski–Krastanow grown quantum dots a few years after the growth. The objective of the second part of this entry is to review this particular field of inquiry. With necessity, only the most general experimental results can be discussed. A simple thermodynamic model, which, in principle, allows for structural transitions from ordinarily strained random semiconductor alloy quantum dots with the structural prototype of the surrounding matrix to crystallographic superlattices (i.e., long-range atomically ordered quantum dots), is also briefly mentioned in the second part.

## EPITAXIALLY GROWN ORDINARILY STRAINED RANDOM SEMICONDUCTOR ALLOY QUANTUM DOTS

Epitaxial semiconductor quantum dots (QDs) are expected to lead to “paradigm changes in semiconductor physics”.<sup>[1]</sup> As reviewed in recent textbooks,<sup>[2,3]</sup> improved optoelectronic devices (such as lasers<sup>[4,5]</sup> and mid-infrared detectors<sup>[6]</sup>), and novel nanoelectronics concepts which depend on single electron transport, tunneling, or interactions (e.g., quantum cellular automata<sup>[7]</sup>) have either been realized or may be realized as the field matures.

For applications in optoelectronic devices, an entity needs to fulfill three conditions simultaneously to be considered a QD.<sup>[4]</sup> The entity needs to possess an appropriate size in all three dimensions (i) and also needs to be a semiconductor with a smaller band gap that is embedded in a semiconductor matrix with a

larger band gap (ii). No detrimental structural defects (such as dislocations, iii), which lead to non-radiative recombination centers, are allowed to exist in the entity.

Note here that there is no restriction on the structural prototype of the entity. It may either be of the same type as that of the matrix or it may possess a distinctly different structural prototype to that of the matrix. Structural prototypes of an epitaxially grown entity that differ from that of the matrix may be realized over time by atomic rearrangements within the initially more or less random semiconductor alloy entity. In short, atomically ordered entities that may arise from such processes will have to be considered as constituting QDs according to the definition above when conditions i to iii are met simultaneously.

Analogous to the well-known particle in a box model, the simplest quantum mechanical model describes a QD as a three-dimensional (3-D) finite potential-barrier trap for an electron–hole pair. When the size of this trap is in all three dimensions smaller than the bulk exciton Bohr radius (order of magnitude 10 nm), discrete energy levels for the electron and hole arise from the spatial confinement of these particles. The energy separation of the electron levels is, for example, for epitaxially grown (In,Ga)As QDs, of the order of magnitude 100 meV,<sup>[1,8]</sup> i.e., significantly larger than the thermal energy at room temperature ( $kT \approx 26$  meV). It is these discrete energy states of an electron in a QD that are exploited in devices that work at room temperature.

As in the particle in a box model, the spacing of the energy levels in QDs depends sensitively<sup>[8]</sup> on a range of parameters of the matter wave trap. For a QD, these parameters are first and foremost its size, shape, net chemical composition and spatial chemical composition distribution, net lattice mismatch strain and spatial strain distribution, crystallographic phase, and orientation with respect to the surrounding matrix. Because a very large number of QDs are simultaneously employed in optoelectronic devices, it is obvious that variations in the parameters of the individual matter wave traps are to be as small as possible to circumvent undue broadening of the discrete electron energy levels on which the operation of the

devices relies. Although addressing this uniformity issue of QDs by optimized growth and postgrowth annealing processes is still a scientific challenge, optimizations of the basic epitaxial growth processes have been achieved in recent years on the basis of structural and spectroscopic analyses.

Currently most popular with the scientific community are QDs that are grown in the Stranski–Krastanow mode and its variants (such as embedding nominal submonolayers and allowing them to form 3-D entities within a 2-D wetting layer).<sup>a</sup> Either molecular beam epitaxy (MBE) or metal organic chemical vapor deposition (MOCVD) is typically employed.<sup>[2,3]</sup> Because these QDs grow epitaxially, they possess per definition of the term epitaxy the same structural prototype as the employed substrates and surrounding matrices. Epitaxial growth of QDs typically results in a compressive lattice mismatch strain in the QDs of a few percent as the QDs need to have a smaller band gap than the surrounding matrix and smaller band gaps are typically obtained for solid substitutional solutions with larger lattice constants.

The nature of the Stranski–Krastanow 2-D to 3-D transition in (In,Ga)As has recently been identified, and it is believed that QD of other semiconductor systems grows in the same basic manner.<sup>[11–13]</sup> Because of the nature of this transition, the QDs and their predecessor islands are always alloyed, should have a more or less random distribution of the mixed cations and/or anions over their respective sublattices in the structural prototype of the employed substrate, and should have a similar net chemical composition regardless of whether nominally pure substances or substitutional solid solutions are deposited.

Structural studies by numerous investigators employing conventional transmission electron microscopy (TEM), high-resolution phase contrast TEM (HRTEM), and atomic resolution Z-contrast scanning

TEM (Z-STEM) of a wide range of Stranski–Krastanow as-grown III–V and II–VI QD and QD predecessor island samples showed (or at least reported) no evidence of atomic ordering in as-grown structures, e.g., Refs.<sup>[11–21]</sup> and references therein. In addition, it is known that the predecessor islands and QDs have a spatially nonuniform chemical composition distribution with a core that is rich of the component with the smaller band gap (and typically larger lattice constant), i.e., a spatially zonal chemical composition distribution.<sup>[8,14,15]</sup> Significant morphological transformations<sup>[16]</sup> and changes in both the net chemical composition and spatial composition distribution<sup>[14]</sup> of the predecessor island structures take place as a result of the QD embedding process.

Such Stranski–Krastanow mode grown QDs are referred to as “ordinarily strained” in the remainder of this encyclopedia entry because they show pronounced strain fields (either so-called “black-white” or “coffee-bean” contrasts) in conventional diffraction contrast TEM micrographs, e.g., Fig. 1A.<sup>[17–19]</sup> The author of this encyclopedia entry will use the quantifier “random semiconductor alloy” synonymously to refer to ordinarily strained QDs. Occasionally, the author

**Fig. 1** (A) Ordinarily strained (In,Ga)Sb quantum dots in GaSb matrix shortly after the growth, showing strain contrast in conventional diffraction contrast TEM images, [001] plan view; the marker “BW” adjacent to a QD stands for “black-white contrast.” (B) (Partly) relaxed (In,Ga)Sb agglomerate in GaSb matrix a few years after the growth, showing  $\pm(002)$  and  $\pm(2\bar{2}0)$  moiré fringes,  $\langle 110 \rangle$  cross-section HRTEM image, Fourier transform power spectrum as insert, modified after Ref.<sup>[27]</sup> and reproduced with permission of the International Society for Optical Engineering (SPIE). The shape of the agglomerate is that of an oblate spheroid/ellipsoid and is believed to result from strain-driven atomic rearrangements in the sphalerite structure. It is well known that if QD predecessor islands grow beyond a certain size/volume limit, the lattice mismatch strain is relaxed to a significant amount by the introduction of misfit dislocation.<sup>[17,18,21]</sup> While the diameter of the quantum dots in (A) is about 10 nm, i.e., below the above-mentioned size limit, the approximate width of the agglomerate in (B) is 47 nm and its height is approximately 28 nm. These latter dimensions result in a volume that is conceivably above the volume limit for lattice mismatch strain relaxation.

<sup>a</sup>What exactly Stranski–Krastanow growth means in semiconductor epitaxy is seldom defined. The classical texts and undergraduate textbooks (e.g., Ref.<sup>[9]</sup>) define this mode simply as one of the three fundamental modes of heteroepitaxial growth (besides the Frank–Van der Merwe and the Volmer–Weber growth mode). Stranski–Krastanow growth is typically described as comprising a sequence in epitaxial growth where first, a 2-D wetting layer is formed, and second, 3-D islands are formed on top of this wetting layer. No particular mechanism is associated with the 2-D to 3-D transition per definition, and the original paper Ref.<sup>[10]</sup> deals only with the energetics of the epitaxial growth of lattice-matched ionic crystals. With explicit mechanisms not being connected to this growth mode, one is free to classify any epitaxial growth where there is a 2-D to 3-D transition of the deposit as Stranski–Krastanow growth. Whether the 3-D entities are formed on top of or within a 2-D wetting layer is thus quite unimportant. Embedding nominal submonolayers of a smaller band gap within a matrix of a larger band gap and allowing them to form 3-D entities within a 2-D wetting layer is therefore just a variant of Stranski–Krastanow growth in semiconductor epitaxy.

will address these QDs with both quantifiers, i.e., as “ordinarily strained random semiconductor alloy QDs,” to emphasize the differences to atomically ordered QDs. Where appropriate, this author will also specify the semiconductor in the general specifier “semiconductor alloy.”

Structural analyses of QDs are mainly performed by transmission electron microscopy and near surface-sensitive X-ray scattering techniques. Only very few of such investigations, however, address the long-term structural and morphological stability of QDs at room temperature over a time period of a few years. Such TEM investigations are therefore reviewed in the second part of this encyclopedia entry.

### ATOMIC ORDER WITHIN EPITAXIAL SEMICONDUCTOR QUANTUM DOTS

As mentioned above, reviewing experimental results on morphological transformations<sup>[21]</sup> and structural transition<sup>[22–32]</sup> in III–V and II–VI compound semiconductor Stranski–Krastanow grown QDs will be the subject of this part of this encyclopedia entry. Because a total of eight original papers are to be reviewed in this part, only the most general result, i.e., the fact that long-range atomic order is present in certain epitaxial compound semiconductor QD systems after the respective samples have been stored at room temperature for a few years, will be discussed in some detail. A variety of TEM images from different QD systems will be shown to demonstrate different kinds of this atomic order. This multitude of TEM images serves the purpose to show the readers (and fellow electron microscopists) the different appearances long-range atomic ordering may take in Stranski–Krastanow grown QDs of different materials systems. Occasionally, the figure captions contain details that complement the text.

The respective structural analyses at the University of Illinois at Chicago, Portland State University, and the University of Oxford, U.K., employed TEM in both the parallel illumination and scanning probe (STEM) mode.<sup>[21–32]</sup> A JEOL JEM-2010F STEM/TEM, a JEOL JEM-3010 TEM, a Philips CM20 TEM/STEM, and a FEI Tecnai G<sup>2</sup> F20 TEM/STEM were used. Parallel illumination TEM utilized conventional diffraction contrast (CTEM), selected area electron diffraction (SAED), and high-resolution phase contrast imaging (HRTEM). Atomic resolution Z-contrast (also known as high-angle annular dark field) imaging in the scanning probe mode (Z-STEM) proved to be especially useful for these investigations because the effects of strain fields in and around QDs and interference effects such as the formation of moiré fringes because of double diffraction are negligible.<sup>[30–32]</sup>

Transmission electron microscopy specimen preparation artifacts were excluded from the analyses by employing both ion milling and chemical thinning to electron transparency. Only those structures that are not an artifact of either of these two physically different specimen preparation processes were likely to be present in both kinds of specimen.<sup>b</sup>

Complementary photoluminescence (PL) spectroscopy analyses were performed at the Physical-technical Federal Institute Braunschweig/Germany on certain II–VI QD structures at a temperature of 6 K. Ar<sup>+</sup> laser light utilizing both the 488-nm line and ultraviolet light of around 350-nm wavelength was used at varying power densities for the excitation of the spectra. The PL emission light was dispersed in a 1-m-long single-grating spectrometer and detected with a cooled (In,Ga)As photomultiplier tube using conventional lock-in techniques.

Although there have been many investigations, there is still some controversy about the actual shape of both the islands that form the QDs when overgrown by a capping layer and of the ordinarily strained QDs themselves. Transmission electron microscopy observations on the shape of ordinarily strained QDs a few years after the growth resulted for a III–V system<sup>[21]</sup> (Fig. 1B) and a II–VI system,<sup>[20,30–32]</sup> in shapes that are oblate spheroids which may have different diameters along  $\pm[110]$  and  $\pm[\bar{1}10]$ , making them, in effect, ellipsoids.<sup>[16]</sup> This shape is known as a possible equilibrium shape of small precipitates that are elastically strained.<sup>[35]</sup> Of each spheroid/ellipsoid, about

<sup>b</sup>The close proximity of three different atomically ordered (Cd,Mn,Zn)Se agglomerates labeled by markers “1,” “2,” and “3” in Fig. 5A can only be interpreted as not being an artifact of the STEM imaging procedure because it is quite incomprehensible how one and the same probing electron beam may have caused three different modes of atomic rearrangements so close to each other. On a similar token, not only atomic ordering, but also phase separation were observed in the same TEM specimen (Fig. 6A–C), and it does not seem likely that the same probing electron beam may have triggered different kinds of atomic rearrangements in the same specimen. On the other hand, thermodynamics allows for the coexistence of atomically ordered and phase-separated entities in many compound semiconductor alloys. Ref.<sup>[33]</sup> Note also the large size of the double period  $\pm(1\bar{1}0)$  agglomerates, i.e., order of magnitude 200 nm (Fig. 4C and D). These entities seem to be by far too large to be caused by the probing electron beam, which had a diameter on the order of magnitude 0.2 nm only. The results of Ref.<sup>[34]</sup> on In agglomeration into QDs within (In,Ga)N quantum wells because of parallel illumination and scanning probe electron beam exposures do not reveal any changes at the structural prototype level. Such structural prototype transitions may, however, have occurred in the sample of Figs. 4C, D, and 5A. One can thus conclude that these entities are definitely not an artifact of the probing electron beam. Because it is quite impossible to produce three different atomically ordered (Cd,Mn,Zn)Se agglomerates in close proximity (Fig. 5A) by means of TEM specimen preparation procedures, such artifacts can also be excluded from the analyses.

one-half was located above the level of the original wetting layer and the other half was located below this level<sup>[20,21,30–32]</sup> (Fig. 1B).

The moiré fringes in Fig. 1B indicate that the (In,Ga)Sb entity possesses its own (partly) relaxed lattice constant, i.e., no longer (fully) strained. Because it must contain dislocations that mediate the relaxed state (i.e., violate the condition iii given in the first part of this entry), it cannot be considered to be a QD and is addressed as an “agglomerate.” The degree of relaxation can only be estimated as the chemical composition of the agglomerate is unknown. This author assumes that the degree of relaxation is less than unity because it is well known that complete relaxation of strained semiconductor structures is rarely achieved. Because numerous STEM and TEM images of QD predecessor islands and QDs by other authors have shown rather different shapes to those oblate spheroids/ellipsoids that were reported in Refs.<sup>[20,21,30–32]</sup>, this author assumes that there are lattice mismatch strain energy-driven morphological transformations over time. As the (In,Ga)Sb agglomerate in Fig. 1B is obviously dislocated but possesses the shape of an oblate spheroid/ellipsoid, even small lattice mismatch strains may have the capacity to cause morphological transformations over time.

Now if one accepts that morphological transformation of QDs may take place over time, the conceptual barrier to accepting that structural transitions in QDs may also take place over a sufficiently long time is lowered. The amount of elastic mismatch strain energy that is stored in ordinarily strained QDs and (partly) relaxed agglomerates may, besides the net chemical composition, be a determining factor for the type of transformation. Either morphological,

structural, or both structural and morphological transformations may thus take place over time. If this strain energy is comparably small (and/or the net chemical composition is unfavorable), as possibly in the case of (partly) relaxed (In,Ga)Sb agglomerates, e.g., Fig. 1B, only morphological transformations may be possible. If, on the other hand, this strain energy is comparably large (and/or the net chemical composition favorable), as possibly in the case of fully strained (In,Ga)Sb QDs, e.g., Fig. 1A, structural transitions may be possible.

Continuing with the (In,Ga)Sb QDs in GaSb matrix system, the results of two CTEM investigations<sup>[18,19]</sup> on the same TEM specimens that were separated by approximately 2 years in time suggest that the number density of ordinarily strained QDs declined over time. This observations could not be explained in 1999, but HRTEM and atomic resolution Z-STEM investigations that were performed on the same specimen about 1 to 2 years later revealed the presence of atomically ordered QDs in these specimen (Fig. 2A–C). If one assumes that ordinarily strained QDs transform structurally into atomically ordered QDs over time while the specimens are stored at room temperature, there seems to be a simple explanation for this inferred decline in the number density of ordinarily strained QDs. In both studies, the ordinarily strained quantum dots were detected by their pronounced strain field contrasts, e.g., Fig. 1A, and only moderate magnifications were employed to cover large specimen areas in a Philips CM 20 (that was not capable of high-resolution phase contrast imaging of medium lattice constant semiconductors). Note here that atomically ordered QDs, e.g., Fig. 2A–C, would, under these experimental conditions,<sup>[18,19]</sup> be

**Fig. 2** Long-range atomically ordered (In,Ga)Sb quantum dots in GaSb matrix a few years after the growth, Fourier transform power spectra as inserts. (A)  $\langle 110 \rangle$  Cross-section Z-contrast STEM image, showing a QD with atomic order in every fourth  $\pm(002)$  plane. (B)  $[001]$  Plan-view HRTEM image which was recorded at 500°C after a thermal treatment in the electron microscope at temperatures of several hundred degrees centigrade for several hours, suggesting that the atomically ordered structure of this QD rather than its original sphalerite prototype structure is thermodynamically stable. (C)  $[001]$  Plan-view SAED pattern to (B) showing the same superlattice spots as the Fourier transform power spectrum insert in (B). This diffraction pattern demonstrates clearly that atomically ordered QDs such as shown in (B) are to be distributed over large areas of the specimen. *Source:* (A) and (B) were modified after Ref.<sup>[27]</sup> and reproduced with permission of SPIE.

effectively undetectable as they are negligibly strained and do not show pronounced strain field contrasts.

It is also noteworthy that short-range order, but no long-range order, was observed in (In,Ga)Sb QDs in GaSb matrix specimen by means of SAED approximately 14 days after the growth.<sup>[17,26]</sup> Similarly to this III–V QD system, both short-range order and beginning long-range atomic order were observed by means of HRTEM in (Cd,Zn)Se QDs in ZnSe matrix samples (Fig. 3A and B) about 3 years after the growth.<sup>[26]</sup> Samples from the same growth run were much earlier analyzed by means of atomic resolution Z-STEM, but no atomic order seemed to have been present at that earlier time.<sup>[20]</sup>

These HRTEM and atomic resolution Z-STEM results from both a III–V and a II–VI system indicate that semiconductor QDs when initially grown are mostly unordered, but during subsequent room temperature storage over a few years (i.e., a long-time low-temperature annealing process), they progressively undergo short-range ordering that eventually goes over into long-range ordering.

Long-range atomically ordered QDs and entities that were probably too large to be considered as a QD (i.e., that probably violated condition i given in the first part of this entry) were also observed in MBE-grown (Cd,Mn,Zn)Se QDs in (Mn,Zn)Se matrix (Figs. 4A–F and 5A).

As the Fourier transform power spectra (Fig. 4E and F) show, the atomic arrangement in the large (Cd,Mn,Zn)Se agglomerate in Fig. 4C and D is a result of atomic ordering of the Cd and (Zn,Mn) cations in every second  $\pm(1\bar{1}0)$  plane. Using the shortest vectors in Fig. 4E as a base (for the sake of coming up with a notation only and assuming that the agglomerate belongs at least to the orthorhombic crystal system),

**Fig. 3** High-resolution TEM [001] plan-view images of atomically ordered (Cd,Zn)Se quantum dots in ZnSe matrix a few years after the growth, showing (A) long-range and (B) short-range atomic order in the same TEM specimen. The insert Fourier transforms power spectra show for (A) superlattice spots and for (B) both a diffuse and a spotty ring. None of this atomic order seems to have existed at the time of a much earlier atomic resolution Z-STEM investigation. Source: From Refs.<sup>[20,30–32]</sup>

the orientation relationship between the agglomerate and the (Mn,Zn)Se matrix becomes  $(020)_{(\text{Cd,Mn,Zn})\text{Se}} \parallel (220)_{(\text{Mn,Zn})\text{Se}}$ ,  $(110)_{(\text{Cd,Mn,Zn})\text{Se}} \parallel (1\bar{1}3)_{(\text{Mn,Zn})\text{Se}}$ , and  $[001]_{(\text{Cd,Mn,Zn})\text{Se}} \parallel [110]_{(\text{Mn,Zn})\text{Se}}$  (whereby  $\parallel$  symbolizes that both sets of reciprocal lattice vectors are within the accuracy of the Fourier transform power spectra parallel and of equal length, and that the direct lattice vectors are parallel). This orientation relationship is obviously lattice mismatch strain (and elastic mismatch strain energy) minimizing.

In the same TEM/STEM specimen, there were actually several more large agglomerates which possessed the same lattice mismatch strain energy-minimizing orientation relationship as shown in Fig. 4E and F. From a discussion of the nominal growth condition of this sample,<sup>c</sup> the large size of these agglomerates cannot be explained. Some of these agglomerates had diameters of up to approximately 250 nm and were also free of detrimental structural defects such as dislocations. The author of this encyclopedia entry believes that it is the elastic mismatch strain energy minimization effect of the particular orientation relationship these agglomerates possess with the (Mn,Zn)Se matrix which allows them to be so large while retaining their ideal translational symmetry. Taking the discussion in footnote c into account, the large size of the agglomerates may thus be explained by both the particular elastic mismatch strain energy-minimizing orientation relationship and atomic rearrangements over time. From the thermodynamics of small misfitting precipitates,<sup>[35]</sup> one can simply argue that smaller entities of the same atomically ordered structure and orientation relationship will not contain misfit dislocations either, i.e., will constitute atomically ordered QDs in this materials system.

Having identified large double-period  $\pm(1\bar{1}0)$  ordered (Cd,Mn,Zn)Se agglomerates as by far the dominant kind of structural entity per unit volume of the TEM specimens, it is now interesting to analyze the PL spectra of this sample (Fig. 5B). The ZnSe band gap being at 6 K approximately 2.8 eV, excitation with 350 nm light can be considered as non-resonant above

<sup>c</sup>It is interesting to contrast the large size of these double period  $\pm(1\bar{1}0)$  atomically ordered agglomerates with the nominal as grown sample structure. Starting with a ZnSe/GaAs pseudosubstrate, there should nominally be a multilayer structure of eight sequences of 10 monolayers (2.83 nm) of  $\text{Zn}_{0.9}\text{Mn}_{0.1}\text{Se}$  cladding layer and 0.3 monolayers (0.09 nm) CdSe sheet, capped by a further 10 monolayers of  $\text{Zn}_{0.9}\text{Mn}_{0.1}\text{Se}$  and 50 nm of ZnSe. The agglomerate in Fig. 4C and D being approximately 100 nm thick is thus thicker than the whole nominal epitaxial multiquantum well structure plus the two capping layers. It seems therefore highly improbable that such a large agglomerate could have originated directly during the growth of the QD structure a few years ago. Note that “remains” of this nominal as-grown structure were actually observed by means of HRTEM. Ref.<sup>[23,28]</sup>

**Fig. 4** TEM/STEM images of long-range atomically ordered (Cd,Mn,Zn)Se quantum dots and agglomerates in (Mn,Zn)Se matrix a few years after the growth; (A), (B), (D), (E), and (F) modified after Ref.<sup>[27]</sup> and reproduced with permission of SPIE. (A)  $\langle 110 \rangle$  Cross-section HRTEM image of a (Cd,Mn,Zn)Se QD in (Mn,Zn)Se matrix, showing cation ordering in every second  $\pm(111)$  plane, i.e., one variant of so-called CuPt-type order, Fourier transform power spectrum as insert. (B)  $\langle 110 \rangle$  Cross-section SAED pattern of (Cd,Mn,Zn)Se QDs in (Mn,Zn)Se matrix, showing  $\pm\frac{1}{3}(2\bar{2}0)$ , full line arrow,  $\pm\frac{1}{3}(\bar{1}13)$ , and  $\pm\frac{1}{3}(1\bar{1}3)$ , broken line arrows, superstructure spots. (C)  $\langle 110 \rangle$  Cross-section atomic resolution Z-STEM image of a part of a large (Cd,Mn,Zn)Se agglomerate in (Mn,Zn)Se matrix, showing atomic order in every second  $\pm(1\bar{1}0)$  plane, the black arrow points to an antiphase boundary. (D) Lower magnification Z-STEM image to (C), the black arrow points to the same antiphase boundary. (E) Fourier transform power spectrum of the large (Cd,Mn,Zn)Se agglomerate in (C). (F) Fourier transform power spectrum of the (Mn,Zn)Se matrix in (C).

this band gap and is expected to reveal most radiatively active structures inside the samples. Light excitation of 488 nm, on the other hand, can be considered as resonant excitation below the ZnSe band gap, is typically of orders of magnitude weaker than non-resonant excitation over the band gap, and is selective of specific structures.

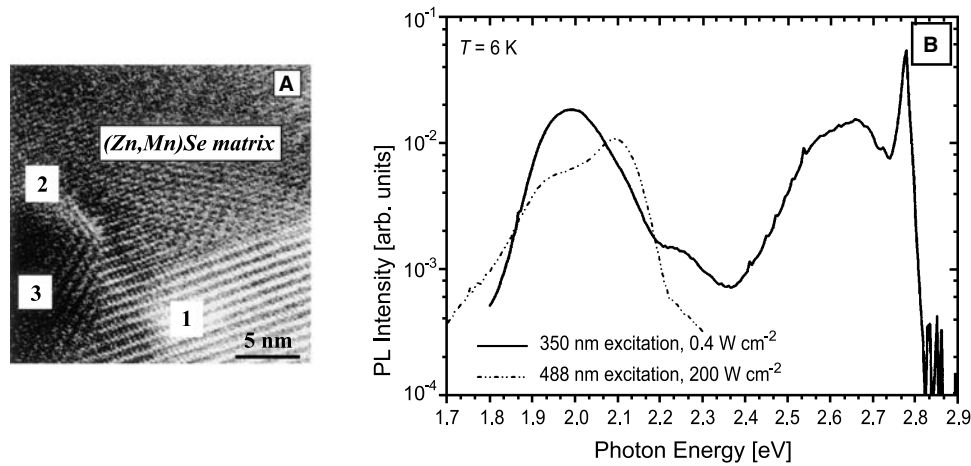

It was suggested that the large and rather broad PL peak at 2 eV in Fig. 5B, which arose when a sample was excited with laser light of approximately 350 nm, is a result of larger and smaller double-period  $\pm(1\bar{1}0)$  agglomerates, as shown in Fig. 4C and D and labeled “1” in Fig. 5A.<sup>[28]</sup> The 2.1-eV PL peak (Fig. 5B), which arose in addition to the 2-eV peak, when the sample was excited with laser light of 488 nm, may be a result of either small double-period  $\pm(1\bar{1}1)$  atomically ordered QDs (Fig. 4A), antiphase boundaries such as marked by an arrow in Fig. 4C and D, or other long-range atomically ordered entities such as labeled “2” and “3” in Fig. 5A.

From Fig. 5B, it can be concluded that the long-range atomically ordered entities must be distributed throughout large regions of the sample because the

PL spectra were collected from areas that were about 6 orders of magnitude larger than the areas that were investigated by means of TEM (Fig. 5A). A brief review of the literature showed that low-energy peaks at approximately 2 and 2.1 eV were also observed in this QD system in comparable nominal structures by several other authors.<sup>[28]</sup> None of these other authors, however, supported their assignment of these PL peaks with structural characterizations.<sup>d</sup>

<sup>d</sup>The high energy PL peaks in Fig. 5B are assigned as follows: 2.78 eV is due to a superposition of the (essentially) 2-D remains of the CdSe submonolayers and the excitonic transition in the ZnSe buffer and capping layers, 2.64 eV is due to a large population of small quasi 2-D CdSe-rich platelets (with sphalerite structure) that act as a first kind of ordinarily strained QD, and 2.25 eV is due to a small population of medium-sized 3-D CdSe-rich QDs (with sphalerite structure) that act as a second kind of ordinarily strained QD Ref.<sup>[28]</sup>. Such a coexistence of small quasi 2-D and medium-sized 3-D ordinarily strained QDs has actually been observed in similar samples of the same QD system Ref.<sup>[23]</sup>. The PL peak at 2.64 eV also shows the typical low-energy tail that is characteristic of a non-uniform Cd distribution in an epitaxial layer that contains small quasi 2-D CdSe-rich platelets Ref.<sup>[36]</sup>.

**Fig. 5** (A)  $\langle 110 \rangle$  Cross-section atomic resolution Z-contrast STEM image of (Cd,Mn,Zn)Se entities in a (Mn,Zn)Se matrix, a few years after the growth; modified after Ref.<sup>[27]</sup> and reproduced with permission of SPIE. Note that there are three different long-range atomically ordered entities, labeled as “1,” “2,” and “3” in close proximity; this remarkable fact is discussed in footnote c as proof that the observed atomic order in QDs is not a result of specimen preparation or probing electron beam artifacts. (B) Photoluminescence spectra of the same (Cd,Mn,Zn)Se entities in a (Mn,Zn)Se matrix. While the non-resonant PL is given by a full line, the resonant PL is given by a dotted line. As the area from which the PL spectra were taken is about 6 orders of magnitude larger than the area of a typical TEM image, this figure proves that atomically ordered entities must be present with a larger number density; courtesy of K. Pierz.

The observations on both III–V and II–VI QD systems with mixed cations are thus consistent with the working hypothesis that atomic rearrangements that lead to lower-energy structures take place over a

sufficiently long time. Some growth-induced short-range order may constitute additional “seeds” from which long-range ordered QDs could grow over time. It is interesting that in a III–V quantum dot system

**Fig. 6** [001] Plan view atomic resolution Z-contrast STEM images of long-range atomically ordered and phase-separated In(As,Sb) quantum dots in InAs matrix, a few years after the growth; modified after Ref.<sup>[27]</sup> and reproduced with permission of SPIE. (A) Atomically ordered QD that possesses a lattice mismatch strain energy minimizing orientation relationship with the matrix which can be inferred from the insert Fourier transform power spectrum. (B) Periodic compositional modulation that may have arisen from spinodal decomposition. (C) Same as (B) but in a higher magnification, showing atomic steps in the compositionally modulated entities that are compatible with the two observed additional periodicities in the insert Fourier transform power spectrum. The power spectrum clarifies that the modulation periodicity is not a result of a moiré effect because there are actually two additional periodicities, marked by arrows. These two periodicities add up to a single compositional modulation parallel to  $\pm[110]$  with a periodicity of 0.4 times the length of the vector (110) and may be explained as a lattice mismatch strain response. In addition, Z-contrast imaging in STEM is known to be essentially incoherent so that double diffraction effects are negligible.

with mixed anions, i.e., In(As,Sb) QDs in InAs matrix (Fig. 6A–C), atomically ordered QDs and phase-separated entities were also observed.

Labeling the two shortest vectors in the Fourier transform power spectrum of Fig. 6A as a base of the reciprocal lattice of the atomically ordered In(As,Sb) QD (for the sake of coming up with a notation only), the insert of this figure shows that the  $\pm(210)$  vectors of this QD are almost at the same position in reciprocal space as the  $\pm(110)$  vectors of the InAs matrix. This indicates that this QD possesses a lattice mismatch strain (and elastic mismatch strain energy) minimizing orientation relationship with the matrix, as one would expect it to have if it originated from a structural transition. For this mixed anions III–V QD system, the results of the two already mentioned CTEM investigations<sup>[18,19]</sup> on the same TEM specimen that were separated by approximately 2 years in time also suggested that the number density of ordinarily strained QDs declines over time. Again, a simple explanation of these observations is structural transitions from ordinarily strained QDs to atomically ordered QDs over time.

To summarize the experimental observations, the only commonality of the samples reported upon in the original papers<sup>[21–28]</sup> was that a few years have elapsed between the growth and the TEM/STEM and PL analyses. The weight of the presented TEM/STEM observations (and the careful exclusion of possible specimen preparation and imaging artifacts<sup>b)</sup>) in semiconductor QDs of different materials systems with either mixed cations or mixed anions, grown by different methods, leads this author to the working hypotheses that there are indeed morphological transformations and structural transitions in ordinarily strained random semiconductor alloy QDs over time.

So far, only a few in situ thermal treatments and structural analyses were performed in the electron microscopes under elevated temperatures, e.g., Fig. 2B. When elevated temperatures and annealing times parameter sets are found that in effect correspond to room temperature anneals over a few years, such experiments have the capacity to directly proof that there are structural transitions in ordinarily strained random alloy semiconductor QDs over time. On the other hand, such experiments are quite difficult to set up as atomically ordered QDs may exist only in certain approximate stoichiometries, which uncontrolled mismatch strain energy-driven out-diffusion of atoms from the ordinarily strained QDs during annealing may prevent from occurring. In addition, there must be a certain critical temperature above which randomness in the semiconductor alloy will prevail because of its larger entropy.

Nevertheless, the preliminary results are encouraging and suggest that the atomically ordered QD structure

in Fig. 2B is thermodynamically more stable than the random alloy sphalerite-type structure in which this QD probably had grown a few years ago (Fig. 1A). More such experiments are to be performed in the future because it is expected that this will lead to both irrefutable evidence for the occurrence of the structural transitions that are currently only inferred from TEM/STEM observations<sup>[22–32]</sup> and to information on the operating mechanisms of atomic rearrangements in ordinarily strained random semiconductor alloy QDs.

As one can easily estimate,<sup>[26,29]</sup> there is an essentially hydrostatic pressure in the 1–10 GPa range on epitaxial ordinarily strained random semiconductor alloy QD and an excess Gibbs free energy of approximately 0.1–1 eV (i.e.,  $\gg kT$  at room temperature) for every atom of such a QD associated with the typically encountered lattice mismatch strains.<sup>c</sup> In addition, grown-in and quenched-in vacancies that remained from the cooling down of the QD structure after the growth will, in strain fields, move to the spatial positions of highest compressive strain,<sup>[40]</sup> which are exactly the positions of the Stranski–Krastanow grown QDs. When these vacancies arrive at the position of an ordinarily strained random semiconductor alloy QD, they can facilitate atomic rearrangements there that lead to a reduction of excess Gibbs free energy which results form the compressive stress on these QDs. It is thus not at all inconceivable that thermodynamics-driven morphological transformations and structural transitions should be possible over a long-enough time, even at room temperature.

While it can be seen directly in the TEM and STEM images (Figs. 2B, 3B, 4A, 5A, and 6A) that the size condition i and the condition of absence of detrimental defects (such as dislocations, iii) are fulfilled, atomically ordered semiconductor alloys (i.e., crystallographic superlattices) and phase-separated semiconductor alloys (i.e., chemical superlattices) are known to possess smaller band gaps than the random semiconductor alloys of the same net chemical compositions.<sup>[41]</sup> Combinations of HRTEM and photoluminescence spectroscopy, e.g., Ref.<sup>[28]</sup> or scanning tunneling microscopy-induced luminescence<sup>[42,43]</sup>

<sup>c</sup>For hydrostatic pressure, the product of the bulk modulus (order of magnitude 100 GPa for semiconductors) and the relative elastic volume change is equal to the product of pressure and volume, which is also the excess Gibbs free energy due to lattice mismatch strains. Starting with an unstrained sphere of 10-nm diameter with a lattice constant of 0.5 nm that contains 33510 atoms, one obtains for an elastic volume change of 5% a pressure of 5 GPa and an excess Gibbs free energy of 0.49 eV per atom. Hydrostatic pressures in this range are known to lead to structural transitions in elemental (group IV) and binary III–V compound semiconductors Ref.<sup>[37]</sup>. The usage of this simple formula is justified by studies on the size dependency of elastic properties of nanometer-sized particles, e.g., Refs.<sup>[38,39]</sup>.

investigations demonstrated that smaller band gaps than the random semiconductor alloys of the same net chemical composition are realized for atomically ordered semiconductor entities.

Failure of optoelectronic devices on the timescale of a few years may be explained by structural transitions in ordinarily strained QDs as discussed in this part because devices which employ less severely strained random semiconductor alloy QDs have been found to possess longer lifetimes.<sup>[5]</sup> Growing ordinarily strained, but thermodynamically unstable, random semiconductor alloy QDs that are under compressive stresses in the GPa range, structurally transforming these entities by means of suitable postgrowth thermal treatments, and recovering these novel structures to ambient or device-operating conditions may, on the other hand, become a way to realize Feynman's 1959 vision<sup>[44]</sup> of creating and exploiting atomic arrangements on the nanometer scale that nature does not otherwise provide.

## CONCLUSION

Epitaxial semiconductor quantum dots as grown in the Stranski–Krastanow mode are typically alloyed, possess a more or less random distribution of the cations and/or anions over their respective sublattices, have a spatially nonuniform chemical composition distribution, and are compressively strained to a few percent. The lattice mismatch strains are believed to trigger atomic rearrangements inside quantum dots when the respective samples are stored at room temperature over time periods of a few years. These atomic rearrangements result in long-range atomic order and/or phase separation. While the results suggest that Stranski–Krastanow grown semiconductor quantum dots of certain III–V and II–VI systems are structurally unstable and that devices based on these quantum dots may fail over time, triggering and controlling structural transitions in epitaxial semiconductor quantum dots may also offer an opportunity of creating atomic arrangements that nature does not otherwise provide.

## INTRODUCTION

The spontaneous formation of nanoscale islands in strained-layer epitaxy, represented by Stranski–Krastanov mode growth, has been widely studied as a simple and efficient method for producing semiconductor quantum dots.<sup>[1–3]</sup> In such a self-organizing approach, quantum dots form randomly on surfaces. If the formation sites of individual quantum dots can be specified, they can be arranged in various configurations, from a single dot to regular, dense, and even coupled dot arrays, and dot placement can be restricted to specific regions, enabling the development of novel electronic and optical devices.

This entry proposes a technique for controlling the self-organization sites of individual quantum dots using scanning tunneling microscope (STM) probe-assisted nanolithography and self-organizing molecular beam epitaxy (MBE).<sup>[4–10]</sup> Two-dimensional (2-D) and three-dimensional (3-D) arrays of InAs site-controlled quantum dots (SCQDs) are successfully fabricated on GaAs substrates with nanoscale pitch and precision. Photoluminescence from the SCQD arrays is investigated at room temperature. The tip repositioning function of the STM system reveals the growth mode of the SCQDs.

## EXPERIMENT

SCQD fabrication was done in situ in an ultrahigh vacuum multichamber system<sup>[6,7,9]</sup> to achieve high-quality structures. As illustrated in Fig. 1, this system consists

of chambers for STM (Large Sample STM, Omicron), solid-source MBE, Auger electron spectroscopy (AES), STM tip cleaning, surface processing, and sample loading, which are connected to each other via a 3-m-long ultrahigh vacuum transfer tunnel. The tungsten (W) probes used for both STM-assisted SCQD fabrication and STM measurements were prepared by electrochemical etching in NaOH solution and cleaned by electron beam heating in the tip-cleaning chamber.

The STM apparatus is specially designed to have a unique tip repositioning function.<sup>[6,7]</sup> This function enables the step-by-step observation of the formation of individual quantum dots. For this purpose, arrays of  $30 \times 30 \mu\text{m}^2$  mesa were patterned on n-GaAs(001) substrates by conventional photolithography and chemical wet etching. After growth of GaAs buffer layers, quantum dot arrays having in-plane array sizes of  $1 \times 1\text{--}2 \times 2 \mu\text{m}^2$  were fabricated at the centers of the mesa top surfaces with a positional accuracy of better than several micrometers. This accuracy was realized by monitoring the approach of the STM probe tip to the mesa top surfaces using a long working distance, high-resolution optical microscope (QM100, Questar; spatial resolution of about  $2 \mu\text{m}$  at a distance of 20 cm) from outside the STM chamber. These dot arrays were easily and repeatedly found in later STM measurements, even when the sample was transferred between the STM and MBE chambers, because of the large scanning area (up to  $15 \times 15 \mu\text{m}^2$ ) of our STM, which enabled detection of the target dot array in a single scan (the typical scan area is  $4 \times 4 \mu\text{m}^2$ ). This technique thus permitted the monitoring of the evolution of an identical quantum dot in the target dot array. STM

images were taken at sample bias voltages of  $-2.4$  to  $-5.1$  V and tunneling currents of  $0.05$ – $0.49$  nA with constant-current feedback. The optical properties of the quantum dots were investigated by microprobe photoluminescence at room temperature. Photocarriers were generated by He–Ne laser ( $633$  nm) of  $3$ - $\mu\text{m}$  beam diameter, and the photoluminescence signal was detected with a cooled InGaAs photodiode array.

## RESULTS AND DISCUSSION

### Nanoscale Site Control

Fig. 2 schematically illustrates the SCQD fabrication procedure. This procedure comprises in situ deposition and growth, without complex processes such as mask layer formation and pattern etching. First, a flat and clean GaAs(001) surface was prepared by MBE, and the STM W tip was located at a surface target position

with a sample bias voltage of  $-3.2$  V and a tunneling current of  $0.1$  nA. Then, (A) nanoscale deposits were created on a GaAs surface by applying 3–5 pulses of voltage and current ( $+7$  to  $+8$  V and  $10$  nA for  $500$  msec) at intervals of  $10$  msec between the surface and the W probe. The primary composition of the deposit is considered to be a W or a W-containing compound, because the STM probe is composed of W. We confirmed that the deposits remain stable at temperatures up to at least  $610^\circ\text{C}$  under arsenic pressure and act as “nanomasks” on which GaAs does not grow directly. Accordingly, when a thin layer of GaAs or GaAs/Al(Ga)As superlattice was subsequently grown on this surface, (B) the GaAs or superlattice tended to avoid the nanomasks at the initial growth stage, but (C) later covered the nanomasks by lateral growth, leading to the natural formation of nanoholes just above the nanomasks. Finally, (D) the supply of InAs on this surface resulted in self-organization of SCQDs at the nanohole sites.

Fig. 3A, B, and C shows STM images for the fabrication process of an SCQD array corresponding to the steps in Fig. 2A, C, and D, respectively. These are step-by-step images of the identical surface region obtained using the tip repositioning function. As shown in Fig. 3A, a  $2 \times 4$  nanomask array was initially created on the GaAs surface. All nanomasks had a similar size of  $3$  nm in height and  $16$  nm in base diameter. Fig. 3B shows GaAs nanoholes produced by subsequent  $15$ -nm-thick GaAs growth at  $460^\circ\text{C}$ . The holes were elongated in the  $[110]$  direction, because of different incorporation rates of Ga atoms in different surface planes, and had an area of  $27 \times 42$  nm<sup>2</sup> and a depth of  $4$  nm. Comparisons of nanomask height, GaAs layer thickness, and hole depth indicated that the nanomasks were completely covered with the GaAs. Then, as shown in Fig. 3C, a  $2 \times 4$  quantum dot array was self-organized exactly at the nanohole sites by  $1.1$ -ML InAs supply at  $460^\circ\text{C}$ . In this dot growth, a  $0.17$  monolayer [ML;  $1$  ML corresponds to the surface atom density of GaAs(001)] supply per  $4$  sec (occasionally,  $0.087$  ML per  $2$  sec) was repeated with a growth interruption of  $1$  min under a continuous arsenic flux of  $1.3 \times 10^{-5}$  Torr. We observed virtually no undesirable Stranski–Krastanov quantum

dots (SKQDs), the occurrence of which became obvious at 1.3 ML, in the flat surface region. This indicates highly selective SCQD formation. The SCQD was 6 nm in height and about 35 nm in base diameter. A magnified STM image of the SCQD revealed a hexagonal base slightly elongated in the  $[-110]$  direction and a faceted dot surface.

STM-induced nanomasks can be created by this method with nanoscale pitch and precision, and the GaAs nanoholes defined above nanomasks are similar in size to SCQDs. Therefore, the resulting SCQDs can be located in close proximity comparable to the dot

diameter. Fig. 4 demonstrates such close dot positioning, showing three SCQD pairs fabricated by the present site-control method. A 100-nm pitch array of paired SCQDs with 45-nm center-to-center distance and 15-nm bottom-edge spacing was successfully produced.

#### Mechanism of Site-Controlled Self-organization

In previous studies, we used submicron-sized GaAs holes to site-control InAs dots.<sup>[11,12]</sup> In those cases, the dots selectively appeared in the holes at the critical InAs amount for 3-D islanding in Stranski–Krastanov growth mode. The selectivity arose from preferential InAs nucleation at specific planes in the holes, which have a high In incorporation rate. However, in the current study, the SCQDs at the nanohole sites were found to occur in a unique manner, unlike the above case, as described below.

Fig. 5 shows other detailed STM images of the SCQD formation process.<sup>[8]</sup> These are images of the identical surface region obtained using the tip repositioning function. Fig. 5A shows nanoholes produced by growing a 21-nm-thick GaAs/AlGaAs superlattice layer (1.5-nm GaAs/1.5-nm Al<sub>0.3</sub>Ga<sub>0.7</sub>As  $\times$  6, capped with 3-nm GaAs) at 620°C on the surface with the STM probe-induced nanomasks. The holes have an area of  $40 \times 55$  nm<sup>2</sup> and a depth of 10 nm. Also seen in the flat region between the holes are terraces and 2-D islands of a single step height (0.28 nm) elongated in the  $[-110]$  direction. This anisotropic shape occurs because the incorporation probability of Ga and Al atoms at B steps (parallel to  $[110]$ ) is greater than that at A steps (parallel to  $[-110]$ ) during superlattice growth.<sup>[13]</sup> Fig. 5B shows an STM image of the identical surface region after 0.7 ML InAs is supplied. The

**Fig. 4** STM image of three InAs SCQD pairs on GaAs. Each quantum dot is 6 nm in height and 30 nm in base diameter. Image area:  $155 \times 300$  nm<sup>2</sup>. Source: Reprinted with permission from Ref.<sup>[9]</sup>. © 2002, AVS—The Science & Technology Society.

**Fig. 5** STM images showing SCQD and wetting layer evolution with InAs supply. InAs: (A) 0 ML, (B) 0.7 ML, and (C) 1.2 ML. The white arrowhead “a” indicates the position of the original hole. These are images of the identical surface region obtained using the tip repositioning function. Image area:  $380 \times 580 \text{ nm}^2$ . Source: Reprinted from Ref.<sup>[8]</sup>. © 2002, with permission from Elsevier Science.

nanoholes are filled and almost planarized, but the filled parts exhibit slightly bright contrast in the STM image, as indicated, for instance, by arrowhead “a” in Fig. 5B. The area of contrast is elliptical in accordance with the shape of the original holes, and the height corresponding to the contrast is less than that of a single step. Most of the terraces and 2-D islands increased in size, although some of the relatively small 2-D islands disappeared. Consequently, the enlarged terraces and 2-D islands on the same level coalesced into one larger terrace or 2-D island elongated in the  $[-110]$  direction. Some terraces at the lower level disappeared as they were covered by the upper terraces. It should be noted that the extending terraces covered most of the filled hole sites in this process. At 1.2-ML InAs, as shown in Fig. 5C, quantum dots were selectively self-organized at the filled hole sites. In the flat region, terrace size further increased, with the result that only three levels of terraces dominated the surface.

In Fig. 5, we assume that the material filling the nanoholes is InAs or InGaAs and that the observed extension of terraces and 2-D islands indicates the formation of an In(Ga)As wetting layer (WL) that covers the filled hole sites prior to SCQD formation. In this case, since the filling In(Ga)As has a larger lattice constant and lower bandgap energy than the surrounding GaAs, the slightly bright contrast at the filled hole sites in the constant-current STM image shown in Fig. 5B can be explained by upheaval due to compression and/or larger tunneling conductivity at the wetting layer surfaces on the filled holes. Then, the subsequently supplied In atoms for 3-D islanding accumulate at the filled hole sites, because the lattice mismatch of InAs with the wetting layer on the filling In(Ga)As is less than that on the surrounding GaAs, leading to selective self-organization of quantum dots. This growth process can be understood by analogy with vertically aligned SKQDs in close stacking.<sup>[14]</sup> A detailed analysis of the evolution of the SCQD and wetting layer is provided in another publication.<sup>[5]</sup>

In order to form the quantum dots at the nanohole sites, it is important to both cover the nanomasks completely with GaAs (or superlattices) and ensure that the holes are deeper than a certain critical value by selecting suitable GaAs growth conditions and thicknesses. For instance, although 5-nm-thick GaAs growth created  $25 \times 35\text{-nm}^2$ -sized holes, the 1.2-ML InAs supply on this surface did not result in dot formation at the nanohole sites. This is because the top part of the nanomask, on which InAs does not grow directly, was still exposed at the hole bottom because of the thin GaAs layer. On the other hand, even when the nanomasks under certain growth conditions were completely covered with GaAs, dots did not form at nanohole sites when the hole depth was less than about 3 nm. In this case, because the volume of In(Ga)As filling the holes was small, the lattice constant of the wetting layer surface on the filling In(Ga)As was presumably so close to that on the surrounding GaAs surface that In atoms could not selectively accumulate at the nanohole sites.

### Three-Dimensional Site Control

When SKQD layers are stacked with thin spacer layers, the dots align vertically<sup>[14,15]</sup> or obliquely,<sup>[16,17]</sup> depending on elastic anisotropy and the thickness of the spacers, because of strain propagation. It has been predicted that regular strain distribution will gradually develop on the spacer-layer surfaces with increasing stack numbers, leading to increasingly uniform size for the topmost dots.<sup>[14,16–19]</sup> If the stacking is started with regular SCQD arrays in place of random SKQDs, the dots can be site controlled into 3-D quantum dot lattices, and uniform SKQDs array will be obtained more efficiently. In addition, this 3-D site control has the potential to realize novel quantum dot structures such as 3-D quantum dot crystals<sup>[16]</sup> with perfect spatial ordering. In this section, we demonstrate 3-D

**Fig. 6** Schematic illustration of a 3-D InAs SK-SCQD lattice structure. *Source:* Reprinted with permission from Ref.<sup>[9]</sup>. © 2002, AVS—The Science & Technology Society.

site control of SKQDs based on the site-initiated multistacking approach<sup>[9]</sup> mentioned above.

Fig. 6 illustrates the structure of a 3-D InAs quantum dot lattice. In this structure, an InAs SCQD array of arbitrary configuration was initially prepared on GaAs surfaces by the STM probe-assisted site-control technique described earlier. This array defines the in-plane lattice symmetry and parameters of the 3-D dot lattice. Then, after growth of a 10-nm-thick GaAs spacer layer, InAs was supplied to form SKQDs just above the arrayed SCQDs by strain-induced preferential self-organization. Hereafter, we denote the SKQDs grown above the SCQDs as Stranski–Krastanov mode-grown site-controlled quantum dots (SK-SCQDs). Repeating the spacer layer [GaAs/AlAs superlattice (SL) in case of Fig. 6] and SK-SCQD growth permitted the formation of a 3-D quantum dot lattice with vertically and horizontally aligned dots.

Fig. 7 shows STM images for the vertical stacking process of the SK-SCQDs in the 3-D quantum dot lattice.<sup>[9]</sup> These are images of the identical surface region.

**Fig. 7** STM images for vertical stacking process of InAs SK-SCQDs. (A) the first SK-SCQD layer, (B) spacer layer, and (C) the second SK-SCQD layer. These are images of the identical surface region obtained using the tip repositioning function. Image area:  $1000 \times 1200 \text{ nm}^2$ . *Source:* Reprinted with permission from Ref.<sup>[9]</sup>. © 2002, AVS—The Science & Technology Society.

The first-layer SK-SCQDs shown in Fig. 7A were grown with 0.9 ML InAs supply. This amount is 0.4 ML less than the critical value for the formation of conventional InAs SKQD on unstrained GaAs surfaces, indicating the existing surface strain field on the spacer layer grown over the SCQDs. The SK-SCQD array exhibits a square lattice, although the alignment is not perfect and some dots are missing due to the initial lack of SCQDs. The lattice has unit vectors in the [100] and [010] directions and a lattice parameter of about 100 nm, which are defined by the embedded SCQD strain template. Fig. 7B shows the surface topography of a 20-nm-thick GaAs/AlAs superlattice spacer, terminated with GaAs, grown on the first SK-SCQD layer. The similar positions of surface steps in this image to those in Fig. 7A confirm that these two images are of the identical surface area. The spacer layer surface is almost planarized and dominated by monolayer-high terraces. However, the strain field at this surface, generated by the embedded SK-SCQDs, was visualized when InAs was grown in the next step. Fig. 7C shows an STM image of the second layer SK-SCQDs formed with 1.3 ML InAs supply on the spacer layer. As confirmed by comparing the positions of missing dots between Fig. 7A and C, the square lattice configuration of the first-layer dots is retained in the second-layer dots. The vertical pairing probability of dots between two layers is almost 100%. On the other hand, no dot is observed at interstitial positions. These results indicate that the spatial strain field can be engineered by the site-control technique.

The in-plane lattice symmetry and parameter of the 3-D quantum dot lattice can be arranged arbitrarily, independent of the crystallographic symmetries of the substrates, by designing the SCQD strain template. An example is presented in Fig. 8, where the SK-SCQDs array has a hexagonal-like unit cell with a lattice parameter of 50–60 nm.<sup>[9]</sup> This configuration can achieve area dot densities as high as approximately  $4 \times 10^{10} \text{ cm}^{-2}$ . Close positioning comparable to the dot diameter is realized through the

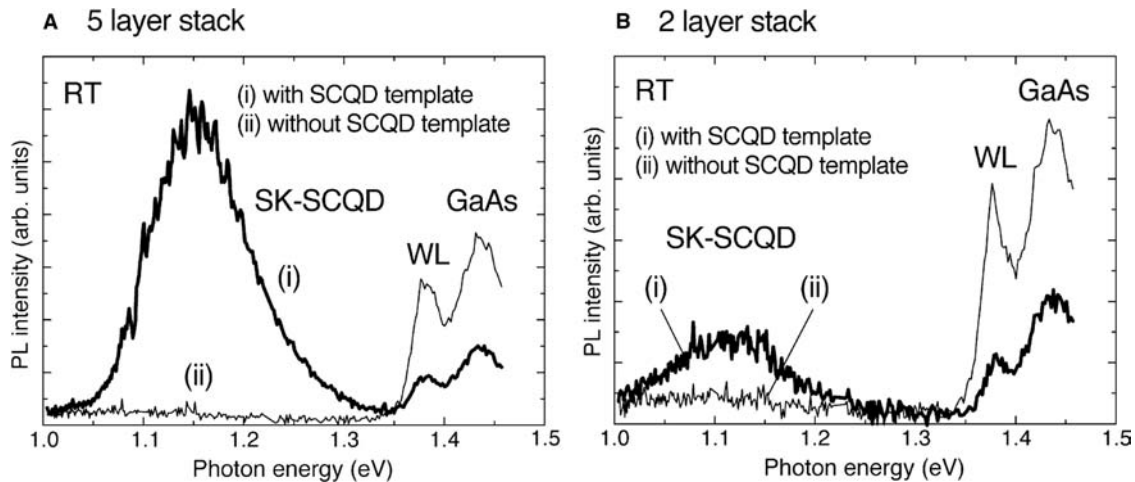

**Fig. 8** STM image of a high-density InAs SK-SCQD array. Hexagonal-like quantum dot configuration is indicated. Image area:  $600 \times 600 \text{ nm}^2$ . *Source:* Reprinted with permission from Ref.<sup>[9]</sup>. © 2002, AVS—The Science & Technology Society.

nanoscale precision of the STM-assisted site-control method.

### Optical Properties

Fig. 9A shows the microprobe-photoluminescence spectrum of a 3-D lattice of InAs SK-SCQDs measured at room temperature.<sup>[9]</sup> The sample comprised five SK-SCQD layers stacked in a manner similar to the structures in Fig. 7. The in-plane lattice parameter of the dot layer was about 100 nm. The total number of

SK-SCQDs within the excitation laser beam was estimated to be about 1200 by STM observation of the top SK-SCQD layer before capping layer growth. As shown for the case “with SCQD template” in Fig. 9A, distinct photoluminescence from the 3-D SK-SCQD lattice is observed from 1.05 to 1.30 eV. The different photoluminescence experiments confirmed that the SCQDs of the strain templates exhibit no emission and do not contribute to the photoluminescence spectra of quantum dots in Fig. 9, probably because of the existence of the STM-induced nano-masks at close positions. When a reference area without the initial SCQD strain template on the same sample is excited, no photoluminescence from quantum dots is detected, as shown for the case “without SCQD template” in Fig. 9A. This means that conventional SKQDs are hardly formed in the stacked structure without the SCQD strain template, showing highly selective formation of the 3-D SK-SCQD lattices. The excitation power dependence of the photoluminescence spectral width indicated that the observed quantum dot emission is mainly due to ground state transitions in the SK-SCQDs. Photoluminescence intensity reduction for the WL and the GaAs barrier in the 3-D SK-SCQD lattice suggests that photocarriers were effectively consumed at dots through radiative recombination. Fig. 9B shows the photoluminescence spectrum of a two-layer stacked SK-SCQD sample fabricated in a manner similar to the five-layer sample. Although the number of dots per single layer was increased to some extent in this sample, the total number of measured dots fell to about 600. However, photoluminescence from the SK-SCQDs remains observable at room temperatures, as shown for the case “with SCQD template” in Fig. 9B. These photoluminescence results reveal the good

**Fig. 9** Room temperature photoluminescence (PL) spectra of 3-D InAs SK-SCQD lattices. Samples include (A) five-layer stacked and (B) two-layer stacked SK-SCQDs. *Source:* Reprinted with permission from Ref.<sup>[9]</sup>. © 2002, AVS—The Science & Technology Society.

**Fig. 10** Room temperature photoluminescence (PL) spectrum of a single-layer InAs SK-SCQD lattice with a pitch of 75 nm. The two peaks at lower photon energies are from the ground and first excited states of the InAs SK-SCQDs, respectively. The peak at about 1.36 eV is from the InAs wetting layer (WL). The peak at around 1.44 eV is from the GaAs substrate. *Source:* Reprinted with permission from Ref.<sup>[10]</sup>. © 2003, American Institute of Physics.

crystallographic quality of the SK-SCQD structures, despite the addition of an artificial STM process and STM observation in some fabrication steps. This is because the present 3-D site control is carried out by ultrahigh vacuum in situ processing, which can keep the sample surface clean during the fabrication process,<sup>[20]</sup> using only the crystal growth technique after the initial nanomask deposition.

In Fig. 9, full width at half maximum of the SK-SCQD emissions is more than 100 meV, even in the two-layer stacked structure. This large line width can be attributed to differences in dot size in intradot layers and in interdot layers. For device applications, it is desirable to decrease both kinds of size differences to obtain a narrow line width. Targeting this improvement, we studied the photoluminescence of a single layer of SK-SCQDs.<sup>[10]</sup> A single layer of an InAs SK-SCQD square lattice with a lattice parameter of 75 nm was fabricated above an InAs SCQD strain template. The SK-SCQDs were grown at lower growth rate and lower arsenic pressure and with a greater supply of InAs than applied to the SCQDs during growth. This resulted in the formation of relatively large SK-SCQDs with an average height of about 9 nm and base diameter of about 45 nm. The SK-SCQDs were then buried with GaAs/Al<sub>0.3</sub>Ga<sub>0.7</sub>As/GaAs. Fig. 10 shows a photoluminescence spectrum from the buried structure at room temperature. From excitation spectral measurements, two respective low energy peaks were identified to arise from the ground and first excited states of the SK-SCQDs. The other

two peaks, at about 1.36 and 1.44 eV, are, respectively, attributable to the WL and GaAs substrate. The full width at half maximum of the ground state peak for the SK-SCQDs is about 40 meV, which is fairly good for artificially arranged quantum dot arrays. This is because the SK-SCQDs, like conventional SKQDs, can be made higher under the specific growth conditions described above, and because the energy variation of such higher dots is relatively insensitive to size fluctuations.

## CONCLUSION

We developed a site-controlled self-organization technique for InAs quantum dots on GaAs(001) surfaces using in situ STM probe-assisted nanolithography and self-organizing MBE. We found that it was possible to create nanoscale deposits on a GaAs surface by applying voltage and current pulses between the surface and an STM probe. When the deposits were used as nanomasks for GaAs growth, GaAs nanoholes were formed naturally above the deposits. Subsequently supplied InAs filled and planarized the GaAs nanoholes, providing flat surfaces with modulated strain fields. Consequently, supplying additional InAs on the surfaces led to SCQD formation at the filled-hole sites. Virtually no undesirable SKQDs were observed, indicating highly selective dot formation. This process resulted in successful fabrication of 2-D arrays of InAs SCQDs with nanoscale pitch and precision. 3-D quantum dot lattices were also demonstrated. In-plane dot arrangement of the 3-D dot lattices was initially defined by 2-D arrays of InAs SCQDs. With the SCQD arrays used as strain templates, self-organized InAs quantum dots were vertically aligned by strain-induced multistacking, resulting in 3-D quantum dot lattices. Photoluminescence measurements revealed good crystallographic quality for the 2-D and 3-D SK-SCQD lattices.

The site-control technique demonstrated here enables the location of an isolated single quantum dot at an intended position on the surfaces, which is useful for developing single-photon and electron devices. The high-density dot arrays with small energy dispersion are also technologically significant structures that can be achieved by this site-control approach, because large dots, whose energy variations are relatively insensitive to size fluctuations, can be formed regardless of density. This independent control of dot size and density is a difficult task for conventional crystal growth. Another attractive application of the site-control technique is the formation of dot arrays in limited areas in the devices. For instance, photonic crystal waveguide structures having quantum

dot arrays at specific regions would make it possible to build miniaturized, ultrahigh speed all-optical switches with high switching efficiency.<sup>[21,22]</sup> Such applications will require improvements in the uniformity of the size of SK-SCQDs in the intra- and interlayers. In 3-D site-control processes, it is also important to control lateral strain interaction between neighboring dot sites in vertical stacking, as we pointed out in a recent study.<sup>[10]</sup> Further experimental investigations and theoretical consideration of growth conditions and spatial strain fields will lead to uniform quantum dot size and the realization of novel nanostructure systems.

## INTRODUCTION

Selective and non-selective solid-state chemical sensors have been developed for a variety of applications in process control, environmental monitoring, and hazardous substance detection. Most rely on an indirect detection mechanism whereby electronic or electro-optical properties of the device are altered by the substance of interest allowing for a measurable response. Sensors based on analyte–sensor interactions, which modify capacitance, conductivity, and refractive index, operate in this manner.<sup>[1–7]</sup>

Recently, a means of directly monitoring charged carriers produced from gas–surface interactions has been described<sup>[8–18]</sup> whereby “hot” electrons/holes (e–h) from gas–surface reactions are themselves detected using ultrathin film metal–semiconductor (MS) Schottky diodes.<sup>[13]</sup> When an adsorbate binds to the surface with a relatively large adsorption energy, the energy may appear as an energetic e–h pair generated at the metal surface; the excited electron may travel ballistically through the thin metal film and transverse the Schottky barrier (SB) if the film is thin compared with the ballistic mean free path and if the kinetic energy of the electron is larger than the barrier height (Fig. 1A). Once injected into the conduction band of the semiconductor [inverse electron emission, (IEE)], the electron is detected as a “chemicurrent” analogous to the photocurrent in a photodiode.

The energetic charge carriers have a ballistic mean free path of tens of nanometers and thus for small-dimension metal structures, the “hot” charge carriers persist at energies well above the Fermi level. Hot electrons have interesting and unusual reactivity and transport properties which may be taken advantage of in Schottky-barrier metal–semiconductor (MS) and metal–oxide–semiconductor (MOS) diode sensors. Using ultrathin metal films on MS and MOS device structures, we have investigated the “chemielectronic” phenomena associated with a variety of molecular and atomic interactions with transition metal surfaces (Ag, Au, Pt, Pd) and found distinct differences in the

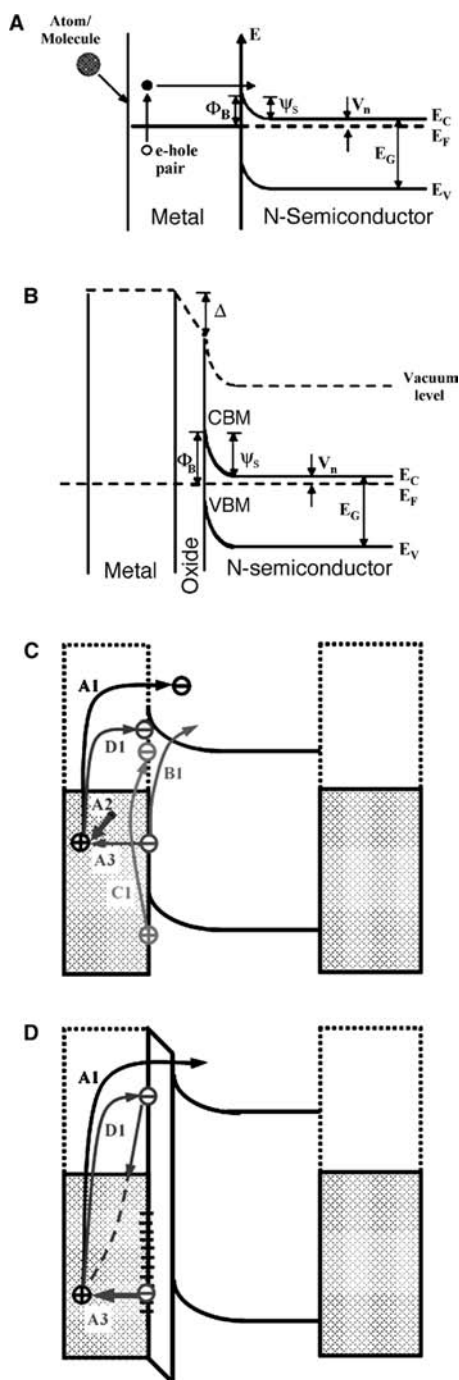

mechanism of signal production between the highly energetic atomic and molecular species and more weakly interacting species such as xenon and hydrocarbons. In this review, the basis for the chemical sensitivity of these diode structures will be addressed, emphasizing the importance of oxide interfacial states in the detection of electronic signals from weakly interacting gases. Experimental evidence linking the surface chemistry to the electronic processes giving rise to signals in MS and MOS diode sensors will be presented.

## BACKGROUND

Gergen et al.<sup>[16,18]</sup> showed that by adding a thin oxide layer between the metal and the semiconductor, the modified metal–oxide–semiconductor (MOS) device had sensitivity to a variety of weakly interacting gas species not detectable on the MS Schottky diode sensor. The original explanation of ballistic charge transport over the Schottky barrier appears valid for species with large adsorption energies including atomic oxygen and atomic hydrogen, O<sub>2</sub>, NO, and NO<sub>2</sub>; however, the mechanism of carrier generation and detection on the same devices for weakly interacting species such as Xe, CO<sub>2</sub>, and hydrocarbons is only now becoming clarified.

Metal–semiconductor and MOS solid-state sensors are used in a variety of sensor applications; however, despite decades of research, there remain controversies regarding a complete description of the detection mechanisms and conduction pathways. The controversy is greatest for devices containing intermediate thin oxides. Formation of a metal–semiconductor junction results in charge redistribution and band bending [Fig. 1A and B, respectively]. The semiconductor barrier height is related to the band bending by  $\Phi_B = \Psi_s + V_n$ , where  $V_n$  is the energy difference between the Fermi level and the majority-carrier band edge and  $\Psi_s$  is the semiconductor work function.

The effect of the intermediate oxide layer is twofold. Primarily, it increases the effective Schottky barrier by enhancing the semiconductor band bending ( $\Psi_s$ ) as a

**Fig. 1.** Energy band diagram illustrating (A) ballistic conduction mechanism in an oxide-free Schottky barrier diode. The contact is between a metal and an n-type semiconductor. (B) Thin oxide MOS diode structure. Presence of a negative charge in the oxide causes the barrier height to increase. (C) Conduction pathways in an MS diode. (D) Oxide-trap assisted conduction in a MOS device.

result of additional negative charges trapped in the intermediate region. The Fermi level ( $E_F$ ) of the system will then be nearer in energy to the valence band edge (VBM) than to the conduction band edge (CBM).

In such a structure, current transport may be dominated by the component of current between the metal and the valence band (minority band) in the n-type semiconductor. Minority-carrier current in the semiconductor region will be the sum of the space charge diffusion current and the generation–recombination current associated with the depletion layer. In a “forward current soak,” majority carriers are slowly trapped in the oxide. This increases the barrier resulting in high minority-carrier injection. The opposite behavior is observed in the case of an “avalanche current soak,” where minority carriers are slowly trapped in the oxide layer. This decreases the barrier height resulting in low minority-carrier injection.<sup>[19–21]</sup> Second, the presence of the oxide “unpins” the Fermi level at the surface of the semiconductor allowing the barrier height to reflect the metal-semiconductor work function difference.<sup>[20]</sup>

Photoconduction in MS junctions from photons with energies less than the band gap is generally thought to involve three basic pathways [Fig. 1C]. Inverse electron emission (IEE) may be observed from photon absorption in the metal which produces “hot electrons” with sufficient energy to reach and surmount the Schottky barrier, pathway A1. The deep-hole state may be filled from metal-based electrons, A2, giving rise to reverse bias current, or from electron donor states at the interface, pathway A3. Inverse electron emission may also be observed from electrons excited from electron donor interface states over the barrier, pathway B1, which are refilled by metal-based electrons. An additional conduction path is given when valence electrons in the semiconductor are photoexcited to acceptor interface states, pathway C1, and trapped at the interface. The valence band hole is filled by recombination from donor (dopant) levels at the interface. In an n-type MS device short-circuited through a current monitor, the dominant pathways are A1 and A2, resulting in an observed reverse bias electron current moving through the semiconductor conduction band to the back contact and through the current monitor to the front contact.

In MOS devices [Fig. 1D], because of the relatively large density of interface electron donor states,<sup>[19]</sup> process A3 becomes increasingly important as a source of electrons to the deep photogenerated holes. If the photoelectron energy is too low for transmission over the barrier, depletion of the interface donors will result in a transient discharging of the interface donor states with an apparent forward bias charging current observed. The relative interface state density and effective barrier height will largely determine the relative importance of these various pathways.

Much of the controversy involving MOS chemical sensors involves the understanding of the interface states and their contribution to conduction.<sup>[19,22–26]</sup> The relationships between interfacial charging and

donor or acceptor interface states are indirectly observable in C–V and I–V measurements.<sup>[27–31]</sup> Quantitative characterization of the shifts cannot be performed unambiguously from such measurements because surface states affect the device electrical characteristics in the following manner: 1) surface states trap electrons and holes and 2) surface states act as recombination centers (dynamic effect). As charge traps, the states provide an additional electric field in the insulating layer, and, consequently, the I–V and C–V are shifted by the amount of the increased potential drop across the insulating layer. As recombination centers, the traps provide a current path as a result of surface recombination in addition to other transport pathways such as majority-carrier thermionic-emission current and minority-carrier diffusion current, increasing the total current density.

An electrical response from a chemical interaction with an MS or MOS device may originate from one (or more) fundamentally different mechanism of modifying the interfacial charge. 1) The species can modify the work function (chemical potential) of the conducting metal layer which consequently results in a modification of the space charge layer. 2) The species can introduce dipoles at the metal/semiconductor interface, thereby modifying the charge distribution of the double layer. 3) The species can significantly change the interface state density in the semiconductor interfacial region (pinning or unpinning the Fermi level), thereby changing the charge and barrier in the semiconductor. 4) The species can diffuse into the semiconductor where it may modify its doping density, thereby changing the charge density in the barrier region and, consequently, the barrier. In general, the species to be detected does not need to be the same entity that causes the changes in the metal, semiconductor, or interfacial region. For example, a reaction product generated catalytically at the conductor surface which interacts with the sensor structure may be the species that causes the change.

In our work, we have attempted to separate the device response as a result of chemically induced changes in the electrical characteristics of the MS and MOS junctions from electrical phenomena resulting from charge generation and transport induced directly by the energy transfer associated with surface reactions (direct effects). To this end, we have investigated reactions of several gas species including O<sub>2</sub>, O, H, H<sub>2</sub>, CO<sub>2</sub>, Xe, C<sub>2</sub>H<sub>4</sub>, and several other hydrocarbon gases on Ag-, Au-, Pt-, and Pd-based MS and MOS diodes.

## EXPERIMENTAL

Sensors were formed on (17.5 × 12 mm) rectangles of n-type ⟨111⟩-oriented silicon (phosphorus-doped,

1–10 Ω cm<sup>-2</sup>). All substrates were prepared using a standard RCA cleaning procedure, (NH<sub>4</sub>OH/H<sub>2</sub>O<sub>2</sub>/H<sub>2</sub>O 1/1/4, followed by HCl/H<sub>2</sub>O<sub>2</sub>/H<sub>2</sub>O 1/1/4, both for 10 minutes at 90°C) followed by a 1-min dip in an aqueous solution of buffered-HF and subsequent rinse in DI-water.<sup>[32]</sup> Metal-semiconductor diodes were formed by deposition of metal films on the oxide-free hydrophobic HF-terminated Si surface. The backside of the silicon wafers has been covered by a 1500-Å-thick Ti film (e-beam evaporated at a pressure <1 × 10<sup>-6</sup> Torr), followed by the deposition of 1500-Å gold to achieve an ohmic contact. Metal-oxide-semiconductor junctions were formed by depositing the metal film on a (~10 Å) silicon oxide layer grown on the front side by means of a 5–10 min dip in an aqueous solution of 30% H<sub>2</sub>O<sub>2</sub>.<sup>[16,18]</sup>

Two (3 × 7 mm) Pt films (4000 Å) separated by 7 mm were used as front contacts. The contacts were isolated from the substrate by a 3000-Å-thick SiO<sub>2</sub> film deposited by evaporation. All the processes described above have been performed under clean-room conditions. The sensors were bonded with indium to a molybdenum sample holder for later transfer into the ultrahigh vacuum (UHV) chemical beam chamber. The (10 × 7 mm) active sensor film was deposited between the contact pads by electron-beam evaporation.

The metal films for the Ag-, Au-, and Pt-based sensors were deposited on the sensor substrates at room temperature by electron-beam evaporation under high vacuum conditions (P ~ 10<sup>-7</sup> Torr) and secondarily transferred to an ultrahigh vacuum (UHV) chemical beam chamber. Pd-based sensors were deposited on sensor substrates cooled to ~125 K after transfer into the UHV chamber (P < 5 × 10<sup>-10</sup> Torr) using a wire source electron beam evaporator. Pd films were deposited at low temperature (125 K) and measured immediately after deposition. Using the same sensor after gas exposure, increasing thicknesses were obtained by a subsequent thermal evaporation of Pd under UHV. The metal thickness was measured using a quartz microbalance to calibrate the evaporation rate. Low-temperature deposition was selected to inhibit surface diffusion, which results in a continuous pinhole-free film of a finer-grained morphology at a lower thickness than what would be achieved at higher temperatures.<sup>[33]</sup>

The chemical composition of the Si/SiO<sub>x</sub> surface was investigated prior to metal deposition using X-ray photoelectron spectroscopy (XPS) (AlK<sub>α</sub> radiation, E = 1486.6 eV). The thickness of the intermediate SiO<sub>2</sub> layer (~7 Å) was obtained from exit angle-dependent XPS measurements (data not shown). The roughness of the Si/SiO<sub>2</sub> interface and the growth morphology of the metal films were studied ex situ by scanning tunneling microscopy (STM) and atomic force microscopy (AFM) before and after gas exposure and annealing. A Nanoscope III multimode scanning

probe microscope (Digital Instruments) operating in STM mode and a Dimensions 3100 scanning probe microscope (Digital Instruments) operating in tapping mode were used to obtain STM and AFM micrographs.

The electrical characteristics of the MS and MOS contacts were investigated at room and low temperature (125 K) in UHV using current–voltage (I–V) (not shown) and capacitance–voltage (C–V) measurements at 1 kHz.

Chemically induced electrical signals were measured in an UHV system. Mixed beams of atomic and molecular gas species were produced and delivered by a three-stage differentially pumped atomic beam source.<sup>[8]</sup> Hydrogen and oxygen molecules were dissociated within a microwave plasma at gas pressures between 150 and 800 mTorr. The plasma source was especially designed to extract any photons from the gas beam because the plasma emits intense ultraviolet light with photon energy of 10.2 eV and the Schottky diodes are sensitive photodetectors.

To investigate the diode response to gas exposure, the active sensors were positioned in line to a shuttered collimated gas beam modulated at 4 Hz (50% duty cycle). The room-temperature thermalized beam had a flux that varied between  $2 \times 10^{12}$  and  $5 \times 10^{12}$  atoms  $\text{cm}^{-2}\text{sec}^{-1}$ . The sensors were exposed to molecular and atomic hydrogen and oxygen, several C2, C3, and C4 hydrocarbons, xenon, and carbon dioxide. The detectors were mounted on a manipulator cooled with a flow cryostat. The reaction-induced chemicurrents were detected by the diode connected in series with a current preamplifier (SRS 570). The preamplifier gain was 2 nA/V and its effective impedance was 1 M $\Omega$  at 4 Hz. The preamplifier output was connected either to a lock-in (SR830) or an A-D convertor (Oscilloscope LeCroy 9361). The signals measured by the oscilloscope were averaged over several cycles to minimize the noise present because of 60-Hz pickup. Additionally, all measurements were carried out at low temperature (125 K) to minimize the noise caused by the thermal drift. Other details of the experimental setup are described elsewhere.<sup>[13]</sup>

## RESULTS

Fig. 2A (left) displays a STM image of a 60-Å-thick Pd film deposited at low temperature (125 K) under UHV conditions on a chemically oxidized Si surface ( $d_{\text{SiO}_2} \approx 7 \text{ \AA}$ , determined by XPS). In Fig. 2A, it is observed that Pd does not grow as a uniform flat film as occurred in the case of the Pd films grown on HF-terminated Si wafer (MS devices.<sup>[34]</sup>), but forms hemispheres of  $\approx 5\text{--}8 \text{ nm}$  in diameter. A Volmer–Weber (3-D islands) or Stranski–Krastanov growth

(monolayer plus islands) is expected from thermodynamic considerations because mid-to-late transition metals do not wet oxide substrates in vacuum.<sup>[35]</sup> A similar fine grain film morphology (3–5 nm in size) was discovered by AFM for a 60-Å-thick RT-grown Pt film (Fig. 2B). Room-temperature silver deposition (60 Å), however, leads to large (30–60 nm) and interconnected islands (Fig. 2C). The pictures on the right-hand side of Fig. 2 are 3-D plots obtained from the analysis of the STM and AFM images on the left after taking into account the height information acquired.

Fig. 3 shows  $C^{-2}$  plots obtained from low-temperature (125 K) C–V measurements performed over the reverse bias range at 1 kHz on Au, Pt, Pd/SiO<sub>2</sub>/n-Si(111), and Pd–MS devices before gas exposure. The experimental data are reasonably well described by a linear fit consistent with uniform doping in the semiconductor.<sup>[24,36,37]</sup> The curves are not entirely parallel to one another because of differences in the carrier concentration of the distinct silicon wafers employed as substrate. The donor concentration ( $N_D$ ) and barrier height ( $\Phi_{\text{BO}}$ ) can be obtained from the fits of the data for the different metals on otherwise identical MOS devices (Table 1).<sup>[24,28,38]</sup> For the oxide-free contact (i.e., Pd–MS, open circles, Fig. 3), the intercept on the voltage axis,  $V_i$  (built-in potential), approximately gives the barrier height,  $\Phi_{\text{BO}} = 0.81 \pm 0.01 \text{ eV}$ . The doping concentration calculated from the slope of the  $C^{-2}$ –V plot is  $N_D = (1.72 \pm 0.07) \times 10^{15} \text{ cm}^{-3}$ . In the case of the thin oxide contact (Pd–MOS, full circles, Fig. 3),  $V_i = 0.89 \pm 0.01 \text{ V}$  is not equal to the barrier height, but is the sum of the voltage drop across the oxide layer ( $V_{\text{ox}}$ ) and the semiconductor band bending ( $\Psi_s$ ). At the doping concentration obtained,  $N_D = (1.01 \pm 0.07) \times 10^{16} \text{ cm}^{-3}$ ,  $\Psi_s \approx \Phi_B$ . For the Pd–MOS sample,  $V_i$  is larger than the one obtained for our nearly oxide-free Pd–Si contact. The same trend was observed for the other metals. This suggests a negative oxide charge ( $V_{\text{ox}}$ ) in the n-type contact. Table 1 also lists the diode characteristic parameters obtained from the linear fit of Fig. 3 following the model described in Ref.<sup>[34]</sup>. The values of the semiconductor surface space ( $Q_s$ ) and oxide charge density ( $N_f$ ) calculated must be regarded as order of magnitude because of the change in occupancy of the oxide traps. The occupancy change causes an error in the doping concentration and in the  $V_i$  values obtained from  $C^{-2}$ –V and has not been taken into account here. Nevertheless, we can conclude from Fig. 3 that there is negative oxide charge in the n-type contact which increases the barrier height substantially (0.1–0.15 eV) over the oxide-free contact. Our C–V measurements showed that contrary to a previous literature report,<sup>[16]</sup> a decrease in the Schottky barrier by introducing an ultrathin oxide between a metal/semiconductor contact does not necessarily occur. Tongson et al.<sup>[39]</sup>

**Fig. 2.** (A) Ex situ STM image ( $z$  range, 3 nm) of a 60-Å-thick Pd film thermally evaporated in UHV at  $T = 125$  K on  $\text{SiO}_2/\text{Si}(111)$ ; (B) ex situ AFM image ( $z$  range, 4 nm) of a RT-deposited 60-Å-thick Pt film grown on  $\text{SiO}_2/\text{Si}(111)$  under high vacuum conditions; (C) ex situ AFM image ( $z$  range, 15 nm) of a RT-deposited 60-Å-thick Pt film grown on  $\text{SiO}_2/\text{Si}(111)$  under high vacuum conditions. The samples were not exposed to any gas after preparation but were imaged under atmospheric pressure.

reported enhancements of the Schottky barrier in Ag and Au MIS devices with respect to MS diodes.

The demodulated lock-in amplifier output from a Pd(60 Å)/n-Si(111) diode during exposure to atomic

oxygen is shown in Fig. 4. In the MS Pd sensor, a large chemicurrent signal was detected upon exposure to energetic oxygen atoms. The initial signal peak of  $\sim 930$  pA corresponds to  $\sim 5.6 \times 10^{-3}$  electrons

**Fig. 3.**  $C^{-2}$  vs.  $V$  plots of (A) Au(60 Å)/SiO<sub>2</sub>/n-Si(111), (B) Pt(150 Å)/SiO<sub>2</sub>/n-Si(111), (C) Pd(60 Å)/SiO<sub>2</sub>/n-Si(111), and (D) Pd(60 Å)/n-Si(111) measured in UHV at 125 K before any gas exposure.

detected per incident O atom on the initially clean polycrystalline Pd surface. The decay over 500 sec is consistent with formation of an oxide coverage assuming a surface site density of  $1.5 \times 10^{15} \text{ cm}^{-2}$ . Similar behavior has been observed with H atoms, NO, and NO<sub>2</sub>.<sup>[18]</sup> The phase ( $\phi$ ) of the lock-in signal,  $-83^\circ$ , is essentially identical to the photocurrent phase corrected for the difference in beam transit times ( $\sim 0.5$  msec) indicating a reverse bias current analogous to IEE generated by photocurrent. The MS devices are insensitive to hydrocarbons, Xe, CO<sub>2</sub>, or other low adsorption energy species.

Unlike the Pd-MS devices, the Pd-MOS devices were sensitive to a range of gas species (H, O, Xe, C<sub>2</sub>H<sub>4</sub>, CO, etc.), although the amplitude of the signals was lower ( $\sim 29$  pA) compared with the analogous MS devices (Fig. 5A). As with the MS devices, an exponentially decaying chemicurrent is observed in both cases upon exposure to O<sub>2</sub>, O, and H; however, a constant “steady-state” current was observed for C<sub>2</sub>H<sub>4</sub> and CO<sub>2</sub> and other species not observed on MS sensors. The relatively large signal detected upon exposure of the fresh sensor to O<sub>2</sub> is attributed to the atomic

**Fig. 4.** Lock-in detected chemicurrent signal from a nearly oxide-free Pd(60 Å)/n-Si(111) diode as a function of exposure time to atomic oxygen. The signal was modulated at 4 Hz. The gas pressure in the beam chamber during gas exposure was 500 mTorr.

oxygen present at the Pd surface after the dissociative adsorption of molecular oxygen. The phases of the O, H, and O<sub>2</sub> signals measured by lock-in techniques were all similar and consistent with a process analogous to what was described for atomic O on the MS device. For the low-energy species, C<sub>2</sub>H<sub>4</sub> and CO<sub>2</sub> (Fig. 5A), the phase was  $\phi = 95^\circ$  and  $154^\circ$ , respectively, indicating a current direction opposite to that of the energetic high species. From the current transient shown in (Fig. 5B) referenced to the molecular flux, an effective forward bias current moves through the device circuit during the ethylene exposure.

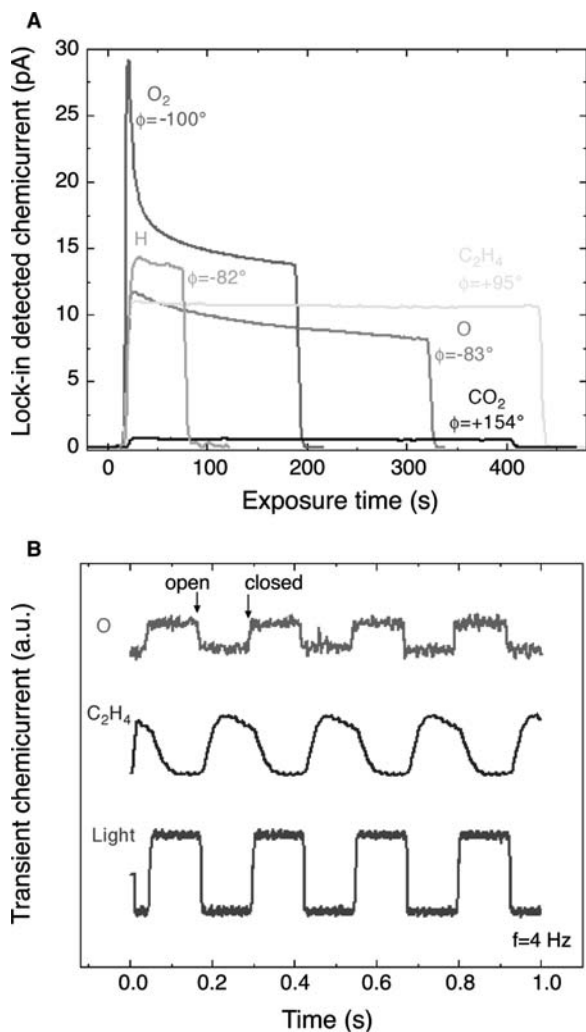

Measurements of the response of both MS and MOS devices to a chopped beam of O, Xe, or ethylene during constant, DC, irradiation with IR or visible light showed no change in the chemicurrent signal (if present) compared with the signal in the absence of irradiation, suggesting that no pulse-to-pulse change in the device electrical characteristics was occurring.

In other experiments, not reported here, we found that the sensitivity to low-energy species was lost after exposure of the Pd sensors to hydrogen atoms or molecules.

**Table 1** Diode characteristic parameters: Capacitance at zero bias ( $C_0$ ), built-in potential ( $V_i$ ), semiconductor surface space charge density at zero bias ( $Q_s$ ), semiconductor surface capacitance per unit area ( $C_s$ ), voltage drop across the oxide layer ( $V_{ox}$ ), and oxide charge density ( $N_f$ ) Obtained from capacitance vs. voltage measurements performed under UHV at 125 K

Sample	$C_0$ (nF/cm <sup>2</sup> )	$V_i$ (eV)	$Q_s$ (nC/cm <sup>2</sup> )	$C_s$ (nF/cm <sup>2</sup> )	$V_{ox}$ (mV)	$N_f$ ( $\times 10^{11}$ cm <sup>-2</sup> )	$\Phi_B$ (eV)
Pt(150 Å)-MOS	12.8	1.08	25.0	12.8	7.9	0.8	$1.07 \pm 0.07$
Au(60 Å)-MOS	23.2	1.00	41.6	23.4	13.0	1.3	$0.99 \pm 0.07$
Pd(60 Å)-MOS	32.0	0.89	50.0	31.0	18.2	4.1	$0.9 \pm 0.2$
Pd(60 Å)-MS	42.7	0.80					$0.807 \pm 0.002$

**Fig. 5.** (A) Lock-in detected chemicurrent signals from a Pd(60 Å)/SiO<sub>2</sub>(7 Å)/n-Si(111) diode as a function of exposure time to O<sub>2</sub>, O, H, C<sub>2</sub>H<sub>4</sub>, and CO<sub>2</sub>. (B) Averaged current traces from individual pulses of O, C<sub>2</sub>H<sub>4</sub>, and light (non-monochromatic) measured by an oscilloscope during Pd-MOS exposure. The signals were modulated at 4 Hz. The gas pressure in the beam chamber during gas exposure was 500 mTorr. The current direction of the signal induced by the interaction of C<sub>2</sub>H<sub>4</sub> (same found for CO<sub>2</sub>, Xe, and other hydrocarbons) with the Pd-MOS sensor is contrary to that of the high energetic species studied such as O or H (not shown) and to that of non-monochromatic white light.

The sensor currents measured during exposure of Pd/SiO<sub>2</sub>/n-Si(111) MOS diodes of increasing thickness to several species (O, H, and C<sub>2</sub>H<sub>4</sub>) and to visible (660 nm) and infrared (1550 nm) photons are shown in Fig. 6. The current intensities detected for Pd thicknesses increasing from 40 to 800 Å decreased approximately exponentially for both chemically and photogenerated electrons. Fits of the data to an exponential decay law gave effective attenuation lengths, which are interpreted below. In general, the

**Fig. 6.** Thickness-dependent chemicurrent after low-temperature Pd evaporation from a Pd(60 Å)/SiO<sub>2</sub>(7 Å)/n-Si(111) structure during C<sub>2</sub>H<sub>4</sub>, O, infrared (1550 nm), and monochromatic visible light (660 nm) exposure. The scales of the IR and visible signals have been reduced by a factor of 0.1 and 0.05, respectively.

energetic gases showed smaller attenuation lengths ( $\lambda_{\text{H}} = 66 \pm 7 \text{ \AA}$  in Pd-MS or  $\lambda_{\text{O}} = 76 \pm 11 \text{ \AA}$  in Pd-MOS) than the ones with low adsorption energies ( $\lambda_{\text{C}_2\text{H}_4} = 106 \pm 8 \text{ \AA}$  in Pd-MOS). These were also smaller than the attenuation lengths measured for visible monochromatic light ( $\lambda_{\text{VIS}} = 139 \pm 5 \text{ \AA}$  in MOS). The values obtained for ethylene and infrared light ( $\lambda_{\text{IR}} = 103 \pm 5 \text{ \AA}$ ) were of the same order. Crowell et al.<sup>[40]</sup> obtained an electron attenuation length of  $170 \pm 30 \text{ \AA}$  from photoemission measurements on Pd/n-Si junctions using photon energies below 1.1 eV (infrared region) which is also on the same order as our data.

Fig. 7 displays the current amplitudes detected at 125 K from exposure to identical fluxes of a variety of C<sub>2</sub>, C<sub>3</sub>, and C<sub>4</sub> hydrocarbons to polycrystalline films of Ag(150 Å), Pt(150 Å), Pd(60 Å), and Au(60 Å) deposited on SiO<sub>2</sub>/n-Si(111) devices. The ordering (left to right) is in approximate increasing order of molecular polarizability (right axis). There is no clear relationship between the polarizability and the relative currents; however, the different sensitivities displayed to different gases by distinct metals suggest that one could fabricate a sensor composed by an array of different metals to selectively detect a wide variety of gases.<sup>[41]</sup>

## DISCUSSION

The signals detected from both MS and MOS devices from the energetic chemisorption of atomic O and H

Fig. 7. Current amplitudes detected at 125 K from exposure to identical fluxes ( $P = 1$  Torr in the beam chamber) of C<sub>2</sub>, C<sub>3</sub>, and C<sub>4</sub> hydrocarbons to polycrystalline films of Pd, Au, Pt, and Ag deposited on MOS Si devices. The ordering (left to right) is in approximate increasing order of molecular polarizability (right axis).

and the energetic dissociative chemisorption of O<sub>2</sub> are consistent with hot electron transmission over the Schottky barrier (direct mechanism) as shown in Fig. 1A. The exponential thickness dependence of the signals from these species (Fig. 6) is consistent with attenuation of ballistic, hot electrons generated at the metal surface. The attenuation lengths of  $\sim 100$  Å are consistent with the electron mean free path in the metal film.<sup>[40]</sup> Thus, for energetic adsorption reactions with  $E >$  Schottky barrier, both MS and MOS devices function by the direct chemically induced IEE.

That the MS devices do not show sensitivity to the low-energy species is expected because their adsorption energies are lower than the Schottky barrier height precluding IEE. The requirement of the interfacial oxide in the MOS device for sensitivity to low-energy species and the apparent reversal of the observed current direction requires a new mechanistic explanation of the device function. The chemical signal from surface interactions of the low-energy species in the MOS devices must either be a result of another direct pathway or by a chemically induced indirect change in the device characteristics.

The I–V (not shown) and C–V characterizations indicate that there are clearly electrical differences between the MS and the MOS devices. In particular, the capacitance of the MOS device is nearly twice that of the MS because of the larger band bending from the large interface charge density associated with the oxide and the higher Schottky barrier. The presence of

charge at the interface and trap states is what accounts for the apparent (false) decrease in the SB measured by I–V compared with C–V.

Although the presence of the oxide gives rise to an MOS sensor that has basic electrical characteristics different than the MS device and a surface morphology which is also considerably different, these differences do not, in themselves, explain the dramatically different response of the two devices. The device characteristics as measured by I–V and C–V were insensitive to variations in the metal thickness or short pulses of the adsorbate gases that would result in an exposure equivalent to the pulse-to-pulse beam exposure. It would be very difficult to postulate a mechanism whereby a hundredth of a monolayer of Xe could significantly alter the electrical characteristics of a metal film. Furthermore, the absence of change in the chopped chemicurrent signal during DC photon irradiation compared with the signal in the absence of irradiation suggests that no pulse-to-pulse change in the device electrical characteristics was occurring. The thickness dependence of the adsorption-related signal and experiments using simultaneous DC visible or IR irradiation together with chopped molecular ethylene or Xe showing no modulation in the IEE signal exclude an indirect mechanism whereby the presence of the adsorbate significantly alters the Schottky barrier or device performance on a pulse-to-pulse basis. If the electrons/holes detected undergo a ballistic transport through the metal, the chemicurrent

signals measured should decrease with increasing metal thickness. However, if changes in the surface chemical potential affect the conduction, a nearly constant current should be detected independent of the thickness of the metal that forms the Schottky contact. The thickness dependence displayed in Fig. 6 suggests that one must, in principle, rule out changes in the chemical potential as responsible for the sensor sensitivity. The thickness dependence also suggests that the known coverage-dependent alteration in the surface work function does not give rise to the observed signal because the increased metal thickness from 20 to 40 nm would not have any effect on the surface charge distribution changes associated with the work function change.

The data described above support a direct mechanism for charge generation, transport, and detection in the MOS devices. The measured large surface donor state density has led us to propose the pathway shown in Fig. 1D. As in the case with highly energetic adsorbates, the gas surface reaction gives rise to electron-hole pair excitations albeit at lower energies. The electron is excited above the Fermi level, but below the Schottky barrier. These electrons are not transmitted to the semiconductor. The hole below the Fermi level accepts an electron by resonant charge transfer (and hot electron transport through the metal from the interface) from the donor state at the interface. To balance the change in the interface charge, a forward bias current is required through the external circuit (thus explaining the phase reversal of the lock-in detected signal and the inverted sign of the transient signals). As the rate of depletion of the interface donor states becomes equal to the rate of refilling, the forward bias signal decays to zero at steady state. The lifetime of the donor states may be energy- and field-dependent. Our proposed mechanism is consistent with the observed thickness dependence and unique sensitivity of the MOS devices and with their particularly high interface donor state density.

The details of the electronic behavior of the intermediate oxide layer in MOS device performance are a complex question that has been the subject of great controversy in the past.<sup>[6,23,26,36,37,39,42,43]</sup> In contrast with other experimental groups,<sup>[44]</sup> alteration of surface states is held responsible here for the high sensitivity of the Pd/Si-MOS diodes. In addition to serving as a high-density source of electron donor states, the  $\sim 10 \text{ \AA}$   $\text{SiO}_2$  acts as a diffusion barrier against metal silicide formation which tends to fix the Schottky barrier height in the MS device.<sup>[29]</sup> The larger Schottky barrier in the MOS devices is such that under minimal forward bias, the interface donor states depleted by the charge transfer to metal hole states created by reaction can be refilled on a continuous basis giving rise to large continuous forward bias currents.<sup>[29]</sup> The loss of sensitivity to low energetic gases ( $\text{C}_2\text{H}_4$  and

Xe) following exposure to hydrogen can also be related to the interface donor states. The hydrogen in the Pd sensor diffuses through to the interface and reacts with the site resulting in an electrical charge variation measurable in the IV and CV curves and forming the basis of other, indirect, hydrogen sensors.<sup>[23,26,36,44,45]</sup>

## SUMMARY

We have investigated chemical reaction-induced electronic phenomena on nanometer-scale metal films deposited on semiconductor junctions. We have attempted to identify and separate chemically induced modifications in the device electrical characteristics (indirect effects) from chemically induced charge generation and transport (direct effects) to clarify the mechanism of signal generation in the thin film-covered MS and MOS devices. Chemical reactions on ultrathin metal surfaces give rise to energetic charges which we have shown to give rise to electrically measurable signals observable in MS or MOS device structures when the metal film thickness is less than the ballistic mean free path of the charge carriers generated by the reaction. Ideal metal-Si Schottky diodes are insensitive to reactions with energies lower than the Schottky barrier; however, the presence of an interface oxide between the metal and the semiconductor provides electron donor states at high density which allow charging and discharging of the device interface. This mechanism allows the detection of the electron-hole pairs created during non-adiabatic energy transfer to the metal from low-energy surface reactions.

# Silane Self-Assembled Monolayers: Nanoscale Domains by Sequential Adsorption

Nitin Kumar

*Institute of Soldier Nanotechnology, Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.*

## INTRODUCTION

In recent years, the applications and demand for solid surfaces with nanometer to micrometer patterns have increased because of extensive developments in the fields of nanoscience and nanotechnology. Solid surfaces with nanometer- and micrometer-scale patterns have many potential applications in many fields of nanoscience and nanotechnology, such as phase separation of polymer mixtures,<sup>[1–3]</sup> localized crystal growth,<sup>[4]</sup> the arraying and immobilization of proteins,<sup>[5]</sup> cells,<sup>[6,7]</sup> nanoparticles,<sup>[8]</sup> etc. Methods for patterning micrometer features on surfaces are well developed and include microlithography of self-assembled units,<sup>[4,9]</sup> microcontact printing,<sup>[10–12]</sup> photopatterning of self-assembled monolayers (SAMs).<sup>[13–15]</sup> On the other hand, methods for developing nanometer-scale features, such as nanowriting,<sup>[16,17]</sup> phase-separated Langmuir–Blodgett (LB) films,<sup>[18–20]</sup> and block copolymers<sup>[21]</sup> are time consuming and cumbersome.

Self-assembled monolayers consist of amphiphiles, which spontaneously adsorb onto a solid surface from solution to form a densely packed two-dimensional ordered monolayers. Self-assembled monolayers have been extensively used for modification of surface chemistry of solid surfaces. Recently, Fan Maldarelli, and Couzis<sup>[22]</sup> have demonstrated that nanometer-scale domains of different chemical functionality can be obtained by co-adsorption and phase separation of different silane molecules. Sequential adsorption of self-assembling monolayers had been suggested as an alternate and simpler route for making such surfaces.<sup>[23,24]</sup> The island growth mechanism in silane monolayer can be exploited to prepare surface with nanodomains. In this article, we demonstrate the use of sequential adsorption of silanes to prepare domains of various sizes by controlling their self-assembly on solid surfaces.<sup>[25]</sup> We describe a procedure to prepare domains of one chemical functionality, with size from nanometer to micrometer surrounded by another chemical functionality, using sequential adsorption of silane self-assembled monolayers. Partial monolayers

of octadecyltrichlorosilane (OTS) consisting of condensed islands with controlled size are prepared by varying the deposition conditions. The area surrounding the OTS islands is filled by sequential adsorption of 11-bromo undecyltrichlorosilane (BrUTS) or decyltrichlorosilane (DTS) to obtain nanometer- to micrometer-scale domains of OTS in a monolayer of DTS or BrUTS. First, we describe in detail the methodology to form partial OTS monolayers composed of domains of a desired size. Then, we discuss the procedure and optimum conditions for successful backfilling. These monolayers were analyzed by atomic force microscope (AFM) to obtain the topographical and friction images.

## OVERVIEW

In our study we use the silane-based SAMs, which were first studied by Sagiv et al.<sup>[26–30]</sup> Recent studies<sup>[31–34]</sup> suggest that the silane monolayers are formed by the adsorption of the hydrolyzed silanes<sup>[31–33,35]</sup> onto a water layer, which typically exists on a silica surface.<sup>[36–38]</sup> In addition, there is no evidence of direct binding of the adsorbing silanes to the surface silanols of the substrate. Because of this water layer and the lack of direct bonding, the adsorbed molecules are mobile and can diffuse laterally on the surface.<sup>[25,39]</sup> This mobility allows OTS molecules to aggregate into islands, which can be exploited to form nanometer-size domains by sequential adsorption. These islands, which are formed by aggregation, have been imaged by atomic force microscopy<sup>[25,33,40–44]</sup> and have been found to be “fractal”-like in structure. This is the result of an adsorption–surface diffusion–aggregation mechanism,<sup>[45]</sup> in which surface diffusion is rate determining.

The formation of OTS monolayers is affected by a number of factors during the deposition conditions. Below a critical deposition temperature ( $28 \pm 4^\circ\text{C}$ ), the complete monolayers exist as condensed into ordered phases resembling the liquid condensed (LC)

states analogous to Langmuir monolayers.<sup>[33,39–47]</sup> A complete monolayer prepared above this critical temperature showed regions of chain disorder resembling the liquid expanded (LE) state. Increasing the deposition temperature resulted in more disorder, until the monolayers were in a completely LE state. The formation of LE or LC phases is analogous to the phase coexistence region for Langmuir films. The silane monolayers with shorter hydrocarbon chains (e.g., DTS) have lower critical deposition temperature. As a result they do not form LC states at room temperatures.<sup>[39]</sup>

The intermediate stages of the SAM formation have been investigated by studying the structure of partial monolayers. Atomic force microscope measurements of partial monolayers of OTS at room temperature ( $\sim 22^\circ\text{C}$ ) have shown a two-step growth mechanism.<sup>[25,33,41,44]</sup> In the first step, fractal islands of constant height,  $\sim 21 \text{ \AA}$ ,<sup>[25,33,41,44]</sup> relative to the background, appear and grow on the surface. This step is referred to as the primary growth step. The height of OTS islands, which are in the LC state, is approximately  $25 \pm 1 \text{ \AA}$ .<sup>[25,39,48–50]</sup> The AFM images of OTS monolayers during this step show that the height of islands is  $\sim 21 \text{ \AA}$ , implying that the primary fractal islands are in fact LC phases surrounded by a low-density liquid phase. In the second step, the growth of the primary fractal islands stops, and the difference in height between the islands and the background begins to decrease.<sup>[25,41,43,44]</sup> These facts indicate that the surrounding is an LE phase whose density, and therefore height, is increasing. As the concentration of the LE phase increases, the surface diffusion to the primary islands is reduced, thereby arresting the primary growth. Finally, nucleation and growth of smaller islands of the same height (as the primary islands) occur in the regions surrounding the primary fractal islands.<sup>[25]</sup> This second step is referred to as the secondary growth step and it continues until a complete monolayer of uniform height is formed.

The OTS monolayers show a different growth mechanism at deposition temperatures well below room temperature ( $< 16^\circ\text{C}$ ).<sup>[25,33,41,43]</sup> In this case it is observed that the height of the primary island domains does not change over time and remains constant at  $\sim 21 \text{ \AA}$ . This suggests that during growth the surrounding phase is either gaseous (G) (if the deposition temperature is below the triple point as supposed by Carraro et al.)<sup>[41]</sup> or a low-density liquid phase, if the deposition temperature is above the triple point (as suggested by Davidovits et al.).<sup>[43]</sup> Irrespective of whether the surrounding phase is G or LE, the region surrounding the primary islands is less dense at low temperatures. The primary growth continues longer with less inhibition from the surrounding phase. The growth of secondary phase is observed only when the

primary islands are very close to each other.<sup>[25]</sup> Finally, at temperatures exceeding  $40^\circ\text{C}$ , all AFM studies show a uniform monolayer without any islands.<sup>[33,41,43]</sup>

The presence of water in the solvent and on the substrate also affects the monolayer formation. Octadecyltrichlorosilane molecules are hydrolyzed by water present in the solvent.<sup>[51]</sup> Excess water in solvent results in the formation of particle oligomers, which can deposit on the solid surface.<sup>[40,52]</sup> However, these particulates are not strongly adsorbed on the surface and can be removed by sonication or by mechanical methods, such as scanning AFM tip.<sup>[25]</sup> The presence of water on the solid surface is required for the formation of a dense OTS monolayer.<sup>[31,49,50,53]</sup> The water layer on the solid surface allows the adsorbing OTS molecules to diffuse on the surface. This surface diffusion is the cause of the fractal growth of the primary islands. Thus the structure of OTS monolayers can be controlled by varying the amount of water on the surface.

The ability of OTS molecules to form island-like aggregates in partial monolayers offers a route to fabricate nanometer-scale domains of one chemical functionality in a continuous phase of a different functionality by sequential adsorption of two different silanes. Various macroscopic controls, such as temperature, amount of water, etc., can be used to control the size and structure of islands. In the second step, a second silane is deposited via sequential adsorption on the area surrounding the islands. In this entry, we describe this procedure to control the size and structure of OTS islands by controlling the deposition conditions. The process of sequential adsorption is demonstrated using two different silanes with different terminal groups. The monolayers are imaged using AFM to study the structure of the nanometer domains.

## MATERIALS AND EXPERIMENTAL TECHNIQUES USED FOR PREPARATIONS AND CHARACTERIZATIONS OF SILANE SAMs

Decyltrichlorosilane (DTS, 97% purity) and 11-bromo undecyltrichlorosilane (BrUTS, 95% purity) were purchased from Gelest, Inc. Octadecyltrichlorosilane (OTS, 95% purity) was purchased from Sigma Aldrich Company. HPLC grade hexadecane, chloroform, and carbon tetrachloride were obtained from Sigma-Aldrich Co. Nochromix<sup>®</sup> and sulfuric acid (98%) were purchased from Fischer Scientific. All chemicals were used as received without any further purification. Deionized water, with a resistivity of  $18 \text{ M}\Omega \text{ cm}$  from a Millipore<sup>®</sup> system, was used. Double-side, polished (n type,  $\langle 111 \rangle$ ), single-crystal silicon wafers were purchased from Montco Silicon Technologies Ltd.

The control of the domain size was achieved by controlling the deposition conditions. We used a procedure<sup>[31]</sup> in which the amount of water in the solvent is controlled. A solvent mixture containing hexadecane, carbon tetrachloride, and chloroform was used for making the silane solutions. Chloroform was saturated with water by keeping it overnight in contact with water. The amount of water in the solvent mixture was estimated to be 4–6 mM and was verified using Karl-Fisher titration. The silane concentration was in the range of 0.2 to 2 mM.

The polished silicon wafers (with roughness of  $\sim 1 \text{ \AA}$  as measured by AFM) were cleaned by sonicating in a mixture of Nochromix® and 98% sulfuric acid for about 30 min, followed by successive water rinsing. The cleaned substrates were stored under water at room temperature and dried in a stream of dry nitrogen just before use. The substrates should not be cleaned by any means that involved physical contact, such as cleaning with tissue paper or cleaning paper. Also, the region that is imaged by AFM should not be touched when holding the substrates. These substrates are hydrated with a water layer of thickness of a few nanometers.<sup>[36,54–56]</sup> The amount of water on the surface is controlled by heating the surfaces. Partially dehydrated substrates were prepared by heating clean silicon wafers at 100°C and 150°C for an hour and then cooling under vacuum in a desiccator. The vacuum was broken using dry nitrogen immediately before immersing the substrates in silane solution. It is important to take maximum care to prevent the dehydrated substrates from exposure to sources of moisture.

Silane solutions were prepared by adding OTS, DTS, or BrUTS in the required quantities to carbon tetrachloride. The low amount of water in  $\text{CCl}_4$  prevents the polymerization of silanes in the solution. The required amount of silane and  $\text{CCl}_4$  solution was added to hexadecane and chloroform mixture, so that the final volume ratio of hexadecane, carbon tetrachloride, and chloroform was 30:5:3 by volume, respectively. The substrates were immersed in the silane solutions after 30–60 sec. This provided sufficient time for the silanes to hydrolyze by the water present in the solvents. If silane solutions are kept for a longer time, then bulk polymerization occurs. Partial OTS monolayers were prepared by immersing clean the substrates in OTS solution for varying deposition times. The deposition was terminated by rinsing the samples in chloroform for about 15 min. Excess chloroform was dried with a stream of dry nitrogen. All sample preparation procedures are carried out under ambient atmospheric conditions.

The mixed monolayers of OTS and the other silane are prepared in the following manner. First, OTS islands of desired size are formed by immersing a

hydrated or dehydrated substrate, prepared as described above, in a 1 mM OTS solution maintained at 10°C for varying deposition times. The substrates are then removed from the OTS solution and rinsed in chloroform, also maintained at 10°C, for approximately 1 sec. The second silane is deposited on these partial OTS monolayers, immersing the substrate immediately in a 1 mM DTS or BrUTS solution at 10°C for 1 hr followed by rinsing in chloroform at 10°C. The structures of the monolayers were analyzed by AFM.

Atomic force microscopy images of the monolayers are obtained in contact and frictional force mode.<sup>[25]</sup> All AFM images were acquired at room temperatures (22–25°C). For some substrates, tapping mode images were obtained using silicon tips. Water contact angles on the monolayers were measured using a contact angle goniometer (Rame-Hart, Inc.) by placing a 2- $\mu\text{l}$  water drop on the sample. The contact angle values of at least six different locations were averaged.

## CONTROL OF OTS MONOLAYER FORMATION

In this section we show how the structure of partial silane monolayers is affected by varying the deposition conditions. The OTS monolayers are prepared under varying deposition time, OTS concentration in solution, deposition temperature, and amount of water on the surface. The OTS molecules are hydrolyzed by water present in the bulk and on the surface and adsorbed on the surface. If a water layer is present on the surface, the OTS molecules diffuse on the surface and aggregate to form fractal-shape islands by diffusion-limited growth mechanism. The size of the island can be controlled by changing the rate at which the OTS molecules are adsorbed from the solution, the ability of molecules to diffuse on the water layer, and the ability of OTS molecules to form condensed LC phases.

The effect of deposition time on the monolayer structure is shown in the AFM images shown in Fig. 1. Water contact angles, height differences, friction differences, and area coverages are summarized in Table 1. The AFM image of a sample with a 1-sec deposition time is shown in Fig. 1A. It exhibits the onset of the formation of the primary islands. The islands appear diffused with a height of  $\sim 11 \text{ \AA}$  compared to  $\sim 21 \text{ \AA}$ <sup>[41]</sup> for a condensed (LC) island, suggesting that the islands have not yet condensed. In the friction image, the regions covered by OTS exhibit lower friction than the surroundings.<sup>[57,58]</sup> The friction force data show that the region surrounding the islands can be either bare silica or G or a very lean LE phase. As the deposition time is increased, more OTS are

**Fig. 1** Height and friction images of partial OTS monolayers deposited at  $22 \pm 1^\circ\text{C}$  on fully hydrated substrates; image size:  $10 \mu\text{m} \times 10 \mu\text{m}$ ; OTS concentration: 2 mM; deposition times: (A)  $\sim 1$ , (B) 5, (C) 15, (D) 30, (E) 45, (F) 120 sec; in the friction images, brighter regions indicate regions with higher friction. *Source:* From Ref.<sup>[25]</sup>. © 1997, American Chemical Society.

adsorbed on the region surrounding the islands and diffuse toward the primary islands. On reaching the perimeter of an existing island, they become immobilized and aggregate with the island. This leads to the growth of the fractal features. The surface coverage of the primary islands grows rapidly during the primary growth. An image of a sample, with a deposition time of 5 sec, is shown in Fig. 1B. The islands are much larger in size, between 4 and  $8 \mu\text{m}$ , and cover approximately 30% of the surface. The height of these islands is  $\sim 21 \text{ \AA}$ . After 5 sec of OTS deposition, the water contact angle has increased to about  $67^\circ$  compared to  $44^\circ$  for the 1-sec deposition time sample. On increasing the

deposition time further, we observe that the rate of growth of the primary islands is reduced. An image of a sample with a 15-sec deposition time is shown in Fig. 1C. The height and friction difference between the primary island and surrounding area indicate that the phase surrounding the primary islands is becoming denser and starting to increase in height. Surface diffusivity of the OTS molecules in the area surrounding the islands is reduced because of the increase in density of the surrounding phase. The reduction in surface diffusivity reduces the growth of the primary islands.

The images of samples with longer deposition times (Fig. 1D) show that the primary islands cease to grow,

but the surrounding liquid phase becomes progressively denser. The height and friction difference between the islands and surrounding phases decrease. The primary islands cover  $\sim 66\%$  of the surface. After 45 sec of deposition, we observe a new growth regime (Fig. 1E). The height difference between the primary islands and the surrounding phase is now reduced to  $11.4 \text{ \AA}$ . Small islands of dimension less than  $0.5 \mu\text{m}$  are observed in the liquid phase surrounding the primary islands. The height of these islands is the same as that of the primary fractal islands. This growth regime is referred to as the secondary nucleation and growth step, in which small, condensed islands nucleate and grow in the surrounding liquid phase. In the friction image, shown in Fig. 1E, the condensed primary and secondary islands exhibit slightly higher friction ( $-0.01 \text{ V}$ ) than the surrounding liquid phase. In all the earlier samples (Fig. 1A–D), the LC primary islands exhibit lower friction than the surrounding phase. This observation suggests that the OTS monolayer in the liquid phase surrounding the islands, as it approaches a “LE–LC phase transition,” has a lower friction than the corresponding denser LC phase. Upon continued adsorption, the secondary condensed islands continue to nucleate and grow from the liquid phase, until all the substrate is covered with a condensed monolayer. An image of a 120-sec deposition time sample (Fig. 1F) shows an almost uniform monolayer. The water contact angle in this sample is approximately  $105^\circ$ , which increases to  $108^\circ$  when the deposition time is increased to 5 min. The primary islands grow rapidly to their fractal-like morphology via adsorption, surface diffusion, and aggregation. On the other hand, the secondary islands grow from the phase surrounding the primary fractal islands as the density of OTS in this phase increases.

The effect of deposition temperature on the primary and secondary growth is shown in Fig. 2, which shows the AFM images of partial monolayer deposited at  $10^\circ\text{C}$ . At this reduced temperature, the primary fractal islands grow at nearly constant height of  $\sim 21 \text{ \AA}$ , until their edges are very close to each other.<sup>[41]</sup> However, at later stages (Fig. 2C), we note the appearance of very small islands in the region between the primary islands (Fig. 2C, inset). These small islands are similar to the secondary islands nucleating in an LE phase as observed at room temperature (Fig. 1E). The height difference between the primary fractal islands and the surrounding phase is  $15\text{--}16 \text{ \AA}$  compared to  $\sim 11.4 \text{ \AA}$  at  $22^\circ\text{C}$  (Fig. 1E). At low temperature, the region surrounding the primary islands is leaner compared to the deposition at higher temperature. As a result, the primary growth continues until the islands are very close to each other. These results show that controlling the deposition time and temperature is an effective way to control the growth of primary islands and the

density of OTS molecules in the region surrounding the primary islands.

The growth of OTS islands is preceded by the adsorption of OTS from the bulk to the surface. The rate of adsorption is also expected to play a role in the formation of OTS islands. Atomic force microscopy image of a hydrated substrate immersed in a  $0.2 \text{ mM}$  OTS solution for a deposition time of approximately 1 sec is shown in Fig. 3. This concentration is  $1/10\text{th}$  of the concentration used for samples described in Figs. 1 and 2. Very small OTS clusters of about  $50\text{--}100 \text{ nm}$  in diameter and  $15\text{--}20 \text{ \AA}$  in height are distributed almost randomly on the surface. For longer deposition times, the OTS monolayer exhibits various phases (as observed at higher concentrations; Figs. 1 and 2) until a uniform coverage is attained. However, adsorption times to achieve a certain surface coverage are longer at lower concentration. Thus nanometer-scale islands of OTS are obtained when the deposition is carried out at low bulk concentrations.

The presence of water in solvent and on surface plays a very important role in the formation of SAMs. Long deposition times are required when dry solvents

**Fig. 3** Contact mode height image of a hydrated substrate immersed for 1 sec in a 0.2 mM OTS solution at 22°C. Image size: 5  $\mu\text{m}$   $\times$  5  $\mu\text{m}$ ; height scale 0–5 nm. *Source:* From Ref.<sup>[25]</sup>. © 1997, American Chemical Society.

are used.<sup>[51,59]</sup> The possibility of formation of particulate OTS in the bulk increases when the amount of water in solvent is high.<sup>[59,60]</sup> The optimum amount of water in the solvent is maintained as described in the section “Materials and Experimental Techniques Used for Preparations and Characterizations of Silane SAMs.” Good OTS monolayers are not formed on dehydrated substrates.<sup>[33,35,49,50,53,59]</sup> The thickness of the water layer determines the diffusivity of the OTS molecules on the surface, which in turn controls the morphology of the OTS monolayer. This is another

effective way of controlling the structure of OTS monolayers. The preparation of substrates with varying degrees of hydration is described in the section “Materials and Experimental Techniques Used for Preparations and Characterizations of Silane SAMs.” Under ambient conditions, a water layer is present on the native silica surface.<sup>[31,49,50,53,61]</sup> The thickness of this water layer depends on the ambient humidity and can have values of a few nanometers.<sup>[36,54–56]</sup> Upon heating the substrate at 100°C, some of the physisorbed water is removed.<sup>[31,39,49,50,53]</sup> We refer to these surfaces as partially dehydrated. Upon further heating to 150°C, most of the physisorbed water is removed and we refer to these substrates as dehydrated. Partial OTS monolayers are deposited on the fully hydrated, partially dehydrated, and dehydrated substrates by immersing in a 2 mM OTS solution for 30 sec at 22  $\pm$  1°C. An image of the OTS monolayer on a hydrated substrate is shown in Fig. 4A. Primary fractal islands and secondary islands are observed on this surface as expected (Fig. 1). The water contact angle is  $\sim$ 93°. On a partially dehydrated substrate (Fig. 4B), we still observe primary fractal and secondary growth. However, the area occupied by the primary fractal islands is reduced and so is their size, when compared to the hydrated substrate (Fig. 4A). The reduced surface mobility of the OTS molecules on the partially dehydrated substrate reduces the size of the primary islands. The water contact angle is  $\sim$ 90°, which is very close to that of the hydrated substrate. On the dehydrated substrate, the AFM images in contact mode were not stable in successive scans. Therefore the samples were imaged in tapping mode, which overcame this difficulty. Such an image is shown in Fig. 4C. A large number of randomly placed “dots” are observed instead of the primary and secondary islands. These “dots” are about 100 nm in diameter

**Fig. 4** Height images of partial OTS monolayers on substrates with different degrees of hydration. Image size: 10  $\mu\text{m}$   $\times$  10  $\mu\text{m}$ ; temperature 22  $\pm$  1°C; OTS concentration: 2 mM; deposition time: 30 sec; height scale: 0–10 nm; (A) fully hydrated substrate (image was acquired in contact mode); (B) partially dehydrated substrate, heated at 100°C (image was acquired in contact mode); (C) dehydrated substrate, heated at 150°C (image was acquired in tapping mode). *Source:* From Ref.<sup>[25]</sup>. © 1997, American Chemical Society.

and 17–18 Å in height. They are clusters of adsorbed OTS molecules, which are unable to form large condensed primary islands because of the negligible surface mobility on the dehydrated substrate. These OTS clusters or “dots” are not strongly adhered to the substrate, and therefore they are swept away by the AFM tip when imaged in contact mode as seen in our experiments. The height of these aggregates is nearly the same as the monolayer height. The water contact angle is only 78° compared to 93° and 90° for a hydrated and partially dehydrated substrate, respectively. This result shows that OTS monolayers do not exhibit the primary and secondary growth on dehydrated surfaces. Much smaller domains of OTS are observed, which are not strongly adhered to the substrate. This result also confirms that the silane molecules do not bind to the surface silanol groups during the monolayer formation process.<sup>[31,49,50,53]</sup> At longer deposition times, the number of random “dots” increases, but no condensed fractal islands are observed. The number of these “dots” continues to grow, until they begin to touch each other to form a disordered monolayer. On a dehydrated substrate, deposition times of about 15 min are required in order to get a monolayer with water at a contact angle of ~105°, compared to a deposition time of 2 min for a hydrated substrate. Similar results are obtained when OTS depositions are carried on dehydrated substrates at 10°C.

These results demonstrate that OTS domains from nanometer to micrometer size can be obtained by proper control of the deposition conditions. The primary and secondary islands are formed during the monolayer formation and are not a result of drying the substrates.<sup>[25]</sup> Primary and secondary growth is controlled by temperature and deposition time. The nanometer-scale OTS domains are obtained by reducing either the adsorption rate of OTS or surface mobility of OTS molecules. The adsorption rate is reduced by reducing the bulk concentration. The surface mobility of OTS molecules is reduced by hydrating the surface. The OTS domains are not strongly adhered to dehydrated surfaces. The density of OTS molecules in the region surrounding the condensed OTS domains is lower at low deposition temperature. For any other silane molecule, the optimum deposition conditions needed to form these domains would be different.

### MIXED MONOLAYERS BY SEQUENTIAL ADSORPTION

The substrates with OTS domains of various sizes and shapes can be used to prepare the mixed monolayers in which the OTS domains are surrounded by other silane

molecules. The surface chemistry of the surrounding region can be changed by varying the terminal group of the second silane. The region surrounding the OTS domains would have a more uniform density of second silane when the OTS density in regions surrounding the OTS domains is low. Thus the OTS domains are prepared at 10°C for the sequential adsorption. The substrates with the desired structure of OTS domains are immersed in the solution of the second silane. We used two different silane molecules for the sequential adsorption. 11-Bromo undecyltrichlorosilane and DTS have bromine and methyl groups at the end of the molecules, as a result they provide different chemical functionality. Both BrUTS and DTS have a low critical temperature (~0°C based on the number of carbons) and as such do not form condensed islands when deposited at 10°C or higher temperatures. The process of the adsorption of second silane in the region surrounding the OTS domains is referred to as backfilling.

Fig. 5 shows the height and friction image of a hydrated substrate that is backfilled with BrUTS after immersing in a 1 mM OTS solution for ~0.5 sec. The AFM image shows small islands with a height of 9 Å and diameter in the range of 30–100 nm. These are OTS islands surrounded by BrUTS. The friction of the OTS islands is lower compared to the region covered by BrUTS. Thus we are able to obtain nanometer-scale islands of methyl functionality surrounded by silanes with bromine functionality. The area covered by the OTS islands is approximately 5.2%. The water contact angle on this sample is ~81°. The lower contact angle is a result of the large fraction of the surface covered by BrUTS. In another

**Fig. 5** Height and friction images of an OTS/BrUTS mixed monolayer showing “nano” islands of OTS surrounded by BrUTS. The procedure is described in the section “Materials and Experimental Techniques Used for Preparations and Characterizations of Silane SAMs.” OTS deposition time ~0.5 sec; hydrated substrate, image size: 2 μm × 2 μm; height scale: 0–10 nm. *Source:* From Ref.<sup>[25]</sup>. © 1997, American Chemical Society.

experiment, larger domains of OTS surrounded by BrUTS are formed as shown in Fig. 6. The larger OTS domains are obtained by increasing the deposition time in 1 mM OTS solution to 3 sec. The fractal islands of OTS are surrounded by BrUTS. No secondary islands of OTS are observed. The height difference between the fractal OTS islands and surrounding BrUTS phase is 12.1 Å. The comparison of heights in the mixed monolayers with the molecular structure suggests that the BrUTS regions are in a disordered state.<sup>[25,39]</sup> Octadecyltrichlorosilane islands on this sample are more condensed than the “nano” islands in Fig. 5. This conclusion is derived from the fact the fractal islands in Fig. 6 are 12.1 Å above the surrounding region, compared to the value of 9 Å for the “nano” islands in Fig. 5. The water contact angle is  $\sim 91^\circ$ , which is a result of the larger surface fraction covered by the OTS regions.

In a similar manner, mixed monolayers of DTS and OTS are also prepared by immersing a hydrated substrate in 1 mM OTS solution for 3 sec and subsequent backfilling with 1 mM DTS solution. Friction and height images of this sample are shown in Fig. 7. As expected, fractal islands of OTS surrounded by DTS are observed. The height difference between the OTS islands and the surrounding phase is 11.4 Å, which suggests that DTS regions are in a disordered state.<sup>[25]</sup> This is expected as complete DTS monolayers have been observed to remain in a disordered state at temperatures above 0°C.<sup>[39]</sup> The water contact angle on this substrate is  $\sim 106^\circ$  compared to  $108^\circ$  on a full OTS monolayer. The similar water contact angles are a result of the same methyl terminal group for DTS and OTS.

**Fig. 6** Height and friction images of an OTS/BrUTS mixed monolayer showing large condensed fractal islands of OTS surrounded by BrUTS. The formation of nanometer-scale domains can also be attained by using the dehydrated substrates. Octadecyltrichlorosilane deposits as small “dots” or clusters on a dehydrated substrate as shown in Fig. 4C. In order to explore this method, silicon substrates are dehydrated at  $150^\circ\text{C}$  as described in the section “Materials and Experimental Techniques Used for Preparations and Characterizations of Silane SAMs.” They are then immersed in 1 mM OTS solution for 3 sec and then backfilled with DTS and

**Fig. 8** Tapping mode image of an OTS/BrUTS mixed monolayer showing “nano” islands of OTS surrounded by BrUTS on a dehydrated substrate. BrUTS. Contact mode AFM images do not show any features, but tapping mode images show “nano” islands of OTS surrounded by DTS or BrUTS. Atomic force microscopy image of a BrUTS sample is shown in Fig. 8. The islands of OTS have a height of  $\sim 7.3$  Å. The diameter of the OTS islands is about 50–100 nm. Atomic force microscopy images for the OTS/DTS samples also show similar nanometer-scale islands of OTS with average heights of about 7.6 Å. These mixed monolayers are not strongly adhered to the substrate. The AFM tip in contact mode is able to remove the monolayer from the surface. In conclusion, the dehydrated substrates could be used to produce nanometer domains, but the silane molecules are not strongly adhered to the surface.

## CONCLUSION

The ability of silane molecules to aggregate and form islands during SAM formation can be exploited by controlling the deposition conditions to produce nanometer- and micrometer-scale domains of varying chemical functionality. We have demonstrated this procedure by controlling the assembly of OTS SAMs. Octadecyltrichlorosilane domains of various sizes and shapes are obtained by controlling the temperature, concentration, deposition time, and substrate hydration. Further, the region surrounding these domains can be filled with silane molecules of different chemical functionality. Octadecyltrichlorosilane islands of about 30–100 nm in diameter are obtained on dehydrated surfaces and at low concentrations. Large fractal condensed islands of OTS are prepared by increasing the OTS deposition time. The region surrounding the OTS islands is backfilled by sequential adsorption of DTS and BrUTS to obtain surfaces in which domains of one chemical functionality are surrounded by other chemical functionality.

## INTRODUCTION

Nanoscale porous structures are attracting a great deal of interest due to their significant potential to biological and technological applications, including catalytic supports, biosensors or nanoscale containers. Silica nanotubes, in particular, are promising materials because of their naturally hydrophilic surface, which allows them to form colloidal suspensions in aqueous solvent without aggregation. Furthermore, the use of template-based synthesis methods allows easy production of monodisperse silica nanotubes<sup>[1,2]</sup> and an important technological advantage of this approach is the ability to systematically change both the size and surface chemistry of the nanotube interior.

In order to use nanotubes as chemical nanocontainers, one must understand the transport properties occurring in the nanotube interiors including diffusion and wetting behavior under a variety of conditions. This can be especially important when nanotube cargo is weakly coupled with the tube interior, for example, by adsorption. Diffusion processes occurring on the nanotube interior surface are of fundamental significance for any application of nanotubes. Adsorption, diffusion, and wetting behavior will ultimately determine the success of applications employing template-synthesized silica nanotubes.

This entry discusses several examples that demonstrate some of the valuable applications of silica nanotubes including separations using nanotube-based membranes,<sup>[3]</sup> selective functionalization of nanotube surfaces for the capture and concentration of target solutes<sup>[4]</sup> and investigations of diffusion and wetting phenomena at the interior nanotube surfaces.<sup>[5]</sup>

## SILICA NANOTUBES

In recent decades, various techniques have been demonstrated to manufacture nanoscale tube

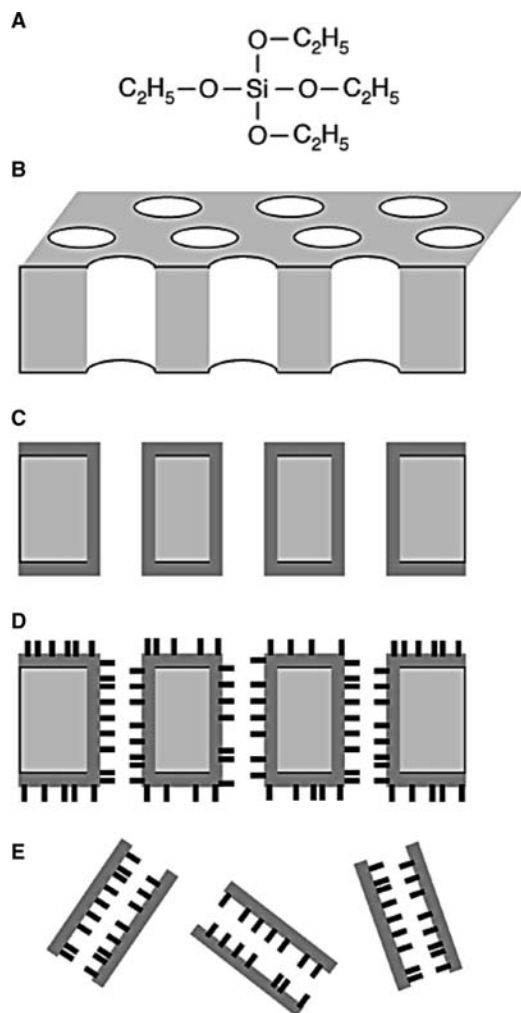

structures with silica. Many groups have employed sol-gel synthesis using TEOS (tetraethyl orthosilicate or tetraethoxysilane; Fig. 1A) with various templates of hollow tubular structure, such as supramolecular assemblies,<sup>[6–11]</sup> biological substrates,<sup>[12–17]</sup> organic ammonium carboxylate crystals,<sup>[18–20]</sup> carbon nanotubes,<sup>[21,22]</sup> fiber-like crystals,<sup>[23,24]</sup> or nanoporous membrane materials.<sup>[1,2,25,26]</sup> A method not using TEOS was also introduced in which a silicon nanowire array is fabricated using semiconductor micromachining technology and the surfaces of the wires are oxidized.<sup>[27]</sup>

A common problem with these techniques is controllability of size, shape, and uniformity. Ideally, one desires the ability to arbitrarily change length, diameter, and surface chemistry with a method that is reproducible and simple. Membrane-based template synthesis satisfies these requirements.<sup>[1,2,25,26]</sup> Martin et al.<sup>[1,2]</sup> pioneered this technique, which enables the production of monodisperse nanotubes from a variety of materials, including silica.<sup>[1,2]</sup>

One easily exploited advantage of Martin's method is the ability to independently functionalize the interior and exterior surfaces during synthesis.<sup>[4]</sup> For example, nanotubes simultaneously having a hydrophilic exterior and hydrophobic interior can be produced so that they disperse readily in aqueous solution but have attractive interactions with hydrophobic or amphiphilic molecules. Such nanotubes can provide the ability to capture and concentrate hydrophobic molecules in solution thus serving as nanocontainers, as discussed further.<sup>[4,5]</sup> Surface modifications can be arbitrarily chosen to provide a range of interactions including antigen-antibody interaction<sup>[3,4]</sup> and electrostatic or covalent interactions.

Silica nanotubes possess several important features, which make them ideal for biophysical/biochemical studies:

1. Because of their naturally hydrophilic surfaces, they easily form colloidal suspension in aqueous solvent.

**Fig. 1** Membrane template method using (A) TEOS (tetraethyl orthosilicate or tetraethoxysilane). (B) Nanoporous membrane is used as a template. (C) Silica is coated on surface of template by sol-gel synthesis. (D) Silica surface can be functionalized by silanization. Inner wall of pores become interior surface of nanotubes. (E) Silica nanotubes are liberated by mechanical polish of top and bottom silica layers and dissolution of template.

- Optical transparency allows the use of optical methods to address the interior contents.<sup>[4,5]</sup>
- Silica is robust and innocuous in most physiological environments.
- Surface chemistry is readily modified and silica nanotubes can be differentially functionalized on exterior and interior surfaces.

### NANOPOROUS MEMBRANE TEMPLATE METHOD

Martin's method employs a membrane film with nanoscale cylindrical pores as the template (Fig. 1B).

Commercial alumina membrane are available for this purpose, while membrane with pores having arbitrary size and density can be made by anodic oxidation on alumina films. Additionally, other materials, such as polycarbonate, can be utilized as template materials.

The process is started by immersing the template membrane in a mixture of absolute ethanol, TEOS, and 1 M HCl (50 : 5 : 1 vol/vol) solution. After sonication for 30 min, unbound reagents are removed by vacuum filtration. The sol-gel coated template surface is then cured overnight at 150° (Fig. 1C).

Chemical modification of the sol-gel layer can be achieved by silanization. While still attached to the template membrane, exterior surfaces of nanotubes are not modified because they are in contact with membrane template. For example, C<sub>18</sub> chains can be attached by immersing membranes for 30 min in 5% octadecyltrimethoxysilane solution (vol/vol) in ethanol, pH adjusted to 5.0. After immersion, the membranes are rinsed with ethanol and dried at 150° (Fig. 1D).

To produce liberated nanotubes, the silica layers on membrane surfaces are mechanically polished to expose the alumina template which is subsequently dissolved overnight in H<sub>3</sub>PO<sub>4</sub>. If necessary, the exterior surface of nanotubes can be functionalized at this point. For the purpose of dispersing nanotubes in aqueous solution, the exterior surface can be left bare (Fig. 1E).

Fig. 2 shows transmission electron microscope (TEM) images of liberated nanotubes with diameter of (a) ~200 nm and (b) ~60 nm, respectively. Homogeneity of shape and size can be clearly seen, and wall with 15–20 nm thickness appears highly uniform. Diameter and length of nanotubes can be controlled by pore size and thickness of template membrane, respectively.

### DEMONSTRATION OF SELECTIVE INTERACTION

Here, we give two examples of previous studies illustrating the utility imparted to silica nanotubes through

**Fig. 2** TEM image of silica nanotubes with diameter of (A) 200 nm and (B) 60 nm.

selective modification of their exterior and interior surfaces.

The selective functionalization of interior and exterior surfaces was demonstrated by Mitchell et al.<sup>[4]</sup> Two kinds of nanotubes were prepared: one with green fluorescent groups on the interior surface and hydrophobic octadecyl ( $C_{18}$ ) groups on the exterior surface, and the other with blue fluorescent groups on interior surface and the exterior surface was left native (hydrophilic). These nanotubes were added to a mixture of water and the immiscible organic solvent cyclohexane. The two liquids were observed to separate into two distinctly colored phases showing the selective partitioning of the modified nanotubes to their respective solvents.

Another compelling example of chemically tailored selective interactions at a nanotube interface was demonstrated by Lee et al.<sup>[3]</sup> In this example, a silica-coated membrane of nanotubes was used to demonstrate facilitated transport to achieve enantiomeric separation. The nanotube interiors were functionalized with an antibody that selectively binds to one enantiomer of a racemic mixture of a drug molecule. The flux through the membrane was measured for each enantiomer by mounting the antibody modified membrane between the two halves of a U-tube permeation cell. A racemic mixture of two enantiomers (RS and SR) was placed on one side of the U-tube. The anti-RS coated nanotubes showed enhanced transport of their target drug molecule with the RS enantiomer having a flux two to four times that of the SR enantiomer. Interestingly, the anti-RS fragments, which specifically bind the RS stereoisomer, actually promote transport. The separation selectivity was observed to decrease with drug concentration which is in agreement with theories of facilitated transport. By decreasing pore size Lee et al. were able to diminish transport of the non-facilitated enantiomer and reach a maximum selectivity ratio of 4.5. Their results show promise for the use of these materials in highly selective transport of a wide range of molecules.

### DIFFUSION MEASUREMENTS IN SINGLE NANOTUBES

In order to observe the behavior of adsorbed molecules inside nanotubes, fluorescence confocal microscopy and fluorescent dye molecules were used.<sup>[5]</sup> Nanotubes having  $C_{18}$ -modified (hydrophobic) interior surface and native (hydrophilic) exterior surface were used to selectively sequester the fluorescent amphiphilic dye DiI $C_{18}$  (Fig. 3A) in aqueous solutions of varying methanol concentration. The surfactant dye molecule DiI $C_{18}$  was loaded into nanotubes by mixing nanotubes in water and methanol (9:1 vol/vol) solution containing  $10^{-6}$ – $10^{-7}$  M DiI $C_{18}$ . DiI $C_{18}$  is adsorbed

at the interface formed by the hydrophobic interior surface and the dye solution (Fig. 3B).

For microscope observation, nanotubes must be stationary during observation. Silane chemistry was used to immobilize nanotubes on microscope coverslip. To achieve immobilization, the surface of glass coverslips were silanated by briefly sonicating (5 min) in a solution of ethanol, TEOS, and 1 M HCl (40:1:1 vol/vol) after the solution was allowed to sit for 30 min. Coverslips were then rinsed with ethanol and a few drops of solution containing dye-filled nanotubes was spread on the coverslip. The samples were allowed to dry in air at which time covalent bonds formed between the nanotubes and unreacted siloxane groups at the modified coverslip surface, thus immobilizing the nanotubes.

A fluorescence image of a nanotube filled with dye is shown in Fig. 4. The uniform distribution of dyes inside the nanotube can be observed. Diffusion of dyes inside nanotubes can be measured using the fluorescence recovery after photobleach (FRAP) technique. A nanotube image before photobleaching is shown in Fig. 5A. When an intense laser beam irradiates a point on nanotube, dye molecules at that point only are photobleached. In subsequent images taken after photobleaching (Fig. 5B), the bleached point appears as a dark spot (indicated with a circle). If the dye molecules are able to diffuse inside the tube, then the bleached dye molecules exchange position with surrounding unbleached dyes and the fluorescence signal at the bleached point recovers with time. The nanotube image after fluorescence recovery is shown in Fig. 5C. From the recovery rate, the diffusion coefficient of dye molecules can be estimated. For the case, in which dyes diffuse only in one dimension and the bleaching beam has a Gaussian profile, the recovery curve as a function

**Fig. 3** (A) Surfactant dye molecule DiI has hydrophilic head and hydrophobic tails, (B) DiI is adsorbed on  $C_{18}$ -attached surface of nanotube interior.

**Fig. 4** Example of fluorescence confocal microscopy image of silica nanotube filled with DiI molecules. The solvent is 0.33 M surfactant (Triton-X-100<sup>®</sup>) solution.

of time  $G(t)$  has the form:<sup>[28]</sup>

$$G(t) = I_{\text{inf}} - \frac{I_0}{1 + 4Dt/s^2}$$

where  $D$  is the diffusion coefficient,  $s$  is the width of Gaussian beam,  $I_{\text{inf}}$  is recovered intensity after infinite time, and  $I_0$  is the bleaching depth.

The diffusion coefficient of DiIC<sub>18</sub> molecules in C<sub>18</sub>-coated nanotube interiors were measured in various solvent environments, including mixtures of water and methanol, and aqueous surfactant solution (0.33 M Triton-X-100<sup>®</sup>). In pure water, diffusion is rarely seen in tubes filled with dyes (Fig. 6A). In pure methanol, dyes are largely extracted from the tube interface and removed to solution (Fig. 6B). At low methanol concentrations and in surfactant solutions, dyes are contained in tubes (Figs. 4 and 5, respectively) and diffusion is often observed.

**Fig. 5** Microscopic images of single nanotube filled with fluorescent dye molecules (A) before photobleaching, (B) just after photobleach (the bleached points are indicated with circles), and (C) after recovery. The solvent is water: methanol = 1:1 (vol/vol) mixture.

**Fig. 6** Microscopic images of single molecules in (A) pure water, (B) pure methanol.

The diffusion of dye molecules in nanotubes can be classified into the following four types in these experiments:

1. Adsorbed and static.
2. Adsorbed and slowly diffusing ( $D \sim 10^{-12}$ – $10^{-14}$  cm<sup>2</sup>/sec).
3. Adsorbed and rapidly diffusing ( $D \sim 10^{-6}$ – $10^{-8}$  cm<sup>2</sup>/sec).
4. Mostly desorbed with some remaining bright spots.

Type 1 is often seen in pure water and water–methanol mixture with a low methanol fraction. This likely results from a dry nanotube interior. This is due to the high surface tension of pure water and the hydrophobic interior of the tube combining to keep the tube interior dry. If the tube were wet inside, one would expect results similar to the diffusion of DiIC<sub>18</sub> at the planar interface formed by C<sub>18</sub>-modified glass coverslips as observed by Wirth, Swinton, and Ludes.<sup>[29]</sup>

Type 2 is often seen in water–methanol mixtures when the methanol concentration is 50% vol/vol or greater, or in 0.33 M surfactant solution. In these cases, the solvent is believed to have wetted the interior of nanotubes. However, the diffusion coefficient is much smaller than that measured on wet C<sub>18</sub>-modified planar surface.<sup>[29]</sup>

Type 3 is sometimes seen in water–methanol mixture with a high fraction of methanol, but not in pure methanol. The observed diffusion coefficient is comparable with that on wet C<sub>18</sub>-modified planar surface. The inside of nanotubes is considered to be completely wet in this case, since the methanol cosolvent has served to increase the wetting power of the solution to easily enter the hydrophobic tube interior. Types 2 and 3 frequently occur in the same sample

and this may be due to different diffusion processes within individual tubes possessing different degrees of wetting. For instance, slow diffusion could result from two-dimensional diffusion along the nanotube interior surface and faster diffusion could be due to combined surface diffusion and desorption/readsorption processes. This may indicate that in Type 2 tubes, the surface is wet enough for the slower process but not for the latter, while Type 3 is wet enough to allow both.

Type 4 is observed to some degree in all solvents but most notably in 100% methanol. Bright spots are likely due to strongly trapped aggregates at defects on interior surface of nanotubes, comparable to DiI adsorption “hot spots” reported by Wirth, Swinton, and Ludes<sup>[29]</sup> on C<sub>18</sub>-coated fused silica coverslips. In pure methanol or water–methanol mixtures with a high fraction of methanol, this behavior dominates or is more noticeable because the majority of dye has been desorbed and released into solution.

Fig. 7 is a plot describing the probability that the inside of nanotubes are wetted as a function of methanol concentration under the assumption that only wetted tubes show diffusion behavior of Types 2, 3, and 4. The probability is calculated from results of FRAP measurements. It is clear from these results that 200 nm hydrophobic nanotubes qualitatively follow what is expected from macroscopic models of wettability. However, some deviations from the expected behavior is observed.<sup>[5]</sup> For instance, the wetting process is very slow and typically >24 hr is required to reach equilibrium when no mechanical assistance is supplied either by shaking or sonication. Additionally, some tubes appear to never wet and wetting can be reversible, i.e., some tubes are observed to reversibly dry out when the solvent is changed from one of high wettability to pure water.

Several theoretical models have treated the behavior of solvents in nanoscale pores having hydrophobic interior surfaces.<sup>[30–35]</sup> Giaya and Thompson<sup>[35]</sup> have investigated the behavior of fluid in the nanoscale

Fig. 7 Probability that inside of nanotube is wet with various fraction of methanol in the mixed solvent.

cylindrical pore. Their results indicate that at room temperature, water behaves as typical bulk water when the pore size is  $\sim 1500$  nm. Below this size, the vapor phase may be more stable if the interaction potential between solvent and wall is zero, i.e., a perfectly hydrophobic wall. Giaya and Thompson also suggested that with stronger fluid–pore–wall interaction, the critical radius at which the fluid phase becomes unstable will decrease. The ability to test theories such as these will be facilitated by using hydrophobically modified tubes in which the tube size and surface hydrophobicity of the nanotube interior can be independently and systematically changed.

## CONCLUSIONS

Silica nanotubes with arbitrary and homogeneous diameter, length, and wall thickness are readily produced by template synthesis and are promising candidates for applications in nanotechnology and bioscience. Their potential applications are far reaching due to the ability to independently functionalize the internal and external surfaces. A variety of applications have already been demonstrated including those discussed above. In addition to technological applications, these materials offer opportunities to systematically examine size and chemical effects on small length scales in well-defined geometries. The distribution and diffusion of dye molecules inside single nanotubes as observed using optical fluorescence confocal microscopy<sup>[5]</sup> has allowed the investigation of wetting of the interior of nanotubes as a function of solvent composition, nanotube surface chemistry, and nanotube size. Further investigation with various materials, surface modification, pore sizes, and solvent will offer unique opportunities to test theories of wettability at extremely small length scales.

# Silica Surfaces Functionalization

V. A. Tertykh

*Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine*

## INTRODUCTION

Imparting desired properties to silica surfaces to obtain functionalized silica surfaces is usually effected in different directions. In some cases, it is necessary to moderate interactions between surrounding molecules and surface sites, while in other cases, such interactions should be enhanced to prepare modified matrices with high specificity and selectivity. Besides, functionalization of silica surfaces is often carried out to immobilize diverse compounds to make them heterogeneous. A description is provided for chemical reactions, which are used to modify surfaces and to produce functionalized silica surfaces. A consideration is given to basic principles that should be adhered to when applying functionalized silica surfaces to various types of chromatographic separation [in such cases as stationary phases in gas and liquid chromatography, reversed and normal phases in high-performance liquid chromatography (HPLC) and affinity chromatography, chiral stationary phases for separating optical isomers]. Examples are presented which are intended to illustrate the production of highly specific and complexing adsorbents based on silicas with functionalized surfaces and their application in solid-phase extraction (SPE) of ions and molecules. A general outline is made of methods for activating surfaces of silica matrices with a view to heterogenize metal complex catalysts, to immobilize enzymes and other biologically active compounds. Also included is a brief analysis of the practical experience acquired in the sphere of application of functionalized silicas in the capacity of chemically active fillers of polymeric compositions and effective thickeners of dispersion media. Some consideration is also given to the state of the art and scope for research into the application of functionalized silica surfaces in formation of nanostructures in various fields of modern materials science (sensitive elements of sensing devices, organically modified silicates, organically modified ceramics, etc.).

## GENERAL NOTIONS

The wide practical use of synthetic silicas (precipitated and pyrogenic silicas, silica gels, and aerogels of silica)

in modern material science and other fields in the capacity of fillers of polymers, thickeners of dispersion media, adsorbents, supports of catalysts, and active compounds is attributable to their chemical, mechanical, and microbiologic stability (silica preparations are resistant to high temperatures, ionizing radiation, oxidizing and reducing agents, solutions of all acids with the exception of the hydrofluoric one; they do not swell in organic solvents and are distinguished for their high mass exchange rate) and to the possible regulation (within certain limits) of their main geometrical characteristics: value of specific surface area, size of particles, diameter, and distribution of pores.<sup>[1]</sup>

The chemical modification of silicas further broadens the opportunities for their effective use because, after deposition or chemical attachment of various functional compounds to the silica surface, the formed functionalized silica surfaces (FSS) retain the major characteristics of starting silica matrices while the attached compounds impart new properties to the support.<sup>[2-4]</sup> Although the modification of silica surface is effected through a thermal treatment (dehydration and dehydroxylation), hydrothermal treatment (hydroxylation and hydration), adsorption of diverse substances (particularly substances with a large molecular weight), and deposition of carbon or metals, the most ample opportunities for a purposeful change of silica properties are provided by the attachment of one chemical compound or another as a result of various chemical reactions with the participation of surface sites. At present, mechanisms of such reactions as well as structures of the formed surface compounds are studied via spectroscopy in infrared (IR), ultraviolet (UV), and visible regions, solid-state  $^{29}\text{Si}$ ,  $^{13}\text{C}$  (and other nuclei) cross-polarization magic-angle spinning nuclear magnetic resonance method (CP-MAS NMR), isotope exchange combined with mass spectrometry, and other contemporary physicochemical techniques.<sup>[3-5]</sup> Under favorable conditions (particularly in nonporous, highly disperse preparations of fumed silicas), infrared spectroscopy enables one to exert a practically direct control over the proceeding of chemical reactions in a surface layer.

The approach employed for imparting desired functional properties to the silica surface depends on the nature of the practical or scientific task in question, and may involve such major methods as weakening of intermolecular interactions of surrounding molecules

with sites of the surface, enhancement of these interactions with a view to lend specificity and selectivity to the surface, and modification of the silica surface to transfer surface compounds to their heterogeneous state (immobilization of active compounds). Specifically, the substitution of structural silanol groups by methylsilyl groups through reactions with appropriate organosilicon compounds substantially moderates the energy of adsorption of polar adsorbates (one can observe a decrease in values of adsorption and heat of adsorption), and the silica surface acquires stable hydrophobic properties. At the same time, such a chemical modification of surface prevents the aggregation of disperse silica particles and facilitates their more uniform distribution in hydrocarbons and polymeric media. Moreover, attachment of sufficiently long hydrocarbon radicals ( $C_{16}$ – $C_{18}$ ) makes it possible to use such modified silicas as a basis for creation of adsorbents intended to concentrate organic compounds, which is of importance in designing methods of analysis for contents of pesticides and other organic impurities when effecting monitoring of environment.<sup>[6]</sup>

Attachment of a layer of chemically grafted organic radicals with various functional groups ( $-NH_2$ ,  $-COOH$ ,  $-CH=CH_2$ ,  $-CN$ ,  $-SH$ , etc.) that differ in their physico-chemical properties and reactivities enables one to enhance desired characteristics of the silica surface, which offers ample scope and novel potentiality for practical application of FSS. Similar functional silicas find much use in the normal-phase variant of high-performance liquid chromatography. Besides, they may hold considerable promise in the development of chemically active fillers of polymers and in the design of selective adsorbents including highly specific affinity and immune affinity adsorbents for separation and purification of biopolymers.

Furthermore, FSS acquired great importance in the sphere of production of heterogeneous metal complex catalysts and immobilization of enzymes, other biologically active compounds, antibodies, cells, sections of tissues, and microorganisms on an inorganic matrix. This approach holds promise for the development of chemical and biological sensors whose application makes it possible to exert a pulsed or continuous control over corresponding components in a gas phase or liquid medium. For example, chemical modification of the surface of electrodes with functional organosilicon compounds (sol–gel transformations) is rather widely used for the attachment of electroactive compounds in a surface layer (electrochemical sensors). From this standpoint, the most promising technique is the chemical binding of an active compound, because the construction of sensing elements of control systems via polymer encapsulation methods does not provide a perpetual accessibility of an active compound and uniformity of its distribution in a film as well as a necessary strength of bonding with the electrode surface.

## TYPES OF CHEMICAL REACTIONS USED TO PRODUCE FUNCTIONALIZED SILICA SURFACES

Most of the reactions used to produce FSS are classified among heterolytic processes of electrophilic or nucleophilic substitution ( $S_E$  or  $S_N$ ), addition ( $Ad_E$  or  $Ad_N$ ), and elimination ( $E$ ).<sup>[3,7]</sup> The surface groups are considered as centers of attack whose direction is determined by the character of electron density distribution on the atoms of surface sites participating in a chemical reaction, and by the nature of a corresponding electrophilic or nucleophilic reagent. From this point of view, one can expect that silicon atoms on the silica surface (to be more exact, atoms that are members of groups  $\equiv SiOH$  or  $\equiv SiOSi\equiv$ ) are more preferable for an attack by nucleophilic reagents. In contrast, oxygen atoms as members of the same groups are more preferable for an attack by electrophilic reagents. Possible types of heterolytic reactions involving silica surface sites are represented below:

Among the reactions used for chemical modification of a surface, there is a large class of processes where an attack is carried out by an electrophilic reagent through oxygen atoms of silanol groups of the surface. These processes are referred to as reactions of electrophilic substitution of protons ( $S_Ei$ ). They proceed during interactions with various chloro- and alkoxy silanes, organosilazanes, organosiloxanes, numerous organo-elemental compounds, and halogenides of various elements. The class also includes processes of electrophilic addition ( $Ad_E$ ) to groups  $\equiv SiOH$  (for example, in the case of isocyanates or ethylene imine). In particular, the interaction between various trimethylsilylating reagents and silanol groups of the silica surface involves an attack on oxygen atoms and proceeds according to the scheme (see next page top):

Another class of reactions involves an attack of a nucleophilic reagent on silicon atoms of the silica surface. This class includes processes of nucleophilic substitution ( $S_Ni$ ) (e.g., interactions between silanol groups of the surface and hydrohalogens or alcohols) and processes of nucleophilic addition ( $Ad_N$ ), e.g., reactions of

a solid-phase hydrosilylation of olefins,<sup>[8,9]</sup> with participation of groups  $\equiv\text{SiH}$  attached to the silica surface:

In a number of cases, the function of reactive sites on the silica surface is simultaneously performed by silicon atoms and oxygen atoms of siloxane bonds so that the corresponding processes proceed by mechanism  $Ad_{N,E}$ , for example:

It is also necessary to allow for the possible proceeding of elimination ( $E$ ) and rearrangement processes with participation of chemical surface compounds.<sup>[3,7]</sup>

Introduction of new sites (e.g., groups  $\equiv\text{SiR}$ ,  $\equiv\text{SiOR}$ ,  $\equiv\text{SiNH}_2$ ,  $\equiv\text{SiHal}$ ,  $\equiv\text{SiH}$ , etc. where  $R$  is an aliphatic or aromatic radical and  $\text{Hal}$  is a halogen atom) into a surface layer of silica leads to an increase in the number of potential heterolytic transformations with their participation. Grafted organic radicals can also participate in homolytic processes of substitution or addition ( $S_H$  or  $Ad_H$ ). These processes have been the subject of experimental studies, but the amount of experience gained for the present is not large.

## FUNCTIONALIZED SILICA SURFACES IN CHROMATOGRAPHY AND SOLID-PHASE EXTRACTION

Functionalized silica surfaces provide considerable expansion of capabilities of chromatography and sorption techniques, which find much use for separation, purification, and concentration of substances.<sup>[2,10-13]</sup> It is appropriate to mention here that in various types of chromatographic separation [gas-adsorption chromatography, high performance liquid chromatography (HPLC), affinity chromatography],

a surface layer of silica should contain sites that are able to participate in diverse kinds of intermolecular interactions. Thus, gas-adsorption chromatography and reversed-phase HPLC make use of siliceous supports with attached nonspecific methyl, phenyl, octyl, octadecyl groups, while in the case of normal-phase HPLC, it is necessary to use FSS with quaternary ammonium compounds or with aminopropyl, cyanopropyl, carboxyl, propylsulfo, alkyldiol, and other groups capable of participating in donor-acceptor interactions with molecules of compounds which are separated. In affinity chromatography, which depends on the formation of biospecific complexes (enzyme-substrate, enzyme-inhibitor, lectin-glycoprotein, antigen-antibody, etc.), one of the constituents of such a complex should be chemically bonded to the surface of a silica matrix. The function of a biospecific ligand is most often performed by lectins, protein A, certain dyes, polysaccharides, amino acids, monoclonal, and polyclonal antibodies, which are attached to functional silica surface with the help of diverse cross-linking agents. Determination of contents of medicinal preparations in biological fluids containing substantial amounts of albuminous compounds calls for the application of porous FSS of diphilic nature, i.e., there should be a hydrophilic external surface (accessible for proteins) and organophilic internal surface (inaccessible to proteins). Such a structure of FSS makes it possible to retain macromolecules of proteins on the external surface of a sorbent and to effect the separation of medicinal preparation molecules (which have smaller sizes and which interact with the hydrophobic internal surface of pores) via reversed-phase mechanism. It should also be noted that functionalized silica surfaces find use for covalent (chemospecific) chromatography of biopolymers. This chromatography technique is based on reversible chemical reactions between functional groups of modified silica and of a compound, which is separated. It is appropriate to mention here thiol-containing silicas activated with Ellman's reagent,<sup>[14]</sup> which are suitable for the isolation and purification of thiol-containing enzymes, proteins, or peptides with the aid of the following reversible reaction proceeding by the thiol-disulfide exchange mechanism (see next page top).

Functionalized silica surfaces form the basis for designing effective chiral stationary phases for separation of optical isomers. With the view of producing enantioselective sorbents of this kind, the chiral

selectors of various electronic and geometric structures are attached to the silica surface. Such grafted selectors must afford to provide two- or three-point interactions with separated optical isomers.<sup>[15]</sup>

Also significant is the fact that FSS are employed for adsorption concentration of ions and molecules in analytical practice [solid-phase extraction (SPE)].<sup>[6,11–13]</sup> For instance, columns containing FSS with grafted octadecylsilyl groups are used for preconcentration of phenols, pesticides, and herbicides. Octadecylsilica with adsorbed derivatives of dithiocarbamates, crown esters, and other compounds is utilized for SPE of metals. In particular, C<sub>18</sub> columns with adsorbed tri-*n*-octylphosphine oxide are used for extraction and determination of uranium and thorium in water.<sup>[16]</sup> In the case of a repeated use of C<sub>18</sub> cartridges with adsorbed bonding or complexing compounds, there proceeds a gradual elution of such compounds from the surface of a sorbent. Therefore, many researchers put forth their efforts to develop methods for chemical bonding of most important analytical reagents on silica and other appropriate matrices. Such modified silicas with covalently bonded complexing compounds are referred to as complexing silicas. By now, efforts have yielded a number of rather versatile methods suitable for immobilization of a large majority of analytical reagents.<sup>[11]</sup> Characteristically, the researchers of such methods derived benefit from the experience, which was acquired when designing procedures for immobilization of enzymes and other biologically active compounds on inorganic matrices. For example, to attach 4-(2-pyridylazo)resorcinol, 1-(2-pyridylazo)-2-naphthol, and 8-hydroxyquinoline to the silica surface,<sup>[17]</sup> a use was made of the single-stage Mannich reaction (see below).

Although complex-forming adsorbents based on organic polymers possess an increased capacity with respect to extracted compounds in comparison with mineral supports, the developed FSS with grafted analytical reagents do not swell in water and organic solvents. Moreover, they are distinguished for their high rate of mass exchange with a surrounding medium and, hence, for better kinetic characteristics.

Complexing silicas may be classified according to the nature of an attached functional group (nitrogen-, oxygen-, sulfur-, phosphorus-containing silicas; modified silicas with functional groups involving unsaturated carbon-carbon bonds; polyfunctional silica surfaces)<sup>[3]</sup> or according to the nature of a bond between an ion and a grafted ligand (donor-acceptor bonds, ion exchange, charge-transfer complexes, inclusion complexes of the “host-guest” type).

### METAL COMPLEX CATALYSTS ANCHORED ON SILICAS

It is known that complexes of transition metals are attached to support surfaces (including FSS) for the purpose of producing catalysts that preserve the specificity and selectivity of homogeneous metal complexes and gain technological advantages afforded by heterogeneous contacts.<sup>[18,19]</sup> Attachment of metal complexes to a surface prevents the agglomeration of coordination unsaturated sites and enhances the thermostability of complexes. At the same time, one cannot foretell the possible influence of the surface of a support on the catalytic activity and selectivity of attached complexes. Although production of heterogeneous

metal complex catalysts on siliceous matrices involves adsorption (metal complexes preliminarily prepared by using suitable solvents as well as metal complexes concurrently synthesized in a surface layer with participation of metal ions and of adsorbed ligands) or ion exchange, the most commonly employed methods consist of formation of coordination bonds between metal ions and ligands chemically bonded to surface. In this case, FSS performs the role of a polymeric macroligand. Anchoring of organic ligands on surfaces of silicas is also often accomplished by using functional organoalkoxysilanes whose functional groups, which contain ligands, are bound to surface through hydrolytically stable bonds Si-C, while alkoxy groups and silanol groups form bonds Si-O-Si. For example, anchoring of phosphorus-containing ligands on the silica surface and subsequent formation of metal complexes with rhodium (Wilkinson catalyst), which are active in reactions of hydrogenation of various olefins, can be effected according to the following general scheme (see below).

Introduction of oxygen- and nitrogen-containing ligands and ions of various transition metals makes it possible to obtain heterogeneous metal complex catalysts possessing high activity and selectivity in processes of linear and cyclic oligomerization, hydroformylation, hydrosilylation of olefins, and in some other reactions. Attachment of chiral ligands and complexes on FSS enables the possibility of substantially expanding the potentialities of asymmetric heterogeneous catalysis, which is employed for synthesis of optically active compounds. Also of further interest is the application of metal complexes anchored on FSS in reactions of transfer and activation of oxygen.

## IMMOBILIZED ENZYMES AND FUNCTIONALIZED SILICA SURFACES

The main aim of immobilization is the production of heterogenized enzymes, which are readily separated from reaction media and which can be repeatedly used under

flow reactor conditions. Immobilization of enzymes on silica matrices is effected by both the adsorption method and method of covalent binding on surface.<sup>[20,21]</sup> Chemical bonding permits one to create more stable immobilized preparations, particularly preparations that are elution-resistant in varying surrounding medium factors (ionic strength, pH, concentration of a substrate, and content of substances which may lead to desorption of enzymes).

At present, the available range of methods for covalent bonding of enzymes with silica surface is rather broad. As a rule, all of them involve a preliminary modification of surface by bifunctional silane and subsequent introduction of active groupings that are able to form covalent bonds with side residues of amino acids of enzymes. The most commonly employed method is a preliminary modification of silica by 3-aminopropyltriethoxysilane and subsequent activation of the surface by various reagents (such as glutaraldehyde, diazonium salts, isothiocyanates, carbodiimides, acylazides, haloalkyls, acid chlorides).<sup>[22]</sup> Good performance is also shown by methods for activating the aminoorganosilica surface with 2,4-toluene diisocyanate (a) and cyanuric chloride (b) (see below).<sup>[14]</sup>

The function of starting organosilicas used for production of activated matrices can be performed not only by aminoderivatives but also by organosilicas with other functional groups (such as  $\equiv\text{SiCH}\equiv\text{CH}_2$ ,  $\equiv\text{SiH}$ ,  $\equiv\text{SiRSH}$ ). In particular, activated silica matrices for immobilization of enzymes were prepared through reactions between grafted vinyl groups and maleic anhydride, addition of acrolein to surface silicon hydride groups, and interaction of grafted sulfhydryl groups with Ellman's reagent.<sup>[14]</sup>

Because the properties of an immobilized enzyme are determined by a package of properties of a biocatalyst and support and are dependent on the method for binding the biocatalyst to the support surface, when carrying out a concrete task it proves useful to test various methods for binding with a view to choose the procedure which is optimal from the standpoint

of activity and stability of products. In porous silica matrices, the geometric characteristics of a support exert a substantial effect on the rate of binding of enzymes, on the capacity of a matrix with respect to a protein, and on the manifestation of activity of immobilized preparations, which is attributable to inside-diffusion retardation. The activity of immobilized preparations is, to a great extent, dependent on the pH of a medium where binding of an enzyme takes place. It has been observed that the maximum degree of binding of a protein to the silica surface is observed at pH values close to the isoelectric point of the protein.

Although the practical application of immobilized enzymes has considerable potential in fine organic synthesis and in various fields of biotechnology, it is in the creation of biosensors that their application is most impressive. In biosensors, a use is made either of flow minireactors with immobilized enzymes or of a biocatalyst that is attached directly to the surface of ion-selective electrodes. In the first case, the function of supports is performed by silica-based materials, which possess a rigid structure and, therefore, set good hydrodynamic conditions in a flow of a buffer and of a solution that is analyzed. Placing an appropriate transducer at the outlet of such a minireactor with an immobilized enzyme makes it possible to create analyzers for a broad spectrum of substances, which are substrates or effectors of the enzyme. The role of transducers is most often played by an oxygen electrode, flow spectrophotometer,  $H^+$ - and other ion-selective electrodes, as well as by a multipurpose enthalpimetric transducer. In the second case, enzymes are directly immobilized on the surface of a sensitive element (such as ion-selective field-effect transistor, piezoelectric quartz element, optical fiber element). So long as the supports used contain silicon dioxide, the chemical attachment of enzymes to their surface should be effected with allowance for the experience acquired in the sphere of immobilization of active compounds on modified silicas.

In recent years, there has been considerable interest in effecting enzyme-catalyzed reactions in non-aqueous solvents with a view to increase yields of products or to carry out novel syntheses. Because of their stability in organic solvent, silica matrices may hold considerable promise in the capacity of supports for appropriate enzymes. For example, it is possible to perform

synthesis of various peptides with the help of immobilized proteases and with allowance for reversibility of hydrolysis of peptide bonds.<sup>[14]</sup> In this case, as a consequence of the absence of racemization, the prepared products possess a higher optical purity in comparison with products prepared via the classical peptide synthesis.

## FUNCTIONALIZED SILICA SURFACES IN POLYMERS AND DISPERSION MEDIA

In numerous cases, efficiency of the application of functionalized silica surfaces in polymers and dispersion media is determined by the ratio of hydrophilic sites to hydrophobic sites in a surface layer. This index is of critical importance for thickeners of lubricants and fillers of polymeric materials. Substitution of surface hydroxyl groups by grafted organic radicals favors a better distribution of silica particles in organic media. At the same time, the complete screening of the silica surface (e.g., by alkyl groups) may impair structural and mechanical characteristics of thickened systems, and filling of polymeric materials may worsen their physicochemical properties.

A substantial reinforcement of filled systems can be attained in the situation when active sites of FSS ( $-NH_2$ ,  $-COOH$ ,  $-SH$ ,  $\equiv SiH$ , etc.) are capable of chemical interaction with functional groups of polymeric macromolecules. Such a chemical mechanism of reinforcement was employed for the first time in glass-fiber composites.<sup>[23]</sup> From this standpoint, functionalized silica surfaces containing grafted amine groups may hold considerable promise as chemically active fillers of chlorine- and bromine-containing elastomers and copolymers, epoxy resins, polyurethane rubbers, melamino-formaldehyde and resorcinol-formaldehyde latex and resins, sulfonated ethylene-propylene-diene terpolymers, carboxyl-containing polymer systems. Specifically, in the case of introduction of FSS with amine groups into carboxyl-containing polymers, formation of salt-type cross bonds between the filler and polymer is observed:<sup>[3]</sup>

On the contrary, FSS with carboxyl groups may considerably reinforce butadiene-vinylpyridine copolymer, elastomeric terpolymer of vinylpyridine, styr-

ene, and butadiene, etc. FSS with grafted unsaturated groups can be advantageously employed for reinforcement of a broad range of olefin-containing copolymers and elastomers. Chemisorption of sterically hindered phenols on the surface of highly disperse silicas makes it possible to produce fillers and thickeners having antioxidant properties.<sup>[3]</sup>

Applications of highly disperse silica in varnishes and paints are based on the thixotropic properties of this thickener and on its ability to increase the viscosity of systems and to decrease the sedimentation of pigments of various types. One of the salient features of such systems with siliceous thickeners lies in the fact that, at an infinitely small shearing stress, their behavior is similar to that of solids, and at high shearing stresses, to that of liquid compositions. The thixotropic properties of highly disperse silica are related to the deformation caused by shear, stirring, or shaking, which leads to breaking of bonds at points of contact of particles (of aggregates of particles) or of solvate shells of particles, and to their subsequent restoration at the state of rest. Application of functionalized silica surfaces enables one to exert control over the viscosity of a system and to substantially enhance the water-resisting property of a coating.

## CONCLUSION

Purposeful variation of properties of the surface of silicas is of great importance in carrying out numerous scientific and practical tasks in adsorption, chromatography, catalysis, and chemistry of filled polymers. Presently, functionalized silica surfaces find much use in the production of immobilized reagents, which are successfully employed in synthetic organic chemistry.<sup>[24]</sup> Of particular significance is the ever-growing role of FSS in modern material science and nanodimensional engineering. Also noteworthy is the prevalent use of polysilsesquioxanes produced by the sol-gel method (cohydrolysis of organofunctional trialkoxysilanes and tetraalkoxysilane), organically modified silicates (ormosils) including silicates doped with diverse dyes, and organically modified ceramics (ormocers) for producing novel optical materials and lasers, sensitive elements of sensing devices, biocompatible ceramics.<sup>[25-29]</sup> New vistas in the production of FSS are furnished by chemical modification of surface and core of ordered mesoporous siliceous materials (such as MCM-41 and MCM-48),<sup>[30]</sup> which possess an exceptionally extended surface and unique structure of pores accessible to large molecules. It is not ruled out that such FSS will form the basis for the development of new generation adsorbents and catalysts. Also of significance is the formulation and establishment of principles of mosaic nanodimensional modification of siliceous

supports because, under favorable conditions on the surface of such supports, it is possible to construct models of active centers of multicomponent metal complex catalysts and biological catalysts, as well as to create ultraselective and affinity sorbents. Functionalized silica surfaces are increasingly used in the field of novel dispersion media, polymeric compositions, and modern materials.

## Abstract

Silicon is the most important material in modern technology; the deep interest in the chemical modification of its surface is due to the trend that is now bringing technology to nanotechnology in various fields, and which makes surface properties prevailing over bulk ones. A promising approach involves the construction of hybrid organic-molecule-silicon devices based on organic molecules covalently grafted onto silicon surface, for applications such as the control of threshold voltage of field-effect transistors (“more Moore”), molecular electronics (“beyond Moore”), sensors and micro-electromechanical systems (“more than Moore”). Silicon is generally considered to have a poor reactivity, so its functionalization with organic moieties is still a critical issue. Synthetic routes in solution and under ultra high vacuum are reviewed and discussed emphasizing the underlying chemistry. Their applicability and process compatibility are also discussed.

## INTRODUCTION

With “silicon functionalization” one usually intends the derivatization of elemental silicon with organic or organometallic species aiming to impart new properties to its surface. The functionalization of silicon may impact the future of electronics in its normal evolution (“more Moore”) or for the preparation of devices with geometry not achievable with standard silicon technology (“beyond Moore”). Furthermore, also the engineering of devices like sensors, actuators, and opto-electrical ones, with new functions with respect to equivalent in the past (“more than Moore”), may be developed.

## MORE MOORE—NON-CONVENTIONAL PROCESSING OF CONVENTIONAL DEVICES

The volume of silicon used in a MOSFET (metal-oxide-semiconductor field effect transistor) at the forefront of the technology (gate length = 0.06  $\mu\text{m}$ ) built on SOI (silicon on insulator) or SON (silicon on nothing) substrate is of about  $10^{-15} \text{ cm}^3$ . For dopant concentration in the range of  $10^{16} \text{ cm}^{-3}$ , the threshold voltage of a MOSFET is thus controlled on the average by a number of atoms of the order of 10. Needless to say, this situation results in an extreme statistical variability of the properties of single devices forming the circuit. In this context, the conduction properties of the device channel are better controlled by modifying its surface potential. That may be

achieved, for instance, derivatizing the surface of the active region with molecules able to impart the desired potential to the channel.<sup>[1]</sup> Of course, in view of the limited thermal stability of organics, this leads to major integration issues. However, in a SON MOSFET the modification is possible by exposing the back-side of the transistor to the functional molecule in the back-end stage of device processing.

## BEYOND MOORE—NON-CONVENTIONAL DEVICES

The scaling down of the MOSFET below a gate length of 0.04  $\mu\text{m}$  seems practically impossible in the frame of the current silicon technology. Below this feature size the crossbar architecture,<sup>[2]</sup> in which the active region is inserted “vertically” in each cross-point formed by the superposition of two perpendicularly oriented conductive-wire arrays, seems producible with methods not involving conventional lithography.<sup>[3–6]</sup>

The first attempt in this direction involved the insertion of reconfigurable conductive molecules between metal arrays:<sup>[7]</sup>

Almost immediately after the original proposal, however, it became evident that the above arrangement was not sufficiently robust to be operated at electric fields useful to produce a sensitive current through

the organic layer (metal electromigration being the weak point).<sup>[8]</sup> Instead, the following arrangement

seems more suitable and consistent with silicon technology,<sup>[5,6]</sup> and can be used to generate a genuine molecular electronics.<sup>[9]</sup>

### MORE THAN MOORE—SENSORS

One of the most prototypical applications of surface functionalization by chemical grafting is chemical sensing.<sup>[10]</sup> A chemical sensor is a device capable of converting in real time chemical information (either qualitative or quantitative) into a physical quantity that can be readily measured, processed, and stored. Surface functionalization has been widely exploited in the field of biosensors, where mainly oxide layers have been used to tailor surface sensitivity to specific analytes.<sup>[11]</sup> Over recent years, silicon surface modifications have proved to be successful also to enhance selectivity and sensitivity toward detection of non-biological targets both in solution<sup>[12]</sup> and in the gas phase.<sup>[13]</sup>

### WHICH CHEMISTRY FOR SILICON DERIVATIZATION?

All the examples considered until here require the ability to bind organic or organometallics (like ferrocenes)<sup>[14]</sup> molecules to silicon surfaces forming an organic layer with assigned electrical properties. Silicon derivatization usually requires a preliminary step leading to an as far as possible homogeneous termination of the surface with species such as halogens, hydrogen, and hydroxyl.

This item is addressed to review the state of the art about the derivatization with organic molecules both of single-crystalline silicon [and especially of its (111) and (100) surfaces, of interest for integrated-circuit processing or molecular electronics] and of porous silicon (of interest not only for sensors, but also for optical devices).

### The Chemistry of Silicon

Even though there are some analogies between the chemistries of carbon and silicon, the differences are prevailing. Similar to carbon, most of the silicon compounds are consistent with  $sp^3$  hybridization of

**Table 1** Some bond dissociation energies and average bond energies

Bond	Bond dissociation energy (eV)	Bond energy (eV)
Si–H	3.6–4.5	
Si–C	3.9–4.1	3.3
Si–Si	3.2–3.4	2.3
Si–F	6.6–7.2	
Si–O	5.3–5.9	4.8
Si–N	4.2–4.7	
H <sub>2</sub> Si=CH <sub>2</sub>	1.6	(of $\pi$ bond only)
H <sub>2</sub> Si=SiH <sub>2</sub>	1.2	(of $\pi$ bond only)
H <sub>2</sub> Si=O	2.6	(of $\pi$ bond only)
H <sub>2</sub> C=CH <sub>2</sub>	2.8	(of $\pi$ bond only)
H <sub>2</sub> C=O	3.25	(of $\pi$ bond only)

outer atomic orbitals of silicon, whose atom in ground state has electronic configuration is  $3s^23p^23d^0$ . Instead, dissimilarly from carbon,

- numerous penta- or hexa-coordinated compounds of silicon are known,
- $sp^2$  and  $sp^1$  hybridizations are observed in very few compounds, and
- silicon has poor tendency toward catenation.

Penta- and hexa-coordinated compounds are usually, but not uniquely, observed when silicon is bonded to very electronegative elements, as in  $[\text{SiF}_6]^{2-}$ . These compounds might easily be explained in terms of lone-electron-pair donation to the empty  $d$  orbital of silicon, but the participation of this orbital in the formation of the bonds is still a matter of debate.<sup>[15]</sup>

The negligible tendency of silicon toward the formation of  $\pi$  bonds is determined by the fact that the stability of the Si=Si double bond is lower than the stability of the Si–Si single bond (see Table 1);<sup>[6]</sup> silenes are thus unstable towards spontaneous decomposition unless the  $\pi$  bonds are protected against internal rearrangements by suitably bulky side groups.<sup>[17]</sup>

Instead, the Si–Si  $\sigma$  bond behaves similarly to the  $\pi$  bond in olefins.<sup>[15]</sup> This analogy is sustained not only by the corresponding bond energies, but also by the following observations:

- disilanes undergo electrophilic cleavage by the same reagents that add to olefins by cleavage of the  $\pi$  bond,

- the Si–Si bond forms dative complexes with Lewis acids;
- the Si–Si bond undergoes ionization with formation of a radical ion  $R_3\dot{Si}\cdots\overset{+}{Si}R_3$  where the complex is not destroyed, as it happens for olefins (e.g.,  $H_2\dot{C}-\overset{+}{C}H_2$ ).

The obvious difference is that while the cleavage of the  $\pi$  bond in  $C=C$  does not demolish the molecule (unless the reagent does not add additively to the  $\sigma$  bond too), the cleavage of the  $\sigma$  bond in Si–Si eventually results in the formation of monomers. This process is at the basis of the most important silicon reaction, the Rochow reaction:

with X being a halogen (typically  $X = \text{Cl}$ ) and  $R = \text{H}, \text{CH}_3, \text{C}_2\text{H}_5, \text{C}_6\text{H}_5$ , etc.

This analogy clarifies also the reason why, contrarily to carbon, silicon has poor tendency toward catenation. Although silanes  $\text{Si}_n\text{H}_{2n+2}$  are formally the silicon analogues of alkanes, taking into consideration their chemical properties, they are the analogues of cumulenes, chemical compounds with two or more consecutive double bonds. Long cumulenes are known to be unstable; correspondingly  $\text{Si}_n\text{H}_{2n+2}$  decompose spontaneously to silicon and  $\text{H}_2$  for  $n > 3$ .

From the viewpoint of the ability to catenation, the silicon species more similar to alkanes are siloxanes,

where silicon atoms are linked through oxo bridges  $-\text{O}-$ . In view of the weak dependence of the energy content of the oxo bridge on angle (Si–O–Si), various allotropic forms of silica and siloxo compounds are indeed possible. It is immediately seen that alkane, alkene, and alkyne species have counterparts in siloxo compounds, for which the names *alksoxan*, *alksoxen*, and *alksoxyn* seem the most natural. Table 2 shows the equivalence. In this case, the silicon analogues of cumulenes and polyynes (organic compounds with alternating single and triple bonds) are linear or cyclic  $(\text{SiO}_2\text{SiO}_2)_n$  or  $(\text{SiO}_3\text{SiO})_n$ , which seem to be (or already are) in the reach of the siloxan chemistry even for  $n > 3$ . The major difference is the absence of aromaticity in siloxo compounds. An even more intriguing analogy is discussed in Ref.<sup>[18]</sup>.

### The Role of Surfaces

Before considering in detail the various processes, we intend to address the problem of the role of any solid surface reactivity. Compared with gas- or liquid-phase reactions, the surface introduces several modifications. In fact, imagining of insulating a small portion of the surface separated from the remainder,

1. the reactivity of any group therein toward a reactant in gas or liquid phase is expected to be the same as for the considered group in the considered phase, provided that:
2. the frontier molecular orbitals are replaced by valence and conduction bands (possibly with

**Table 2** Formal analogy between hydrocarbons and siloxo compounds

Name	Formula	Name	Formula
<i>Alkane:</i>		<i>Alksoxan:</i>	
Methane	$\text{CH}_4$	Methsoxan	$\text{Si}(\text{OH})_4$
Ethane	$\text{CH}_3\text{CH}_3$	Ethsoxan	$\text{Si}(\text{OH})_3\text{OSi}(\text{OH})_3$
Propane	$\text{CH}_3\text{CH}_2\text{CH}_3$	Propsoxan	$\text{Si}(\text{OH})_2\text{OSi}(\text{OH})_2\text{OSi}(\text{OH})_3$

Polyyne	$(\text{C}\equiv\text{C})_n$	Polysoxyn	$(\text{SiO}_3\text{SiO})_n$

population controlled by doping of the solid), and

- the steric constraint of the surface (which can in turn be considered as an extremely bulky group holding approximately half a space) is considered.

Feature (1) explains how gas-phase chemistry can be imported into surface chemistry to predict on analogical bases the reactivity; features (2) and (3) define the limits of the analogy. Feature (2) is extremely important in redox reactions, where an electron transfer from/to surface occurs and the energy levels involved play a fundamental role. On the contrary, steric constraint plays certainly an important role in any type of on-surface reaction; it forbids free geometrical arrangement of intermediate species and final adduct, and reduces the solvent effect occupying a part of solvation sphere. Of course, steric constraint becomes critical when the reactant has a size comparable with the short-range peak-to-valley roughness of the surface; it is intuitively obvious that an atomically flat surface may be derivatized with a more ordered and dense film than a rough surface.

To understand how strange may be the chemistry at a surface and to rationalize it, consider on one side that silenes in gas phase can only be prepared by protecting the Si=Si double bond with sufficiently bulky unreactive groups, which protect the  $\pi$  bond not only against other molecules but also against internal rearrangements;<sup>[17,19]</sup> their effect is thus progressively destroyed as temperature increases. On another side, observe that the clean,  $2 \times 1$  reconstructed, (100) surface of single crystalline silicon may be seen as a two-dimensional lattice of silene units (for more information on silicon dimers at the  $2 \times 1$  (100)Si<sub>2</sub>, see Ref.<sup>[20]</sup>) stabilized by the underlying entire crystal—an extremely bulky group. Since the silene bonds are accessible to external molecules, they are extremely reactive (and indeed they can be preserved in ultra high vacua only), but they are nonetheless stable at very high temperature too (indeed, they are formed, for instance, by thermal decomposition of silanic bonds at hydrogen-terminated surfaces at temperature higher than approximately 750°C).

## SILICON SURFACES

Silicon wafers are commercially available with various orientations: [111], [100], [110], [113], etc. Of them, only the (100) and (111) surfaces are currently produced and used in semiconductor silicon processing—and the (100) surface alone covers almost all applications.

For many years, the quality of such a surface has been related to

- the polishing procedure, which produces surfaces with prevailing hydrogen terminations, but also containing residual oxo centers (Si–O–Si and Si–O–H);<sup>[21,22]</sup>
- the cleaning process after polishing.

The most widely used cleaning processes were developed by RCA in the mid-1960s. The RCA cleaning employs two steps:

- (SC1) standard cleaning 1, where the wafer is exposed to a hot mixture of H<sub>2</sub>O<sub>2, aq</sub> + NH<sub>3, aq</sub>, aimed at removing organics and particles; and
- (SC2) standard cleaning 2, where the wafer is exposed to a hot mixture of H<sub>2</sub>O<sub>2, aq</sub> + HCl<sub>aq</sub>, designed to remove metals.

The combination of this procedure with “piranha” etching (a concentrated aqueous solution of H<sub>2</sub>SO<sub>4</sub> and H<sub>2</sub>O<sub>2</sub>) before SC1, between SC1 and SC2 or after SC2, leaves the surface oxidized and hydroxylated. The oxo-terminated surfaces exposed to humidity at room temperature undergo further oxidation<sup>[23,24]</sup> and the early stages of oxidation produce a chemically heterogeneous surface region where the silicon oxidation state is distributed between 0 and 4.<sup>[25]</sup> Finally, an etching in HF<sub>aq</sub> followed by a rinsing in de-ionized H<sub>2</sub>O is usually considered an adequate treatment achieving the surface hydrogenation.<sup>[26]</sup> The extent of residual oxidation and hydroxylation depends on HF<sub>aq</sub> concentration, solution pH, concentration of O<sub>2</sub> dissolved in water, air humidity, and duration of exposure. Since these quantities are often known only partially, the state of the surface (the native surface) is generally unknown in a broad distribution of allowed states.

Over the last years, the attention has gradually shifted from the removal of contaminants (organics, metals, particulates) to the chemical termination of the surface after the cleaning process because it affects appreciably the behavior of the Si–SiO<sub>2</sub> interface on gate oxidation in integrated-circuit processing. In the following, we shall describe the methods developed for the preparation of surfaces minimizing the oxo terminations.

## The Surface of Single-Crystalline Silicon

Clean surfaces—reconstructed and highly reactive

**The (111) surface.** There are in principle two (111) surfaces: one is characterized by three unsaturated

dangling bonds per surface atom, and the other is characterized by one dangling bond per atom perpendicularly oriented to the surface. The attention is usually limited to the second case because it occurs at the cleavage plane of silicon.

The clean unreconstructed  $1 \times 1$  (111) surface is unstable and reconstructs first with the formation of  $2 \times 1$  (111) dimers and eventually forming a complex  $7 \times 7$  (111) structure. The passivation of the dangling bonds at the unreconstructed surface produces an almost ideal  $1 \times 1$  (111) SiH surface.<sup>[27]</sup>

**The (100) surface.** The ideal (100) surface is characterized by two dangling bonds per surface atom. This surface is unstable and admits several reconstructions. The most stable one is the  $2 \times 1$  (100) reconstruction, characterized by double-bonded silicon dimers in silene configuration (the bonds being a strained  $\sigma$  bond and a very weak  $\pi$  bond). This surface is formed on heating in an ultra high vacuum (UHV); because of the weakness of the  $\pi$  bond, the  $2 \times 1$  (100)  $\text{Si}_2$  reacts almost immediately with air.<sup>[28]</sup>

#### Hydrogen-terminated surfaces—the search of environmentally stable surfaces

The common belief that defect-free hydrogen-terminated silicon would be indefinitely stable (on the laboratory time scale) in air at room temperature, explains why several methods for the hydrogen termination of (100) silicon have been developed. They include both wet and dry processes:

- the wet etch with  $\text{HF}_{\text{aq}}$  under special  $p\text{H}$  conditions of a sacrificial, thermally grown oxide;
- a two-step process, involving (i) the demolition of the native oxide by heating (at  $T > 850^\circ\text{C}$ ) under UHV with the formation of a clean  $2 \times 1$ -reconstructed surface; and (ii) the subsequent exposure to controlled amounts of atomic hydrogen H;
- the exposure of the native surface to  $\text{H}_2$  at sub-atmospheric pressure (typically in the range  $10^2$ – $10^3$  Pa) and high temperature (typically 800–1100°C).

Hydrogen-terminated surfaces can greatly differ according to the preparation procedure:

**The surface resulting after aqueous HF etching of sacrificially grown  $\text{SiO}_2$ .** The dipping of the native or thermally grown oxide in  $\text{HF}_{\text{aq}}$  results typically in a rough and heterogeneous surface. The quality of the surface is controlled by the  $p\text{H}$  of the etching solution (in turn controlled by  $\text{HF}_{\text{aq}}$  dilution and the presence of

buffering species such as  $\text{NH}_4\text{F}$  or of acids such as HCl), the amount of dissolved  $\text{O}_2$  in the water, and the duration of rinsing. Nonetheless, the following features are usually observed quite irrespective of these details. The (100) surface resulting after  $\text{HF}_{\text{aq}}$  etch displays  $1 \times 1$  reconstruction, and is characterized by a heterogeneous distribution of  $\text{SiH}_3$ ,  $\text{SiH}_2$  (prevalently), and SiH terminations.<sup>[29,30]</sup> Inspected by scanning tunneling microscopy,  $\text{HF}_{\text{aq}}$ -etched surfaces usually display no evidence for regularity; images with atomic resolution, giving evidence for  $1 \times 1$  symmetry, have been obtained only using as etchant a very acidic solution ( $\text{HF}:\text{HCl} = 1:19$ ,  $p\text{H} < 1$ ).<sup>[31]</sup> Almost ideal hydrogen termination of the (111) surface is instead obtained after etching in an HF aqueous solution buffered with  $\text{NH}_4\text{F}$  or  $\text{NH}_3$  at  $p\text{H} > 5$ .<sup>[32]</sup>

Understanding why the silicon surface after etching in  $\text{HF}_{\text{aq}}$  has prevailing hydrogen, rather than fluorine, termination is not trivial, especially in view of the fact that silicon and fluorine combine to form one of the most stable bonds. The first explanation of this fact was given by Ubara, Imura, and Hiraki in terms of polarization of Si–Si backbonds to Si–F bonds. Assuming that the strength of the Si–F bond derives from an electrostatic reinforcement because of electron transfer from silicon to fluorine, the ionicity of the Si–F bond polarizes the Si–Si backbonds, which allows an easy insertion of HF into the weakened Si–SiF bond. If this bond is cleaved with the addition of fluorine to the SiF site and of hydrogen to the other silicon atom, the ionicity is increased and so is the polarization of the residual backbonds. Reiterating this argument, one obtains that the formation of a  $\text{SiF}_n$  moiety becomes easier the higher is  $n$ , and that the process is concluded with the formation of a volatile molecule,  $\text{SiF}_4$ , and of hydrogen terminations at the silicon surface.<sup>[33]</sup>

This scheme was investigated quantum mechanically on model molecules (such as  $\text{H}_3\text{Si-SiH}_2\text{F}$  or  $\text{H}_3\text{SiF}$ ) by Trucks et al. They showed that the activation energy of the process leading to two fluorine atoms attached to the same silicon atom is 1.0 eV, while the transferring of fluorine to the adjacent silicon atom needs an activation energy of 1.4 eV. Then, the latter process is not favored and the reiterated addition of fluorine on the same SiF site is confirmed. Moreover, they showed that the Si–H bond is spontaneously destroyed by reaction with HF (the reaction being exothermic by 1.3 eV), but an activation energy of 1.2 eV was calculated for this process. The difference between the activation energy for the destruction of the Si–H bond (1.2 eV) and that for the attachment of another fluorine atom to fluorinated silicon (1.0 eV) is of 0.2 eV. Although small, it is sufficient to make the time constant of the former reaction four orders of magnitude higher than that of latter reaction.<sup>[34]</sup> These

calculations support therefore the opinion, first formulated by Ubara, Imura, and Hiraki that the formation of hydrogen-terminated surfaces is kinetically, rather than thermodynamically, controlled.

The assumption that undissociated HF is the etching agent is, however, contradicted by the following facts:

1. In diluted aqueous solution, HF is completely dissociated,

Its behavior as a weak acid is a result of the reduction of the  $\text{H}_3\text{O}^+$  activity resulting from tight ion pairing  $\text{H}_3\text{O}^+\cdots\text{F}^-$  between the oxonium and fluoride ions (Ref.<sup>[35]</sup>, Chapter 3).

2. In concentrated aqueous solution, the  $\text{H}_3\text{O}^+$  activity is increased because of the formation of the hydrogen-bonded adduct  $\text{F}^-\cdots\text{HF}$  via the equilibrium

The concentrated aqueous solution does therefore contain undissociated HF, but its binding energy to  $\text{F}^-$  is so high ( $E_b[\text{F}\cdots\text{HF}] = 2.2\text{ eV}$ ; Ref.<sup>[36]</sup>, p. 76) that the adduct  $\text{F}^-\cdots\text{HF}$  is considered a well-defined ion  $\text{HF}_2^-$  (Ref.<sup>[35]</sup>, Chapter 3).

3. In gas phase (where the etching species is undissociated HF), the attack results mainly in fluorine-terminated silicon surfaces.<sup>[37]</sup>

Following the criticism of Ref.<sup>[38]</sup> and using the results of high-level quantum mechanical calculations of the stability of the Si–Si bond in relation to its terminations, Cerofolini thus proposed an ionic route able to account for the observed hydrogen termination resulting after attack by HF-concentrated aqueous solution to thermally oxidized silicon.<sup>[39]</sup> The route is constituted by three cycles each composed by four consecutive steps, the rate-determining one being  $\text{F}^-$  transfer from the etching solution to the coma of  $\text{SiF}_n$  termination.<sup>[40]</sup>

**Hydrogen-terminated silicon via exposure to atomic hydrogen.** The exposure of  $2 \times 1$  (100)  $\text{Si}_2$  to a few langmuirs of atomic hydrogen results in nearly homogeneous surfaces. The obtained surface phase depends on the silicon temperature:<sup>[28]</sup>

- the  $1 \times 1$  dihydride phase,  $1 \times 1$  (100) $\text{SiH}_2$ , is produced at 300 K;

- the  $3 \times 1$  mixed monohydride–dihydride phase,  $3 \times 1$  (100) $\text{SiH}_2(\text{SiH})_2$ , is produced at 400 K; and
- the  $2 \times 1$  monohydride phase,  $2 \times 1$  (100) $(\text{SiH})_2$ , is produced at 600 K.

**Hydrogen-terminated silicon via exposure to molecular hydrogen.** Homogeneously hydrogen-terminated silicon is also obtained after exposing the  $\text{HF}_{\text{aq}}$  etched surface to  $\text{H}_2$  at sub-atmospheric pressure in the temperature interval 800–1100°C. According to the operative conditions, this process results in  $2 \times 1$  (100) $(\text{SiH})_2$ <sup>[29,41]</sup> or  $1 \times 1$  (100) $\text{SiH}_2$ .<sup>[42]</sup> The conditions that allow one phase to prevail on the other are not clear yet.

**The evolution in air of hydrogen-terminated silicon.** As already mentioned, an ideally hydrogen-terminated surface is presumed to be indefinitely stable (on the laboratory time scale) in air. The (100) surface resulting after  $\text{HF}_{\text{aq}}$  etching of the overlying oxide, however, not only is formed by a heterogeneous family of mono-, di- and tri-hydride species, but also contains silicon–oxygen centers, their amount depending on the preparation.<sup>[24]</sup> Such oxygen-containing centers are responsible for the environmental instability of these surfaces via the oxidation of the backbonds to Si–O bonds; this process, initiated at oxygen defects and mediated by adsorbed water, proceeds with the growth of an oxide cluster, and is eventually responsible for surface roughening.<sup>[24]</sup>

A microscopic model was proposed by Cerofolini and co-workers in a series of papers in terms of tunneling either of a proton from adsorbed water<sup>[43,44]</sup> or of an electron to adsorbed oxygen.<sup>[45]</sup>

### Halogen-terminated surfaces

The great environmental stability of the Si–H bond is guaranteed more by its modest polarization than by its strength. For instance, the Si–H bond dissociation energy in  $\text{H}_3\text{SiH}$  is  $92\text{ kcal mol}^{-1}$  vs. a Si–F bond dissociation energy of  $157\text{ kcal mol}^{-1}$  in  $\text{H}_3\text{SiF}$  and a Si–Cl bond dissociation energy of  $109\text{ kcal mol}^{-1}$  in  $\text{H}_3\text{SiCl}$ . The Si–H bond dissociation energy is, however, nearly the same as the Si–Br one ( $90\text{ kcal mol}^{-1}$  in  $\text{H}_3\text{SiBr}$ ) and appreciably larger than Si–I one ( $71\text{ kcal mol}^{-1}$  in  $\text{H}_3\text{SiI}$ ).<sup>[16]</sup> The relatively large polarization and length and the weak dissociation energy of the Si–I bond make this an interesting site for the functionalization of the silicon surface.

Halogen-terminated surfaces are prepared by high-temperature treatment of hydrogen-terminated surfaces with the corresponding halogen:

## The Surface of Polycrystalline Silicon

With “poly-silicon,” one intends a variety of materials, typically in the form of ingots, tiles, or films.

*Poly-silicon ingots* are produced via pyrolytic decomposition of  $\text{SiHCl}_3$ ; this material is used (after crushing, melting, and crystallization) as intermediate for the growth in Czochralski pullers of single-crystalline ingots.

*Poly-silicon tiles* are produced by melting in Bridgman furnaces the scraps remaining when the single crystalline ingots are sliced for wafer production. The poly-crystalline silicon grown by the Bridgman technique is formed by large grains (with diameter in the 1–10 cm length scale) and is one of the main materials for photovoltaic applications.

*Poly-silicon films* for microelectronics are generally produced via chemical vapor deposition from  $\text{SiH}_4$ . The typical thickness of these films is in the interval 0.1–1  $\mu\text{m}$ . The large interest of poly-silicon films in nanoelectronics is determined by the fact that in the crossbar structure at least one (but most likely two) wire arrays are formed by poly-silicon. The average grain diameter in poly-silicon films depends on the growth temperature and ranges from the nanometer length scale (for low-temperature deposition, say  $<600^\circ\text{C}$ ) to the whole film thickness (for high-temperature deposition, say  $>800^\circ\text{C}$ ); the grain diameter increases after heat treatments. After sufficiently strong heat treatments, all grains are prevalingly defined by (111) surfaces so that the functionalization of the film surface can be carried out in the same way as for the (111) surface.

## The “Surface” of Porous Silicon

Porous silicon (*por-Si*) is a sponge-like system obtained by dissolution of crystalline silicon on anodization in a solution containing  $\text{HF}$ .<sup>[46–48]</sup> Its internal area can be from  $10^2$  to  $10^3$  times its macroscopic geometrical area.<sup>[49]</sup> Pore diameter, porosity, and porous layer thickness depend sensitively on the electrolyte composition, bulk silicon resistivity, anodization current density, reaction time, and temperature. *Por-Si* is known to be hydrogen-terminated, with spectroscopic evidence<sup>[50]</sup> for  $\text{SiH}_3$ ,  $\text{SiH}_2$ ,  $(\text{SiH})_2$  groups, thus being viewed as a mixture of hydrogenated  $2 \times 1$  (1 0 0)Si and  $1 \times 1$  (1 0 0)Si. Because of its room-temperature photoluminescence,<sup>[51]</sup> *por-Si* attracted the interest of the scientific community as a light emitting material to be used in optoelectronic and photovoltaic devices.<sup>[52,53]</sup> However, owing to its compatibility with the existing silicon-processing technology,<sup>[54]</sup> *por-Si* has also found extensive applications in several other fields, from biorecognition<sup>[55]</sup> to prosthetic systems<sup>[56]</sup>

and chemical sensing.<sup>[57]</sup> Whatever the application is, the surface termination plays a crucial role: partial hydroxylation is known to completely suppress *por-Si* photoluminescence,<sup>[58]</sup> while even mild chemical environments (e.g. aqueous solutions at physiological pH) can quickly etch away its surface. Grafted organic functionalities may impart specific tunable properties.

## SILICON DERIVATIZATION

Silicon can be derivatized both via gas-phase chemistry and via wet chemistry.

### Gas-Phase Processing

The most spectacular results come from experiments carried out exposing in UHV the extremely reactive  $2 \times 1$  (100)  $\text{Si}_2$  to an atmosphere of unsaturated species. The extremely weak  $\pi$  bond of the  $2 \times 1$  (100)  $\text{Si}_2$  dimer reacts at room or even lower temperature with the  $\pi$  bond of the organic molecule via cycloaddition (e.g.,  $2 + 2$  or  $2 + 4$ ) forming superficial heterocycles:<sup>[59]</sup>

[4+2] cycloaddition

[2+2] cycloaddition

The practical exploitation of this elegant route meets, however, serious difficulties: In fact, not only does it require ultra high vacua to preserve the highly reactive silicon dimer (that might not be a technological barrier), but also can be applied for volatile reagents only. This second constraint is almost fatal for practical applications because none of the molecules that have been demonstrated as able to impart interesting electronic properties to silicon is volatile. This difficulty suggests focusing the attention on wet chemistry.

## Wet Processing

There is not yet a uniformly accepted classification of organosilicon reactions. A non-exhaustive list includes alkyl/arylation, oxoalkylation, and silanization. Detailed information of the chemistry involved in the organic functionalization of silicon is given in Ref.<sup>[60]</sup>.

### Alkyl/arylation

This reaction includes a large variety of processes and may be carried out exploiting different surface terminations, such as

- halogen-<sup>[61,62]</sup> or hydrogen-terminated<sup>[63,64]</sup> surfaces through organometallic (Grignard or organolithium) reagents,
- hydrogen-terminated surfaces through anodization in Grignard electrolytes,<sup>[65]</sup>
- hydrogen-terminated surfaces through cathodic electrografting of alkynes,<sup>[66]</sup>
- hydrogen-terminated surface through self-<sup>[67]</sup> or electrochemically activated<sup>[68]</sup> diazonium salts and
- hydrogen-terminated surfaces via hydrosilation of unsaturated molecules; this process may occur via one of the following methods:
  - mediated by a metal complex;<sup>[69–72]</sup>
  - initiated by radicals;<sup>[73]</sup>
  - photoexcitation under ultraviolet<sup>[74–76]</sup> or white light<sup>[77,78]</sup> illumination;
  - via anodic electrografting;<sup>[66]</sup>
  - under thermal<sup>[80–85]</sup> or microwave<sup>[79]</sup> excitation.

In most cases, hydrosilation has been demonstrated to occur not only with terminal alkenes and alkynes<sup>[80–83]</sup> but also with aldehydes<sup>[84]</sup> and alcohols.<sup>[85]</sup>

### Oxoalkylation

The oxoalkylation is a well-known process for the functionalization of silica surfaces. For silicon, it can be carried out at

- hydrogen-terminated surfaces through condensation of molecular reactants containing alcoholic groups,<sup>[86]</sup>
- halogen-terminated surface through condensation of alcohols<sup>[87]</sup> or primary amines.<sup>[88]</sup>

### Silanization

Silanization involves the derivation of silicon surface by means of organic groups bonded to chlorosilanes,

alkoxysilanes, or azanes. This reaction has been demonstrated to occur at

- hydroxyl-terminated surfaces<sup>[89,90]</sup> and hydrogen-terminated surfaces<sup>[91]</sup> through reaction with chlorosilanes and elimination of HCl,
- hydroxyl-terminated surfaces<sup>[92]</sup> through reaction with alkoxysilanes and elimination of alcohols, and
- hydrogen-terminated surfaces via reaction with azanes and elimination of NH<sub>3</sub>.<sup>[91]</sup>

## Integration Issues

If the attention is concentrated on the possibility of integrating the derivatization in the back-end stage of integrated circuit processes, one must consider the following constraints:

1. absence of aggressive reaction products (like HCl or HBF<sub>4</sub>),
2. occurrence even in recessed regions (where illumination and electrical bias are impossible),
3. absence of any species (like transition metals, LiCl or MgCl<sub>2</sub>) that may contaminate the silicon circuitry,
4. environmental stability (and thus absence of oxo bridges linking the organic moiety to the silicon),
5. poor dependence of the process on surface orientation and reconstruction.

The combination of all these factors leads to identify the thermally assisted hydrosilation at hydrogen-terminated surfaces of functional molecules with unsaturated terminal(s) as the candidate process for silicon functionalization.

## Hydrosilation

Hydrosilation is a reaction involving hydrogen shift from silicon to a carbon atom involved in the bond and bond formation between the silicon atom and the other carbon atom (Fig. 1). If the number  $n$  of carbon atoms in the alkane chain is small (say,  $n < 8$ ), the alkene hydrosilation occurs only in the presence of a catalyst (e.g., H<sub>2</sub>PtCl<sub>6</sub>) or after activation (radical formation); for long chains (say,  $n > 8$ ), the reaction occurs spontaneously at a temperature of about 200°C.<sup>[93]</sup>

Since hydrosilation involves only one silicon atom, it was mainly studied on the 1 × 1 (111) SiH and only few works have been devoted to study alkene hydrosilation on 1 × 1 (100)H SiH<sub>2</sub>. The hydrosilation of 1-alkenes at 1 × 1(100) SiH<sub>2</sub> is expected to occur according to pathways (I') or (I''), as shown in Fig. 1.

**Fig. 1** Hydrosilylation of 1-alkene [pathway (I)] and 1-alkyne [pathway (II)] at the hydrogen-terminated,  $1 \times 1$ -reconstructed, (100)-oriented, silicon surface; R denotes a suitably terminated alkane chain.

Although the reactivity of 1-alkynes is similar to that of 1-alkenes, there is, however, an important difference: after the first addition (II), the formed species,  $2'$  and  $2''$  contain a double bond in the vicinity of another hydrogen termination of silicon, so that the reaction can, in principle, proceed, via (III) or (IV), with the formation of the species  $3$  or  $4$ . Understanding the nature of the interfacial species is not without interest: for instance, if the reaction stopped after (II), the silicon surface would be equipped with a second reactive group (the C=C group) in addition to the one, if any, carried by R. The persistence of a  $\pi$  bond at the silicon-organic interface might be useful not to destroy the complete  $\pi$  conjugation of  $\pi$ -conjugated molecules grafted to the silicon surface.

# Silicon Nanoclusters: Simulations

Aaron Puzder

Lawrence Livermore National Laboratory, Livermore, California, U.S.A.

## INTRODUCTION

The field of research surrounding the optical properties of semiconductor nanoclusters has seen enormous growth over the past decade.<sup>[1–7]</sup> As the dimensions of a semiconductor are reduced below its exciton Bohr radius, quantum confinement causes its bandgap to widen, the electronic states to become discrete, and the oscillator strength of the smallest electronic transitions to increase.<sup>[8,9]</sup> In direct gap II/VI semiconductors such as CdSe, several experiments have reproduced the one-to-one correspondence between the size and the wavelength of absorbed and emitted visible light.<sup>[4,10,11]</sup> The reproducibility and generally straightforward synthesis techniques have made CdSe the cornerstone of emerging technologies such as biological markers<sup>[6,7]</sup> and nanostructure lasers.<sup>[12]</sup> Other semiconductor nanoclusters, specifically those in group IV, are also known to absorb and emit visible light when their size is reduced to the nanometer scale.<sup>[2,5,13–15]</sup> The efficient photoluminescence (PL) observed in porous silicon<sup>[2]</sup> and in freestanding silicon nanoclusters<sup>[5,13,14]</sup> suggests that these structures may serve as an alternative for CdSe in certain applications. One benefit of exploiting the optical properties of silicon nanoclusters is its potential to be integrated within existing silicon technologies to create nanoscale optoelectronic devices. Additionally, the biocompatibility of silicon makes it an ideal candidate for replacing fluorescent dyes as biotags.

Despite the efforts being placed on synthesizing and characterizing silicon nanoclusters, the size dependence of the optical gap has, so far, been difficult to reproduce experimentally. As the physical properties of a material are strongly governed by the surface at the nanometer scale (where surface-to-volume ratios are greatly increased), the interplay of quantum confinement and surface properties is still unclear. Few surface-sensitive probes are available, and distinguishing bulk effects from surface effects is difficult. Theoretical modeling<sup>[16–21]</sup> is challenging within this size regime as a full quantum mechanical description of both the core and the surface atoms are required to provide accurate and predictive data. Developing a thorough understanding of the electronic and optical properties of silicon nanoclusters, in particular

the effect of the surface on their optical properties, is a crucial step toward the utilization of these particles for new technologies. Therefore, theoretical predictions are required to improve our understanding of the influence of the surface on the properties of silicon nanostructures.

The school of thought advocating quantum confinement as the *only* mechanism responsible for PL in silicon would suggest that, regardless of the specific surface chemistry, the same results should be observed as long as all the surface dangling bonds are saturated.<sup>[22–24]</sup> However, recent studies have shown that the surface can affect the optical properties of silicon.<sup>[25–29]</sup> The combination of different passivating surfaces, contaminant atoms, and surface reconstructions are often responsible for disagreement among different experiments and among theories in characterizing the gap dependence on size.

## BACKGROUND

Taking into account the difference between absorption and emission further contributes to experimental and theoretical discrepancies. Experiments generally measure the PL, i.e., the emitted light, whereas theory generally calculates an absorption spectrum, or the lowest absorption gap. In CdSe, this difference between absorption and emission has been attributed to a “dark exciton,”<sup>[30]</sup> a state with zero oscillator strength which will not absorb, but may emit a photon. In silicon, this difference may be due to structural relaxation of the cluster while in its excited state.<sup>[31–38]</sup> Although opinion is divided, evidence exists that this difference can vary by 0.5–1 eV depending on the size of the cluster and the local surface.<sup>[34–38]</sup>

In this entry, we present ab initio calculations of a number of hydrogen-passivated silicon nanoclusters with diameters of up to 2 nm. In our calculations, we replaced one or more of the hydrogen atoms with a number of different passivants including oxygen, sulfur, CH<sub>2</sub>, fluorine, chlorine, and a hydroxyl group (OH). We also reconstructed the silicon surfaces, forming either reconstructed dimers or reconstructed steps. We found that any passivant or reconstruction that distorts the tetrahedral  $sp^3$  network significantly

reduces the gap compared to that of a completely hydrogenated cluster. We found that more than one of these passivants on a single cluster reduces the gap even further, allowing a wide range of gaps to be observed. Conversely, we show that single-bonded passivants have a minimal effect on the optical gap. Finally, we calculated the Stokes shift of different structures by relaxing each cluster in its excited state. Depending on the size and surface, we find that this difference can be as large as 1.2 eV. These results may provide an explanation for the discrepancies found among various experiments with each other<sup>[5,13,22–25,39,40]</sup> and with theory.<sup>[16,17,20,21]</sup>

The rest of this entry is organized as follows: the section “Computational Methods” discusses the theoretical methods we used to perform our calculations, “Effect of Different Surface Passivation” discusses the effect of different surface passivants on silicon nanoclusters, “Surface Reconstructions” discusses the effect of surface reconstructions on silicon nanoclusters, “Emission Gaps Via the Stokes Shift” shows how absorption and emission may generate different results in silicon nanoclusters, and finally the last section offers some concluding remarks.

## COMPUTATIONAL METHODS

Ab initio calculations, capable of covering a range of silicon nanoclusters up to 2 nm in diameter, were performed by using density functional theory (DFT) and quantum Monte Carlo (QMC). Our DFT calculations are based on the local density approximation (LDA) using the Ceperley–Alder exchange–correlation functional and potential<sup>[41]</sup> and the generalized gradient approximation (GGA) using the Perdew–Burke–Ernzerhof (PBE) functional.<sup>[42]</sup> We employed a pseudopotential plane wave approach<sup>[43]</sup> with periodic boundary conditions applied to a supercell having a large enough spacing so that no interactions existed between the periodic replicas. All the clusters were placed in a box with enough vacuum region between clusters for the total charge density to approach zero ( $<10^{-7}$ ) well before the supercell edge. The interactions between the ionic cores and the valence electrons are described by a fully norm conserving, non-local pseudopotential of the Hamann type,<sup>[44]</sup> except for hydrogen in which we used a pseudopotential of the Giannozzi type.<sup>[45]</sup> The Kohn–Sham orbitals are expanded in a plane wave basis set,  $\psi(\mathbf{r}) = \sum_{\mathbf{G}} C_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}}$ , where  $C_{\mathbf{G}}$  is the Fourier coefficient,  $\mathbf{G}$  is a three-dimensional reciprocal lattice vector, and  $\mathbf{r}$  is the three-dimensional coordinates in real space. The kinetic energy cutoff used is at least 35 Ry corresponding to about  $10^5$  plane waves in a cell of 41–46 a.u. per side. We found

that a higher cutoff (up to 70 Ry) had a negligible effect (less than 0.3% in all cases) on the difference between eigenvalues of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), i.e., the single-particle gap as defined within DFT.

All silicon clusters were initially constructed on a diamond structure lattice with bulk silicon–silicon bond lengths. Dangling bonds were passivated with hydrogen placed along the appropriate tetrahedral direction at the experimental silicon–hydrogen distance in SiH<sub>4</sub>. The structures were then relaxed to zero temperature by using molecular dynamics simulations, with the ions treated classically and the electrons quantum mechanically, until the correct ground state structure was reached. In every case, each atom was relaxed until the residual forces on all atoms were less than  $2 \times 10^{-4}$  eV/Å. GGA calculations on a number of representative clusters, including full geometry reoptimization, tested the effect of gradient corrections in the exchange–correlation potential. Despite slight changes to the structure (e.g., 1.6% longer silicon–silicon bond lengths), the single-particle gaps agree to within 0.05 eV with LDA gaps for all cases tested. Nanoclusters with reconstructed surfaces were generated by first removing a hydrogen atom from each of any neighboring pairs of SiH<sub>2</sub> groups, forming an additional Si–Si bond (dimers). Second, clusters large enough to support a single dihydride bonding with a step ( $\geq 1.8$  nm) were constructed, further reducing the hydrogen coverage of the surface.

Although the LDA HOMO/LUMO gap was shown to qualitatively reproduce the trends of the optical gap, a proper treatment of the self-energy and the exciton binding energy (Coulomb interaction between the excited electron and its resulting hole) requires a more accurate tool to quantitatively calculate optical gaps. For this purpose, we adopted the fixed node, diffusion quantum Monte Carlo (DMC) method,<sup>[46–48]</sup> in which one solves the many-particle, imaginary time Schrödinger equation  $-\partial_{\tau}\Phi(\mathbf{R},\tau) = (\hat{H} - E_{\text{T}})\Phi(\mathbf{R},\tau)$ , where  $\tau$  is imaginary time,  $\mathbf{R} = (r_1, r_2, \dots, r_N)$  is a configuration of electron coordinates in real space,  $\hat{H}$  is the many-body Hamiltonian of the system, and  $E_{\text{T}}$  is a trial energy. Representing the Schrödinger equation in this form allows it to be stochastically sampled when recast in integral form. The true ground state wavefunction is then projected out from a suitably chosen trial wavefunction. Our trial wavefunctions are of the Slater–Jastrow form with one-, two-, and three-body terms expanded as Chebyshev polynomials,<sup>[49]</sup>

$$\Psi = D^{\dagger} D^{\downarrow} \exp \left[ \sum_i^N \chi(r_i) + \sum_{i<j}^N u(r_i, r_j, r_{ij}) \right] \quad (1)$$

We use the recently implemented linear scaling QMC approach<sup>[48]</sup> which constructs the Slater determinants,  $D^\dagger$  and  $D_1$ , from a set of maximally localized Wannier functions.<sup>[50]</sup> The one-body,  $\chi$ , and two- and three-body Jastrow  $u$  functions contain 18–40 variational parameters which are optimized by using the variance minimization approach.<sup>[51]</sup>

Within the QMC approach, the optical gap is defined as  $E^{\text{opt}} = E_N^* - E_N$ , where  $E_N$  is the ground state total energy of the system with  $N$  electrons filling all the occupied states and  $E_N^*$  is the total energy of the system in an excited state. Both the excited electron and the resulting hole introduced into the valence band are present in the system at the same time by exciting an electron from an occupied (valence) orbital to an unoccupied (conduction) orbital. As QMC is a full many-body formalism, gaps calculated within QMC do not suffer from the LDA “band gap problem,” even if the nodal structure for the QMC wavefunction is constructed from LDA orbitals.

The Stokes shift calculations were carried out by considering Frank–Condon-like relaxations for a number of different structures. On absorption of a photon, a cluster undergoes a vertical electronic excitation (Fig. 1). During the excitation, the atoms are instantaneously frozen in their ground state positions. Once in the excited electronic state, the atomic geometry of the cluster relaxes to a lower energy configuration (point 3 in Fig. 1), as the electronic excitation of the cluster has generated new forces on the atoms.<sup>[34,36]</sup>

**Fig. 1** Energy states involved in the transitions leading to the Stokes shift. Point 1 is the relaxed ground state structure, point 2 is the forced excited state in the ground state structure, point 3 is the relaxed excited state, and point 4 is the ground state in the excited state relaxed structure. The Stokes shift has been calculated by either a difference between total energies  $(E_2 - E_1) - (E_3 - E_4)$  or the single-particle (optical) gap of the structure in state  $E_1$  and  $E_4$  in LDA (QMC).

We calculated the Stokes shift by performing this relaxation within LDA, i.e.,  $E^{\text{Stokes}} = (E_2 - E_1) - (E_3 - E_4)$ , where  $E_{1-4}$  are the total energies at each of the points in Fig. 1. Within QMC, the Stokes shift was calculated as the difference in the gaps of each configuration. A full detailed description of this method is given in Ref.<sup>[37]</sup>.

## EFFECT OF DIFFERENT SURFACE PASSIVATION

### One Impurity Atom

The effect of different passivants on hydrogenated silicon nanoclusters was initially studied within the LDA on  $\text{Si}_{35}\text{H}_{36}$  clusters (diameter 1.1 nm). Keeping the entire cluster intact, we replaced a single hydrogen with the highly electronegative fluorine atom, which is present in hydrogen fluoride (HF), commonly used for etching porous silicon. Other highly electronegative species, such as chlorine and an OH group, were also considered. In addition to having similar properties to fluorine, chlorine is used often as a precursor in colloidal synthesis of silicon nanoparticles, while OH is a possible passivant of nanoclusters synthesized in a peroxide solution. Fig. 2A shows the density of states (DOS) of each of these systems. The DOS profiles for the clusters with single-bonded passivants (H, F, Cl, OH) are virtually identical, indicating that most single-bonded passivants are likely to generate similar single-particle gaps, regardless of their electronegativity

**Fig. 2** Local density approximation calculation of the electron density of states and single-particle gaps of 1.1-nm hydrogenated silicon clusters with A) single-bonded and B) double-bonded passivants. Each curve is Lorentzian broadened by 0.06 eV. The fully hydrogenated (idealized) case is given in the top center.

or individual atomic levels. As shown in Fig. 3A, the probability density of the HOMO and the LUMO of  $\text{Si}_{35}\text{H}_{36}$  are both confined to the core of the cluster. This confinement is similar to that seen in clusters with single-bonded passivants. Using chlorine as an example (Fig. 3B), the HOMO and LUMO densities are only slightly altered with respect to the fully hydrogenated cluster, as the majority of the HOMO and LUMO density remains core-confined.

The second set of passivants considered here are those forming a double bond with a surface silicon atom. In addition to the common contaminant oxygen, we considered sulfur and  $\text{CH}_2$ . The effects of the double-bonded passivants on the HOMO/LUMO gap are profound (Fig. 2B), with the LDA gap decreasing from the completely hydrogenated case by an amount ranging from 0.9 eV (when  $\text{CH}_2$  is added) to 1.6 eV (when sulfur is added). These results offer an explanation of the discrepancies observed in the measured values of the optical gap in silicon nanoclusters. In experiments performed in the presence of oxygen,<sup>[5,22–25]</sup> the actual transition may involve localized oxygen states. Fig. 3C shows that these states in  $\text{Si}_{35}\text{H}_{34}\text{O}$  are indeed localized around the double bond, with little of the core confinement seen in the  $\text{Si}_{35}\text{H}_{35}\text{Cl}$

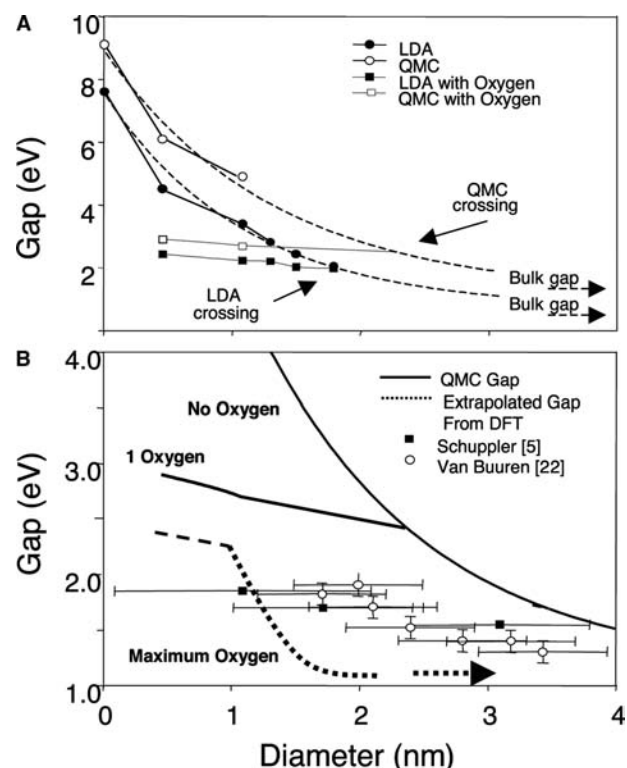

**Fig. 3** The density of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) for A)  $\text{Si}_{35}\text{H}_{36}$ , B)  $\text{Si}_{35}\text{H}_{35}\text{Cl}$ , and C)  $\text{Si}_{35}\text{H}_{34}\text{O}$ . The isosurfaces are plotted at 50% the maximum value for A) and B), and at 10% the maximum value for C). In the ball and stick representation, Si is gray, H is white, and O (Cl) is red (pink).

cluster. This localization suggests that these states might be pinned at a fixed energy determined by the oxygen atom and relatively independent of the size of the cluster.

### Size Dependence of the Effects of Oxygen Passivation

The size dependence of the effect of oxygen passivation on the optical properties of hydrogenated silicon nanoclusters was carried out in silicon clusters with a single oxygen atom, double-bonded to the surface. Fig. 4A shows the values of the LDA HOMO–LUMO gap (solid circles and squares) for these clusters, as well as those with pure hydrogen termination as a function of the diameter,  $D = a(3/4\pi N)^{1/3}$ , where  $N$  is the number of silicon atoms and  $a$  is the lattice constant. In clusters without oxygen contamination, the gap

**Fig. 4** A) Local density approximation (LDA) and quantum Monte Carlo (QMC) calculations of the single-particle and optical gaps of hydrogenated Si clusters with and without oxygen as a function of size. The curves are fit to the points and the bulk value, and have been extrapolated to estimate the crossing point beyond which the “oxygen gap” will no longer be observed. B) Comparison of QMC predictions of the optical gap of silicon clusters with and without oxygen to experimental results. The maximum oxygen curve is extrapolated by shifting the LDA calculated curve by an amount equal to the QMC shift in a single oxygen-contaminated cluster.

increases as the size of the cluster decreases, thus demonstrating quantum confinement effects. In clusters with an oxygen contaminant, the “oxygen gap” is smaller than the gap of the purely hydrogenated clusters for clusters smaller than 1.8 nm. As the cluster size increases beyond this critical 1.8-nm diameter, the fundamental HOMO/LUMO gap of pure hydrogenated silicon nanoclusters decreases below this “oxygen gap” and the lowest gap is governed by the core transitions.

Quantum Monte Carlo calculations on several clusters terminated completely with hydrogen, and those including a double-bonded oxygen verify that the LDA trends are well reproduced by QMC (Fig. 4A). The shift in the gap from LDA to QMC in totally hydrogenated clusters is much greater (around 1.5 eV) than in those with oxygen contamination (around 0.6 eV). We believe that the difference in shifts originates from the larger excitonic binding in the oxygen-contaminated clusters, where the oxygen-derived HOMO and LUMO states are more localized than in the absence of such contaminants. Extrapolation of our QMC calculations (dashed line in Fig. 4A) suggests that the critical size beyond which the “oxygen gap” will no longer be observed is between 2 and 2.5 nm, larger than the 1.8 nm size predicted by LDA, yet smaller than the 3.0 nm predicted by empirical tight-binding calculations.<sup>[25]</sup>

### Effect of Multiple Oxygen Termination

In Fig. 4B, we compare our QMC predictions for the optical gap of silicon nanoclusters with two experiments in which oxygen was present. The optical gap predicted by our QMC calculations for clusters passivated with a single oxygen double-bonded to the surface is too large compared with this experimental data.<sup>[5,22]</sup> In addition to the problem of wide experimental size distribution, the effect of multiple oxygen passivation should be considered. The strain introduced by the presence of a single oxygen passivant will not necessarily deter the bonding of additional oxygen passivants, which may also affect the gap. In fact, if the chemical potentials of hydrogen and oxygen is such that it is favorable to replace two surface hydrogen atoms with an oxygen, the oxygenation reaction is likely to continue.<sup>[28]</sup> By shifting our QMC-predicted optical gaps according to the effects of multiple oxygen passivation predicted within LDA, we compare these predictions with the aforementioned experiments (Fig. 4B). The wide range of possible gaps that may be obtained when oxygen contaminates the surface can perhaps explain the wide discrepancy between so many experiments, in which either oxygen was present or the impurities were unknown.

## DISCUSSION

The gaps of silicon clusters containing fluorine, chlorine, and OH indicate that the electronegativity of a passivant does not play a key role in altering the gap. That OH does not alter the gap indicates that lone pair states are not responsible for the reduction observed by the presence of oxygen. This conclusion is further supported by the results obtained for clusters passivated with CH<sub>2</sub>, which has no lone pair when double-bonded to the cluster, yet closes the gap significantly more than all the single-bonded passivants. The presence of a double bond induces a considerable distortion of the tetrahedral *sp*<sup>3</sup> network on the surface and this distortion is possibly responsible for a gap reduction. To support this conclusion, we considered oxygen-bonded in different geometries. In addition to replacing two hydrogen atoms from an SiH<sub>2</sub> surface group to form an Si=O double bond, oxygen may also bond with the surface of a silicon nanocluster in a bridged (Si–O–Si) network, replacing two hydrogen atoms from two separate Si atoms.

Two different silicon nanoclusters were compared, both with a diameter of ≈1 nm (Si<sub>29</sub>H<sub>36</sub> and Si<sub>35</sub>H<sub>36</sub>). In Si<sub>29</sub>H<sub>36</sub>, the proximity of SiH<sub>2</sub> pairs on a (100)-like facet allows oxygen to replace two hydrogens (Si<sub>29</sub>H<sub>34</sub>O) from adjacent SiH<sub>2</sub> groups and to form a bridged bond without significantly distorting the *sp*<sup>3</sup> network. The bond angle between any of the atoms bonded to the silicon and the oxygen is altered by no more than 2° from the initial tetrahedral bonding angle. The resulting LDA single-particle gap is only 0.5 eV lower than the LDA gap in Si<sub>29</sub>H<sub>36</sub> and the QMC gap is also only 0.5 eV lower than the Si<sub>29</sub>H<sub>36</sub> QMC gap. The shift from LDA to QMC is therefore 1.5 eV and *not* 0.6 eV as in the cluster with a double-bonded oxygen. In Si<sub>35</sub>H<sub>34</sub>O, no such aligned dihydrides exists, and so forming an Si–O–Si bridge significantly alters the ideal bond network, with the resulting bond angles distorted by more than 30° from the original *sp*<sup>3</sup> structure. This distortion causes a gap reduction by a significantly greater amount than that of the hydrogenated cluster, over 1 eV in LDA and almost 3 eV in QMC. Therefore any passivation process that significantly distorts the *sp*<sup>3</sup> network will also alter the gap.

## SURFACE RECONSTRUCTIONS

Because the optical gap in silicon nanoclusters will change as a result of bonding networks at the surface and not necessarily because of a specific contaminant atom, surface reconstruction may also affect the optical gap.<sup>[29,52]</sup> Fig. 5 shows the atomic structure of three 1.8-nm clusters: 1) Si<sub>148</sub>H<sub>120</sub>, which has an

**Fig. 5** Hydrogen-passivated, 1.8-nm-diameter silicon nanocluster A) without a reconstructed surface, B) with reconstructed dimers on the surface, and C) with reconstructed dimers and steps on the surface. In the ball-and-stick model, the Si atoms are gray and the H atoms are white.

unreconstructed surface, 2)  $\text{Si}_{148}\text{H}_{96}$ , which has reconstructed dimers but no reconstructed steps, and 3)  $\text{Si}_{148}\text{H}_{72}$ , which has reconstructed dimers and steps. The Si–Si bond lengths of the reconstructed dimers and the reconstructed steps are similar to those predicted by LDA calculations for flat, hydrogen passivated (100) surfaces<sup>[53]</sup> and reconstructed steps on a (100) surface,<sup>[54]</sup> respectively. The dimer reconstructions are not limited to large clusters with (100)-like facets, but may also occur on clusters with aligned dihydrides, such as  $\text{Si}_{66}\text{H}_{64}$  and  $\text{Si}_{29}\text{H}_{36}$ ,<sup>[55]</sup> although reconstructed steps will not form on clusters smaller than 1.8 nm. That these reconstructions are energetically advantageous in specific situations is demonstrated through the following argument.

The additional energetic advantage from forming dimers on curved silicon surfaces is reflected in the negative formation energy of  $\text{Si}_{148}\text{H}_{120}$  with respect to  $\text{SiH}_4$  and bulk silicon. A negative formation energy is consistent with the formation of nanoscale features in porous silicon formed by HF etching. To predict the relative stabilities of the structures thermodynamically (Fig. 6), we follow a prescription previously used for flat silicon surfaces.<sup>[53]</sup> The relative stability of these nanocluster structures is obtained by the zero temperature formation energy,  $\Omega$ , given by

$$\Omega = E_{\text{Tot}} + E_{\text{ZPE}} - n_{\text{Si}}\mu_{\text{Si}} - n_{\text{H}}\mu_{\text{H}} \quad (2)$$

where  $E_{\text{Tot}}$  is the total energy,  $E_{\text{ZPE}}$  is the zero-point energy,  $n_{\text{Si}}(n_{\text{H}})$  is the number of silicon (hydrogen) atoms, and  $\mu_{\text{Si}}(\mu_{\text{H}})$  is the chemical potential of bulk silicon (hydrogen gas). At  $\mu_{\text{H}} > -0.3$  eV, the structure with the most hydrogen on the surface, and hence no reconstructions ( $\text{Si}_{148}\text{H}_{120}$ ), has the lowest formation energy. As  $\mu_{\text{H}}$  decreases, it becomes energetically favorable to form dimers ( $\text{Si}_{148}\text{H}_{96}$ ). When  $\mu_{\text{H}}$  is decreased even further ( $< -0.7$  eV), reconstructed steps ( $\text{Si}_{148}\text{H}_{72}$ ) become energetically favorable. Fig. 6 demonstrates regions in which each structure is more favorable. Increasing the temperature reduces  $\mu_{\text{H}}$  due to entropic effects; therefore, we predict that nanoclusters synthesized in an  $\text{H}_2$  environment will generally have surfaces with reconstructed dimers and steps, while those formed in higher  $\mu_{\text{H}}$  environments, for

example, in colloidal solutions, may have unreconstructed surfaces.

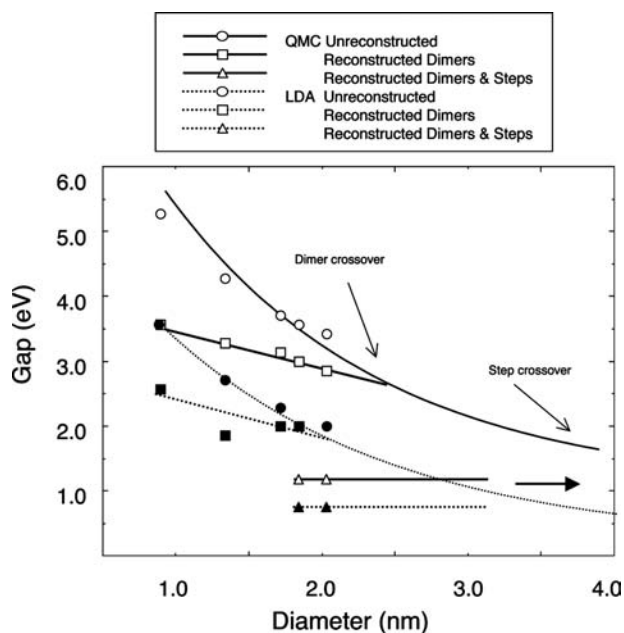

Reconstructed dimers and steps should affect the electronic and optical properties of silicon nanoclusters as a result of the distortion of the  $sp^3$  bonding network. Fig. 7 shows calculated single-particle gaps within LDA and the optical gap within QMC. Reconstructed dimers demonstrate a relatively flat impurity level at  $\approx 2$  eV (as calculated within the LDA). This flat impurity level is confirmed by QMC calculations, although shifted higher by about 1 eV (the curvature in  $\text{Si}_{29}\text{H}_{24}$  causes the gap in that structure to be slightly larger). The impurity state does not occur in clusters larger than  $\approx 2$  nm and thus reconstructed dimers will not affect larger clusters. However, reconstructed steps generate a separate impurity level at  $\approx 0.7$  eV (as calculated within the LDA). A QMC calculation of this cluster reveals a gap about 0.5 eV higher than the LDA value at  $\approx 1.2$  eV. Because this level is about the same as the bulk gap value of Si, such an impurity level may be seen in clusters as large as 5 nm.

Evidence for the existence of reconstructed surfaces has been observed in porous silicon and in

**Fig. 6** Local density approximation formation energy of  $\text{Si}_{148}$  nanoclusters with different surface reconstructions. The origin of  $\mu_{\text{H}}$  is the value at which the formation energy of silane is zero.

**Fig. 7** Local density approximation (LDA) and quantum Monte Carlo (QMC) gaps of hydrogenated silicon nanocrystals with and without reconstructed dimers and steps. The point at which the impurity levels due to different reconstructions will no longer be observed are indicated by arrows.

nanoclusters about 1.8 nm in diameter. Van Buuren et al.<sup>[56]</sup> used X-ray absorption and valence band photoemission to investigate the shift in the valence and the conduction band edges of porous silicon as a function of thermal annealing. The wavelength of the observed PL suggests that the optical emission in these samples originates from nanoscale features with dimensions and quantum confinement effects similar to the nanoclusters studied here. At an annealing temperature of 500°C, the optical gap is reduced by 1 eV from that at room temperature, consistent with the reduction predicted in Fig. 7 due to reconstruction. Additionally, van Buuren et al. present mass spectrometer measurements showing significant hydrogen evolution during annealing beginning at 400°C, consistent with hydrogen desorption from SiH<sub>4</sub> species. This result is in agreement with our results, demonstrated in Fig. 6, in which structures with reconstructed surfaces and lower hydrogen content are favored as the temperature is increased, that is where  $\mu_{\text{H}}$  is decreased.

Wilcoxon, Samara, and Provencio<sup>[39]</sup> observed two distinct gaps and excitonic lifetimes in similarly sized clusters synthesized using inverse micelles. Our QMC calculations of optical gaps of unreconstructed and reconstructed surfaces of clusters this size are in good agreement with the two gaps measured in that particular work. Therefore, our calculations strongly support the conjecture that the smaller of these two gaps is attributable to surface reconstruction. Therefore in

experiments in which oxygen contamination is controlled, smaller optical gaps than those theoretically predicted may occur, as surface reconstruction is another potential source for disagreement between theory and experiment.

## EMISSION GAPS VIA THE STOKES SHIFT

In addition to the different surface structures affecting the absorption gap from the idealized structure, the difference between the absorption gap and the emission gap is yet another source of discrepancy among experimental results and theoretical calculations. The difference between the two gaps is often referred to as the Stokes shift. Calculating this difference exclusively through relaxation of the excited state, Table 1 summarizes our calculated Stokes shifts for a number of silicon nanoclusters with different surface contaminants and reconstructions. The large difference between absorption and emission gaps could account for further discrepancy among experiment and theory.

Generally, the emission gap is red shifted relative to the absorption gap. The LDA and QMC values of the Stokes shift show that, in a similar manner to optical gaps, the LDA qualitatively predicts correct trends as a function of size and surface structure; however, LDA consistently underestimates the value of the Stokes by 0.2–0.3 eV compared with QMC. As we were able to do many more LDA calculations, we quote those results here. Clusters with unreconstructed hydrogenated surfaces produce values of the Stokes shift that range from 0.3 to 0.8 eV as a function of size. Clusters with oxygen double-bonded (Si–O) to the surface exhibit larger Stokes shifts of 1.2 eV, relatively independent of size. Clusters with reconstructed surfaces and surfaces with bridged oxygen consistently exhibit the smallest Stokes shifts, ranging from 0.1 to 0.3 eV as a function of size.

To gain insight into the large differences in the above Stokes shifts, we examined the nature of the electronic states responsible for absorption and emission, i.e., the band edge HOMO and LUMO. The HOMO and LUMO orbitals of three clusters, all approximately 1 nm in size, are shown in Fig. 8. Fig. 8A shows that in a nanocluster with pure hydrogen passivation and no reconstruction of the surface (e.g., Si<sub>35</sub>H<sub>36</sub>), the HOMO and LUMO densities are delocalized throughout the core of the nanocluster. Fig. 8B shows that the HOMO and LUMO densities are also delocalized in clusters with surface reconstruction, but around the surface. Finally, Fig. 8C shows that the placement of a single oxygen atom in a Si=O double-bonded position on the surface of an otherwise unreconstructed cluster (e.g., Si<sub>35</sub>H<sub>34</sub>O) almost completely localizes both the HOMO and

**Table 1** Local density approximation (LDA) and Quantum Monte Carlo (QMC) calculated absorption gaps and Stokes shifts for a number of silicon nanoclusters with different surface structures

Cluster	Structure	Diameter	Optical gap		Stokes shift		RMS displacement
			LDA	QMC	LDA	QMC	
Si <sub>29</sub> H <sub>36</sub>	Hydrogenated	0.9	3.6	5.3(1)	0.69	1.0(1)	0.31
Si <sub>35</sub> H <sub>36</sub>	Hydrogenated	1.1	3.4	5.0(1)	0.57	0.8(1)	0.25
Si <sub>66</sub> H <sub>64</sub>	Hydrogenated	1.3	2.8	4.7(1)	0.50		0.19
Si <sub>87</sub> H <sub>76</sub>	Hydrogenated	1.5	2.5	4.2(2)	0.22		0.14
Si <sub>148</sub> H <sub>120</sub>	Hydrogenated	1.8	2.1	3.9(3)	0.13		0.11
Si <sub>211</sub> H <sub>140</sub>	Hydrogenated	2.0	2.0		0.06		0.05
Si <sub>29</sub> H <sub>24</sub>	Reconstructed	0.8	2.6	3.6(1)	0.34	0.4(1)	0.13
Si <sub>66</sub> H <sub>40</sub>	Reconstructed	1.3	1.9	3.3(1)	0.16		0.08
Si <sub>29</sub> H <sub>34</sub> O	Si–O–Si	0.9	3.1	4.7(1)	0.27	0.5(1)	
Si <sub>35</sub> H <sub>34</sub> O	Si=O	1.1	2.2	2.5(1)	1.16	1.3(1)	0.30
Si <sub>66</sub> H <sub>62</sub> O	Si=O	1.3	2.2		1.22		0.33
Si <sub>87</sub> H <sub>74</sub> O	Si=O	1.5	2.0		1.13		0.31

All values are quoted in eV and QMC statistical error bars are shown in parenthesis. The RMS displacements are in Å. Structures with bridged oxygen are labeled Si–O–Si and double-bonded oxygen is labeled Si=O.

LUMO densities on the Si=O double bond at the surface of the cluster.

The structural changes resulting from the creation of an exciton in each cluster, expressed as the root

mean squared (RMS) displacement of the atoms, are summarized in Table 1, and more visually expressed in the right-hand column of Fig. 8. The RMS displacement of atoms in the completely hydrogenated structures, e.g., Si<sub>35</sub>H<sub>36</sub>, is  $\approx 0.3$  Å for 1-nm structures and decreases quickly to  $< 0.1$  Å as the cluster size increases to around 2 nm. Because the change in charge density resulting from the HOMO to LUMO excitation is distributed throughout the cluster, all atoms in the cluster experience forces of approximately equal magnitude. The displacements shown in Fig. 8 demonstrate that the excited state structural relaxation of hydrogenated clusters corresponds to a change in shape from a spherical to elliptical geometry, i.e., a global relaxation. As the size of these clusters increases, the relative change in charge density around each atom due to the excitation of a single electron decreases inversely proportionally to the number of atoms in the cluster, and hence the RMS displacements also decrease. The clusters with reconstructed surfaces, e.g., Si<sub>29</sub>H<sub>24</sub> (Fig. 8B) and the clusters with Si–O–Si bridged oxygen on the surface show smaller RMS displacements than the completely hydrogenated clusters. In these clusters, the charge density change associated with the HOMO–LUMO excitation is localized on the surface of the cluster; however, the additional Si–Si or Si–O–Si bonds produced by the reconstruction of the surface restrict the movement of these surface atoms, resulting in significantly lower observed RMS displacements.

In the clusters with oxygen double-bonded to the surface, e.g., Si<sub>35</sub>H<sub>34</sub>O (Fig. 8C), the RMS displacement is slightly larger. However, in this class of clusters, considering the RMS displacement is somewhat

**Fig. 8** Highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) density isosurfaces of 1-nm clusters with different surface structures. In the ball-and-stick representation, the Si atoms are gray, the H atoms are white, and the oxygen atom is red. The isosurfaces are chosen at 50% the maximum amplitude in A) and B) and 10% the maximum amplitude in C). The right column shows arrows proportional to the displacement of each atom due to the Stokes shift, magnified by 10 for clarity.

misleading as almost all the atomic relaxation is concentrated on the double-bonded oxygen atom. The displacement vectors plotted in Fig. 8C show that the double-bonded oxygen atom rotates around its attached silicon atom by over  $40^\circ$  when relaxed within its excited state. In these clusters, the Stokes shift is relatively independent of the size of the cluster as the relaxation mechanism is localized on a single bond on the surface.

The above description of the Stokes shift mechanism and calculation of values may be treated through comparison with experiment. A wealth of experimental measurements of the optical absorption and emission wavelengths of silicon nanostructures has been accumulated, much of which appears contradictory.<sup>[14,38,57–64]</sup> However, many apparently conflicting measurements can be explained by considering differences in the sizes and surface properties of the samples.

Fig. 9 combines the results of a number of published values of the Stokes shift plotted as a function of the nanocluster size. For comparison, we include the results of our LDA calculations from Table 1. As a guide to the eye and as a means of extrapolating our results to sizes beyond those currently accessible with first-principles techniques, we fit our results with the dotted lines. Three calculated curves are shown corresponding to the three classes of Stokes shift we have identified. The bulk-derived, hydrogenated nanoclusters are represented by curve (A), which shows Stokes shifts that rapidly decrease from over 2 eV for 0.5-nm clusters to 0.1 eV for 2-nm clusters. The hydrogenated

**Fig. 9** A comparison of a number of different experimentally measured values of the Stokes shift (synthesized under different conditions) with local density approximation predicted values. The dotted lines are fit to the A) unreconstructed crystalline structure, B) the reconstructed crystalline structure, and C) the clusters with a double-bonded oxygen on the surface.

nanoclusters with reconstructed surfaces and bridged Si–O–Si oxygen are represented by curve (B), which shows Stokes shifts that are smaller than curve (A) and also decrease to  $<0.1$  eV in 2-nm clusters. The nanoclusters with oxygen double-bonded to the surface are represented by curve (C), which shows Stokes shifts of  $\approx 1.2$  eV, roughly independent of size.

Despite large error bars, the experimental values for the Stokes shift can be broadly divided into three classes that approximately correspond to the three classes of Stokes shift predicted by our calculations. The most striking agreement is between the results of Wu et al.<sup>[63]</sup> and our results for the Stokes shift of clusters with oxygen double-bonded to the surface. Wu et al. found values of the Stokes shift of  $\approx 1.2$  eV that are almost independent of the size of the nanocluster. These measurements agree with our model for the Stokes shift of clusters, where the structural relaxation is focused almost entirely on the silicon oxygen double bond, because of the localization of the HOMO and LUMO charge densities on this bond. The Stokes shifts measured by von Behren et al.<sup>[61]</sup> display a Stokes shift that decreases as the size of the cluster increases. We interpret these particular results as corresponding to the idealized hydrogenated clusters studied here (similar to  $\text{Si}_{35}\text{H}_{36}$ ). The quantitative agreement is even more striking if we consider the 0.2–0.3 corrections due to the LDA error. The Stokes shifts measured by Garrido et al.<sup>[64]</sup> are much smaller over a range of sizes/gaps. These clusters are surrounded by an  $\text{SiO}_2$  matrix and may well contain the bridged Si–O–Si bonds at the surface of the cluster, which we have also shown to significantly suppress the magnitude of the Stokes shift. Likewise, the much smaller clusters characterized by Belomoin, Therrein, and Nayfeh<sup>[38]</sup> which are believed to be reconstructed, show size dependence slightly smaller than that of unreconstructed clusters consistent with our calculated results.

Besides structural changes induced by an exciton, additional phenomena may also contribute to the Stokes shift. A red shift can be introduced by 1) a singlet–triplet splitting of the band edge levels due to the electronic exchange interaction. Light is then absorbed into the higher-energy singlet exciton level and emitted from the lower energy, optically forbidden “dark exciton.” We believe that, in these nanoclusters, the singlet–triplet splitting is negligible and is not included here.<sup>[33,36]</sup> 2) The existence of “surface traps” that exist at energies in the middle of the optical gap of an idealized hydrogenated cluster. An exciton is initially formed in the core of the cluster and then either the electron and/or hole migrate to a lower energy surface localized trap state before recombination and the emission of a photon. Adding such an effect would increase the predicted value of the Stokes shift, but the magnitude is extremely sensitive to the

nature of the trap. 3) A broad size distribution itself can contribute to the Stokes shift. Light is absorbed by clusters with a range of sizes, such that the absorption peak is close to that of the mean size cluster. The excitons then lower their energy by transferring to neighboring larger clusters, before recombination and emission. In this manner, the average measured emission tends to be from the larger clusters of a given size distribution, which, in turn, leads to larger measured Stokes shifts.

In addition to comparing our calculations with measured values of the Stokes shift, we also compared our results with previous calculations.<sup>[31–35]</sup> In general, our results agree with the calculations that have found relatively large ( $\sim 1$  eV) values of Stokes shifts,<sup>[34,35]</sup> and disagree with those predicting significantly smaller (a few meV) Stokes shifts.<sup>[31–33]</sup> In general, we agree with those models that predict large Stokes shifts as a result of structural changes<sup>[35]</sup> and agree with trapped exciton models for the Stokes shift;<sup>[34]</sup> however, we found trapped excitons on double-bonded oxygen, and *not* on reconstructed dimers.<sup>[34]</sup>

The calculated values of the Stokes shift serves two purposes in explaining discrepancies among experimental results. First, the difference between the emission and absorption gaps is not negligible and thus contributes to differences among experiments, especially the ones using different methods to obtain a gap. Second, the difference in observed and calculated Stokes shifts is widely different among nanocrystals with different surface structures. The values are so different that the Stokes shift itself may be used to infer the structure at the surface.

## CONCLUSION

In conclusion, we have demonstrated that quantum confinement is just one mechanism responsible for optical transitions in silicon nanoclusters, and that the specific surface chemistry and the Stokes shift must be considered to interpret experimental results. The interplay between surface and bulk effects requires detailed *ab initio* calculations to properly account for all physical mechanisms contributing to optoelectronic properties. Our calculations show that surface effects due to the different chemistry of single-bonded passivants do not appreciably contribute to optical transitions, even in the case of highly electronegative passivants. We demonstrated that the local distortion of the  $sp^3$  network at the surface significantly affects the energy of photoluminescence. We also discovered that multiple contaminants can further alter the gap, giving a large (over 2.0 eV) range of observed results. Disruption of the  $sp^3$  network also occurs when surfaces are reconstructed, forming dimers or steps. Under

standard synthesis conditions, both unreconstructed and reconstructed surfaces can be thermodynamically stable. Studies of surface reconstructions of clusters with ranges of sizes suggest that even clusters with diameters of up to 5 nm will be sensitive to surface reconstructions, thus increasing the size range by which numerous absorption gaps may be observed.

A further large reduction in gaps may be attributable to differences between absorption and emission, which also varies with respect to the surface structure. Silicon nanostructures exhibit a strong difference between absorption and emission, or Stokes shift. We have determined that the Stokes shift is extremely sensitive to the size, surface structure, and chemistry of the nanocluster. For  $\approx 1$ -nm sized clusters, the Stokes shift ranges from less than 0.1 eV to greater than 1.0 eV, depending on the detailed surface structure and the presence of oxygen in either bridged or double-bonded configurations. Our results enable us to provide explanations for the seemingly contradictory results of a number of experiments. These results demonstrate that combining measurements of the absorption spectrum with measurements of the emission energy provides a powerful tool for optically characterizing both the size and surface structure of semiconductor nanoclusters.

# Silicon Nanocrystals: Quantum Confinement

James R. Chelikowsky

Chemical Engineering and Materials Science, University of Minnesota,  
Minneapolis, Minnesota, U.S.A.

## INTRODUCTION

Silicon is *the* electronic material of choice; it is used for almost all modern electronic devices, e.g., in the manufacture and design of integrated circuits. However, silicon is flawed in one respect. Namely, it is not a particularly good optoelectric material. Laser photodetectors, photocells, and so on are not constructed from elemental silicon. The optical gap of silicon is not amenable for such devices; the gap in silicon is too small to interact effectively with the visible spectrum. In addition, the transitions at the optical threshold in silicon are forbidden unless lattice vibrations are included.<sup>[1]</sup> If the gap could be increased, silicon could be used for virtually any electronic or optical application. Owing to such technological motivation, numerous theoretical methods to predict or simulate the optical properties of silicon nanostructures have been implemented. This section will review some of these methods with an emphasis on atomistic approaches.

## OVERVIEW ON QUANTUM CONFINEMENT

One method to increase the gap size in silicon involves altering the “size of the excitation.” Usually, one alters the properties of matter by changing its chemical composition or its structure. However, it is also possible to change the properties of matter by altering the size of the system. Specifically, the physical properties of matter can have very different behavior at small dimensions. This effect can be illustrated by considering a particle confined by rigid walls to a one-dimensional box of size  $a$ . The lowest energy level of this system is given in elementary textbooks as

$$E = \frac{\pi^2 \hbar^2}{2ma^2} \quad (1)$$

where  $\hbar$  is Planck’s constant divided by  $2\pi$ , and  $m$  is the mass of the particle. If the size of the box is reduced then  $E$  increases. This phenomenon where the energy level increases with reduced dimensionality is called *quantum confinement*. This effect can be readily

understood from the Heisenberg uncertainty principle. The uncertainty principle states that the uncertainty in momentum and position must be such that the product exceeds  $\hbar/2$ :

$$\Delta p \Delta x \geq \hbar/2 \quad (2)$$

where  $\Delta p$  is the uncertainty in the momentum and  $\Delta x$  is the uncertainty in the position of the particle. Consider the energy of a free particle with momentum  $p$ :

$$E = \frac{p^2}{2m} \quad (3)$$

Since the uncertainty in the momentum cannot exceed the momentum itself, one can write  $p > \Delta p$ . Moreover, if the particle is confined to a box of size  $a$ , then

$$E > \frac{\hbar^2}{8ma^2} \quad (4)$$

As one tries to confine the position of a particle, the energy of the particle must increase and diverge as the confining region vanishes.

Although this argument was given for one dimension, it is also true for a particle confined to a box in three dimensions. For example, if a particle is confined within a sphere whose radius is  $R$ , one might expect an energy level to vary with  $R$  according to

$$E(R) = E_\infty + \frac{\alpha}{R^2} \quad (5)$$

where  $\alpha$  is a constant and  $E_\infty$  is the energy as  $R \rightarrow \infty$ .

Suppose we consider an optical gap,  $E_{\text{gap}}$ , as the difference between the highest filled and lowest empty states for a system confined in a sphere of size  $R$ . In the simplest description of the gap we might expect  $E_{\text{gap}}$  scale as

$$E_{\text{gap}}(R) = E_{\text{gap}} + \frac{\beta}{R^2} \quad (6)$$

where  $\beta$  is a constant.

Quantum confinement has been observed experimentally for nanostructures such as silicon *quantum dots* or large clusters. A quantum dot is a *nanocrystal* in which the surface has been passivated. In Fig. 1, an idealized

**Fig. 1** Ball and stick model for a quantum dot. The gray dots represent silicon atoms and the white dots, hydrogen. The interior of the dot has the structure of crystalline silicon. The surface of the dot is passivated with hydrogen.

quantum dot of silicon is illustrated. The interior of the dot consists of silicon atoms in the diamond structure; the surface of the dot is hydrogenated. Hydrogen removes any dangling bonds on the surface. As such, all the atoms in the system should be fully coordinated. Unsaturated bonds should not contribute to the electronic properties of the quantum dot. Typically, a quantum dot is a few nanometers to tens of nanometers in size. The smallest dots contain hundreds of atoms, whereas a large dot may contain hundreds of thousands of atoms.

In Fig. 2, one of the first measurements of quantum confinement in silicon nanocrystals is illustrated.<sup>[2]</sup> The nanocrystals measured were about 2–3 nm in diameter. The measured optical gap is between 2.0 and 2.6 eV. This is in contrast to the gap in crystalline silicon, where the gap is known to be about 1.1 eV at room temperature.<sup>[1]</sup> Eq. (6) can be used to fit the data by adjusting the  $\beta$  parameter. Owing to an uncertainty in the nanocrystallite structure and size, there is some scatter in the experimental data, but the overall trend is consistent with what one would expect from quantum confinement. Other experiments have also confirmed the role of quantum confinement in silicon nanostructures. For example, silicon can be so extensively etched as to produce a porous material, which contains nanostructures. Porous silicon is observed to have dramatically altered optical properties; for example, these forms of silicon can exhibit visible photoluminescence at room temperature.<sup>[3]</sup>

## COMPUTATIONAL APPROACHES TO EXCITED STATE PROPERTIES IN CONFINED SYSTEMS

Whereas the general concept of quantum confinement has been validated, *quantitative* simulations of the optical properties of nanostructures are difficult. Optical properties require an understanding of both the ground state and excited state for large systems with numerous degrees of freedom. Owing to this situation, several approximate methods have been developed. These methods include empirical descriptions of excitations based on “particle in a box” descriptions to *ab initio* methods based on density functional theory or quantum Monte Carlo methods as described below.

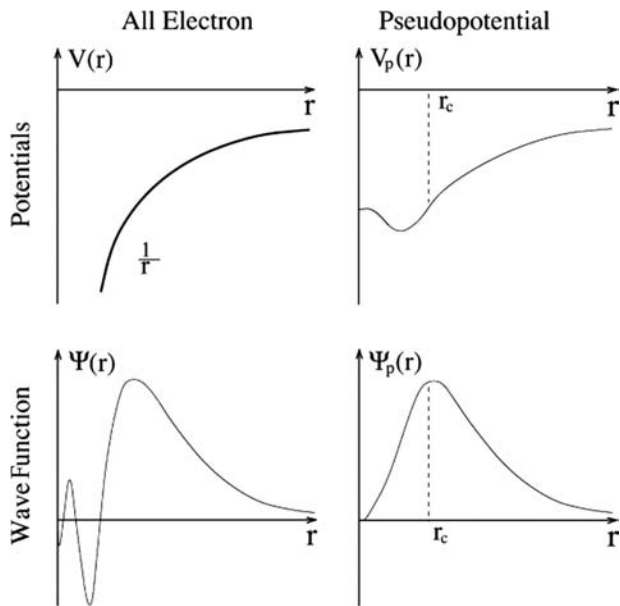

### Empirical Pseudopotential Method

The empirical pseudopotential method is based on several approximations.<sup>[4]</sup> The first approximation concerns the nature of the electronic interactions within matter. It is assumed that these interactions can be accurately replicated by a simple one-electron potential. This approximation can be justified by a Hartree–Fock description of matter in which each electron moves in the average potential of the rest of the electrons. The one-electron approximation results in a Schrödinger equation of the form:

$$\left[ \frac{-\hbar^2 \nabla^2}{2m} + V(\vec{r}) \right] \Psi_n(\vec{r}) = E_n \Psi_n(\vec{r}) \quad (7)$$

where  $V(\vec{r})$  is the electronic potential including electron–nuclear interactions and electron–electron screening,  $E_n$  is the energy level for the  $n$ th state,  $\Psi_n(\vec{r})$ . Another

**Fig. 3** Schematic pseudopotential and all-electron potentials. The pseudopotential and pseudo wave function match the all-electron results outside of a core radius given by  $r_c$ .

approximation recognizes the physical content of the periodic table: Electronic properties depend on the valence electron configuration, not the tightly bound core electrons. Consider atoms of silicon ( $1s^2 2s^2 2p^6 3s^2 3p^2$ ) and germanium ( $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^2$ ). These atoms have an outer electron, or valence electron, configuration of  $s^2 p^2$  and possess similar electronic and structural properties; that is, they are semiconductors and both occur in the diamond crystal structure. The pseudopotential approximation recognizes this physical content by focusing only on the valence electrons and removing the core electrons from the system.

A schematic atomic pseudopotential is illustrated in Fig. 3. Unlike the “all-electron” potential, which binds both core and valence electrons, the pseudopotential binds only the valence electrons. Within a region around the core ( $r < r_c$ ), the pseudopotential departs strongly from the all-electron potential; for example, the  $1/r$  singularity near the nucleus is removed. The pseudopotential is not only weaker than the all-electron potential; the resulting wave function is nodeless. This transformation between the all-electron potential and the pseudopotential can be made rigorous. Within the empirical pseudopotential approximation, the only requirement is that the pseudopotential be weak and converge rapidly in Fourier space. Typically, one expands the potential in atomic pseudopotentials. For an elemental crystal like silicon (Fig. 4), the pseudopotential for the diamond structure can be written as

$$V_p(\vec{r}) = \sum_{\vec{R}, \vec{\tau}} V_p^a(|\vec{r} - \vec{R} - \vec{\tau}|) \quad (8)$$

**Fig. 4** Diamond crystal structure for elemental silicon.

where

$$\begin{aligned} \vec{R} &= a(l\hat{x} + m\hat{y} + n\hat{z}) \\ \vec{\tau} &= \pm a(\hat{x} + \hat{y} + \hat{z})/8 \end{aligned}$$

$a$  is the lattice constant, ( $\vec{R}$ ) is a lattice vector and  $\vec{\tau}$  is a basis vector.<sup>[1]</sup> ( $lmn$ ) can take on any integer value. For each atom, one assumes a spherically symmetric pseudopotential,  $V_p^a$ . In Fourier space, Eq. (8) can be rewritten as

$$V_p(\vec{r}) = \sum_{\vec{G}} V_p^a(G) \cos(\vec{G} \cdot \vec{r}) \quad (9)$$

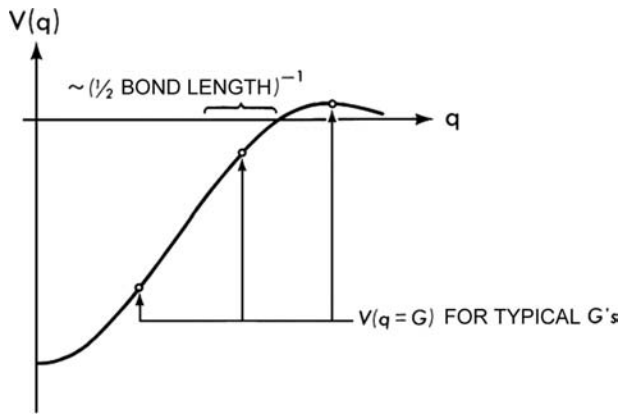

where

$$\vec{G} = \frac{2\pi}{a}(h\hat{x} + j\hat{y} + k\hat{z})$$

( $\vec{G}$ ) is a reciprocal lattice vector. The integers ( $hjk$ ) are constrained to be either all odd or all even.  $V_p^a(G)$  is called a form factor and is defined as

$$V_p^a G = \frac{1}{\Omega_a} \int V_p^a(r) \exp(i\vec{G} \cdot \vec{r}) d^3r \quad (10)$$

where  $\Omega_a$  is the atomic volume. If the pseudopotential converges rapidly in Fourier space, only a few form factors are needed for convergence. These form factors correspond to the smallest  $G$  vectors. This is illustrated in Fig. 5. For crystalline silicon, only three unique form factors are required to define the electronic properties.<sup>[4]</sup> These form factors can be calculated

**Fig. 5** Schematic pseudopotential,  $V(q)$  in Fourier space. The values of  $V(q)$  for the lowest reciprocal lattice vectors,  $G$ , are called form factors.

or fit. Within the empirical pseudopotential method, they are commonly fit to experimental data.

Once the potential is defined, the energetic and spatial distribution of electron states can be determined. A common procedure for this task is to define a plane wave basis:

$$\Psi_{n,\vec{k}}(\vec{r}) = \sum_{\vec{G}} \alpha_n(\vec{k}, \vec{G}) \exp(i(\vec{k} + \vec{G}) \cdot \vec{r}) \quad (11)$$

where  $\Psi_{n,\vec{k}}$  is a Bloch function,<sup>[4]</sup>  $n$  is a band index, and  $\vec{k}$  is a wave vector. The wave function and energy bands are determined by solving a secular equation:

$$\det \left( \left( \frac{\hbar^2(\vec{k} + \vec{G})^2}{2m} - E \right) \delta_{\vec{G},\vec{G}'} + V_p^a(|\vec{G} - \vec{G}'|) \times \cos((\vec{G} - \vec{G}') \cdot \vec{\tau}) \right) = 0 \quad (12)$$

This eigenvalue problem gives the values for the energy bands  $E_n(\vec{k})$  and  $\Psi_{n,\vec{k}}$ . Typically, less than 100 plane waves need be considered. Accurate energy bands can be obtained with only three unique form factors. Optical properties of the crystal are used to fit the form factors in this case.

The optical properties of the crystal can be determined by using the imaginary part of the dielectric function,  $\varepsilon_2(\omega)$ , for cubic semiconductors:<sup>[4]</sup>

$$\varepsilon_2(\omega) = \frac{e^2 \hbar}{3\pi m^2 \omega^2} \sum_{\vec{k}, v, c} \delta(\omega_{v,c}(\vec{k}) - \omega) |P_{v,c}(\vec{k})|^2 \quad (13)$$

where

$$\omega_{v,c}(\vec{k}) = (E_c(\vec{k}) - E_v(\vec{k}))/\hbar$$

and

$$\vec{P}_{v,c}(\vec{k}) = \int \Psi_{c,\vec{k}}^*(\vec{r}) \nabla \Psi_{v,\vec{k}}(\vec{r}) d^3r$$

The sum is over occupied valence bands ( $v$ ), empty conduction bands ( $c$ ) and wave vector  $\vec{k}$ .  $\vec{P}_{v,c}(\vec{k})$  is a dipole matrix element. The Dirac delta function in Eq. (13) insures that energy is conserved and the dipole matrix element reflects the allowed symmetry for an optical transition. Once the imaginary part of the dielectric function is known, the real part,  $\varepsilon_1(\omega)$ , can be obtained from the Kramer–Kronig dispersion relation.<sup>[1]</sup> The complex index,  $N$ , is given by

$$N^2 = \varepsilon_1 + i\varepsilon_2 \quad (14)$$

and the normal incident reflectivity is given by

$$R = \left| \frac{N - 1}{N + 1} \right|^2 \quad (15)$$

The reflectivity of a silicon crystal as calculated by the empirical pseudopotential method and as measured<sup>[5]</sup> is illustrated in Fig. 6.

It is possible to apply the empirical pseudopotential method to quantum dots as illustrated in Fig. 1. However, several more approximations must be made. For example, a confined excitation does not possess translational symmetry. Bloch's theorem [Eq. (11)] does not hold; that is, the wave vector  $\vec{k}$  no longer has any physical meaning. One method of overcoming this obstacle is to introduce artificial periodicity into the system by constructing a “supercell.” Each supercell contains a quantum dot surrounded by vacuum. This permits the same formalism to be implemented

**Fig. 6** Reflectivity for crystalline silicon. Source: From Ref.<sup>[5]</sup>

as for the crystal. Another issue concerns the construction of the form factors. As the supercell grows in size more than just three form factors are required. Effectively, the full curve for  $V_p^a(G)$  must be known. In practice, empirical extrapolations are made from bulk pseudopotentials, often including fits to experimental or theoretical surface properties<sup>[6]</sup> to construct the form factors.

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) define a HOMO–LUMO gap,  $E_g$ . This gap cannot be directly compared to the optical gaps shown in Fig. 2. Quantum dots physically localize the excited electron and hole such that the Coulombic interactions are enhanced. An empirical and approximate expression for the optical gap,  $E_g^{\text{opt}}$ , is given by

$$E_g^{\text{opt}} \approx E_g - \frac{1.8e^2}{\epsilon R} \quad (16)$$

where  $E_g$  is the HOMO–LUMO gap of the dot,  $\epsilon$  is the dielectric constant of the dot, and  $R$  is the dot radius.<sup>[6,7]</sup> The second term in Eq. (16) represents the electron–hole Coulombic interaction. The scaling of the exciton energy is what one would expect for a particle in a sphere. This expression is quite crude in that it assumes the dielectric properties of the dot can be quantified by a constant value of the dielectric function. For small dots of diameter less than a few nanometers, such approximations will certainly break down.<sup>[8]</sup> Another deficiency of the empirical pseudopotential method concerns the interpretation of the gap,  $E_g$ . For crystalline matter, this gap corresponds to the band gap and includes excitonic interactions, which are small in the crystalline case. However, in the limit of small quantum dots, the gap may be ill defined. It is not clear whether the empirical approach scales many-body interactions correctly.

### Tight Binding Method

Another method for extracting the optical gap of silicon quantum dots is based on tight binding. Within this method a localized basis is taken. For example, one can write the wave function as

$$\Psi_n(\vec{r}) = \sum_{j,k} a_{j,k}^n \Phi_j(\vec{r} - \vec{R}_k) \quad (17)$$

where the sum is over (j,m). These indices label the atomic positions, given by  $\vec{R}_m$ , and a local orbital,  $\Phi_j$ , associated with an (s,p,d, ...) state. The local orbitals,  $\Phi_j$ , can be taken to be atomic orbitals, Gaussians, exponentials, and so on.

Suppose we consider a tight-binding Hamiltonian,  $H_{\text{TB}}$ , and use Eq. (17) as the basis. At this point,  $H_{\text{TB}}$ , need not be specified. Using the basis in Eq. (17), one must solve an eigenvalue problem of the form:

$$H_{lm} \Psi_n = E_n S_{lm} \Psi_n \quad (18)$$

where the Hamiltonian matrix element,  $H_{lm}$ , are given by

$$H_{lm} = \sum_{jj'kk'} a_{j,k}^l a_{j',k'}^m \int \Phi_j^*(\vec{r} - \vec{R}_k) H_{\text{TB}} \Phi_{j'}(\vec{r} - \vec{R}_{k'}) d^3r$$

and the overlap matrix element,  $S_{lm}$ , is given by

$$S_{lm} = \sum_{jj'kk'} a_{j,k}^l a_{j',k'}^m \int \Phi_j^*(\vec{r} - \vec{R}_k) \Phi_{j'}(\vec{r} - \vec{R}_{k'}) d^3r$$

The matrix elements can be computed directly if  $H_{\text{TB}}$  is specified. Otherwise, the matrix elements can be fit to experimental data. Once the matrix elements are specified, the energies and wave functions can be found using standard matrix operation packages.

Tight binding methods have some advantages over the empirical pseudopotential method. Each atom can be represented by a small number of orbitals; for example, one might consider an  $sp^3$  configuration associated with each silicon atom. Instead of having 50–100 plane waves associated with each atom, one might have only four orbitals. The resulting secular equation is correspondingly much smaller. Moreover, one need not have a detailed knowledge of the electronic potentials or the tight-binding Hamiltonian. Usually some rather strong approximations are made in evaluating the Hamiltonian and overlap matrix elements; for example, often the elements are assumed to vanish, save for the first few neighboring atoms. Only matrix elements representing two and three body overlaps are required to solve for the eigenvalues and eigen vectors.<sup>[9–11]</sup> Evaluating accurately the matrix elements is the most difficult aspect of the tight-binding method. Typically, 10–20 elements must be determined. Usually, this task is performed by parameterizing the matrix elements; for example, the parameters are often fit to experimental data or to calculated energy bands. In general, obtaining a robust set of parameters is difficult; however, modeling quantum dots is reasonably straightforward, as one does not need to fit unsaturated bonds or miscoordinated atoms.

Very large dots can be treated within the tight-binding model; dots of several hundred atoms have been examined. The energy levels between the highest and lowest levels can be calculated and the role of

quantum confinement determined in a manner similar to the empirical pseudopotential method.

### Density Functional Methods and Ab Initio Pseudopotentials

One drawback of both empirical pseudopotentials and tight binding concerns the parameterization procedure. In the case of the pseudopotentials, one must transfer bulklike interactions to surfaces or to confined systems where such transfers might be problematic. Likewise, tight-binding methods may involve bases that are too limited to represent the subtleties of charge transfer and hybridization in confined systems. Neither approach allows for screening changes or charge readjustments in a natural way.

Contemporary pseudopotentials are predominantly based on density functional theory.<sup>[12,13]</sup> Within density functional theory, the many-body problem is mapped on to a one-electron Hamiltonian. The effects of exchange and correlation are subsumed to a one-electron potential that depends only on the charge density. This mapping of the many-body problem to a one-body problem is in principle exact, but in practice approximate because the exact functional form for the one-electron exchange-correlation potential is not known. The mapping is usually accomplished via the local density approximation<sup>[13]</sup> in which the exchange-correlation potential is assumed to be that of a homogenous electron gas. Density functional theory, in any of its approximate forms, allows for a great simplification of the one-electron problem. Without this approach, most electronic structure methods would not be feasible for systems of more than a few dozen electrons.

Within the density functional theory approach one can write down a one-electron Hamiltonian and a corresponding one-electron Schrödinger equation, often called the “Kohn–Sham” equation.<sup>[13]</sup> For an atom, the Kohn–Sham equation can be written as:

$$\left[ \frac{-\hbar^2 \nabla^2}{2m} - \frac{Ze^2}{r} + V_H(\vec{r}) + V_{XC}[\rho(\vec{r})] \right] \Psi_n(\vec{r}) = E_n \Psi_n(\vec{r}) \quad (19)$$

where  $Z$  is the atomic number,  $V_H$  is the Hartree or Coulomb potential, and  $V_{XC}$  is the exchange-correlation potential. The Hartree and exchange-correlation potentials can be determined from the electronic charge density,  $\rho$ . The eigenvalue and eigenfunctions,  $E_n, \Psi_n(\vec{r})$ , can be used to determine the total electronic energy of the atom. The charge density is given by

$$\rho(\vec{r}) = -e \sum_{n, \text{occup}} |\Psi(\vec{r})|^2 \quad (20)$$

The summation is over all occupied states. The Hartree potential is determined by

$$\nabla^2 V_H(\vec{r}) = -4\pi e \rho(\vec{r}) \quad (21)$$

This term can be interpreted as the electrostatic interaction of an electron with the charge density of system. The exchange-correlation potential is more problematic. The central tenant of the local density approximation is that the total exchange-correlation energy may be written as

$$E_{XC}[\rho(\vec{r})] = \int \rho(\vec{r}) \varepsilon_{XC}[\rho(\vec{r})] d^3r \quad (22)$$

where  $\varepsilon_{XC}$  is the exchange-correlation energy density (i.e., the exchange correlation energy per electron at a density,  $\rho$ ). The exchange-correlation potential,  $V_{XC}$ , is obtained from the functional derivative:

$$V_{XC}(\vec{r}) = \frac{\delta}{\delta \rho} E_{XC}[\rho(\vec{r})] \quad (23)$$

It is not difficult to solve the Kohn–Sham equation [Eq. (19)] for an atom. The charge density is taken to be spherically symmetric; that is, the problem reduces to solving a one-dimensional problem. The Hartree and exchange-correlation potentials can be iterated to form a self-consistent field.

The atomic solution provides the input to construct a pseudopotential representing the effect of the core electrons and nucleus. This “ion core” pseudopotential,  $V_p^{\text{ion}}$ , can be transferred to other systems such as a silicon quantum dot. One can invert the Kohn–Sham equation to write:

$$V_p^{\text{ion}}(\vec{r}) = E_n - V_H(\vec{r}) - V_{XC}(\vec{r}) + \frac{\hbar^2 \nabla^2 \Psi_n}{2m \Psi_n} \quad (24)$$

If the atomic solution is inserted in Eq. (24) for ( $E_n, \Psi_n$ ), the ionic pseudopotential will reduce to the atomic potential. To construct a pseudopotential, one inserts the all-electron energy level and a modified wave function. For example, consider the 3s state of silicon. The silicon atom is solved so that ( $E_{3s}, \Psi_{3s}$ ) are known. A pseudo wave function,  $\Phi_{3s}$ , is constructed so that the wave function be nodeless and identical to the “all-electron” wave function outside a core region. A typical pseudo wave function,  $\Phi_{3s}$ , is illustrated in Fig. 7. Ion core pseudopotentials formed via Eq. (24) will yield the exact energy level and wave function outside the core region by construction. In principle, the ion core pseudopotential constructed in Eq. (24) is state dependent; for example, the pseudopotential for the 3s and 3p states will be different.

Fig. 7 Wave functions for the Si 3s state from an all-electron potential and from an ab initio pseudopotential.

This state dependency results in an additional complexity: The pseudopotentials are non-local operators. While non-locality complicates the pseudopotential construction, there are straightforward techniques for its implementation. Also, several methods exist for constructing pseudopotentials within density functional theory.<sup>[14]</sup>

Once the pseudopotential has been determined, the resulting eigenvalue problem needs to be solved for the system of interest. Several techniques are available to accomplish this task. For example, one approach is to use a plane wave basis with supercells, as discussed for the empirical pseudopotential method. Another approach is to solve the eigenvalue problem in real space.<sup>[15,16]</sup> The real-space method is highly advantageous over the plane wave method in some respects. Real-space methods do not require supercells and, as a consequence, can examine charged systems without adding artificial compensating backgrounds. Also, no cell-cell interactions exist. Real-space methods for silicon quantum dots have used a three-dimensional cube as shown in Fig. 8. The Kohn–Sham equation can be discretized via a higher-order finite differencing procedure over the grid to yield:

$$\begin{aligned} & \frac{-\hbar^2}{2m} \sum_{n_1 n_2 n_3 = -N}^N C(n_1, n_2, n_3) \Psi_n(x_i + n_1 h, y_j \\ & + n_2 h, z_k + n_3 h) + V_p^{\text{ion}}(x_i, y_j, z_k) \Psi_n(x_i, y_j, z_k) \\ & + V_H(x_i, y_j, z_k) \Psi_n(x_i, y_j, z_k) \\ & + V_{\text{XC}}(x_i, y_j, z_k) \Psi_n(x_i, y_j, z_k) \\ & = E_n \Psi_n(x_i, y_j, z_k) \end{aligned} \quad (25)$$

Fig. 8 Example of a grid used for a real-space solution of the Kohn–Sham equation [Eq. (25)].

where  $h$  is the grid spacing,  $C(n_1, n_2, n_3)$  are coefficients for the finite difference, and the summation is over  $N$  neighboring grid points; for example, if  $N = 1$ , then standard finite differencing is used. Real-space methods are easy to implement and have been used for dots up to 1000 atoms in size.

The total electronic energy of the system can be obtained from

$$\begin{aligned} E(N) = & \sum_{n=1}^N E_n - \frac{1}{2} \int V_H(\vec{r}) \rho(\vec{r}) d^3 r + \int [\epsilon_{\text{XC}}(\vec{r}) \\ & - V_{\text{XC}}(\vec{r})] \rho(\vec{r}) d^3 r \end{aligned} \quad (26)$$

where  $N$  is the total number of electrons in the system. The second term in Eq. (26) is required to remove double counting the electrostatic interactions. The last term removes the exchange-correlation potential and replaces it with the exchange-correlation energy density. Eq. (26) allows one to extract the ionization energy,  $I$ , and the electron affinity,  $A$ . In particular, one can then compute gap for elementary excitations involving a “quasiparticle.” (A quasiparticle corresponds to a single-particle excitation in a many-body system. The excitations of the individual particle, in this case an electron, can be modified by interactions between the particle with the electron density). The quasiparticle gap using the definitions of electron affinity and the ionization energy is given by

$$\begin{aligned} E_{\text{gap}}^{\text{qp}} = & I - A = E[N + 1] + E[N - 1] \\ & - 2E[N] \end{aligned} \quad (27)$$

The quasiparticle gap is the energy required to create a non-interacting electron–hole pair. Provided one has a functional for the exchange–correlation energy, this expression can be readily implemented for quantum dots.

However, this gap does not correspond to an optical excitation. Within a quantum dot, the electron and hole interact via Coulombic forces. The Coulombic energy, or exciton energy, can be approximated by

$$E_{\text{Coul}} = -e^2 \iint \frac{|\Psi_e(\vec{r})|^2 |\Psi_h(\vec{r}')|^2}{\epsilon(\vec{r}, \vec{r}') |\vec{r} - \vec{r}'|} d^3r d^3r' \quad (28)$$

where the electron and hole wave functions are given by  $\Psi_e$  and  $\Psi_h$ , respectively.  $\epsilon$  is the full dielectric matrix, which includes any polarization or surface terms. The optical excitation gap,  $E_{\text{gap}}^{\text{opt}}$ , is given by

$$E_{\text{gap}}^{\text{opt}} = E_{\text{gap}}^{\text{qp}} + E_{\text{Coul}} \quad (29)$$

Equation (29) should be compared to the empirical expression [Eq. (16)] where similar terms are considered.

There are a few issues with Eq. (29). The local density approximation, which is commonly used to implement density functional theory, is flawed in the limit of infinite systems.<sup>[17,18]</sup> Namely, the quasiparticle gap as calculated using the local density approximation is about one-half the measured gap.<sup>[19]</sup> The difference, known as a “self-energy correction,” is commonly fixed by the infinite system and transferred without change to finite systems. This transfer is unlikely to be correct, especially for small dots.<sup>[20]</sup>

For small, localized systems, the local density approximation appears to be valid and gives reasonable values for the quasiparticle energies.<sup>[21]</sup> It is not clear how well Eq. (27) holds for larger confined systems, e.g., for dots larger than a few nanometers. Another issue concerns the dielectric function used in Eq. (28). In empirical studies,<sup>[6]</sup> the dielectric function is crudely approximated by a constant. More rigorous attempts have included spatial variations in the dielectric constant.<sup>[10,21]</sup> The full dielectric matrix, which includes the effect of the surface, has not been implemented to date.

An alternative approach using density functional theory is *time-dependent density functional theory*. Just as for “static” density functional theory, it is common to use the local density approximation. In this case, the method is called the *time-dependent local density approximation*. Within the time-dependent local density approximation, the excited state properties are derived as a linear response to an applied periodic (in time) perturbation. The system response is described by a coupling matrix, which can be used to determine the electronic excitations. Within an

adiabatic approximation, this matrix is given by

$$\mathbf{K}_{ij\sigma,kl\tau} = \iint \Psi_{i\sigma}^*(\vec{r}) \Psi_{j\sigma}(\vec{r}) \left( \frac{e^2}{|\vec{r} - \vec{r}'|} + \frac{\delta V_{\text{XC}}^\sigma(\vec{r})}{\delta \rho_\tau(\vec{r}')} \right) \times \Psi_{k\tau}(\vec{r}') \Psi_{l\tau}^*(\vec{r}') d^3r d^3r' \quad (30)$$

The indices ( $ij\sigma$ ) correspond to the occupied state, the unoccupied state, and the spin parameter, respectively. The wave functions for the one-electron wave functions are given by  $\Psi_{j\sigma}$ . The electronic transition energies can be obtained from the solution of the following eigenvalue problem:

$$\left[ E_{ij\sigma}^2 \delta_{ik} \delta_{jl} \delta_{\sigma\tau} + 2\sqrt{f_{ij\sigma} E_{ij\sigma}} \mathbf{K}_{ij\sigma,kl\tau} \sqrt{f_{kl\tau} E_{kl\tau}} \right] \mathbf{F}_n = \epsilon_n^2 \mathbf{F}_n \quad (31)$$

where  $E_{ij\sigma}$  is the transition energy between states ( $ij$ ), i.e., the energy difference between the Kohn–Sham eigenvalues from Eq. (25).  $f_{ij\sigma}$  is the occupation number.  $\epsilon_n$  is the excitation energy and the eigenvectors,  $\mathbf{F}_n$  are related to the oscillator strength.<sup>[22]</sup> Note that if the coupling matrix,  $\mathbf{K}_{ij\sigma,kl\tau}$ , is set equal to zero, the excitation energies would correspond to the standard Kohn–Sham eigenvalues,  $E_{ij\sigma}$ . In general, time-dependent local density methods tend to blue shift the optical gap, which improves agreement with experimental data. Implementations in real time of the time-dependent local density approximation are available.<sup>[23]</sup>

In principle, the time-dependent local density approximation incorporates electron screening and relevant correlation effects for electronic excitations.<sup>[22]</sup> A model screening dielectric function is not required as in Eq. (28) to estimate the screened Coulombic interactions in excitons. It should be noted that in addition to the local density approximation, time-dependent density functional methods almost always assume the adiabatic approximation; that is, the electrons are assumed to follow the external field instantaneously. The validity of this approximation has been questioned and remains an open question.

Time dependent density functional theories have been applied to hydrogenated silicon clusters and quantum dots. Such systems are illustrated in Fig. 9. Optical gaps for the small clusters have been measured and the agreement between the time-dependent local density approximation values for the optical gaps and experiment is quite good.<sup>[23]</sup>

## Hartree–Fock and Configuration Interaction Methods

A rigorous approach to the total energy of a silicon nanocrystal is to use a solution to the many-body

**Fig. 9** Ball and stick models for hydrogenated silicon clusters ( $\text{Si}_n\text{H}_m$ ).

Schrödinger equation. This entails solving a complex problem with numerous degrees of freedom. The electronic part of the Hamiltonian for an  $N$  electron system in its simplest form is given by

$$\left[ -\sum_i \frac{\hbar^2 \nabla_i^2}{2m} - \sum_{im} \frac{Z_m e^2}{|\vec{r}_i - \vec{R}_m|} + \sum_{i > j, i \neq j} \frac{e^2}{|\vec{r}_i - \vec{r}_j|} \right] \Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3, \dots, \vec{r}_N) = E \Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3, \mathbf{K}, \vec{r}_N) \quad (32)$$

The nuclear positions are given by  $\vec{R}_m$  with an atomic number of  $Z_m$ .  $E$  gives the total electronic energy of the system. This difficult problem can be solved, at least approximately, by invoking some approximations.

For example, in the Hartree–Fock approximation the many-body wave function can be written as

$$\Psi(\vec{r}_1 s_1, \vec{r}_2 s_2, \vec{r}_3 s_3, \dots, \vec{r}_N s_N) = \det \begin{vmatrix} \phi_1(\vec{r}_1 s_1) & \phi_1(\vec{r}_2 s_2) & \dots & \phi_1(\vec{r}_N s_N) \\ \phi_2(\vec{r}_1 s_1) & \phi_2(\vec{r}_2 s_2) & \dots & \dots \\ \dots & \dots & \dots & \dots \\ \phi_N(\vec{r}_1 s_1) & \dots & \dots & \phi_N(\vec{r}_N s_N) \end{vmatrix} \quad (33)$$

where the spin coordinate is explicitly written as  $s$ . This form of the wave function is known as a *Slater determinant*.<sup>[24]</sup> It reflects the proper symmetry of the wave function for fermions and incorporates the Pauli principle. If two electrons occupy the same orbital, two rows of the determinant are identical and the wave function will vanish. Likewise, the determinant will vanish if two electrons occupy the same point in space, as two columns of the determinant would be identical.

If one uses a Slater determinant to evaluate the total electronic energy and maintains the orbital normalization, then the orbitals can be obtained from a solution of the Hartree–Fock equation:

$$\begin{aligned} & \left( \frac{-\hbar^2 \nabla^2}{2m} + V_{\text{ion}}(\vec{r}) + \sum_{j=1}^N \int \frac{e^2 |\phi_j(\vec{r}')|^2}{|\vec{r} - \vec{r}'|} d^3 r' \right) \phi_i(\vec{r}) \\ & - \sum_{j=1}^N \left( \int \frac{e^2}{|\vec{r} - \vec{r}'|} \phi_j^*(\vec{r}') \phi_i(\vec{r}') d^3 r' \right) \delta_{s_i, s_j} \phi_j(\vec{r}) \\ & = E_i \phi_i(\vec{r}) \end{aligned} \quad (34)$$

where  $V_{\text{ion}}$  is given by

$$V_{\text{ion}}(\vec{r}) = - \sum_m \frac{Z_m e^2}{|\vec{r} - \vec{R}_m|}$$

This equation is commonly reformulated<sup>[24]</sup> as

$$\begin{aligned} & \left[ \frac{-\hbar^2 \nabla^2}{2m} - V_{\text{ion}}(\vec{r}) + V_{\text{H}}(\vec{r}) + V_x^i(\vec{r}) \right] \phi_i(\vec{r}) \\ & = E_i \phi_i(\vec{r}) \end{aligned} \quad (35)$$

where the Hartree potential is defined as before [Eq. (21)]. This equation is similar to the Kohn–Sham equation [Eq. (19)], save for the presence of an exchange potential given by  $V_x^i(\vec{r})$ . The presence of this potential greatly complicates the solution of the Hartree–Fock problem vis-à-vis the Kohn–Sham potential, as the exchange potential is orbitally

dependent. The exchange potential is given by

$$V_x^i(\vec{r}) = -\frac{1}{\phi_i(\vec{r})} \sum_{j=1}^N \phi_j(\vec{r}) \delta_{s_i, s_j} \times \int \frac{e^2}{|\vec{r} - \vec{r}'|} \phi_j^*(\vec{r}') \phi_i(\vec{r}') d^3 r' \quad (36)$$

Once the Hartree–Fock orbitals,  $\phi_i(\vec{r})$ , are known, the total energy of the system can be evaluated from

$$E(N) = \sum_{n=1}^N E_n - \frac{1}{2} \int V_H(\vec{r}) \rho(\vec{r}) d^3 r - \frac{1}{2} \sum_{i=1}^N \int \phi_i^*(\vec{r}) \phi_i(\vec{r}) V_x^i(\vec{r}) d^3 r \quad (37)$$

By evaluating the total energy with and without an electron, the electron affinity and ionization energy can be determined as in density functional theory [Eqs. (26) and (27)]. This allows one to determine the energy of creating a non-interacting electron–hole pair.

The Hartree–Fock approximation is deficient in that it fails to include *correlation* energies. “Correlation” energies are usually defined as the difference between the exact solution and the Hartree–Fock solution. This can occur because the Slater determinant does not have sufficient flexibility to provide the exact many-body wave function. To overcome this deficiency, one can incorporate determinants containing empty or virtual orbitals. These methods are called “configuration interaction” (CI) methods. Typically only a few dozen electrons can be handled using CI methods and contemporary computational platforms.

## Other Methods

Additional methods have been applied to silicon quantum dots. These methods tend to be computationally intensive and have only recently been applied to silicon quantum dots. These methods are the “GW–Bethe–Salpeter” method<sup>[25–27]</sup> and the “quantum Monte Carlo” method.<sup>[28–30]</sup>

The GW–Bethe–Salpeter method is a many-body method based on a Green function approach that explicitly treats the dynamics of an electron–hole pair in a quantum many-body system. The method proceeds in two steps. In the first step, the energy to create a non-interacting electron and hole pair is considered. This step is analogous to Eq. (27) in which the quasiparticle energy is computed by differencing the electron affinity and ionization energies. This step is referred to as the “GW” part of the calculation. In the second step, the electron and hole are

allowed to interact. In insulators and semiconductors, the electron–hole pair can bind to form localized “excitonic” states. The second step solved the “Bethe–Salpeter” equation. This method has been applied to insulating solids with large excitonic gaps such as silica or magnesium oxide. It has also been applied to hydrogenated silicon clusters. The largest cluster examined to date contained less than 50 atoms.

Solving the full many-body Schrödinger equation can be accomplished using quantum Monte Carlo methods. This approach has only recently been applied to silicon clusters. The method starts with the full Hamiltonian [Eq. (32)] and uses a modified form of the Slater determinant [Eq. (33)] to go beyond the Hartree–Fock approximation and include correlation energies. The quantum Monte Carlo method, as the name implies, is a stochastic technique. One can specify the desired accuracy and perform the Monte Carlo algorithm until the energy criterion is met. Historically, owing to the computational load of quantum Monte Carlo methods, systems with only a few electrons have been examined until recently. Progress in developing new algorithms has made it possible to examine quantum dots with a few hundred electrons.<sup>[28]</sup> Currently, quasiparticle energies can be calculated, but including the oscillator strength is more problematic. As such, optical spectra have not been calculated.

## Predicted Optical Gaps and Spectra for Passivated Silicon Nanocrystals

To expedite the discussion, two size regimes will be considered: small quantum dots and molecular forms of hydrogenated silicon and larger quantum dots. In Fig. 10, predicted optical gaps for dots of diameter of less than 15 Å are shown. The predictions in this figure come from tight-binding, quasiparticle local density approximation, quantum Monte Carlo, time-dependent density functional theory, GW–Bethe–Salpeter, and Hartree–Fock configuration interaction calculations. Despite the variety of theoretical approaches, the six methods agree fairly well in this size regime. One might assume the quantum Monte Carlo and GW–Bethe–Salpeter methods to be the most rigorous and the most accurate. If this is a valid assumption, then the Hartree–Fock configuration interaction results are probably not as accurate as the time-dependent density functional theory, tight-binding, and quasiparticle local density approximation calculations, which are in better agreement with the quantum Monte Carlo and GW–Bethe–Salpeter methods.

As one might expect, the more rigorous methods like quantum Monte Carlo have not considered dots with diameter above 10 Å. Current computational

**Fig. 10** Predicted optical gaps for “small” hydrogenated silicon quantum dots. Indicated are predictions from tight-binding (TB),<sup>[11]</sup> time-dependent local density approximation (TDLDA),<sup>[23]</sup> quasiparticle local density approximation (QP-LDA), quantum Monte Carlo (QMC),<sup>[29]</sup> GW–Bethe–Salpeter equation (BSE),<sup>[27]</sup> and Hartree–Fock configuration interaction (HF-CI)<sup>[31]</sup> calculations. The dashed line is a guide to the eye.

platforms are not sufficient to describe systems with more than a few hundred atoms. However, unlike empirical methods, these methods are capable of spanning systems from small molecular species such as silane up to systems with a hundred atoms or so.

**Fig. 11** Predicted optical gaps for “large” hydrogenated silicon quantum dots. Indicated are predictions from TB,<sup>[11]</sup> TDLDA,<sup>[23]</sup> QP-LDA, and empirical pseudopotential method (EPM)<sup>[32]</sup> calculations. The dashed line is a guide to the eye.

In general, the role of quantum confinement appears to hold down to systems with a few atoms, as the predicted optical gap increases as the size of the dot shrinks. However, one must be careful in this assessment; for example, the ratio of Si–H bonds to Si–Si bonds is larger as the surface to volume ratio is larger for small dots than for large dots. This difference is not reflected in a rigid confinement model, which

**Fig. 12** Photoabsorption spectra for hydrogenated silicon clusters and quantum dots (as in Fig. 8). The solid line represents spectra calculated using the time-dependent local density approximation. The dotted line represents a static local density approximation.

would predict the gap to diverge as the size of the dot diminished, as in Eq. (6).

In Fig. 11, predicted gaps for dots of diameter from 10 to 40 Å are presented. The predictions are based on time-dependent density functional theory, tight-binding, quasiparticle local density approximation, and empirical pseudopotential method calculations. The general trend of quantum confinement is well reproduced within this size regime. All of the methods, save the empirical pseudopotential method are in surprisingly good accord. The empirical pseudopotential method requires a fitting of the potentials to either experiment or theory as does the tight-binding method. It may be that this particular fitting for the pseudopotential was not as accurate as for the tight-binding method.

In Figs. 10 and 11, only the value for the lowest excitation was presented. Higher excitations were not considered, nor were the oscillator strengths. The latter can be an issue with methods such as quantum Monte Carlo, where higher-order excitations and oscillator strengths have not been explicitly considered. In contrast, methods such as the time-dependent local density approximation include higher excited states and oscillator strengths. In Fig. 12, photoabsorption spectra are presented for hydrogenated silicon clusters as indicated in Fig. 9. Both static and time-dependent local density approximation calculations are illustrated. The static calculations were obtained using Eq. (13), where for clusters the sum is over occupied and empty states, but not wave vector. For small clusters, the spectra tend to have sharp structures as expected for “molecular-like” systems. As the size of the system evolves, the spectra exhibit less structure and resemble the bulklike spectrum of crystalline silicon. Although it may not be apparent in Fig. 11, the oscillator strength for low-lying excitations decreases dramatically with increasing dot size.

## CONCLUSION

Major progress has been achieved within the last decade in simulating optical properties of silicon nanostructures and quantum dots. In particular, traditional approaches such as the empirical pseudopotential method and tight binding have been applied to large quantum dots. In addition, new formalisms and implementation have been developed such a GW–Bethe–Salpeter, quantum Monte Carlo, and time-dependent density functional theory. These new formalisms appear to be consistent for nanocrystals and quantum dots of a few hundred atoms or less and to be in agreement with experimental data, where available. A challenge to workers in this field will be to extend these systems to larger and more complex

systems with no loss of accuracy. Such complex systems will include the role of adsorbates, defects, and passivating media. An additional challenge will be to consider higher excitations and extract the full optical spectra of silicon nanocrystals.

## INTRODUCTION

Secondary ion mass spectrometry (SIMS) is capable of imaging biological molecules across single cells with several hundred nanometer lateral resolution, and has the potential to examine the functional segregation of lipids in cell membranes. Lipids are believed to play a crucial role in fundamental biological functions, such as intercellular communication.<sup>[1]</sup> For example, high curvature lipids may be concentrated in regions of the lipid bilayer where membrane fusion preferentially occurs, because these lipids allow the bilayer to bend into the high curvature structures that form throughout the membrane fusion process.<sup>[2,3]</sup> Additionally, abnormalities in lipid composition may be involved in a wide range of diseases including Parkinson's disease, Alzheimer's disease, HIV, and atherosclerosis.<sup>[4-6]</sup> Research to better understand the biological role of lipids could help in the development of disease therapies, thus improving the quality and longevity of life. This article will review SIMS as it pertains to biological samples and will address relevant progress in SIMS including fundamental ionization studies of lipids, instrumental developments, and novel applications of SIMS imaging to single-cell analyses.

## SIMS

### Theory and Background

An important goal of SIMS research is to directly image the chemical distribution of small molecules across the surface of biomaterials.<sup>[7-10]</sup> With this method, ionic species that are emitted (or sputtered) from a sample following the impact of an incident, or primary, projectile are detected. More specifically, SIMS analysis uses a pulsed beam of primary ions that is focused onto a sample (Fig. 1).<sup>[11]</sup> Depending on the desired application, a variety of primary projectiles ( $\text{Cs}^+$ ,  $\text{Ar}^+$ ,  $\text{Ga}^+$ ,  $\text{In}^+$ ,  $\text{SF}_5^+$ ,  $\text{Au}_n^+$ ,  $\text{Bi}_n^+$ ,  $\text{C}_{60}^+$ , etc.) may be suitable. The impinging primary particles transfer energy and momentum to the sample, resulting in a

series of complex collisions within the sample. These energetic interactions ultimately cause sample electrons, neutral species, and ions (or secondary species) to be ejected from the sample (Fig. 2).<sup>[12-16]</sup> Secondary ions can form through several routes including electron ejection, protonation, deprotonation, cationization, loss of a functional group, and fragmentation resulting in charged species.<sup>[14]</sup> The secondary ions are then electrostatically collected and directed into a mass analyzer.

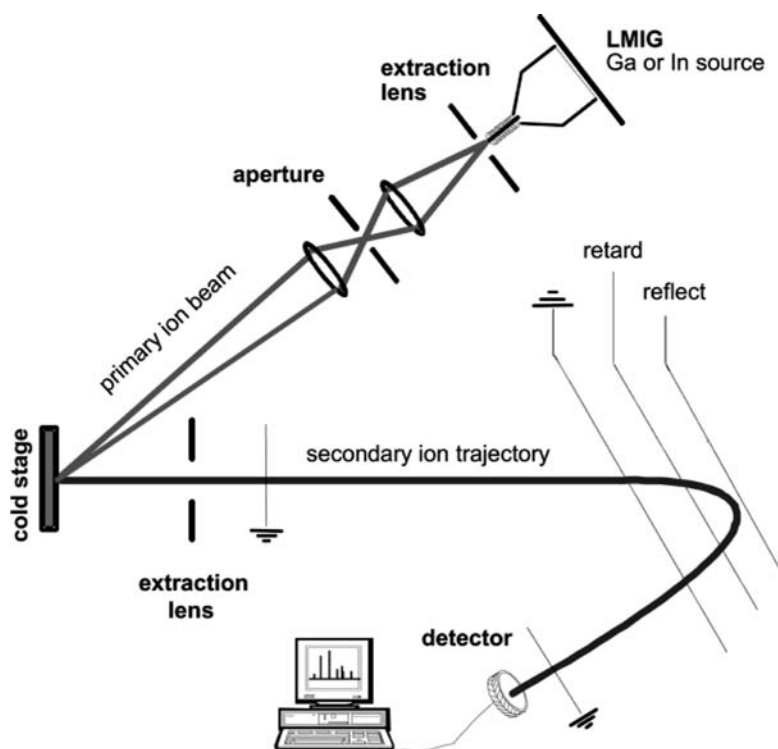

Secondary ion mass spectrometry can be divided into two different modes called static SIMS and dynamic SIMS, which are distinguished by the incident dose of primary ions. Secondary ion mass spectrometry is described as static when the primary ion flux is less than 1% of the total number of surface atoms; SIMS is dynamic when the incident dose is greater than this value.<sup>[17]</sup> Dynamic SIMS is marked by extensive beam-induced damage, which destroys molecular information and limits dynamic SIMS to elemental and isotopic studies. Static SIMS is inherently less damaging to the molecular integrity of a sample because of the low primary ion flux (1 nA/cm<sup>2</sup> or less).<sup>[14]</sup> There is minimal chemical damage and spatial perturbation of sample molecules. Therefore, static SIMS is favored for applications where large molecules or molecular fragments are investigated. Another unique aspect of the static regime is that only the top-most sample monolayer is probed, making static SIMS a surface sensitive technique.<sup>[18]</sup> Because of its ability to analyze molecules at surfaces, the static mode of SIMS has been used for examining lipids on tissues and cell membranes.<sup>[9,10]</sup>

## Instrumentation

### Primary ion source

Secondary ion mass spectrometry instruments employ a variety of primary ion source configurations including electron impact ionization-based sources, duoplasmatron sources, and field evaporation-based sources, like the popular liquid metal ion sources (LMIS).<sup>[14]</sup>

**Fig. 1** Time of flight SIMS (ToF-SIMS) instrumental setup. *Source:* From Ref.<sup>[11]</sup>.

By far, the most commonly used primary ion sources are the LMIS, such as gallium ( $\text{Ga}^+$ ) and indium ( $\text{In}^+$ ), because of their brightness, small spot size, and simplicity. Liquid metal ion sources are mounted on the end of a primary ion gun column adjacent to a negative potential field that initiates primary ion emission from the LMIS.<sup>[14]</sup> The gun column also contains several electrostatic lenses and octupoles to focus the beam down to a 50-nm diameter, and a pair of electrostatic plates that pulse the ion beam for SIMS experiments.

Advances in primary ion beam technology have directed the communities' attention to the benefits of cluster ion primary sources, such as  $\text{Au}_n^+$ ,  $\text{Bi}_n^+$ ,  $\text{SF}_5^+$ , and buckminsterfullerene,  $\text{C}_{60}^+$ .<sup>[19–21]</sup> Experimental results indicate that  $\text{C}_{60}^+$  offers enormous improvements

in secondary ion yield and minimal chemical damage to sample molecules.<sup>[21]</sup> Molecular dynamics simulations suggest that upon surface impact,  $\text{C}_{60}$  cluster projectiles break into individual carbon atoms and disperse the primary projectile energy among the individual atoms.<sup>[15]</sup> This phenomenon allows for a more shallow penetration depth and more surface-localized primary bombardment energy for cluster projectiles, in comparison to their atomic counterparts. The  $\text{C}_{60}^+$  sputtering mechanism allows intact molecules to be gently lifted off the surface, creating higher secondary ion yield, particularly for high mass molecules, and minimal chemical damage.<sup>[21]</sup> Therefore,  $\text{C}_{60}^+$  and other cluster ion sources are attractive alternatives as SIMS primary ion sources for biological applications, where there is a desire to greatly reduce molecular fragmentation of larger-mass target analytes. Additionally, the attributes of  $\text{C}_{60}^+$  suggest that molecular depth-profiling is possible, which will allow 3-D imaging of tissue and cells.<sup>[22–25]</sup>

Secondary ion mass spectrometry images are obtained by scanning the primary ion beam across the sample surface and collecting a unique mass spectrum for every image pixel (Fig. 3).<sup>[26]</sup> The signal sent to the computer contains the location of the primary ion impact and the spectrum collected at that position. The computer uses this information to output a spectrum, called the “total ion spectrum,” which contains the integrated intensities for all the ions at every pixel of the image. Additionally, the computer generates a

**Fig. 2** Illustration of sputtering and ionization by SIMS. *Source:* From Ref.<sup>[12]</sup>.

**Fig. 3** Chemical imaging with ToF-SIMS. The primary ion source is rastered across the sample surface and a mass spectrum is collected at each pixel. For every mass range of interest, an intensity plot, which maps the distribution of that signal across the sample, can be generated. The intensity plots can be color coded and overlaid. In this example, an electronic device composed of titanium ( $m/z$  48, green) and barium ( $m/z$  138, blue) is chemically imaged. *Source:* From Ref.<sup>[26]</sup>.

“total ion image,” which is an intensity map for all of the ions in each pixel (Fig. 4). Computer software is then used to extract spatial, chemical-specific information from the “total ion” image and spectrum. In one method of data analysis, the user selects a mass range of interest in the total ion spectrum, and the software creates a 2-D intensity map of the distribution of that signal across the sample (Fig. 4). In an alternative way to analyze the data, the user can select a region of interest in the total ion image, and the computer generates a mass spectrum with integrated intensities for the ions in only the selected pixels.

### Secondary ion extraction

The primary ion source directs the primary ion beam onto the sample, which is mounted on a sample stage

**Fig. 4** Secondary ion mass spectrometry images of a copper London Finder grid. The grid was adhered to a copper sample block with silver paste. (A) Total ion image; (B) chemical image of the distribution of copper (green) and silver (blue).

at  $\pm 2.5$  kV. The stage potential can be pulsed or held constant and repels ions of like charge, which are then collected by an extraction lens oppositely biased at 4.7 kV. For example, if the target analyte is a cation, the sample stage would be positively charged, and the extraction lens would be negatively charged. This mode of operation is called “positive SIMS,” because the positive ions are being analyzed. The instrumental polarities must be switched to generate spectra of negatively charged species.

### Mass analyzers

The extraction lens directs the secondary ions into the mass analyzer, which can be a magnetic sector, quadrupole, or ToF. Of these three mass analyzers, the ToF analyzer is the best equipped for static SIMS imaging, because it detects all ions in parallel, boasts a high transmission, and has a virtually unlimited mass range.<sup>[17]</sup> Additionally, advances in electronic timing systems have allowed ToF analyzers to provide a competitive mass resolution of 10,000.<sup>[14]</sup> The general concept of a ToF analyzer is that the secondary ions are accelerated to a specific kinetic energy and then allowed to travel a defined distance.<sup>[14]</sup> The mass of each secondary ion can be calculated from the time it takes to travel the distance.<sup>[14]</sup> After the secondary ions are separated in the mass analyzer, they impact a detector, such as a multichannel plate detector. The molecules reach the detector sequentially because each molecule has a unique mass, allowing quasi-parallel detection.<sup>[14]</sup>

### Biological Samples: Frozen-Hydrated Sample Preparation for Sims

Maintaining the native chemical distribution in hydrated samples, such as cells, in the ultra-high vacuum environment of a SIM spectrometer is challenging. The low pressures cause rapid sublimation of water, which results in the membranous material and intercellular content of a cell smearing across the sample surface.<sup>[27]</sup> To prevent this phenomenon, a fast-freeze, freeze-fracture sample preparation methodology has been adapted from the electron microscopy community, to preserve biological samples for SIMS analysis (Fig. 5).<sup>[28,29]</sup> A cell sample is delivered onto a clean silicon wafer and a shard of silicon is placed on top of the cells. The sample assembly is then plunged into a cryogen to freeze the cells, while minimizing the ice crystal-induced sample damage.<sup>[30]</sup>

Prior to analysis, the top shard of the fast-frozen sample assembly is removed by a cryogenically cooled knife in a sample preparation vacuum chamber adjoining the SIMS analysis chamber.<sup>[27]</sup> This “freeze-fracture”

**Fig. 5** Cryogenic preservation of hydrated samples. The sample, containing cells (shown in pink) and polystyrene beads (shown in yellow), is delivered onto a silicon wafer. A silicon shard is placed on top of the sample droplet to create a sandwich assembly. The sandwich assembly is then plunged into a liquid cryogen. *Source:* From Ref.<sup>[27]</sup>.

process results in the exposure of a fresh surface to the vacuum interface. Fracturing is performed at a pressure-dependent sample temperature that equilibrates the condensation and sublimation fluxes of water.<sup>[27]</sup> The sample temperature is controlled throughout the preparation and analysis, by several chamber components that are cryogenically cooled. The details of the freeze-fracture chamber have been described.<sup>[27]</sup>

## OVERVIEW OF ADVANCES IN BIOLOGICAL SIMS

Images of both elemental and molecular analytes have provided a wealth of information, learned using SIMS. For example, dynamic SIMS elemental analysis has allowed Chandra and coworkers<sup>[8]</sup> to assess the efficacy of boron neutron-capture therapy (BNCT) cancer drugs at the single-cell level.<sup>[8]</sup> Images of the subcellular distribution of boron were used to compare the accumulation of two BNCT drugs, *p*-boronophenylalanine (BPA-F) and sodium borocaptate (BSH), in normal and cancerous cocultured cells. *p*-Boronophenylalanine accumulated in both cell types at significantly higher levels than BSH, indicating that BPA-F enters the cell by an active uptake mechanism and not by simple passive diffusion. This research group has been at the forefront of biological dynamic SIMS with many other notable applications including the mapping of elevated concentrations of  $\text{Ca}^{2+}$  in the Golgi apparatus to determine how it is affected by hormone and antigen treatment.<sup>[31]</sup>

Lechene and coworkers<sup>[32–34]</sup> also have worked on an impressive repertoire of mass spectrometric elemental imaging applications. In particular, Lechene utilizes a variation of SIMS called multi-isotope imaging mass spectrometry (MIMS), in which isotopic signals can be

simultaneously monitored, because the instrument has a very high mass resolution. For example, the instrument can distinguish between  $^{12}\text{C}^{15}\text{N}$  ( $m/z = 27.0001$ ) and  $^{13}\text{C}^{14}\text{N}$  [ $m/z = 27.0064$  with a mass resolution ( $m/\Delta m$ ) of 4287].<sup>[32]</sup> One study demonstrated that MIMS is a useful technique to image and quantify isotope ratios in free fatty acids (FFA) on the subcellular scale.<sup>[34]</sup> Adipocytes are cells that sequester FFA from the blood and store them as triacylglycerol in lipid droplets, which are 1  $\mu\text{m}$  sized features within the cells. Adipocytes were incubated in  $^{13}\text{C}$  oleic acid; with MIMS imaging, a higher level of  $^{13}\text{C}$  accumulation was found in the lipid droplets than in the extracellular space or in the remaining intracellular space (Fig. 6). These results illustrated that FFA transport across the cell membrane is protein mediated, because FFA moves against its concentration gradient. In addition to supporting a hypothesis for the controversial FFA transport mechanism, this work was yet another example of the wide range of subcellular, biological questions that isotope ratio quantification with MIMS imaging can answer.

The Levi-Setti research group is renowned for using the elemental imaging capabilities of SIMS for biological applications. In one study, they obtained 50 nm lateral resolution SIMS images of the cation distribution in mammalian interphase cells, mitotic cells, and isolated metaphase chromosomes that supported a role for cations in the regulation of the cell cycle.<sup>[35]</sup> The SIMS images demonstrated that the localization of  $\text{Na}^+$  and  $\text{K}^+$  remained constant during the cell cycle, but  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  changed depending on the stage of the cell cycle: In the interphase these divalent cations were predominately present in the cytosol, whereas during mitosis they were aggregated in the chromatin. Quantification of the SIMS signal revealed that the total intercellular divalent cation concentration

**Fig. 6** Images of unwashed adipocytes treated with  $^{13}\text{C}$  oleate: BSA. The MIMS images of (A)  $^{12}\text{C}^-$  and (B)  $^{13}\text{C}^-$ ; (C) MIMS ratio image of  $^{13}\text{C}/^{12}\text{C}$  showed the enhanced accumulation of isotopically labeled lipid in the lipid droplets. The MIMS images of (D)  $^{12}\text{C}^{14}\text{N}^-$  and (E)  $^{12}\text{C}^{15}\text{N}^-$ ; (F) MIMS ratio image of  $^{12}\text{C}^{15}\text{N}^-/^{12}\text{C}^{14}\text{N}^-$  had no contrast because no exogenous  $^{15}\text{N}$  was added. (G) A hue saturation intensity image of the  $^{13}\text{C}/^{12}\text{C}$  ratio. (H) A reflection differential interference image prior to MIMS analysis. (I) A MIMS ratio image of  $^{13}\text{C}^{14}\text{N}^-/^{12}\text{C}^{14}\text{N}^-$  further demonstrated the accumulation of labeled lipid in the lipid droplets. Scale bar is  $5\ \mu\text{m}$ . Source: From Refs.<sup>[31,34]</sup>

did not change significantly during the cell cycle. From this data, the authors concluded that progression through the cell cycle resulted in a redistribution of divalent cations without a major influx or efflux of the ions. Therefore,  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  likely play a role in chromatin compaction only during the mitotic stage, whereas  $\text{Na}^+$  and  $\text{K}^+$  are involved in compaction throughout the cell cycle. A combination of SIMS imaging and immunofluorescence (IF) have indicated that only  $\text{Ca}^{2+}$  localizes at the chromosome axis with the nonhistone binding protein, topoisomerase II $\alpha$

(Topo II) (Fig. 7). It follows that  $\text{Ca}^{2+}$  probably inhibits the catalytic activity of the protein and plays an important role in stabilizing the chromosomal scaffolding proteins, such as Topo II. When the authors incubated mitotic chromosomes with chelating agents, SIMS and IF images exhibited a loss of Topo II and a decondensed chromosome structure, indicating that  $\text{Ca}^{2+}$  must also be involved in maintaining the chromosome structure during mitosis. This research provided the first evidence, without secondary markers, that cations have specific, functional interactions

**Fig. 7**  $\text{Ca}^{2+}$  SIMS image (A) and Topo II antibody IF image (B) of metaphase chromosomes. The cation and scaffolding protein antibody colocalize, indicating that  $\text{Ca}^{2+}$  binds to Topo II and mediates its activity. *Source:* From Refs.<sup>[32,35]</sup>.

with chromatin binding proteins, and that cations help control chromosome structure during the cell cycle.

Static SIMS molecular imaging has also been applied to investigations of single cells. The seminal paper in this area presented static SIMS images of molecular species, as well as elemental analytes, on dopant-treated paramecia.<sup>[7]</sup> The cocaine molecular ion, a cocaine fragment ion, dimethyl sulfoxide, and potassium, all colocalized to the treated protozoa. This work demonstrated the capability of SIMS to image molecular analytes across single cells, thus paving the way for single-cell studies of large molecule drugs, and biological molecules such as vitamins and membrane lipids.

Identifying mass spectral peaks from biological molecules in a complex system, such as a cell membrane, is very challenging. Therefore, experiments that associate a peak of a particular mass with a fragment of a biological molecule mark significant advances toward realizing the utility of SIMS for biological applications. Todd and coworkers<sup>[9]</sup> identified abundant high-mass peaks at  $m/z$  184 and  $m/z$  86 observed in several types of tissue as fragment peaks from phosphatidylcholine and sphingomyelin. The identification of mass spectral peaks for lipid fragments presented the option of using SIMS imaging to investigate the lipid distribution in tissue, model membrane systems, and cells.

Experiments with model systems have proven that SIMS imaging of lipid domains is possible, and, therefore, the goal of studying the functionality of lipid domains in cells can be realized. Benninghoven used Langmuir Blodgett (LB) films as lung surfactant model systems to assess lipid involvement in the compression/exhalation and expansion/inhalation of the lung.<sup>[36]</sup> An LB film composed of dipalmitoylphosphatidylcholine (DPPC), dipalmitoylphosphatidylglycerol, and the lung surfactant protein (SP-C) was prepared, and, upon severe compression, a distinctly heterogeneous distribution of the film components

was observed. Specifically, SP-C reorganized into a SP-C-rich phase following film compression, which supported the hypothesis that lung compression causes non-DPPC components to leave the monolayer.<sup>[36]</sup>

Winograd and Ewing have also investigated LB films with static SIMS. In these experiments, LB films of varying amounts of DPPC, dipalmitoylphosphatidylethanolamine (DPPE), and cholesterol were analyzed.<sup>[37]</sup> Micrometer-sized cholesterol domains were observed in LB films of mixtures containing DPPE; however, LB films containing the same percentage of cholesterol and DPPC were homogeneous. The authors explained these results by the interaction strength differences between the three molecules. The DPPE headgroup is known to interact more strongly with other phospholipid headgroups than with cholesterol. Therefore, the phospholipids preferentially aggregated, which excluded cholesterol and resulted in lipid domains. The propensity of cholesterol to induce domain formation implicated a functional role for cholesterol in cell signaling and trafficking.<sup>[37]</sup>

Liposomes are another common artificial model for cell membranes. Molecule-specific images of dynamic membrane events were captured during several stages of fusion between chemically distinct multilamellar liposomes.<sup>[27]</sup> Specifically, liposomes 20  $\mu\text{m}$  in size were prepared that contained cholesterol and either DPPC, dipalmitoylphosphatidyl-*N*-monomethylethanolamine (DPPNME), or dipalmitoylphosphatidyl-dimethylethanolamine (DPDME). The separate batches of liposomes were mixed onto a single substrate, and the samples were frozen after various mixing times.<sup>[27]</sup> Chemical snapshots of three stages of liposome fusion were obtained: liposomes in close proximity, liposomes undergoing initial contact, and liposomes that had fully fused (Fig. 8). Interestingly, during fusion, the liposomes joined at a contact point, where lipid heterogeneity was evident, while fully fused liposomes displayed a completely uniform lipid distribution. These results showed that liposome fusion involves initial lipid domain formation followed by a homogeneous redistribution of lipids throughout the fused liposomes. This publication highlighted liposome model systems as an effective way to investigate membrane dynamics with ToF SIMS.

In addition to imaging lipids in model membrane systems, many research groups have applied SIMS imaging to single-cell membranes. For example, lipids have been localized to single rat pheochromocytoma (PC12) cell membranes, using SIMS imaging.<sup>[10]</sup> Pheochromocytoma cells are an exciting system for neurochemistry applications, because they can be differentiated to have neuronal-like properties when exposed to the nerve growth factor protein.<sup>[38]</sup> Undifferentiated PC12 cells undergo regulated exocytosis and can be used to learn if the lipid composition affects

**Fig. 8** Liposomes with distinct lipid compositions: DPPC/cholesterol, DPPNME/cholesterol, and DPPDME/cholesterol, that were mixed together and frozen after different times. In all images, the blue pixels represent water ( $m/z$  17.9–19.1). From left to right, the images are mapped for  $C_3$  hydrocarbons ( $m/z$  40.9–43.3, yellow), two phosphorylated headgroups (various  $m/z$ , yellow and red), and cholesterol ( $m/z$  384.1–387.1, yellow). A DPPC/cholesterol and DPPDME/cholesterol liposomes were mixed and frozen after 30 sec of mixing. The phosphorylated headgroups mapped in the center column were phosphocholine ( $m/z$  183.9–184.3, yellow) and phosphodimethylethanolamine headgroup ( $m/z$  169.9–170.3, red). The two types of liposomes have not yet begun to fuse. B. and C. DPPC/cholesterol and DPPNME/cholesterol liposomes were frozen together after B. 120 sec and C. 60 sec of mixing time. The phosphorylated headgroups mapped in the center column were phosphocholine ( $m/z$  183.9–184.3, yellow) and phospho-*N*-monomethylethanolamine ( $m/z$  155.9–156.3, red). A homogeneous distribution of the two phospholipids was observed after full fusion in B., but a heterogeneous distribution was evident during initial fusion in C. *Source:* From Refs.<sup>[24,27]</sup>

the abnormalities in exocytosis, observed in many neurological diseases. Using SIMS, phosphocholine and cholesterol were imaged across single PC12 cells.<sup>[10]</sup> This study demonstrated the ability of SIMS to detect multiple lipids in biological samples.

In a separate experiment, Ewing and coworkers<sup>[39]</sup> found that freeze-fracture sample preparation can expose different section planes through a cell. Pheochromocytoma cells were dyed with the lipophilic dye, 1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (DiI), which is known to incorporate only onto the outer leaflet of the membrane.<sup>[39]</sup> Therefore, the outer leaflet of the cell membrane contained lipid and DiI, the inner leaflet of the cell was composed of lipid and no DiI, and the interior of the cell contained elevated amounts of potassium. Using SIMS imaging of stained PC12 cells, chemical signatures for five

possible cell sections were determined. Two of these cell sections were from exposure of the outer leaflet (top or bottom) of the cell membrane during fracturing. In this scenario, the SIMS images showed colocalization of DiI and phosphocholine, while sodium, potassium (ions present in the freezing medium), and water were depressed at the site of the cell. The top and bottom inner leaflet of the membrane were two other exposed cell sections, and were identified by localization of phosphocholine and potassium to the cell, the absence of DiI signal, and decreased intensities of water and sodium at the area of the cell. Finally, through-cell fractures were characterized by a strong localization of potassium and some phosphocholine from free lipid in the cytoplasm, lipid from organelles, and lipid from the edges of the cell membrane. This cell section contained no DiI signal and showed an inverse

localization of water and sodium. Identifying chemical signatures that define the section of a cell exposed to the surface–vacuum interface was an important advance for the biological SIMS community.

Besides the lipids and steroids discussed above, another important chemical in membrane chemistry is vitamin E, because it affects membrane fluidity and has been implicated in lipid oxidation and, therefore, in numerous neurodegenerative disorders.<sup>[40]</sup> Recently, Sweedler and coworkers<sup>[40]</sup> discovered that a peak at  $m/z$  430 in biological samples arises from vitamin E. Along with this peak identification, the Sweedler group has reported exciting SIMS images that suggest a possible functional role for vitamin E in neuronal membranes.<sup>[40]</sup> Subcellular molecular images of an isolated neuron from *Aplysia californica* revealed that vitamin E ( $m/z$  430 and  $m/z$  165) was strongly localized to the junction between the cell soma and the neurite, compared to the rest of the cell body (Fig. 9). The authors compared a normalized vitamin-E signal

for the soma–neurite junction to the cell body, and found that the junction contained  $165 \pm 11\%$  more vitamin E. These results suggested a possible structural role for vitamin E, in terms of modulating the membrane radius of curvature at the junction, and a possible functional role, in terms of transport mechanisms and neuronal signaling.

Along with mammalian cells, other types of cells have been investigated with SIMS to progress towards the goal of understanding lipid distribution during membrane fusion events. For example, the mating *Tetrahymena thermophila* were imaged with SIMS by Ostrowski et al.<sup>[41]</sup> During mating, two *Tetrahymena* join at their anterior ends and their membranes fuse, creating hundreds of nanometer-sized fusion pores within a well-defined 8- $\mu\text{m}$  region, called the conjugation junction. Secondary ion mass spectrometry images reveal a heterogeneous distribution of signals for specific lipids across the mating cells. Specifically, the total lipid content remained constant across the

**Fig. 9** Molecule-specific SIMS images and corresponding line scans of an isolated single neuron. (A) SIMS image of choline,  $m/z$  86, a fragment of phosphatidylcholine and a common marker for the cell membrane. (B) SIMS image of a fragment of a lipid acyl chain,  $m/z$  69, another common cell membrane marker. (C) SIMS image of vitamin E,  $m/z$  430, which is strongly localized to the junction between the cell body and the neurite. (D) Line scans for vitamin E (top) and choline (bottom), normalized to  $m/z$  69 and taken along the line indicated in the inset, beginning at the soma. Vitamin E displays a higher signal at the soma–neurite junction than the rest of the cell body, whereas, the choline signal is relatively constant across the distance. *Source:* From Refs.<sup>[37,40]</sup>

mating cells (Fig. 10A and B). However, there was a decreased amount of PC at the conjugation junction, as evidenced by a  $67 \pm 8\%$  decrease in phosphocholine signal at the junction vs. the cell body (Fig. 10C and D). Additionally, statistical analysis of the SIMS images suggests an increase in a cone-shaped lipid, 2-aminoethylphosphonolipid, at the junction. From the observed lipid heterogeneity, it was concluded that *Tetrahymena* synthesize or redistribute lipids to allow the formation of high curvature membrane structures. This work is an elegant example of the capability of molecular SIMS imaging to probe sub-cellular, micrometer-sized membrane regions that contain structures in the nanometer regime.

### Sample Preparation and Instrumental Design Improvements in Biological SIMS

Although all of these application-based advances have been invaluable in promoting SIMS as a bio-analytical technique, instrument and sample preparation developments have also been an important part of the picture. First, epifluorescence microscopy was incorporated into the optical assembly of a SIMS instrument.<sup>[10]</sup> Epifluorescence was a valuable instrumental addition, because it allowed easy location of small, fluorescently labeled cells in ice prior to SIMS analysis. For instance, 15- $\mu\text{m}$  PC12 cells were fluorescently labeled with DiI, located in situ with fluorescence microscopy, and subsequently imaged with SIMS.<sup>[10]</sup>

One notable challenge in SIMS imaging has been that information in the images is limited because of the low secondary ion yield of biomolecules. To circumvent this obstacle and improve signal, different sample preparation protocols and instrumental advances have been developed. Sjovall et al.<sup>[42]</sup> developed an alternate sample-preparation methodology in which cell membranes were imprinted onto Ag foil ex situ. Membranous matter was transferred from cells adhered onto glass to an Ag foil, by placing the foil on the backside of the foil and applying a specific pressure to the backside of the foil. The foil was then transferred into the SIMS analysis chamber. This method was advantageous, because silver cationization enhanced the secondary ion signal from biological fragment ions and molecular ions. In one particular experiment, the distributions of phosphatidylcholine and cholesterol were imaged, with a 500 nm lateral resolution, across blood cell imprints.

A significant instrumental advance that has revitalized biological SIMS has been the advent of cluster primary ion sources, like  $\text{C}_{60}^+$ , as previously discussed.<sup>[19–21]</sup> Vickerman and coworkers have reported impressive secondary ion yields, produced by  $\text{C}_{60}^+$  relative to  $\text{Ga}^+$ . For example, the ion yields for a thin film of DPPC were found to be 158 times higher for  $m/z$  100–200 and 3985 times higher for the molecular ion.<sup>[21]</sup> This signal enhancement will make analyte masses easier to discern from noise in complex biological samples. Also, the contrast between adjacent pixels in images will be improved, because resolution in SIMS

**Fig. 10** Secondary ion mass spectrometry images and line scans of mating *T. thermophila*. (A) SIMS image and (B) line scan for a lipid acyl chain fragment,  $m/z$  69, which is representative of the total lipid distribution. The inset indicates the region of the image selected for the line scan. The total lipid signal is relatively constant across the distance of the mating cells. (C) SIMS image and (D) line scan for phosphocholine,  $m/z$  184. The phosphocholine signal shows a dramatic drop in signal at the junction between the two cells. images is determined by the number of ions that are collected at each pixel.

## CONCLUSIONS

The abundance of previous SIMS research provides a wealth of examples showcasing the compatibility of this technique and biological applications. Already, SIMS has been used to study the effects of cancer drugs on single cells, to elucidate the role of cations in isolated metaphase chromosomes, and to image large-molecule dopants, vitamins, and lipids across single cells. The ambitious pursuit of challenging applications, coupled with instrumental advances, has set the groundwork for future studies of the cellular functionality of lipid domains.

## INTRODUCTION

The optical detection of single molecules in the condensed phase was first demonstrated just over a decade ago by Moerner and Kador,<sup>[1]</sup> Orrit and Bernard,<sup>[2]</sup> and Shera et al.<sup>[3]</sup> Since that time, single molecule spectroscopy has developed into a valuable tool for probing nanoscale heterogeneity in a wide variety of materials.<sup>[4–7]</sup> For such studies, carefully selected dye molecules are doped into samples of interest at low concentrations. The individual molecules are then located and probed one at a time. Their signals are isolated from each other by spectral selection at cryogenic temperatures,<sup>[1,2]</sup> and/or by spatial selection in an optical microscope.<sup>[3,8–11]</sup> Detailed information on the time dependence, wavelength dependence, and polarization dependence of the excitation and emission processes can be obtained. Numerous spectroscopic parameters associated with the excitation and emission events in dye molecules are highly sensitive to the local environment in which each molecule resides. Therefore single molecule spectroscopy can be used as a direct means to assess the chemical and physical properties of the local environments found in almost any sample. The methods associated with the collection and interpretation of optical single molecule spectroscopic data for the purposes of understanding the environmental properties of nanostructured materials is the primary focus of this article.

## Scope

Single molecule spectroscopy is now employed in a wide variety of scientific and engineering disciplines. Hundreds of manuscripts on the subject are published each year. The discussion in this article is limited to methods of direct relevance to the characterization of nanoscale environments in and on condensed-phase materials. Primary emphasis is given to studies performed at room temperature, as these are deemed most broadly applicable. However, no attempt is made

to present a comprehensive review even of this much narrower subject. The interested reader is directed to a number of more comprehensive reviews for more information.<sup>[5–7,12–19]</sup>

## Why Single Molecules?

It is abundantly clear that a large number of chemically distinct nanometer-scale environments exist in virtually all materials. These environments may be comprised of different atoms, molecules, and ions. They may also be physically different, with their constituents organized and oriented in different ways.

In gas- and liquid-phase samples, the atoms, molecules, and ions move at relatively rapid rates. As a result, the local environments are dynamic and rapidly interconvert. Over a short period of time, the components in each region explore the entire range of possible configurations. New chemical species may continuously migrate in and out of each region as well. In time, each local environment possesses the same average properties exhibited by the entire sample. This is the basis for ergodicity.<sup>[5]</sup> One can obtain valuable (and nearly complete) information on the chemical and physical properties of the sample by simply measuring its average (i.e., bulk) properties. Indeed, classic bulk optical spectroscopic methods have long been employed to better understand the static and dynamic properties of a wide variety of samples.<sup>[20]</sup>

In solid samples, the local environments do not rapidly interconvert. Each individual environment may exhibit unique properties over relatively long periods of time. This is especially true in today's nanostructured materials, for which variations in the local sample properties are designed to be especially large. In such materials, it becomes impossible to fully understand the relevant material properties by bulk spectroscopic methods alone. As a result, spectroscopists long ago began seeking methods to probe the properties of individual sample environments. These include methods such as spectral hole burning<sup>[21]</sup> and a variety of

multiresonant non-linear optical spectroscopies (i.e., site-selective spectroscopies).<sup>[22]</sup> While these techniques are extremely powerful, and have their own important advantages, they still probe relatively large numbers of different environments.

With the recent development of single molecule spectroscopic methods,<sup>[1–3,8–10]</sup> means to directly probe the properties of single nanoscale environments now exist. A primary benefit of single molecule methods is that the inhomogeneous distribution in virtually any spectroscopic parameter can be directly visualized,<sup>[4]</sup> without the extensive averaging of bulk spectroscopic experiments. Additional information, inaccessible by bulk techniques, can also be obtained from certain quantum mechanical events that are directly observable by single molecule methods.<sup>[23]</sup>

A dramatic example of the sensitivity of single molecules to their nanoscale environment is shown in Fig. 1. This work, published by the Moerner group,<sup>[4]</sup> depicts a high-resolution fluorescence excitation spectrum for pentacene doped into a *p*-terphenyl matrix maintained at cryogenic temperatures. The individual peaks in the wings of this spectrum are predominantly from excitation of single molecules. While these materials might naively be thought to be homogeneous, clear nanoscale variations in their properties are apparent in the data. Variations in the local properties of these samples arise from the presence of defects, impurities, and resulting lattice strain. The emission

from each individual molecule contains important clues as to the nature of its local environment. Particularly interesting are those molecules having properties far different from the mean. In any sample, such environments are obscured in bulk spectroscopic measurements. However, their presence may be of profound chemical importance. This is especially true in nanostructured materials, for which “minority” sites may control the overall chemical properties of the materials. Single molecule spectroscopic methods represent valuable new means for their identification and characterization.

## Historical Perspective

The optical detection of single molecules labeled with multiple chromophores was first demonstrated in the 1970s and 1980s.<sup>[24–26]</sup> However, the first report describing the actual detection of individual chromophores was published by Moerner and Kador in 1989.<sup>[1]</sup> They used two different double-modulation techniques to record the absorption spectra of single pentacene molecules doped into a *p*-terphenyl host crystal held at cryogenic temperatures (i.e., 1.5 K). A short time later, Orrit and Bernard<sup>[2]</sup> demonstrated the detection of single molecules by fluorescence excitation in the same system. At the same time, Shera et al.<sup>[3]</sup> published a study showing the first detection of single dye molecules in solution, at room temperature.

The spatial location and interrogation of single molecules found at “fixed” positions in room temperature solids was first demonstrated by Betzig and Chichester<sup>[8]</sup> in a paper published in 1993. This work employed near-field scanning optical microscopy (NSOM) methods.<sup>[27]</sup> It was realized shortly thereafter that more conventional far-field (i.e., confocal and wide-field) optical microscopic methods could also be used to detect single molecules,<sup>[9–11]</sup> and that these methods were much more experimentally tractable. Explosive growth in the number of papers published per year began immediately after these initial demonstrations, indicative of the general importance of single molecule methods and the realization that much new knowledge could be uncovered by their implementation.

**Fig. 1** Fluorescence excitation spectrum for pentacene in *p*-terphenyl at liquid helium temperatures. (A) Excitation scan across the entire zero phonon line. (B) Expanded region of the spectrum shown in A. The well-separated peaks in the spectrum result from excitation of single molecule fluorescence far out in the wings of the inhomogeneous distribution. ## SINGLE MOLECULE DETECTION METHODS

Detection of single molecules requires methods that are both sensitive and selective. The method used must allow for efficient detection of the desired molecule, while effectively eliminating all sources of background. Today, the methods of choice usually involve fluorescence excitation. Fluorescence is emitted into an

inherently “background-free” spectral region, because of the Stokes shift between the excitation and emission wavelengths. The selective detection of one molecule over many others in a sample can be achieved by either one of two methods, or a combination thereof. They involve: (1) spectral selection and (2) spatial selection of the single molecule signals. In both cases, the fluorescence from a single molecule can be usually detected with a signal-to-noise ratio limited only by shot noise.

## Spectral Selection

For spectral selection, dye molecules with rigid molecular structures are doped into crystalline, glassy, or amorphous matrices at low concentrations. The sample is cooled to very low temperatures (i.e., liquid He temperatures).<sup>[1,2]</sup> With proper selection of the dye and matrix, a dramatic reduction in the excitation and emission linewidths can occur. In general, so-called fluorescence line-narrowing<sup>[21]</sup> occurs when the molecules are excited at the electronic origin. That is, the photons employed must have just enough energy to excite the molecules electronically, without exciting vibrations in the molecule and/or its surrounding matrix (i.e., phonons). Under these conditions, the spectral linewidths<sup>[28]</sup> of the molecules are predominantly lifetime-limited.<sup>[2,29]</sup> Individual molecules in the sample can then be selectively excited by the use of a tunable laser with spectrally narrow emission. Often, some form of spatial selection (see below) is employed in these experiments as well.<sup>[1,2,29]</sup> This serves to reduce the probability that more than one molecule will be in resonance with the laser at any given time.

## Spatial Selection

Experiments based on the spatial selection of individual molecules utilize samples doped with very low (i.e., subnanomolar) concentrations of probe dyes. The host system can be a gel<sup>[30]</sup> or solid.<sup>[8]</sup> One of a variety of optical microscopic configurations is then used to spatially resolve the individual molecules in the sample. Spatial selection methods work well at room temperature. Fig. 2 presents a diagram showing some of the possible optical configurations that have been employed; included are both far-field<sup>[3,9,10]</sup> optical and near-field<sup>[8]</sup> optical systems.

### Far-field scanning methods

Far-field microscopic methods are widely used in single molecule detection because of their relative simplicity.<sup>[11,31]</sup> The spatial resolution in all far-field microscopes is limited by diffraction to  $\approx \lambda/2$ .<sup>[32]</sup> This places a lower limit on the spacing between dopant molecules that must be achieved in order to resolve them. A maximum areal density of about 1 molecule/ $\mu\text{m}^2$  is the upper limit. In these methods, the sample is mounted on a “conventional” light microscope. Fluorescence images of the sample can be recorded by sample scanning,<sup>[31,33,34]</sup> beam scanning,<sup>[35,36]</sup> or wide-field illumination.<sup>[10,37]</sup> Each has its own advantages and disadvantages, as discussed below. Oftentimes, the system is operated in an epi-illumination mode, as depicted in Fig. 2A.

In the sample and beam scanning methods, fluorescence images of small sample regions are collected by raster-scanning the sample<sup>[34]</sup> over a focused laser spot, or by scanning a focused laser spot<sup>[36]</sup> over a stationary

**Fig. 2** Common experimental configurations used for the spatial selection and detection of single molecules. (A) Epi-fluorescence geometry. (B) Total internal reflection geometry. (C) Near-field scanning optical microscopy.

sample. Fig. 3 presents examples of typical images obtained in a sample-scanning system. The appearance of such images provides valuable initial information on the single molecules and their local environmental properties.<sup>[38–40]</sup>

Confocal imaging methods<sup>[35]</sup> are usually employed to achieve extremely low background levels. Modern high numerical aperture (NA) microscope objectives produce focused spot sizes near the theoretical diffraction limit ( $\approx \lambda/2$ ).<sup>[32]</sup> They also have small depths of focus,<sup>[35]</sup> ensuring a small detection volume. Moerner and coworkers<sup>[41,42]</sup> have presented expressions for predicting the signal and background levels in specific optical systems. As background from (relatively high concentration) impurities and Raman scattering by the host matrix are both proportional to the volume of sample illuminated, smaller illumination volumes (at constant incident intensity) result in lower background signals. Consequentially, as a single chromophore is much smaller than the focused excitation spot, its signal remains constant as the focused spot size is reduced (again, for a constant incident intensity). To take full advantage of such signal-to-background enhancement, the single molecule excitation process must not be saturated.<sup>[43,44]</sup>

On the detection side, the high NA objective does an excellent job of efficiently collecting fluorescence

from molecules in all possible molecular orientations.<sup>[45]</sup> Single photon counting avalanche photodiodes (SiAPDs) are most often used for detection of single molecule emission. Microchannel plate photomultiplier tubes (PMTs) are also employed in systems designed for picosecond-resolved single-molecule lifetime measurements, although SiAPDs also work for this purpose.<sup>[11,31,46,47]</sup> Spectrally dispersed fluorescence from single molecules is recorded by using efficient imaging spectrographs and sensitive liquid-N<sub>2</sub>-cooled charge-coupled device (CCD) detectors.

### Wide-field imaging methods

Wide-field illumination<sup>[10,37]</sup> represents an important alternative to sample- and beam-scanning confocal microscopy. In these methods, a relatively large sample area (i.e., several square micrometers) is illuminated. Spatial selection of the fluorescence from individual molecules is accomplished on the emission side alone. To achieve the lowest background levels, such experiments are best performed in a dark-field configuration (Fig. 2B),<sup>[10,24,48–50]</sup> although other configurations also work.<sup>[51,52]</sup> The incident light is brought to the sample surface by using a prism or optical waveguide.<sup>[50]</sup> The angle at which the incident light strikes the working interface is beyond the critical angle. It is the evanescent wave generated by total internal reflection at this interface that excites the single molecules. A microscope objective similar to that described above is then used to collect the single molecule emission. The fluorescence from the sample is imaged onto a liquid-N<sub>2</sub>-cooled CCD, operating in imaging mode. Such multichannel imaging systems have the distinct advantage that images of large sample areas are obtained all at once (i.e., in a short time window). The images can be rapidly acquired and in sequential fashion so that phenomena such as rotational<sup>[49,51]</sup> and translational<sup>[37,53,54]</sup> single molecule motions can be readily followed. However, the recording of single molecule fluorescence spectra is difficult in wide-field systems.

### Near-field optical methods

Near-field optical methods have been used in a number of single molecule experiments.<sup>[8,31,55–62]</sup> Recent reviews cover all the important aspects of NSOM, and its applications in single molecule spectroscopy and other experiments.<sup>[27,63]</sup> Using NSOM, a subdiffraction-limited region of the sample is illuminated by funneling light through a small aperture fabricated at the end of a tapered, metalized fiber-optic probe.<sup>[64]</sup> Figure 2C shows a schematic of how such an aperture-based NSOM system works. At most, an aperture-sized region of the sample (in the transverse plane) is illuminated at any one time, as long as the

**Fig. 3** Fluorescence images of  $5 \times 5 \mu\text{m}$  regions of thin silicate films prepared by the sol-gel process. The films were doped with Rhodamine B at the nanomolar level. (A) “Fresh” silicate film image. The molecules yield round fluorescent spots of diffraction limited size in this sample. (B) Image of “dried” silicate film. The molecules blink on and off on a time scale similar to the image pixel time (40 msec) in this sample. Source: From Ref.<sup>[39]</sup>. © 2000, American Chemical Society.

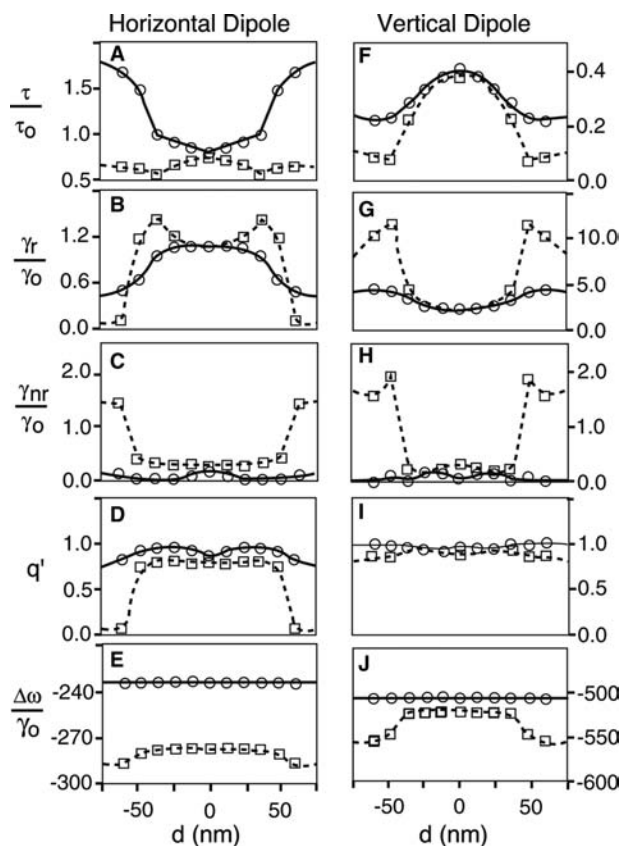

distance between the probe and sample is much smaller than the wavelength of the light employed. Fluorescence from a molecule excited by the probe light is then collected by an objective lens, in a manner similar to the far field methods. The same detection systems described above are employed.

Single molecule NSOM methods have several advantages over far-field methods. Because spatial resolution as good as  $\approx \lambda/10$  can be achieved in single molecule NSOM experiments, the areal density of single molecules in the sample can be increased accordingly (i.e., to a few per square micrometer). It is also advantageous that the illumination volume is greatly reduced, often leading to enhanced signal-to-background ratios. In addition, because the tip and sample must be maintained in close proximity, the sample topography must be followed. This is usually accomplished by the so-called tapping mode<sup>[56,65,66]</sup> or shear-force<sup>[67,68]</sup> methods. The availability of topographic information along with the single molecule spectroscopic data makes NSOM methods particularly powerful for characterizing nanostructured materials, because variations in the local sample properties can be correlated with sample morphological features.<sup>[69]</sup> An important final advantage of NSOM-based single molecule detection experiments is that they provide a unique means for “visualizing” the 3-D orientations of single molecules.<sup>[8,55,61,62,70]</sup> However, similar information can now also be gleaned from far-field methods via the use of modified optical systems.<sup>[48,49,51,71]</sup>

The disadvantages of NSOM methods include their comparative difficulty, and the fact that the close proximity of the metalized dielectric probe to the sample can perturb single molecule emission. Several groups have studied probe perturbation effects in detail.<sup>[31,58,62,72]</sup> Theoretical results from Bian, Dunn, and Xie<sup>[58]</sup> are presented in Fig. 4. Their results show that as a molecule is positioned beneath the aluminum coating of the probe, energy is efficiently transferred to the metal, and the rate of non-radiative decay increases. When the molecule is moved nearer to the optical aperture (fused silica), interactions with the probe actually lead to enhanced radiative decay. Position-dependent variations in the emission spectrum are also predicted. Significantly, these perturbations are also shown to depend on the exact orientation of the molecule. Experimental results have provided support for these conclusions, and demonstrated that such perturbations can result in complicated variations in the single molecule emission properties.<sup>[31,57,62]</sup>

## General Experimental Considerations

A number of optical components are common to most forms of single molecule detection. Each uses a light

**Fig. 4** Simulations of relevant spectroscopic parameters in near-field optical microscopy studies of single molecules, using a 96-nm-diameter probe aperture. Results are plotted for horizontally oriented transition dipoles (left) and vertically oriented dipoles (right) as a function of lateral tip-molecule displacement. The calculations were performed for two different tip-molecule vertical distances (squares: 6 nm, circles: 24 nm). Shown are the normalized fluorescence lifetime ( $\tau/\tau_0$ ), normalized radiative rate ( $\gamma_r/\gamma_0$ ), normalized nonradiative rate ( $\gamma_{nr}/\gamma_0$ ), quantum yield ( $q'$ ), and spectral shift ( $\Delta\omega/\gamma_0$ ). *Source:* From Ref.<sup>[58]</sup>. © 1995, American Physical Society.

source that allows for resonant excitation of the single molecules by either linear or non-linear<sup>[73–75]</sup> optical methods. Common sources include the green HeNe laser, argon ion and krypton ion systems, Nd:YAG lasers, tunable dye lasers, Ti:sapphire lasers, and other solid-state systems. In addition, all systems rely on the use of appropriate bandpass filters, dichroic mirrors, and notch filters for background rejection and isolation of single molecule emission. Finally, polarization optics are also employed to control the excitation polarization and to select the polarization of the light to be detected.<sup>[76]</sup>

In most experiments, the samples of interest are coated onto commercially available, optically transparent substrates. Glass and fused quartz

microscope coverslips are most often employed. Besides being optically flat, these substrates must be clean and free of fluorescent impurities (i.e., rare earth ions). They can be cleaned either by wet-chemical, plasma etching, or flaming procedures. Undoped samples are often used to verify that any residual fluorescent impurities will not interfere with the single molecule measurements.

### Verification of Single Molecule Detection

Verification that data such as those shown in Figs. 1 and 3 come from single molecules is derived from several observations. First, as a result of changes in the local environment (whether spontaneous or photoinduced),<sup>[4]</sup> single molecule emission peaks often exhibit discrete jumps to new spectral positions (a phenomenon known as “spectral diffusion”).<sup>[16,29,41,77–79]</sup> Second, discrete photobleaching transitions may also be observed. In this case, the signal from a single molecule abruptly drops to the background level. If the signal resulted from multiple molecules, a gradual reduction in the signal would be expected as individual molecules were bleached away.

Observations of photon bunching and antibunching provide additional evidence for single molecule emission.<sup>[2,23,80,81]</sup> Photon antibunching is observed when photon emission from single molecules is detected with high time resolution. As a molecule seldom absorbs additional photons when in an excited state, and only emits a single photon as a result of prior excitation, there is always some finite time (i.e., nanoseconds) between photon emission events for single molecules. This time corresponds to the excited state lifetime. The observation of these short “dead times” provides excellent evidence that a single chromophore has been excited.<sup>[23]</sup> Photon bunching occurs on a longer time scale and is associated with infrequent transitions of the excited molecule to a long-lived “dark” state (usually a triplet). This leads to the observation of relatively long dark periods (i.e., approaching 1 msec) separated by periods where bunches of individual photons are detected as the molecule cycles between the ground and excited states in the singlet manifold.

Additional evidence of single molecule detection may be obtained by verifying that the number of fluorescent spots observed in images (Fig. 3) of a given region scale linearly with the concentration of dye dopant employed. Lastly, the signal levels expected for single molecules can be estimated and compared to that which is observed. Of course, this comparison is relatively crude, because the fluorescence excitation and detection efficiencies vary between molecules for a variety of reasons.

## MATERIALS CHARACTERIZATION

Single molecule spectroscopic methods have the potential to uncover a vast body of new information on the nanoscale properties of a range of materials and surfaces. A number of examples of such experiments are given below. While not all were undertaken for the purpose of understanding nanoscale materials environments, they provide an overview of the types of information that can be obtained. The studies presented are divided into sections based on the type of experiments performed. Wavelength-resolved spectroscopic studies are covered first, followed by those in which the temporal emission characteristics of the molecules are used to assess nanoscale environmental properties.

### Spectroscopic Variability

Bulk optical spectroscopic methods have long been used to probe the average properties of a wide variety of samples.<sup>[20]</sup> In many cases, identical experiments can be performed at the single molecule level. Such single molecule data provides a direct means for observing the inhomogeneous distribution of sites in a sample. Clearly, more information is contained in these distributions than can be gleaned from the average value of a particular spectroscopic parameter alone. For example, the shape of the distribution (i.e., skewed, Gaussian, multimodal, etc.) and the differences between the most common and average environments in a sample can be visualized.<sup>[82]</sup>

### Spectral perturbations by the local environment

One example of the new information that can be obtained when the interactions<sup>[11,31,57,58,62,83]</sup> between dye molecules and their local environment are probed at the single molecule level is shown in Fig. 5. In this work, English, Harbron, and Barbara<sup>[84]</sup> discovered stable (over hours) “rare sites” in poly(methyl methacrylate) (PMMA) films. The authors collected spectra from single sulforhodamine 101 molecules embedded in the films and compared them to those obtained by “bulk” methods. Dramatic molecule-to-molecule variations were observed in the single molecule spectra, reflective of nanoscale variability in the film properties. When the single molecule data were combined to simulate the bulk spectrum of a low concentration sample, a broad fluorescence peak with a prominent vibronic feature was obtained. These features were not observed in bulk spectra at higher concentrations. It was concluded that these single molecule spectra arose from the presence of rare nanoenvironments that were saturated at dye concentrations as low as  $10^{-9}$  M. These sites

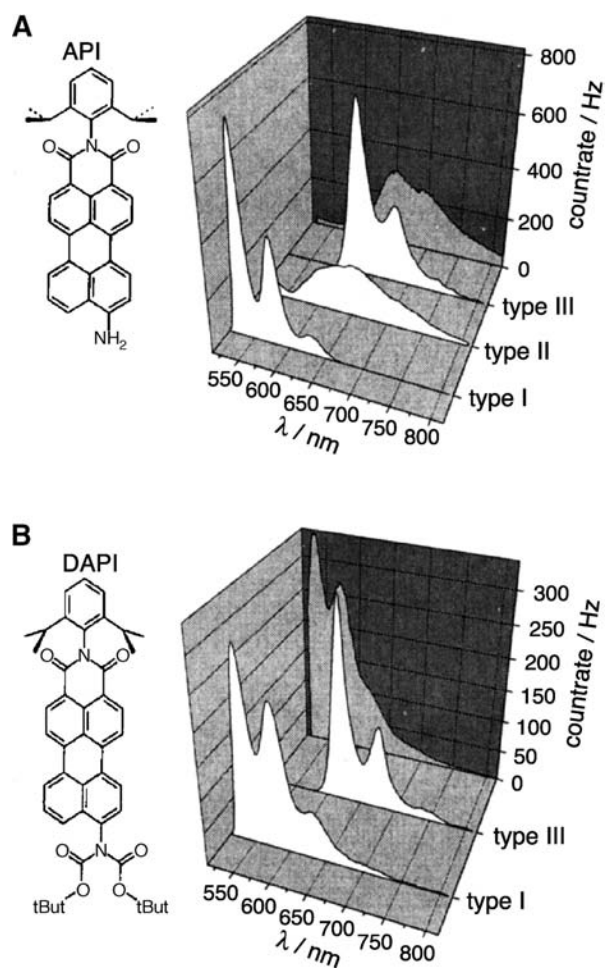

**Fig. 5** Bulk fluorescence spectra of Sulforhodamine 101 in PMMA films (dark solid line and dashed line) and a spectrum obtained by averaging the individual fluorescence spectra from 42 single molecules (light line). *Source:* From Ref.<sup>[84]</sup>. © 2001, American Institute of Physics.

were attributed to the presence of extreme sample heterogeneities or trace impurities, and could reflect the presence of sites differing in matrix rigidity.<sup>[38,85–88]</sup>

The dye molecules employed in such studies must be carefully selected or designed and synthesized to provide information on specific material properties.<sup>[87–89]</sup> Often, such dyes will have pendant functional groups that can undergo conformational changes under certain circumstances. For example, the Meixner group has employed two different aminoperylene derivatives (API and DAPI, as defined in Fig. 6) to probe the local properties of polystyrene thin films. Figure 6 shows data from their experiments.<sup>[87,88]</sup> In these particular molecules, the torsional angle of the pendant amine group, with respect to the aromatic ring structure, is most important in determining the extent to which the amine group is electronically coupled to the  $\pi$ -electronic system. Two (or more) sets of electronic states are possible and two (or more) emission spectra may be observed. Data reflecting the efficiency of amine group rotation and the emission characteristics of each state can yield valuable information on local sample fluidity and polarity.<sup>[38]</sup>

Three different classes of spectra were observed for API single molecules (Fig. 6A), while only two were observed for DAPI (Fig. 6B), in which amine group motions are sterically hindered. Spectra exhibiting pronounced vibronic structure were attributed to emission from a state in which the amine group is decoupled from the  $\pi$ -electronic system. Broad, almost featureless

**Fig. 6** (A) and (B) Bulk and single molecule fluorescence spectra for the API and DAPI dyes, respectively. The bulk spectra were recorded in toluene and are displayed at the back of each set. The single molecule spectra were recorded for molecules dispersed in polystyrene. Three characteristic types of single molecule spectra were observed, as designated in the figure. *Source:* From Ref.<sup>[87]</sup>. © 2001, American Chemical Society.

API spectra were attributed to emission from a state in which the amine group is conjugated to the ring structure. The observation of all three types of spectra for API is attributable to the presence of different environments in the polymer films that each favors one conformation over the other.

Meixner and coworkers also made extensive use of these molecules to assess the dynamic properties of the local film environments. While some environments allow rapid conformational changes of the molecule, others do not. They observed the frequency of spectral jumps associated with interconversion of the various forms of these molecules and used the results as a means for evaluating the dynamic fluidity of local regions in their samples.

## Polarity measurements

One common application of organic dyes has been in the determination of solvent polarity by bulk spectroscopic methods.<sup>[90,91]</sup> So-called “solvatochromic”<sup>[91]</sup> dyes exhibiting either hypsochromic or bathochromic spectral shifts with changes in solvent polarity are employed. A number of solvent polarity scales have been developed, based on the spectra obtained.<sup>[20,91]</sup>

Higgins, Collinson, and coworkers have demonstrated the application of similar methods in single molecule studies of organic polymer films<sup>[38]</sup> and sol-gel-derived silicate films.<sup>[39,82,92–94]</sup> Importantly, their results reflect the polarity of the nanoscale environment in which each molecule resides. For these measurements, the highly solvatochromic dye Nile red<sup>[95]</sup> was selected (Fig. 7). Its excitation and emission spectra exhibit a dramatic shift to shorter wavelengths upon transfer from polar to non-polar media.<sup>[96–99]</sup> Unfortunately, its fluorescence quantum yield is also very sensitive to its environment and is appreciably larger in non-polar surroundings.<sup>[96]</sup> This is believed to be a result of the enhanced participation of a non-fluorescent twisted intramolecular charge transfer (TICT) excited state when the dye is dissolved in polar solvents.<sup>[38,99,100]</sup> It must be noted that single molecule results obtained by using dyes such as Nile red can be biased toward environments in which the probe dye is more fluorescent.<sup>[93,94,96]</sup> Care must be taken to ensure the bias is not significant. Bardo, Collinson, and Higgins have evaluated the extent of bias by comparing single molecule results with those of bulk spectroscopic experiments.<sup>[93,94,96]</sup>

In the methods employed by the Higgins group, data reflecting both the static and dynamic nanoscale polarity were obtained by applying a modified form of Marcus theory<sup>[101–104]</sup> for charge transfer transitions to single molecule results. The parameters measured include the shift in the transition energy from that in a vacuum,  $\Delta\Delta G^\circ$ , and the local reorganization energy,  $\lambda$ , associated with the residual environmental and dye motions not frozen upon entrapment of the dye in relatively “rigid” materials environments.<sup>[103]</sup> Several assumptions were required to make use of this model; these were outlined in detail in the original publications.<sup>[38,93,94]</sup>

Figure 7 shows examples of data obtained for Nile red in a poly(methyl methacrylate) (PMMA) thin film.<sup>[38]</sup> Plotted are histograms of the emission maximum,  $\nu_{fl}$ , and full width at half maximum of the highest energy vibronic band,  $\delta\nu_{fl}$ , in each spectrum. Also shown are histograms of the  $\Delta\Delta G^\circ$  and  $\lambda$  values obtained. Bimodal distributions in  $\nu_{fl}$  and  $\delta\nu_{fl}$  lead to a bimodal distribution in  $\lambda$ . A single “Gaussian-shaped” inhomogeneous distribution appears in the  $\Delta\Delta G^\circ$  histogram. These results were attributed to the existence of two

**Fig. 7** Structure of Nile red and single molecule data. (A) Histogram of single molecule emission maxima for Nile red in a poly(methyl methacrylate) thin film. (B) Histogram of the spectral widths (FWHM) for the single molecule spectra. (C) Histogram of single-molecule  $\Delta\Delta G^\circ$  values. (D) Histogram of single-molecule  $\lambda$  values. Source: From Ref.<sup>[38]</sup>. © 2000, American Chemical Society.

classes of environments in the films. The two differ primarily in their dynamic polarity (or local fluidity),<sup>[38]</sup> and likely arise from the presence of relatively rigid “semicrystalline” polymer environments and more fluid “amorphous” regions. These conclusions

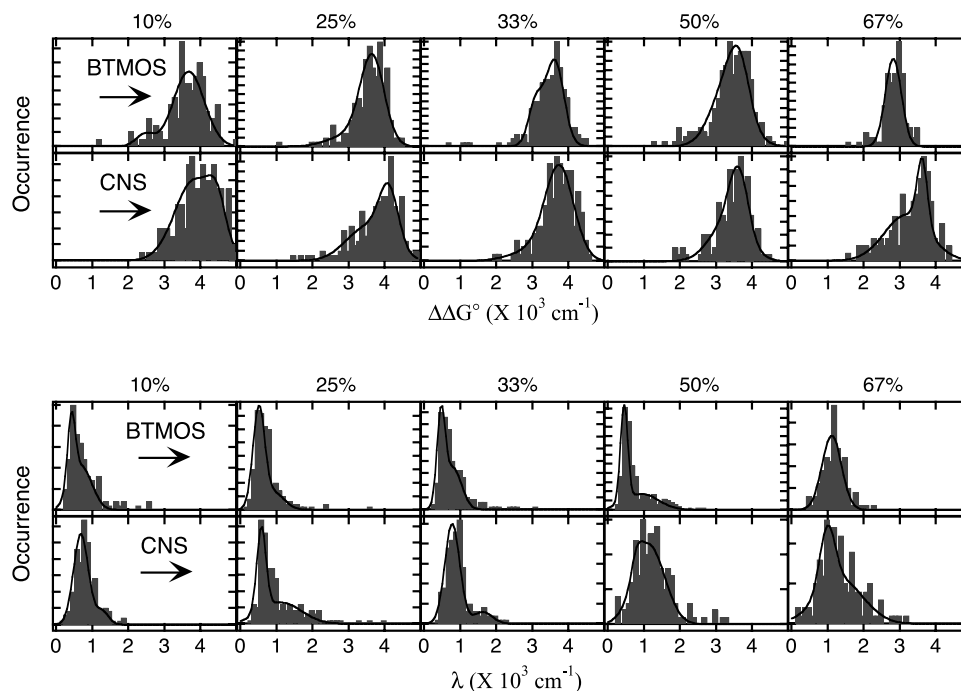

are consistent with those of Ishikawa et al.,<sup>[85,86]</sup> who show bimodal distributions in the emission count rates obtained from dye molecules incorporated into PMMA films (see below).

In a collaborative effort, the Higgins and Collinson groups<sup>[82,93,94]</sup> employed the same modified Marcus methods to uncover nanoscale variations in static polarity and environmental rigidity in a series of organically modified sol-gel-derived silicate films. In these studies, films prepared by the hydrolysis and condensation of mixtures containing varying mole percentages of tetraethoxysilane (TEOS) and isobutyltrimethoxysilane (BTMOS), or 3-(triethoxysilyl)propionitrile (CNS) were investigated. Figure 8 shows representative histograms of the  $\Delta\Delta G^\circ$  and  $\lambda$  values obtained.<sup>[82]</sup> The data are presented as a function of the mole percent of organically modified silicate (BTMOS or CNS) used in sample preparation. The authors interpreted this data to reflect gradual changes in local film environments in the CNS series of samples, consistent with molecular mixing of the inorganic and organic precursors. In stark contrast, the samples prepared from mixtures of TEOS and BTMOS showed abrupt changes in environmental polarity and rigidity with increasing BTMOS content, a likely indicator of nanometer (or larger)-scale phase separation of organic- and inorganic-rich domains.

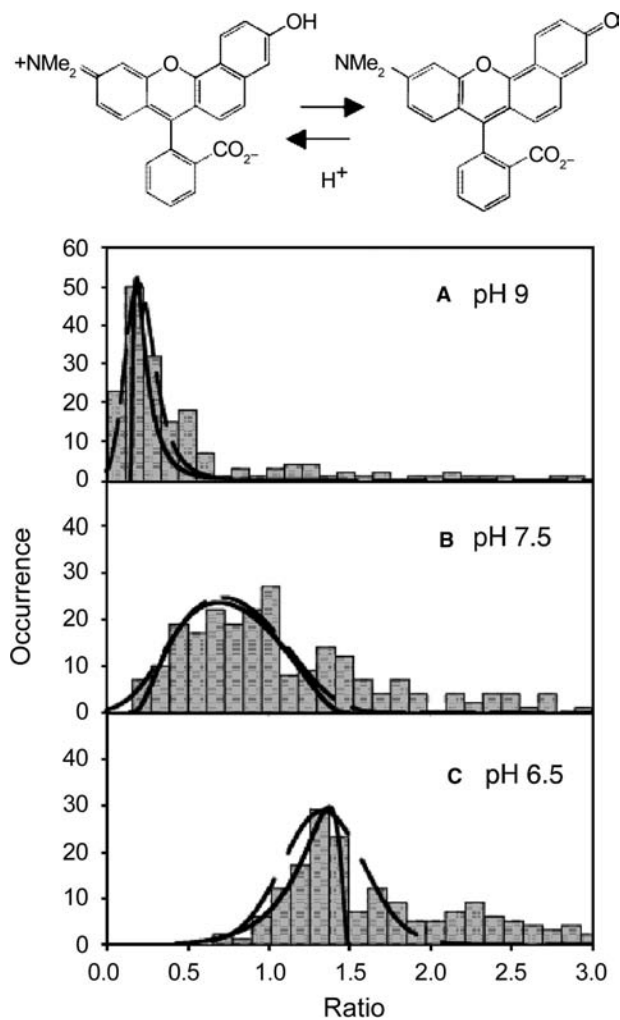

## Acid/base chemistry

Single molecule methods also represent a valuable new means for assessing the nanoscale acid/base properties of a sample, as recently reported by Brasselet and Moerner.<sup>[105]</sup> In their work, the authors describe some of the challenges associated with pH measurements at the single molecule level. Perhaps, most important is the selection of a dye molecule that remains reasonably fluorescent in both its acidic and basic forms. At the same time, the molecule must exhibit a measurable change in its excitation and/or emission spectrum with pH.

Brasselet and Moerner<sup>[105]</sup> employed a dextran-linked seminaphthorhodafluor dye commonly known as SNARF-1 to probe the local acid/base chemistry of agarose gels. The chemical structure of SNARF-1 is shown in Fig. 9; its bulk emission spectrum as a function of solution pH is given in the original work.<sup>[105]</sup> By simultaneously recording single molecule fluorescence in two different wavelength bands, the authors were able to observe pH-dependent variations in the single molecule emission spectra. They constructed histograms of the relative emission observed at the two different wavelengths. Their results are reproduced in Fig. 9. At high and low bulk pH, the single molecule emission results were consistent with the bulk pH

**Fig. 8** Top: Histograms of the  $\Delta\Delta G^\circ$  values for Nile red single molecules doped into organic/inorganic composite silicate thin films. The tick marks denote increments of two molecules. Bottom: Histograms of the single molecule  $\lambda$  values for each film. The tick marks denote increments of five molecules. The organic precursor content of the sol used in the preparation of each film is given at the top. The solid lines represent fits of the data to double Gaussian functions. *Source:* From Ref.<sup>[82]</sup>. © 2000, American Chemical Society.

**Fig. 9** Chemical structure of SNARF-1 in its protonated and deprotonated forms and histograms of single molecule emission ratios as a function of bulk pH for SNARF-1-dextran in agarose gels. The emission ratio is defined as the ratio of fluorescence from the protonated (580 nm) and deprotonated (640 nm) forms of SNARF-1. The dashed and solid lines give the distributions expected for  $pK_a$  variations in the sample with and without, respectively, accounting for experimental noise. *Source:* From Ref.<sup>[105]</sup>. © 2000, Wiley-VCH.

dependence of SNARF-1. The widths of the histograms were concluded to be dominated by experimental noise under these pH conditions. However, at intermediate bulk pH, near the dye's  $pK_a$ , a broader distribution was observed. The dynamic equilibrium between the protonated and deprotonated forms of the dye was noted to be too rapid to observe on the time scale of their experiments, as was the rate of proton diffusion through the sample. Therefore the authors attributed the increased histogram breadth (for  $pH \approx pK_a$ ) to variations in the  $pK_a$  of the dye

resulting from local variations in the properties of the gel samples.

### Vibrational information

By far, the most detailed nanoscale information may be obtained by resolving the vibrational structure in single molecule fluorescence spectra obtained at low temperatures.<sup>[7,12,42,106–108]</sup> A number of excellent examples have been published by Tchenio, Myers, and Moerner.<sup>[106,107]</sup> In one series of studies, dramatic variations in the emission spectra of terrylene single molecules in polyethylene were reported. Molecule-to-molecule variations in these spectra were manifested as both variations in the band intensities and band positions, and were attributed to the presence of two distinct nanoenvironments in the samples, one crystalline in nature, and the other amorphous.

While such single molecule resonance Raman experiments<sup>[7]</sup> are possible at low temperatures, single molecule Raman data cannot be obtained at room temperature without substantial signal enhancement. However, room temperature single-molecule/single-particle surface-enhanced Raman scattering (SERS) has been demonstrated.<sup>[109–111]</sup> Single molecules in these experiments were deposited on single silver nanoparticles.<sup>[112]</sup> Extremely large enhancement factors, on the order of  $10^{14}$ – $10^{15}$ , have been reported,<sup>[109,111]</sup> making the Raman cross sections as large as those for fluorescence excitation.<sup>[110]</sup> Such large enhancements are believed to involve both electromagnetic and chemical enhancement mechanisms.<sup>[110,111,113]</sup> If these vibrational methods can be generalized to a wider range of nanostructured materials, they will represent extremely powerful methods for assessing nanoscale environmental properties.

### Temporal Emission Characteristics

The temporal emission characteristics of single molecules can also yield valuable information on the nanoscale environments found in a sample. Significantly, they also yield information on the rate at which the environments interconvert in time. The measurements covered involve a wide range of different experiments. Simple observations of spectrally integrated fluorescence time transients can provide substantial information. These measurements allow for the observation of quantum mechanical and quantum chemical phenomena not directly observable in bulk spectroscopic experiments.<sup>[23,80,114–118]</sup> More complicated methods allow for observation of molecular translational and rotational diffusion.<sup>[40,54,82,93,94,119–123]</sup> The effects of changes in molecular conformation,<sup>[38,85,86,88,115,118,120,124–133]</sup>

electron transfer events,<sup>[134]</sup> and other chemical dynamics<sup>[10,39,129,130,135–138]</sup> can also be observed. Finally, spectrally resolved time transients can be used to observe spectral diffusion phenomena.<sup>[16,29,41,77–79]</sup>

### Survival times and total emission

Photobleaching is observed in virtually all single molecule experiments. Under continuous illumination, single molecules undergo an abrupt and permanent transition to a non-fluorescent form at some point. Again, such behavior has long been used as evidence that single molecules are being probed. However, it has since been demonstrated that multichromophoric species with electronically coupled emitters often exhibit similar signal transitions.<sup>[115,128,139–141]</sup> These permanent signal transitions are attributable to photochemical reactions resulting from excitation of the chromophore. The most common mechanism for photobleaching of dye molecules involves their reaction with singlet dioxygen. Quenching of the triplet state of the dye by triplet dioxygen leads to the initial production of reactive singlet dioxygen. Other proposed mechanisms have included photoinduced conformational changes, especially in multichromophoric species.<sup>[115,128,139,142]</sup>

Wennmalm and Rigler described measurements of the survival time and total emission (i.e., the integrated number of photons) obtained from single molecules, and noted their sensitivity to the molecule's environment.<sup>[143,144]</sup> Measurements of these parameters represent a viable means for uncovering nanoscale materials heterogeneity. Such measurements have recently been used for the characterization of environmental properties in sol–gel-derived silicate films.<sup>[39,120]</sup> Fig. 10 shows representative results from the silicate studies. In these particular experiments, the survival times and total photons obtained from single rhodamine B molecules entrapped in the silicate films were measured as a function of film preparation conditions. The silicate films were characterized: (1) immediately after spin casting, (2) after drying overnight under vacuum, and (3) after drying at 80°C under vacuum for at least 12 hr. The results show an approximately fourfold increase in the survival times of single molecules in the vacuum oven-dried films over those of the fresh films. Simultaneously, a fourfold increase in the total number of photons emitted by the average molecule was also observed for the vacuum oven-dried films. These results are consistent with a dramatic increase in the chemical stability of the dye molecules in the dried materials. Increased dye stability was attributed to a reduced rate of oxygen and/or dye diffusion, as well as a possible reduction in the oxygen concentration of the dried films.

**Fig. 10** (A) Representative fluorescence transient recorded for a single Rhodamine B molecule entrapped in a dried silicate film. This transient exhibits signal fluctuations on a number of different time scales and ends in a discrete and permanent transition to a dark state (presumably a non-fluorescent photoproduct) at approximately 20 sec. The total integrated emission counts and total survival time of each molecule are derived from these transients. (B), (C) Histograms of the total photons detected from a number of single molecules, for fresh and dried silicate samples. The insets show histograms of the total survival time. *Source:* From Ref.<sup>[39]</sup>. © 2000, American Chemical Society.

### Emission intensity and fluorescence lifetimes

The signal levels obtained from single dye molecules can reflect local environmental fluidity. Figure 11 shows data from a study by Ishikawa et al.,<sup>[85,86]</sup> in which crystal violet and Texas red were used to probe the local environments of poly(methyl methacrylate) (PMMA) thin films. A bimodal count distribution was obtained from crystal violet, a flexible molecule, while a single Gaussian distribution was obtained from the more rigid Texas red. The bimodal distribution for crystal violet was attributed to the presence of two general classes of environment in the PMMA materials. One environment was concluded to be less viscous than

**Fig. 11** (A), (B) Histograms of the fluorescence photocounts obtained from single molecules of crystal violet and Texas red, respectively (structures shown), in poly(methyl methacrylate) films. *Source:* From Ref.<sup>[86]</sup>. © 1999, American Chemical Society.

the other, leading to differences in the rate of non-radiative relaxation of the excited molecules in the two regions. Variations in the viscosity were attributed to local variations in the PMMA side-chain motions.

Measurements of the fluorescence lifetimes of individual molecules provide valuable additional data on the origins of the environmental sensitivity of single molecule emission. In the studies by Ishikawa and coworkers,<sup>[85,86]</sup> the crystal violet molecules exhibited

dramatic molecule-to-molecule variations in their fluorescence lifetimes. In contrast, the Texas red molecules yielded considerably less variable lifetime data. Variations in the crystal violet lifetimes were assigned to environment-dependent variations in the non-radiative relaxation rate of the molecule. Molecules exhibiting relatively large fluorescence signals and long lifetimes were concluded to be entrapped in more viscous film regions. Similarly, less fluorescent molecules were assigned to less viscous film regions.

It is well known that other phenomena can also affect single molecule emission. For example, proximity to a dielectric interface can have a noticeable effect on the emission lifetime of a single molecule. Macklin, et al.<sup>[11]</sup> and Vallee, et al.<sup>[83]</sup> have presented detailed studies of such effects.

### Emission intensity fluctuations

Temporal fluctuations in the emission intensity of single molecules are often attributed to conformational dynamics. Such dynamics may lead to spectral diffusion,<sup>[16,29,41,77–79,87,88,133]</sup> and/or changes in a molecule's fluorescence quantum yield.<sup>[87,115,120,128,142]</sup> To the extent these dynamics are limited by the local environment, the rate of such signal fluctuations may also be reflective of the local environmental properties, or fluctuations therein.<sup>[136,137]</sup>

Table 1 presents results showing the sensitivity of single molecule signal fluctuations to local materials environments. In this work, Talley and Dunn<sup>[131]</sup> studied films of relatively well-controlled properties, namely DiIC<sub>18</sub>-doped lipid films prepared by the Langmuir–Blodgett (LB) technique. The films incorporated phase domains having distinctly different lipid densities. Results for “liquid expanded phase” and “solid condensed phase” regions were obtained. The authors located individual molecules in these different film regions, recorded their emission time transients, and subsequently calculated the signal autocorrelation

**Table 1** Results from autocorrelation analysis of single-molecule fluorescence transients for DiIC<sub>18</sub> in lipid films prepared by the Langmuir–Blodgett technique

Film condition	Subphase	$\tau_1$ (sec)	$\tau_2$ (sec)	<i>N</i>
Liquid expanded phase	10 mM MgCl <sub>2</sub>	0.44 ± 0.10	14.2 ± 3.9	66
Solid condensed phase	10 mM MgCl <sub>2</sub>	1.17 ± 0.27	24.1 ± 5.5	48
Liquid expanded phase	water	0.77 ± 0.22	18.2 ± 6.3	46
Solid condensed phase	water	1.31 ± 0.36	13.1 ± 4.1	37
Bilayer (probe on bottom)	water	2.06 ± 0.50	41.9 ± 12.5	43
Bilayer (probe on top)	water	2.14 ± 0.64	28.9 ± 11.2	32

Listed are the lipid film phase, subphase conditions, time constants ( $\tau_1$  and  $\tau_2$ ) derived from the analysis, and the number of molecules (*N*) employed in the analysis for each case. The error bars give the 90% confidence limits.

*Source:* From Ref.<sup>[131]</sup>. © 1999, American Chemical Society.

function<sup>[79,115,124,131]</sup> for each transient. The autocorrelation functions decayed exponentially in time and could be fit with double exponentials. The fitting procedure provided characteristic signal fluctuation times (i.e., the signal correlation times  $\tau_1$  and  $\tau_2$ ) for each molecule. The signals were observed to fluctuate more rapidly in the liquid expanded phase regions, as evidenced by the smaller value obtained for  $\tau_1$  in these regions (Table 1). Conformational dynamics of the dye, which in turn resulted in time-dependent variations in the dye's emission yield, were concluded to be the source of the fluctuations. The results reflect the much greater fluidity of the liquid expanded phase, in comparison to the solid condensed phase regions and lipid bilayers also described in this study.<sup>[131]</sup>

### Triplet lifetimes and quantum yields

Triplet blinking is the quantum mechanical phenomenon to which repeated, power-dependent signal fluctuations to and from the background level are often assigned.<sup>[114]</sup> When a molecule crosses from its singlet excited state to a long-lived triplet excited state, it usually cannot be excited further and does not emit. Both the rate of intersystem crossing and the rate of triplet relaxation can be obtained for single molecules. These data are obtained either by autocorrelation procedures or by directly measuring the “off times” (or “dark times”) and photon yields between dark periods.<sup>[79,115,124,131]</sup> Photoinduced processes occurring from the triplet state have also been monitored.<sup>[145]</sup> All such phenomena are influenced by the molecule's local environment.<sup>[116,117]</sup> For example, because triplet dioxygen often quenches triplet excited states, the lifetime of a molecule's triplet state may reflect the local concentration of oxygen molecules and/or their mobility.<sup>[39,117,118,146,147]</sup> The singlet–triplet gap and intersystem crossing rate are also expected to depend on the properties (i.e., polarity) of the local environment.<sup>[118]</sup>

### Spectral diffusion

So-called spectral diffusion phenomena,<sup>[16,29,41,77–79,148]</sup> in which the fluorescence excitation and emission spectra for a molecule change in time, are also reflective of dynamic fluctuations in local sample environments.<sup>[136,137]</sup> In studies of DiC<sub>12</sub> on glass surfaces,<sup>[127]</sup> Weston et al. observed that spectral jumps and changes in the appearance of single molecule emission transients are frequently correlated. They also observed these signal variations to be coupled with a change in the appearance of the vibronic structure in the single molecule spectra. The authors attributed those spectra exhibiting resolved vibronic structure to molecules present in highly restricted environments. Broad,

featureless spectra were attributed to environments in which the molecules were free to move. Abrupt conversions between these two classes of behavior are attributable to changes in the environment, the molecule itself, and/or its interactions with the environment.

### Translational diffusion and adsorption phenomena

Observation of the translational motions of single molecules in materials and on their surfaces represents an obvious means of detecting and assessing nanoscale materials heterogeneity. The extent to which such motions occur is highly dependent on the fluidity of the matrix and the prevalence and strength of molecule–matrix interactions. Such molecular translational motions can be observed by single-point illumination methods,<sup>[3,9,122]</sup> or by sample scanning,<sup>[60]</sup> beam scanning,<sup>[36]</sup> or wide-field microscopies.<sup>[37,53,120,149]</sup> The latter three allow for the recording of diffusional trajectories in which the actual motions of the molecules may be directly followed.

Recently, Wirth et al.<sup>[122,123,150]</sup> have been using single molecule methods to uncover nanoscale heterogeneity at chromatographically important interfaces by observing single molecule diffusion and adsorption events. In this work, they studied silicate glass surfaces derivatized with alkylsilanes and submerged in water. The experiments were performed in a single-point illumination mode similar to that used in other solution-phase single molecule experiments.<sup>[3,9]</sup> The fluorescence signal obtained from individual DiI molecules by illuminating a small ( $\approx 80 \mu\text{m}^2$ ) sample region was recorded in time and subsequently analyzed by autocorrelation methods. Information on the rate of single molecule diffusion through the detection volume was obtained. Figure 12 shows an example of their data. In most instances, brief flashes of light were observed from the molecules as they passed through the illuminated spot. For these molecules, (near-surface) diffusion rates could be obtained. However, in certain cases, relatively stable fluorescence signals were also obtained. These signals remained stable for relatively long periods of time (i.e., seconds). The authors attributed these events to adsorption of individual dye molecules at specific sites on the sample surface. It was proposed that these sites were regions of the glass surface left underivatized during the surface silanization procedure. Their observations are reflective of nanoscale variations in the chemical properties of chromatographic surfaces and point to the origins of peak tailing in many forms of column chromatography.

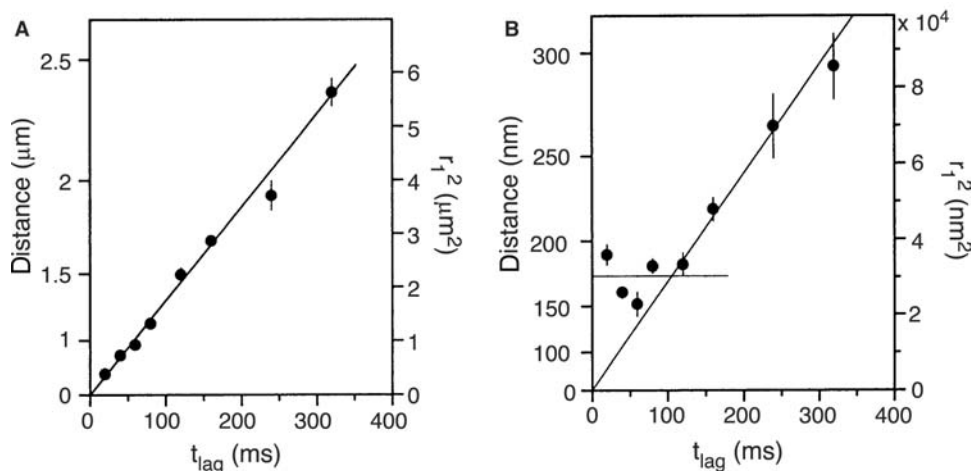

Detailed information on the paths taken by single molecules as they diffuse through materials and across their surfaces has been obtained in a number of experiments. Such single molecule diffusional trajectories have been recorded by near-field<sup>[60,151]</sup> and far-field

**Fig. 12** (A) Fluorescence transient from the interface between water and a dimethyloctadecylsilane derivatized glass surface in the presence of dilute DiI. The sharp signal spikes represent fluorescence from single DiI molecules diffusing rapidly through the detection volume. A specific adsorption event occurs at about 21.2 sec into the transient, as depicted by the relatively stable fluorescence observed beginning at this time. (B) Expanded section of this transient, showing the stable fluorescence signal from a single molecule. *Source:* From Ref.<sup>[122]</sup>. © 1998, American Chemical Society.

confocal imaging methods.<sup>[36,37,53,54,149,152]</sup> Diffusional trajectories have been obtained in two<sup>[36,37,53,60,152]</sup> and three<sup>[30]</sup> dimensions. Sample scanning methods are best suited to observation of relatively slow molecular

motions having diffusion coefficients in the  $10^{-12}$ – $10^{-13}$   $\text{cm}^2/\text{s}$  range.<sup>[60,120]</sup> Much faster diffusional processes, with diffusion coefficients approaching  $10^{-7}$ – $10^{-8}$   $\text{cm}^2/\text{s}$ , are readily studied by wide-field

**Fig. 13** Diffusion data for dye-labeled phospholipids in a fluid-supported phospholipid membrane. Diffusion is observed to occur on two different time scales. (A) Expectation value for the squared displacements (right axis) resulting from the fast diffusional component. The data show a linear trend in time. (B) Expectation value for the squared displacements (right axis) resulting from the slow diffusional component. The data show a linear trend in time for  $t_{\text{lag}} > 100$  msec. *Source:* From Ref.<sup>[149]</sup>. © 1997, Biophysical Society.

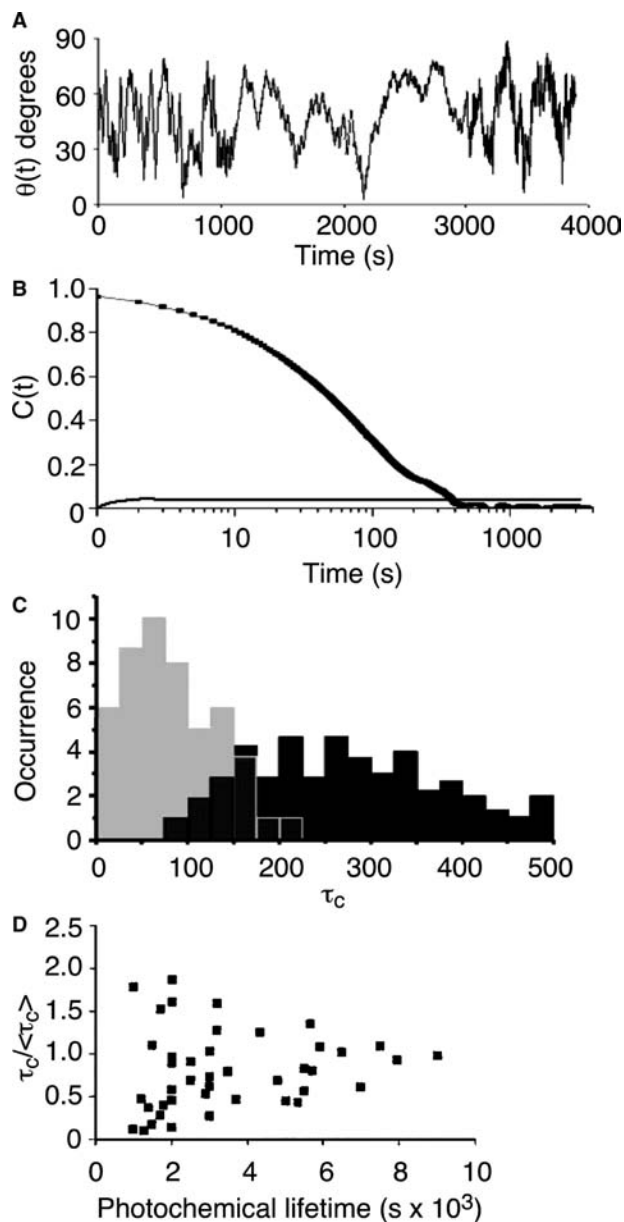

illumination methods.<sup>[149]</sup> While the resolution of far field methods most commonly employed in such studies is limited, it is important to note that the locations of the single molecules in each image can be determined to relatively high precision (i.e.,  $\pm 30$  nm in far-field imaging<sup>[53]</sup> and  $\pm 1$  nm by near-field methods<sup>[60]</sup>. Such high precision is obtained by curve fitting the Gaussian intensity profiles obtained from the single molecule emission spots in the images. Under appropriate circumstances, the precision to which the position of a molecule can be determined is primarily limited by the signal-to-noise ratio.<sup>[53]</sup>

These methods have tremendous potential for uncovering nanoscale heterogeneity in a wide variety of materials systems. As an example, Schmidt et al.<sup>[37,53,149]</sup> have uncovered anomalous diffusion in fluid- and polymer-supported phospholipid membranes, by using a tetramethylrhodamine-labeled phospholipid as the probe. Data from their studies on fluid-supported membranes are shown in Fig. 13.<sup>[149]</sup> Their results show that diffusion occurs on two different time scales in the fluid-supported samples, yielding diffusion coefficients of  $4.4 \times 10^{-8}$  and  $7 \times 10^{-10}$  cm<sup>2</sup>/s. The more mobile molecules exhibited a linear increase in square displacement in time ( $t_{\text{lag}}$  being the time between consecutive images), as expected for Brownian motion. The less mobile molecules also exhibited such behavior for time scales longer than 100 msec. However, at shorter times, the square displacements for these less mobile molecules were found to be independent of time, suggestive of diffusion confined to small “corrals.” Diffusion restricted to small (140 nm) “corrals” was also observed for polymer-supported lipid films.<sup>[149]</sup>

### Reorientation dynamics

The orientations of single molecules can be determined in the laboratory reference frame via the use of polarization-dependent excitation and emission methods.<sup>[76]</sup> A wide variety of methods for measuring the orientations of single molecules have been demonstrated to date. These include direct polarization-dependent methods,<sup>[30,40,45,71,76,119,121,141,152–154]</sup> in which polarization control optics are used to set the excitation polarization and/or to determine the emission polarization. Elegant polarization-dependent imaging methods using aberrated far-field optical systems<sup>[48,49,51]</sup> and near-field optics<sup>[8,55,61,62,70]</sup> have also been demonstrated. Time-dependent changes in the molecular orientation can also be accurately followed and orientational “trajectories” recorded.<sup>[40,49,51,119,121,152]</sup> Such motions reflect the mobility of the dye molecules within their local environments.<sup>[40,119,121]</sup> Hence the results provide physical evidence of the nanoscale fluidity of each sample.

An excellent example of the information that may be obtained is provided by recent work of Deschenes and Vanden Bout.<sup>[40,119]</sup> In their studies, orientation-sensitive single molecule methods were used to monitor temperature-dependent reorientation dynamics in

**Fig. 14** (A) In-plane first-quadrant orientation angle for a single rhodamine 6G molecule in poly(methyl acrylate) at  $T_g + 10$  K in time. (B) Autocorrelation of the transient shown in panel A. The data is fit to a stretched exponential (solid line). (C) Histograms of the single molecule rotational correlation times measured for rhodamine 6G molecules in poly(methyl acrylate) (gray) and poly(n-butyl methacrylate) (black). (D) Single-molecule rotational correlation times relative to the ensemble average correlation time as a function of survival time. *Source:* From Ref.<sup>[119]</sup>. © 2001, American Chemical Society.

organic polymer films held near their glass transition temperatures ( $T_g$ ).<sup>[40,119]</sup> A better understanding of the spatial and temporal heterogeneity in molecular motions was sought. New information on the local time scales for molecular reorientation was obtained, along with information on the rate at which the single molecule dynamics approached those of the bulk. This work builds on extensive previous bulk studies.<sup>[155]</sup> Figure 14 depicts representative results from single molecule studies of poly(methyl acrylate) ( $T_g = 281$  K) and poly(*n*-butyl methacrylate) ( $T_g = 285$  K), using rhodamine 6G as the probe molecule.<sup>[119]</sup>

In these studies, the in-plane first-quadrant angle  $\theta$  between the molecular transition dipole and an arbitrarily defined laboratory “*x* axis” was obtained as a function of time, by detecting the fluorescence emitted into two orthogonal polarizations. The angle  $\theta$  is readily calculated from the ratio of these two signals,<sup>[119]</sup> and is plotted in Figure 14A. Clearly apparent in the data are temporal variations in the in-plane orientation of the molecule. Temporal variations in the rate of molecular reorientation are also observed. Figure 14B shows the autocorrelation function derived from this data. By fitting the autocorrelation data to stretched exponentials, the authors obtained parameters that allowed them to determine a weighted average for the rotational correlation time of each molecule. Histograms of these average rotational correlation times are shown in Figure 14C. These data show that the rotational correlation times are larger on average and substantially more variable for molecules in poly(*n*-butyl methacrylate) samples than for those in poly(methyl acrylate).

Deschenes and Vanden Bout<sup>[40,119]</sup> also sought information on the temperature-dependent environmental exchange times. Figure 14D shows results for poly(methyl acrylate) at  $T_g + 10$  K. In these experiments, they determined the (averaged) rotational correlation times for a number of single molecules having different survival times. They found that the rotational correlation times for the longest-lived single molecules most closely approached those of the ensemble average. The rate of decay to the ensemble average value yielded information on how rapidly the reorientation dynamics changed in a particular nanoscale region.

## CONCLUSION

Although new single molecule methods continue to be developed and a complete understanding of all single molecule photophysical phenomena has not yet been obtained, the methods and experiments described above represent important initial steps toward a better understanding of nanoscale phenomena by single molecule methods. The methods themselves represent

powerful means for characterizing the static and dynamic properties of a broad range of materials spanning a range of disciplines. The main advantages of such methods over more conventional bulk methods arise from their ability to probe chemical and physical phenomena at the single molecule level, thereby retaining the information obscured by averaging in bulk methods. As all chemistry occurs on the single molecule level and in single nanoscale environments, information obtained by single molecule methods will be important to the future development of nanoscale materials with tailored physical/chemical properties.

## ACKNOWLEDGMENT

The authors gratefully acknowledge the support of the National Science Foundation (CHE-9701509 and CHE-0092225), the Army Research Office (DEPSCoR), 3M Company, and Kansas State University in the preparation of this article. Prof. M. M. Collinson and the members of the Higgins group are thanked for their comments on early versions of this manuscript.

## INTRODUCTION

Ongoing developments in the production and characterization of carbon nanotubes, as previously summarized,<sup>[1]</sup> have opened up new fields in science and technology in the last few years. These materials are shown to be versatile building blocks because of their unique electronic,<sup>[2,3]</sup> optical,<sup>[4,5]</sup> and mechanical<sup>[6,7]</sup> properties; for example, most recently, carbon nanotubes were found to act as ballistic field-effect transistors (FET),<sup>[8]</sup> were fabricated as FETs with multiple, individually addressable gate segments,<sup>[9]</sup> were applied in composites,<sup>[10]</sup> and were shown to be photoconductive.<sup>[11]</sup>

Furthermore, because carbon nanotubes emit high currents (up to 1 A/cm<sup>2</sup>) at low field ( $\sim 5$  V/ $\mu$ m),<sup>[12]</sup> and significant advances have been attained in the production of well-aligned tubes, the applicability for field emission previously recognized by de Heer, Chatelain, and Ugarte.<sup>[13]</sup> has now been widely acknowledged,<sup>[14]</sup> and a prototype of a flat panel with color display was achieved.<sup>[15]</sup> Most recently, different production procedures and treatments of nanotubes were shown to result in varying degrees of field emission.<sup>[16–25]</sup>

Despite these technological developments, there are still unanswered questions regarding the field emission mechanism, as it was observed that the  $I$ - $V$  characteristics of Single-Wall Carbon NanoTubes (SWCNTs) could deviate from Fowler–Nordheim’s (FN) theory,<sup>[26]</sup> which assumes the emission to occur by a tunneling mechanism. A range of experimental and theoretical studies were reported to explain this behavior, e.g., by Saito et al., suggesting that the deviation may occur because of the non-metallic behavior of SWCNTs at the tip,<sup>[27]</sup> while Bonard et al. attributed the nonlinearity to tube interactions,<sup>[28]</sup> and others<sup>[29–31]</sup> observed that the exposure of SWCNT samples to

gas adsorption alters their emission properties. Although the effects of gas adsorption, in particular O<sub>2</sub>, were previously reported experimentally,<sup>[32,33]</sup> the detailed chemistry at the adsorption sites under an external field and the resulting field emission properties are still not fully understood. Theoretically, much attention has been devoted thus far to the study of O<sub>2</sub> adsorption at SWCNT tips,<sup>[34–41]</sup> and their effects on field emission, including our recent systematic examination of the adsorption at capped and uncapped tips, performed under a local field to mimic the emission environment.<sup>[42]</sup>

In this review, we outline some of the findings of our previous work,<sup>[42]</sup> and in addition, report preliminary results on the effects of ozonation on SWCNTs. Indeed, although ozonation of carbon nanotubes enhances the propensity for functionalization,<sup>[43]</sup> and alters the field emission properties, e.g., an enhancement in the first 3 min upon exposure to O<sub>3</sub> has been observed,<sup>[32]</sup> Thus far the effects of O<sub>3</sub> have not been extensively explored theoretically. While a mixed quantum mechanics/molecular mechanics (ONIOM) study of O<sub>3</sub> adsorption at the sidewall of a SWCNT, assuming only a 16-atom model at a high level of accuracy, has been recently reported,<sup>[44]</sup> we carried out all-electron Linear Combination of Atomic Orbitals (LCAO) Density Functional Theory (DFT)<sup>[45]</sup> calculations in our preliminary investigation, previously also applied to extended SWCNT systems.<sup>[46]</sup> We identify possible reaction sites for ozonation, which could play a role in the experimentally observed field emission enhancement. Such comprehensive studies, reiterated in this review for O<sub>2</sub> adsorption, and including our new results for the ozonation at the tips, provide an outline for our ongoing interest in gaining insight into the effects of adsorbates on field emission characteristics in these materials, e.g., enhancement by Cs intercalation or deposition.<sup>[47–51]</sup>

## RESULTS AND DISCUSSION

### Computational Details

The Perdew–Burke–Ernzerhof (PBE) exchange–correlation ( $x$ -c) functional<sup>[52]</sup> within the generalized gradient approximation was employed to reduce the overbinding effects caused by the local density approximation, also known to adequately predict the density of states as compared to experiment,<sup>[53]</sup> using a double numerical polarized basis set. As we have previously pointed out, it is important to emphasize that, to accurately discern long-range dispersion effects using DFT, recently assessed for weakly bound test problems,<sup>[54]</sup> theoretical studies have to be systematically carried out with an appropriate ( $x$ -c) functional. Improvements suggested to take into account dynamical correlations, including semiempirical methods,<sup>[55]</sup> hybrid approaches, improved correlation functionals,<sup>[56]</sup> or time-dependent DFT calculations,<sup>[57]</sup> could enable more accurate calculations in the future.

We studied C(5,5) capped and open-ended (uncapped) SWCNT tips (for comprehensive details, see Ref.<sup>[42]</sup>); three-unit cell C(5,5) tubes, terminated with a half C<sub>60</sub> molecule or open-ended, on one end, respectively, and saturated with hydrogen atoms at the other end, were used. As the emission in these systems involves the topmost layers, only adsorption at the tip was taken into account. A uniform external field directed from the top toward the tube tip was applied to simulate the emission environment. Under an applied electric field, the stems of the tubes were fixed to simulate an attached nanotube to a substrate. Geometries were optimized in the absence and presence of an electric field. Transition state geometries were evaluated.<sup>[42]</sup> Note that Kim et al.<sup>[58]</sup> have previously calculated O<sub>2</sub> adsorption for an uncapped SWCNT, also with an applied field; however, an analysis for C(10,0) was primarily emphasized. The work function<sup>[59]</sup> is approximated by the first ionization potential (IP), not dependent on the tube length,<sup>[42]</sup> as compared to the Highest Occupied Molecular Orbital (HOMO)–Lowest Unoccupied molecular Orbital (LUMO) gap, adopted by Kim and Kim.<sup>[60]</sup> The adsorption energy ( $E_{\text{ad}}$ ) was defined as:  $E_{\text{ad}} = E(\text{SWCNT} + \text{O}_2) - E(\text{SWCNT}) - E(\text{O}_2)$ ; a positive or a negative change in  $E_{\text{ad}}$  refers to an endothermic, or exothermic reaction, respectively.

### O<sub>2</sub> Adsorption

Reaction paths of O<sub>2</sub> interacting at the (h–h) and (p–h) sites of a capped tube, for configs.-(a) and -(c), respectively, are summarized in Fig. 1. The initial adsorption process at the (h–h) site forms weak single O–O and O–C bonds, changing the C–C double bond to a single bond. In the absence of an electric field, the reaction is

**Fig. 1** O<sub>2</sub> adsorption on a capped tube. Top: At the hexagon–hexagon (h–h) site represented by config.-(a), leading to config.-(b) through an etched transition state. Bottom: O<sub>2</sub> adsorption at the hexagon–pentagon (p–h) site as shown by config.-(c), leading to the etched config.-(d). The transition states were confirmed by vibrational frequency calculations, obtaining one imaginary frequency in each case: 274 and 396 cm<sup>-1</sup> for the transition states leading to configs. -(b) and -(d), respectively. *Source:* From Ref.<sup>[42]</sup>.

endothermic with an adsorption energy of 0.11 eV (Table 1 in Ref.<sup>[42]</sup>), suggesting that the reaction is not favorable; however, if the conditions for chemisorption exist, the O<sub>2</sub> molecule can further react to etch the tube. During etching, structures with a partial double C=O bond are formed after the dissociation of the O–O bond, lowering the energy by about 1.5 eV with respect to the initial structure. However, a large energy barrier of 3.4 eV needs to be overcome for the etching to occur; this result is larger than a previously estimated value (1.02 eV), using a self-consistent tight-binding method.<sup>[35]</sup>

In comparing the energetics and structural parameters for the adsorption at the (p-h) and (h-h) sites, we note that the O<sub>2</sub> adsorption at the (p-h) site has a higher energy (0.85 eV) (Table 1 in Ref.<sup>[42]</sup>). The etching process takes place by overcoming an energy barrier of about 3.2 eV, slightly lower than that at the (h-h) site, but larger than a previously reported value of 0.9 eV. The formation of the O-C bonds in the etched configurations stabilizes the structure by lowering the energy by ca. 2 eV, through an exothermic reaction.

The reaction path of a physisorbed O<sub>2</sub> configuration toward chemisorption on the (p-h) site, shown in Fig. 2, finds an energy barrier of 0.77 eV, which is lower than the energy barrier needed to etch the tube, suggesting that the transition from physisorption to chemisorption could occur if the thermodynamic conditions exist to trigger it. Even in the absence of an electric field, we found physisorption to be exothermic, with no structural changes, and an adsorption energy of -0.12 eV at a distance of 3.3 Å from the tip. Interestingly, the adsorption energy is comparable to H<sub>2</sub> physisorption (-0.1 eV).<sup>[61]</sup> Although the adsorption energy compares well with that reported by Peng and Cho<sup>[62]</sup> for O<sub>2</sub> physisorbed on the sidewall of a (10,0) nanotube (-0.1 eV), the adsorption distance was smaller (2.7 Å). A larger value was obtained at 2.7 Å (-0.25 eV), by applying DFT to model sidewall adsorption.<sup>[34]</sup> Note that our results are consistent with recent MP2 calculations on the interaction of O<sub>2</sub> with a (9,0) carbon nanotube.<sup>[63]</sup>

**Fig. 2** The reaction path from an O<sub>2</sub> physisorption configuration to a chemisorbed configuration in the (p-h) site on a capped SWCNT. *Source:* From Ref.<sup>[42]</sup>.

O<sub>2</sub> chemisorption is more favorable (negative adsorption energies for uncapped tip configurations) in the open-ended tip. Fig. 3 shows an O<sub>2</sub> molecule reacting with the open-ended tip (config.-f), as well as the adsorption of O<sub>2</sub> on top of the arm site of the tip (config.-g), forming two O-C bonds with bond lengths of 1.23 Å, and an O-O distance of 2.8 Å (Table 1 in Ref.<sup>[42]</sup>). We studied part of the reaction path to config.-h, which is the most stable state in this case. A slight increase in the O-O bond length drives the structure to config.-h, overcoming a small energy barrier of 0.23 eV, and gaining about 0.5 eV through an exothermic reaction.

In addition, we investigated the effects of O<sub>2</sub> adsorption for fully saturated tips [configs.-i) and -(j) for C(5,5), and configs.-k) and -(l) for C(10,0); Fig. 4]. Config.-i) is a metastable state with an adsorption energy of -2.73 (eV/O<sub>2</sub>) and an IP of 6.17 eV (Table 2 in Ref.<sup>[42]</sup>). These values are comparable to

**Fig. 3** O<sub>2</sub> adsorption on an uncapped tube. Top: Intermediate states, shown by config.-f) and config.-g). Bottom: A partial reaction path of O<sub>2</sub> adsorbed on an uncapped tube represented by config.-g); an increase of O-O distance leads to config.-h), where one of the oxygens is bonded with two carbons. The transition state was also confirmed in this case, with a 196 cm<sup>-1</sup> imaginary frequency. *Source:* From Ref.<sup>[42]</sup>.

**Fig. 4** Effects of saturating uncapped SWCNT tips by  $O_2$  adsorption are shown for: (Top)  $O_2$  adsorption on the C(5,5) armchair tube—configs.-(i) and -(j). (Bottom)  $O_2$  adsorption on the C(10,0) zigzag tube—config.-(k) shows an  $O_2$  adsorption and config.-(l) represents a saturated tip. Source: From Ref.<sup>[42]</sup>.

those of config.-(f), suggesting that the saturation at the tip in this case has a small effect on field emission properties. On the other hand, the IP in config.-(j) increased by 9% and the tip opening stretched out by about 4% compared to the pristine nanotube, because of the formation of a C=O double bond, and repulsion of neighboring oxygens.

In the initial adsorption process, characterized by configs.-(a) and -(c) for the capped tubes (Fig. 1), values of the adsorption energies decrease smoothly as a function of field strength. This suggests that an applied voltage lowers the adsorption energy, thus setting the conditions for a chemisorption process to take place, which in turn, leads to etching. A  $2\text{ eV/\AA}$  increase in the field significantly alters the structural parameters, resulting in a lower energy barrier for an etching process to occur. Indeed, a  $2\text{ eV/\AA}$  applied field has desorbed the oxygen from the tip in config.-(c), whereas in the final adsorption process [configs.-(b) and -(d)], it is difficult to achieve desorption without disintegrating the nanotube tip. In our study, the C(5,5) open-ended tip was examined, and although the adsorption energies for configs.-(f), -(g), and -(h) are systematically up-shifted by about  $1.4\text{ eV}$ , as

compared to previous self-consistent tight-binding calculations,<sup>[35]</sup> the relative values between intermediate configurations are comparable. Furthermore, we found that under a  $1\text{ eV/\AA}$  field, config.-(f) converges to config.-(g), by forming a double bond (structural results in Table 1 of Ref.<sup>[42]</sup>). Stronger adsorption under a  $1\text{ eV/\AA}$  field is shown, as has been observed for capped tubes. In configs.-(g) and -(h), we note small structural changes, suggesting no desorption at  $1\text{ eV/\AA}$  field strength; however, longer O–C bonds were observed at a higher field ( $2\text{ eV/\AA}$ ).

Overall, our results show that  $O_2$  chemisorption is endothermic on a capped tip, with the (h–h) adsorption site being energetically more favorable than the (p–h) site. If the thermodynamic conditions exist for chemisorption to occur, an energy barrier larger than  $3\text{ eV}$  is required to etch the tube. The application of an electric field sets the conditions for the chemisorption to take place. In open-ended tips, the examined interactions were exothermic with lower adsorption energies. This suggests that the observed current suppression on exposure to  $O_2$  can be rationalized in terms of the presence of a high percentage of open-ended tips or tubes with structural defects.

Under a zero electric field, a small increase of about 2% in the IP was noted for capped tubes, suggesting that  $O_2$  adsorption plays a role in the current suppression observed experimentally (Table 2 in Ref.<sup>[42]</sup>). An applied field exacerbates this current suppression, as shown by the notable increase of the IP, ranging from 2% to 6% for config.-(c), and 8% for config.-(d). While in config.-(a) a small change of the IP has been observed with an applied field, config.-(b) shows a much higher IP, with an increase of about 46%, which could be explained by the specific geometry at the adsorption site. As expected, charge transfer occurs upon adsorption from carbon to oxygen (cf. Fig. 5 in Ref.<sup>[42]</sup>). We also note that an applied field appears to increase the negative partial atomic charge on the oxygen atom.

Upon  $O_2$  adsorption in the absence of an electric field in uncapped tubes, no significant effect on the IP is observed in config.-(f) with respect to pristine C(5,5); however, an increase of 2% is shown for the intermediate and final configs.-(g) and -(h), respectively. The corresponding HOMO energies are consistent with the IP's trend ( $-4.81$ ,  $-4.82$ ,  $-4.96$ , and  $-4.93\text{ eV}$ , for a pristine tube and configs.-(f), -(g), and -(h), respectively). However, under a  $1\text{ eV/\AA}$  applied field, the IPs increase to about 5% in configs.-(f) and -(g), and 9% in config.-(h), respectively. Once again, this implies that the current suppression is exacerbated by an applied field, accompanied by an increase in the charge transfer from carbon to oxygen. We note that the IPs of the pristine capped and uncapped tubes, under zero electric field, are

comparable. However, under a  $1 \text{ eV/\AA}$  field strength, the IP of the uncapped tip is 6% higher than that of a capped tube. As for the  $\text{O}_2$  adsorbed tips, different values were obtained depending on the adsorption sites. The effects of  $\text{O}_2$  adsorption on the field emission properties is, in general, more pronounced in the C(10,0) than in the C(5,5) tip, with an IP increase of 13% and 30% in configs.-(k) and -(l), respectively, compared to the pristine C(10,0) tube. The increase in the IPs for the saturated tip models is also in agreement with experimental results, where a decrease in the output current as a function of the  $\text{O}_2$  exposure time was observed.

### $\text{O}_3$ Adsorption

An enhancement of the field emission current in the first 3 min upon ozonation of carbon nanotubes has been experimentally observed<sup>[32]</sup> although decaying is observed as exposure time increases, indicating the beginning of the tubes' degradation by etching.

**Fig. 5**  $\text{O}_3$  adsorption on a capped tube: A) physisorption:  $d(\text{O}-\text{C}) = 3.31 \text{ \AA}$  and  $d(\text{O}-\text{O}) = 1.450 \text{ \AA}$ ; B) chemisorption at the p-h site:  $d(\text{O}-\text{C}) = 1.44 \text{ \AA}$  and  $d(\text{O}-\text{O}) = 1.47 \text{ \AA}$ ; C) chemisorption at the p-h site:  $d(\text{O}-\text{C}) = 1.40 \text{ \AA}$ ,  $d(\text{O}-\text{O}) = 1.23 \text{ \AA}$ , and  $d(\text{OO}-\text{OC}) = 1.82 \text{ \AA}$ ; D) etching at the p-h site with the front two O-C bonds at  $d(\text{O}-\text{C}) = 1.22 \text{ \AA}$  and one back O-C bond at  $d(\text{O}-\text{C}') = 1.35 \text{ \AA}$ .

**Table 1** IPs and adsorption energies for  $\text{O}_3$  adsorbed at capped tips

Config.	5a	5b	5c	5d
IP (eV)	6.14	6.28	5.84	6.91
$E_{\text{ad}}$ (eV/ $\text{\AA}$ )	0.62	-1.71	-1.02	-2.34

Fig. 5 shows the optimized structures of  $\text{O}_3$  adsorption on a capped SWCNT. Config.-(5A) represents  $\text{O}_3$  physisorption on a capped tip; the reaction was found to be slightly endothermic, contrary to  $\text{O}_2$  adsorption, where such a reaction was calculated to be exothermic. Config.-(5B) depicts a chemisorption of  $\text{O}_3$  at the p-h site, and as noted from the calculated adsorption energy (cf. Table 1), it is more exothermic than with  $\text{O}_2$ . This configuration may further lead to etching, such that the middle O atom will form the third C=O bond at the tip, and therefore break it. Interestingly, our results are consistent with the binding energies calculated for sidewall ozonation.<sup>[44]</sup>

Although for the (p-h) capped tip site adsorption, the calculation of the vertical IP reveals a suppression of current, it is interesting to note that for config.-(5C), where the ozone reaction takes place at an h-h site, our preliminary calculations predict an enhancement of the current, depicted by a reduction of ca. 5% in the IP compared to the pristine nanotube. In this case, a five-member ring-like structure at the p-h site cannot form, but instead an  $\text{O}_2$  molecule and an O=C double bond are formed. Mulliken analyses reveal that  $\text{O}_2$  acts as charge donor to the O=C structure, hence reducing the work function of the system, which could serve as a possible explanation of the experimentally observed emission enhancement.<sup>[32]</sup> Following  $\text{O}_3$  chemisorption at the p-h site, etching may occur, as shown in config.-(5D), where the two O atoms are double-bonded to the tip, while the other O-C forms a partial double bond. The larger IP of the structure shows suppression of field emission, which is, once again, consistent with experiment, as the field emission decays if the carbon nanotubes are exposed to  $\text{O}_3$  for a longer time. Preliminary calculations of ozonation at uncapped tubes reveal that the ozone strongly reacts with the tube.

### CONCLUSION

In conclusion, the review of our comprehensive examination of the adsorption mechanisms on capped and uncapped SWCNT tip geometries provided insight into the chemistry upon exposure of SWCNTs to  $\text{O}_2$  and  $\text{O}_3$ , in comparison with other studies. We showed that  $\text{O}_2$  adsorbs through a physisorption mechanism, whereas  $\text{O}_3$  prefers to chemisorb on capped tips. However, on uncapped tips, both  $\text{O}_2$  and  $\text{O}_3$  adsorb chemically at the tip apex.

The desorption mechanism of O<sub>2</sub> was examined under an applied field, revealing that once O<sub>2</sub> dissociates and attaches to the tip, it becomes difficult for desorption to take place. Indeed, the inclusion of an electric field provided a more realistic emission environment, showing that the field exacerbates current suppression upon O<sub>2</sub> adsorption by lowering the adsorption energy at the capped tip, thus setting the conditions for an etching process to occur. Our adsorption energies and first IPs clearly illustrate the sites involved in current suppression, and the increase in IP for saturated open-ended tubes is in agreement with experimental results. Further studies on O<sub>3</sub> adsorption under an applied field are being carried out.

## ACKNOWLEDGMENTS

We thank the ASC/MSRC for their excellent support in carrying out the calculations.

## INTRODUCTION

Carbon nanotubes were discovered<sup>[1]</sup> in 1991 by means of transmission electron microscopy in the multiwalled form that consists of concentric shells of seamless cylinders of graphene (a layer of graphite). The quasi one-dimensional structure, large mechanical strength, and the conjugated electronic structure are among the most commonly mentioned properties of carbon nanotubes. Current and potential applications of carbon nanotubes include the probing tip in scanning tunneling microscopy,<sup>[2]</sup> artificial “muscle”,<sup>[3]</sup> units of electronic memory storage,<sup>[4]</sup> to name just a few. The fascinating properties and potential uses have attracted much research interest in the carbon nanotubes.

The geometries, electronic properties and actuation of single-walled carbon nanotubes (SWNTs) obtained from high-level quantum mechanical calculations are presented in this entry. The commonly used quantum mechanical methods are first reviewed, then the behaviors of small to medium SWNTs with different structures are discussed and comparison with experimental results is made when possible. The behaviors of different groups of SWNTs are attributed to their electronic band structures.

## OVERVIEW

Shortly after the discovery of carbon nanotubes, the geometries and electronic band structures of these quasi one-dimensional extended systems were described in general terms.<sup>[5,6]</sup> Idealized single-walled carbon nanotubes can be viewed as formed by rolling up a graphene sheet along the chiral vector  $(n,m)$ , where  $n$  and  $m$  are numbers of the two lattice vectors ( $a_1$  and  $a_2$ ) of graphene needed to construct the chiral vector. The translational vector is perpendicular to the chiral vector, thus parallel to the tube axis. Fig. 1 shows the chiral vector of a (5,3) chiral SWNT.

Because of the two-dimensional symmetry of graphene,  $(n,m)$  is the same as  $(m,n)$ , therefore by convention  $n$  is larger than or equal to  $m$ . Depending on the values of  $n$  and  $m$ , SWNTs can be achiral or chiral:  $(n,n)$  armchair and  $(n,0)$  zigzag nanotubes are achiral, whereas general  $(n > m > 0)$  nanotubes are chiral. For a detailed discussion of the general aspects of the geometrical and electronic structures of SWNTs, see other related entries in this encyclopedia. The characteristic behavior of SWNTs shows significant deviations from the behavior of graphene, mostly because the finite dimension perpendicular to the tube axis introduces quantization of the energy levels leading to subgroups of “metallic” and “semiconducting” tubes. The importance of the remainder of the  $(n - m)/3$  division has been discovered by applying a simple tight binding theory to the electronic structure of SWNTs. This simplification leads to results that we refer to as “ideal” in this entry. The remainder of  $(n - m)/3$  is related to the mapping of the highest occupied and lowest unoccupied levels of SWNTs to the energy levels of graphene that are closest to the Fermi energy, and this leads to the broad categories of “metallic” ( $n - m = 3i$ ,  $i$  is an integer) and “semiconducting” ( $n - m = 3i + 1$  and  $3i + 2$ ) SWNTs.<sup>[5,6]</sup>

The observed SWNTs<sup>[7,8]</sup> have diameters from a half to a few nanometers and lengths up to several micrometers, hence the name. In both graphite and nanotubes, the carbon atoms are in an  $sp^2$  hybridized form with one p atomic orbital perpendicular to the surface of graphene or the tube left to form the  $\pi$  molecular orbitals. The planarity of the graphite layer ensures that the overlap between the p atomic orbitals of adjacent carbon atoms is maximal, thus the strongest possible in-plane bond is formed in graphite. In the cylindrical nanotubes, the orbital overlap is reduced because of the curvature. When the diameters are large, the reduction in the bond strength should be minimal, therefore the properties of large nanotubes are expected to mostly follow that of graphene. On

**Fig. 1** The chiral vector of the (5,3) single-walled carbon nanotube. Rolling up the graphene sheet along this chiral vector forms the chiral (5,3) nanotube. The translational vector is perpendicular to the chiral vector. The two lattice vectors of graphene,  $a_1$  and  $a_2$ , are also shown. The achiral nanotubes  $(n,n)$  and  $(n,0)$  are commonly referred to as armchair and zigzag nanotubes, respectively.

the other hand, small diameters introduce large curvatures, thus large changes in both geometrical and electronic properties should occur for small diameter nanotubes. While it was largely ignored early on, recent theoretical and experimental studies have shown that the curvature effect introduces noticeable deviations for the small diameter nanotubes from the “ideal” behaviors expected from that of the idealized SWNTs.

Experimentally, SWNTs are usually formed in bundles where each bundle consists of many intertwined nanotubes. The interaction between the individual tubes in a bundle is small but sometimes noticeable.<sup>[9,10]</sup> Such influences include the observed pseudogap of  $\sim 0.1$  eV (a dip of the density-of-states, DOS, curve at  $E_F$ ) for the bundled (8,8) armchair SWNT instead of the smooth DOS curve at  $E_F$  for the isolated nanotube.<sup>[9]</sup> In this entry, we focus on the intrinsic geometries and electronic band gaps of isolated SWNTs.

This entry reviews the latest understanding of the unique features of small to medium nanotubes based on theoretical studies employing quantum mechanical calculations. First, the commonly used computational methods are reviewed. Second, in groups of different chiralities, we look at the geometrical parameters and the electronic band gaps of neutral nanotubes. The  $(n,n)$  armchair nanotubes and three subgroups of  $(n,0)$  zigzag nanotubes with  $n = 3i$ ,  $3i + 1$ , and  $3i + 2$  show unique trends in these properties. Third, following a brief discussion of the dimensional change in the in-plane lattice of graphite intercalation compounds, we discuss the actuation of isolated SWNTs upon charge injection. Finally, all the unique geometrical and electronic properties of small to medium SWNTs are attributed to the allowed states in the reciprocal  $k$ -space, i.e., their band structures.

## COMMONLY USED COMPUTATIONAL METHODS

The length-to-diameter ratio for SWNTs is on the order of thousand, making them suitable for the application of periodic boundary conditions. Inclusion of one unit cell under periodic boundary conditions has been used by many authors and will therefore be the emphasis of this entry. An oligomer approach, on the other hand, must include at least several unit cells and thus requires a few hundred atoms even for the simplest SWNTs, which becomes computationally expensive when combined with high-level quantum mechanical theory. The oligomer approach is useful in studying the end effect of finite-length SWNTs and several studies have appeared in the literature.<sup>[11–13]</sup>

Quantum mechanical calculations are needed in order to predict reliable geometrical and electronic data for SWNTs. Moreover, the conjugated nature of their electronic structures requires accurate treatment of the electron correlation effects, which calls for post-Hartree–Fock (post-HF) ab initio methods such as the second-order Møller–Plesset perturbation theory (MP2).<sup>[14]</sup> However, the computational cost for the traditional post-HF ab initio methods would be prohibitively expensive. The general need to correctly treat electron correlation effects within reasonable computation time has made density functional theory (DFT)<sup>[15]</sup> a commonly used alternative. Within the framework of DFT, local density approximation (LDA) and generalized gradient approximation (GGA) have both found application for isolated SWNTs. LDA calculations were first carried out by Blasé et al.<sup>[16]</sup> for  $(n,0)$  zigzag nanotubes with  $n = 6–9$ . Kanamitsu and Saito<sup>[17]</sup> used the Ceperley–Alder LDA functional,<sup>[18]</sup> while Kürti et al.<sup>[19,20]</sup> used the Perdew and Zunger LDA functional.<sup>[21]</sup> Sun et al.<sup>[22–24]</sup> used the Perdew–Wang 91 (PW91) GGA functional,<sup>[25]</sup> which has been shown<sup>[26]</sup> to give better bond lengths than LDA functionals for, among others, *trans*-polyacetylene when experimental data. The PW91 functional was also used by Liu and Chan<sup>[27]</sup> for SWNTs with 4 Å diameter and by Gülseren, Yildirim, and Ciraci<sup>[28]</sup> for zigzag SWNTs. Plane-wave basis sets were used in these studies, in combination with either pseudopotentials in the forms of Kleinman–Bylander,<sup>[29]</sup> Vanderbilt,<sup>[30,31]</sup> or in combination with projector augmented-wave methods.<sup>[32,33]</sup> To minimize the effect of neighboring nanotubes, intertube distances were normally set to substantial values, ranging from 6 Å up to 11 Å.

Mintmire and coworkers used a first-principles, all-electron, self-consistent local-density functional (LDF) method and Gaussian-type orbitals in their studies.<sup>[34–36]</sup> This approach specifically takes advantage of the helical symmetry of the SWNTs. The geometry, elastic

properties, and vibrations of selected SWNTs were studied by Ordejón and coworkers<sup>[37–39]</sup> with the Perdew–Zunger LDA functional and the minimum pseudoatomic orbitals<sup>[40]</sup> within the linear combination of atomic orbitals (LCAO) approximation.

A new functionality utilizing periodic boundary conditions<sup>[41]</sup> has been introduced in the newly released Gaussian 03 program package.<sup>[42]</sup> This functionality uses Gaussian-type basis sets and can perform calculations with HF and DFT Hamiltonians. A few applications using this feature have been reported in the literature, including the geometries<sup>[41,43]</sup> of isolated armchair SWNTs using the Perdew, Burke, and Ernzerhof (PBE) functional.<sup>[44,45]</sup> It was also shown<sup>[46]</sup> that the PBE functional gives good results for metallic tubes, whereas the PBE0 hybrid functional<sup>[47,48]</sup> gives good results for semiconducting tubes. More results on SWNTs are expected soon partly because of the availability of many functionals in Gaussian 03 that appear to give good results on geometries and other properties.

## GEOMETRY OF SINGLE-WALLED CARBON NANOTUBES

Each carbon atom in graphite is  $sp^2$  hybridized and has three bonds connecting with its neighbors. These three bonds are symmetrically related and have identical length of 1.42 Å.<sup>[49]</sup> Upon rolling-up to form a SWNT, the equality along the in-plane lattice vectors  $a_1$  and  $a_2$  of graphite is lost, resulting in two types of C–C bonds in achiral nanotubes and three types in chiral nanotubes. We refer to the bonds oriented mainly around the circumference in achiral nanotubes as b1 and the bonds mainly along the tube axis as b2. Two and three types of bond angles also result for achiral and chiral nanotubes, respectively. In the following, results for these parameters from quantum chemical calculations are reviewed. We will also look at the diameters and the lengths of the translational vectors along the tube axis as they describe the overall geometry of the isolated SWNTs.

### Armchair SWNTs

The structures of  $(n,n)$  armchair SWNTs with  $n = 5–16$  were studied by Sun et al.<sup>[24]</sup> using the PW91 GGA functional. The bond lengths (1.419–1.427 Å) for both b1 and b2 are very close to the calculated bond length of graphene, 1.419 Å Fig. 2(A). The larger bond lengths are predicted for b1 in the smallest nanotubes, while the lengths of both b1 and b2 approach that of graphene in medium diameter nanotubes. Both types of bond angles are slightly smaller than the graphene value of 120°. As a result, the diameters are larger than

**Fig. 2** The predicted (A) bond lengths and (B) bond length differences between b1 and b2 for armchair and zigzag nanotubes. Lines connecting the calculated points are provided to show trends. Source: From Ref.<sup>[24]</sup>. © 2003, The American Chemical Society.

the values expected from a perfect roll-up of graphene by as much as 0.10 Å, while the lengths of the translational vectors are shorter than the ideal corresponding value by up to 0.03 Å. The structure of the (3,3) armchair SWNT was studied by Liu and Chan using the PW91 functional, where b1 was found to be 0.01 Å longer than b2.<sup>[27]</sup> This is consistent with the results of Sun et al. in that the difference between b1 and b2 should increase from 0.004 Å for (5,5) with decreasing diameter. A similar increase of the diameters for armchair nanotubes was also obtained from LDA calculations by Kürti et al.<sup>[19]</sup>

Bettinger, Kudin, and Scuseria<sup>[43]</sup> calculated the geometries of armchair nanotubes with  $n = 3–10$  and 12 at the PBE/3-21G level of theory. The basis set is probably too small for the accurate absolute bond length values, but the trends appear reliable. The bond lengths of b1 and b2 are in the range of 1.43–1.45 Å with the longer bonds occurring in the small diameter nanotubes. These bond lengths are longer than the abovementioned results, but are consistent with the slightly longer bond length in graphene (1.431 Å) by the same method. Similar results for

$n = 5-6, 8,$  and  $10$  were obtained earlier from LDA-LCAO calculations by Sanchez-Portal et al.<sup>[37]</sup>

### Zigzag SWNTs

The isolated  $(n,0)$  zigzag SWNTs so far are the most intensely studied nanotubes by theory, because they not only have smaller unit cells than armchair and chiral nanotubes with similar diameters, but also display more features in their geometrical and electronic structures. Employing an LDA method, Kanamitsu and Saito showed<sup>[17]</sup> that b1 bonds in zigzag nanotubes with  $n = 5-12$  are elongated relative to graphene, whereas b2 bonds are shortened. The deviations of b1 and b2 from the ideal value of graphene are roughly proportional to  $1/D^2$ , where  $D$  is the diameter of the nanotube. The angle between a b1 bond and a b2 bond remains close to  $120^\circ$  for all zigzag nanotubes studied. In contrast, the angle between two b1 bonds is predicted to be as small as  $111^\circ$  for  $(5,0)$  and increases toward  $120^\circ$  proportionally to  $1/D^2$ . A similar behavior of the bond lengths and bond angles was reported in GGA calculations by Gülseren, Yildirim, Ciraci.<sup>[28]</sup>

The earlier LDA and GGA results were largely confirmed by Sun et al. using PW91 GGA method.<sup>[24]</sup> An interesting trend emerged in the GGA results shown in Fig. 2(A), but was not seen in the earlier results. The bond lengths of the 12 nanotubes form four groups, encompassing from  $n = 5-7, 8-10, 11-13, 14-16$ , respectively. Within each group, the smallest nanotube has the longest b1 and shortest b2, and vice versa. The difference within each group diminishes with increasing  $n$ , i.e., when the diameter increases. This trend is amplified in Fig. 2(B) where the bond length differences between b1 and b2 are shown. This behavior is a direct consequence of the triad periodic feature of the electronic band structures of the zigzag SWNTs, which will be discussed below.

The translational vectors in small zigzag SWNTs are slightly shorter than the values expected from graphene [by  $0.015 \text{ \AA}$  for  $(5,0)$ ], and with larger index  $n$ , the translational vectors approach the graphene value of  $4.257 \text{ \AA}$ .<sup>[24]</sup> Following the trend of bond lengths, a similar triad behavior is seen for the predicted lengths of the translational vectors for zigzag nanotubes. All the calculated diameters are longer than the ideal values by as much as  $0.17 \text{ \AA}$  ( $4.1\%$ ) for  $(5,0)$  and a triad periodicity is also seen.<sup>[50]</sup>

### Chiral SWNTs

Because the repeat units of chiral nanotubes are much larger than those of achiral ones of similar diameters, high-level quantum mechanical results were only recently reported by Kürti et al.<sup>[19,20]</sup> Employing an

LDA functional, these authors studied SWNTs with diameters up to  $8 \text{ \AA}$  for chiral nanotubes and up to  $16 \text{ \AA}$  for achiral ones. For most of the chiral nanotubes, two of the three bonds elongate, whereas the third bond that forms the smallest angle with the tube axis shortens. The shortening of the third bond is consistent with the shortening of bond b2 in zigzag nanotubes. Two chiral nanotubes  $(3,2)$  and  $(4,3)$  have quite different bond lengths from the others. In contrast to other chiral tubes, the third bond in these two nanotubes elongate by up to  $1\%$ . These two tubes have  $(n - m) = 1$ , and this may be the cause of their unusual bond lengths. The lengths of the translational vectors of most chiral tubes are all shorter than the idealized values by up to  $1.3\%$ , except those of  $(3,2)$  and  $(4,3)$ , which are longer. Similar to the achiral tubes, the diameters of the chiral tubes are predicted to be larger than the idealized values, and the change is larger for small nanotubes. The bond angles are all smaller than  $120^\circ$  in chiral nanotubes, and the magnitude of the deviation depends on the particular angle and the  $(n,m)$  index of the nanotube.

## ELECTRONIC PROPERTIES OF SWNTs

The band structures of SWNTs have been the subject of many theoretical studies. Earlier works<sup>[5,6,34,51]</sup> showed that  $1/3$  of the nanotubes with  $(n - m) = 3i$  ( $i$  is an integer) are one-dimensional metals, whereas the remaining  $2/3$  of the nanotubes with  $(n - m) = 3i + 1$  and  $3i + 2$  are semiconductors. This conclusion, based on the tight-binding theory, is valid for nanotubes that have relatively large diameters. For small isolated SWNTs, the curvature effect substantially changes their electronic structures and the deviation from the tight-binding results has been observed in density functional theory calculations.

### Armchair SWNTs

Armchair  $(n,n)$  nanotubes are all metallic as there is a level crossing at  $k = \pm 2\pi/(3c)$  in the tight-binding theory. The recent GGA calculations<sup>[24]</sup> confirmed the tight-binding prediction. Indeed, the level crossing at the Fermi level is predicted to be very close to the above position and all armchair nanotubes with  $n = 5-10, 12,$  and  $15$  have very similar band structures. A similar result was also reported for  $(3,3)$  SWNT.<sup>[27,36]</sup>

### Zigzag SWNTs

The band gaps of zigzag  $(n,0)$  nanotubes occur at  $k = 0$  in the tight-binding theory. They are confirmed by both LDA and GGA calculations as being the gaps

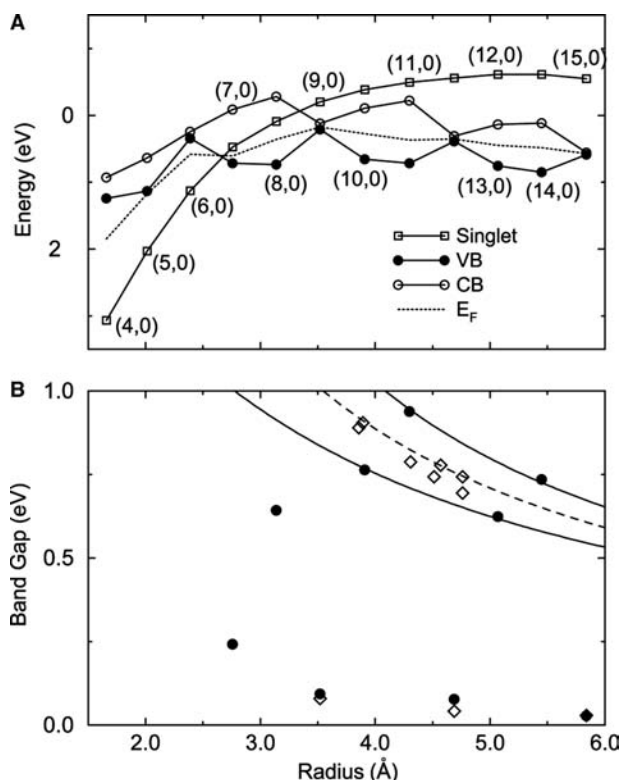

between  $\pi$  and  $\pi^*$  bands.<sup>[16,17,24,28,36]</sup> These  $\pi$ - $\pi^*$  gaps are the overall band gaps for zigzag tubes with large diameters. But for small diameter zigzag tubes, the overall band gaps are the gaps between the doubly degenerate  $\pi$  bands and a non-degenerate band. The non-degenerate band is lower than the doubly degenerate  $\pi^*$  bands and this is the result of the strong  $\sigma^*$ - $\pi^*$  hybridization in small nanotubes.<sup>[16]</sup> In the band structure of (6,0), the non-degenerate band is lower than the doubly degenerate highest occupied  $\pi$  bands at  $k = 0$ , thus a level crossing occurs at a generic  $k$ -point at  $k = \sim 0.16\pi/c$ . As a result, the band gap for (6,0) is zero instead of the small nonzero  $\pi$ - $\pi^*$  gap. This is also true for (4,0) and (5,0) SWNTs.<sup>[17,24,28,36]</sup> For (7,0) and (8,0) SWNTs, the non-degenerate band lies between the  $\pi$  and  $\pi^*$  bands at  $k = 0$ , resulting in overall band gaps that are smaller than the  $\pi$ - $\pi^*$  gaps. For (9,0) and larger nanotubes, the non-degenerate band is above the  $\pi^*$  bands at  $k = 0$ , making the  $\pi$ - $\pi^*$  gap the overall band gap. Both LDA and GGA give similar results for the band gaps of small zigzag nanotubes. Subtle differences include the values of the band gaps and whether the (7,0) tube is metallic<sup>[17]</sup> or semiconducting.<sup>[16,24,28,36]</sup>

According to their band gaps, the zigzag nanotubes can be divided into three subgroups:<sup>[24]</sup>  $n = 3i$ ,  $3i + 1$ , and  $3i + 2$  following the pattern given by the remainder of  $(n - m)/3$ . The zigzag nanotubes with  $n = 3i$  have very small gaps, those with  $n = 3i + 1$  have large gaps and those with  $n = 3i + 2$  have even larger gaps than  $n = 3i + 1$ . These three subgroups are related to the triad periodicity in the bond length and are caused by the allowed states in the  $k$ -space, which will be discussed in the last section in detail.

Gülseren, Yildirim, and Ciraci.<sup>[28]</sup> further addressed the band gaps of zigzag SWNTs. While the energies of the non-degenerate band, the highest occupied  $\pi$  bands, and the lowest unoccupied  $\pi^*$  bands all rise with increasing diameter, the non-degenerate band rises much faster than the others, as shown in Fig. 3(A). The non-degenerate band crosses the highest occupied  $\pi$  bands before (7,0) and further becomes higher than the lowest unoccupied  $\pi^*$  bands at  $n = 9$ , thus all  $n < 7$  zigzag nanotubes are metallic whereas the  $\pi$ - $\pi^*$  separations are the band gaps for  $n \geq 9$ . Consequently, the band gaps of medium zigzag nanotubes ( $n \geq 9$ ) closely follow the  $1/R$  relationship, while the  $(n,m)$  index also plays an important role. The equations earlier derived from tight-binding theory were able to account for the band gaps of medium to large zigzag nanotubes.<sup>[52-54]</sup> Fig. 3(B) illustrates the agreement between the GGA band gaps and the curves obtained from Eq. (1):<sup>[28]</sup>

$$E_g = V_{pp\pi} \frac{d_0}{R} \left[ 1 + (-1)^p \gamma \cos(3\theta) \frac{d_0}{R} \right] \quad (1)$$

**Fig. 3** (A) Energies of the doubly degenerate  $\pi$  states (VB), the doubly degenerate  $\pi^*$  states (CB), and the non-degenerate  $\pi^*$  state as a function of nanotube radius. Each data point corresponds to  $n$  ranging from 4 to 15 consecutively. (B) The calculated band gaps as a function of the tube radius shown by filled symbols. Solid (dashed) lines are the plots of Eq. (3) [Eq. (2)] in Ref.<sup>[53]</sup>. The experimental data are shown by open diamonds (Refs.<sup>[9,55,56]</sup>). Source: From Ref.<sup>[28]</sup>. © 2002, The American Physical Society.

where  $V_{pp\pi} = 2.53$  eV is the hopping matrix element and parameter  $\gamma$  has a value of 0.43. Other parameters are the bond length  $d_0$  in graphene, the tube radius  $R$ , the chiral angle  $\theta$ , and the index  $p$  defined as  $n - m = 3i + p$ . [Note that this definition is for the  $(n,m)$  notation where  $n \geq m$  instead of  $n \geq 2m$  in Ref.<sup>[53]</sup>.] Good agreement between the GGA results and experimental data<sup>[9,55,56]</sup> is also seen in Fig. 3(B). Note that comparing the DFT predictions with experimental gaps usually requires systematic empirical corrections, for instance scaling. The trends among the calculated gaps are more reliable than the absolute values.

### Chiral SWNTs

Limited quantum mechanical results are available in the literature for the electronic properties of chiral SWNTs. A much-reduced indirect band gap of about 0.2 eV was reported for the (4,2) chiral nanotube.<sup>[27]</sup> In contrast to the symmetric DOS predictions by tight-binding theory, the predicted DOS curve for the

(4,2) nanotube is asymmetric, highlighting the need for high-level quantum mechanical treatment. The asymmetric DOS curve is a consequence of the curvature effect in small nanotubes. Mintmire and White predicted a direct band gap of 0.9 eV for (9,2) SWNT occurring at about one-third of the way from  $k = 0$  to  $\pi$ .<sup>[35]</sup> Mintmire and coworkers<sup>[36]</sup> also studied the band gaps of five other chiral SWNTs. The (4,2) tube is predicted to have an indirect band gap of 0.34 eV, in qualitative agreement with Liu and Chan.<sup>[27]</sup> The (4,3) tube has a gap of 1.28 eV, implying it as the largest band gap among all possible SWNTs. The band gaps for other chiral tubes are 0.46 eV for (3,2) and 0.00 eV for (5,1), respectively, whereas the (4,1) tube is metallic. The analysis of additional chiral SWNTs is certainly desirable and is currently in progress.

## ACTUATION OF SWNTS UPON CHARGE INJECTION

### Graphite Intercalation Compounds

It has long been known that the C–C bonds in *trans*-polyacetylene<sup>[57]</sup> and graphite<sup>[49]</sup> elongate/shorten when doped with electron donors/acceptors. The recent discovery of electrochemical actuation of SWNTs<sup>[3]</sup> has brought renewed attention to these two systems. This asymmetric strain response upon charge injection has recently been reproduced by DFT calculations for both doped *trans*-polyacetylene<sup>[58]</sup> and graphite intercalation compounds.<sup>[59]</sup> Here we briefly summarize the results for the latter as a way of introducing the subject for SWNTs. The geometries of a series of graphite intercalation compounds were optimized by Sun et al.<sup>[59]</sup> using the PW91 GGA functional and pseudopotential plane-wave basis sets. Good agreement was obtained between the calculated interlayer distances and experimental values. The strain–charge relationship (strain is percentage change in the in-plane lattice) for  $\text{LiC}_6$ ,  $\text{KC}_6$ ,  $\text{CaC}_6$ ,  $\text{BaC}_6$ ,  $\text{C}_{18}\text{PF}_6$ , and  $\text{C}_{24}\text{AsF}_6$  agrees well with experimental values,<sup>[60–64]</sup> as shown in Fig. 4. The charge transfers between graphene and dopants are calculated to be complete for  $\text{LiC}_6$ ,  $\text{KC}_6$ ,  $\text{C}_{18}\text{PF}_6$ , and  $\text{C}_{24}\text{AsF}_6$ , whereas they are 85% and 81% for  $\text{CaC}_6$  and  $\text{BaC}_6$ , respectively. Numerical experiments show that the charge value in a hypothetical graphite intercalation compound  $\text{KC}_6$  decreases with increasing interlayer distance, resulting in reduced strain response [Fig. 4B]. This behavior is comparable to the measured low strain values at low doping levels, where the charge transfer from each dopant is complete, but the large carbon-to-dopant ratio makes the per carbon charge small. The generic strain of the carbon network was obtained from calculations that include only the carbon atoms whereas the

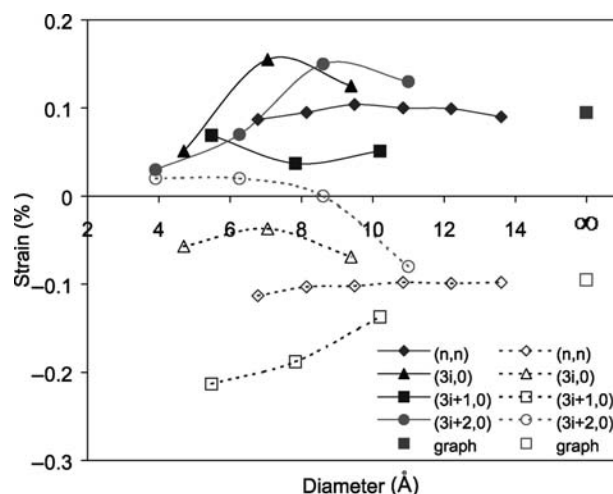

**Fig. 4** Strain in graphite intercalation compounds and charged graphene as calculated by density functional theory and compared with experiment. The continuous curve corresponds to the jellium calculations at  $d = 6 \text{ \AA}$  in all three panels,  $q$  is the per carbon charge. (A) Theoretical results using the relaxed counterion model and the jellium model. (B) The predicted strain in  $\text{KC}_6$  (five different interlayer distances) and  $\text{C}_6\text{Cl}$  (four different interlayer distances) by the fixed counterion model. (C) The strain predicted by the jellium model is compared with experimental data. References: K (Ref.<sup>[60]</sup>), Li (Ref.<sup>[61]</sup>), Ba (Ref.<sup>[62]</sup>),  $\text{MnCl}_2$  (Ref.<sup>[63]</sup>),  $\text{AsF}_5$  (Ref.<sup>[64]</sup>). Source: From Ref.<sup>[59]</sup>. © 2003, The American Physical Society.

dopants are represented by a uniform background charge (jellium model). When negative charges are injected, the in-plane lattice of graphite increases, whereas positive charges cause the in-plane lattice to decrease. As illustrated in Fig. 4C, the generic strain value calculated using an interlayer distance of 6 Å is in good agreement with results from both full calculations and experimental measurements. Earlier studies have predicted larger strain values by Pietronero and Strässler,<sup>[65]</sup> and smaller strain values by Kertesz, Vonderviszt, and Hoffmann<sup>[66]</sup> and Chan et al.<sup>[67]</sup>

Similar results were also obtained for the strain–charge relationship in doped *trans*-polyacetylene using the same theoretical method.<sup>[58]</sup> The different behavior for electron and hole injections in these systems has been tied to the breaking of the electron-hole symmetry due to second neighbor interactions in PA, graphene, and in SWNTs as well.<sup>[68]</sup>

### Isolated SWNTs

Sheets of SWNTs were shown recently to actuate in electrochemical cell upon charge injection, which may find many important applications.<sup>[3]</sup> As no dopant intercalation is required, the electrochemical actuation of SWNTs is considered superior to those techniques that do require it. Quantum chemical and double-layer electrostatic effects were postulated as the cause of the expansion upon electron injection and the contraction upon hole injection. Sun et al. studied the generic strain response of isolated achiral SWNTs using PW91 GGA functional in the DFT calculations.<sup>[22–24]</sup> Different strains were predicted for the  $(n,n)$  armchair nanotubes and the  $(n,0)$  zigzag nanotubes with different  $(n/3)$  values. The armchair nanotubes all have strain–charge curves similar to that of graphene. Generally, this similarity is more pronounced for the larger diameter tubes, as expected. The zigzag nanotubes with  $n = 3i$  also have strain values similar to that of graphene at any given charge transfer value, except for the small  $(6,0)$  tube which shows reduced strain on the negative charge side. For zigzag nanotubes with  $n = 3i + 1$ , the strain curves initially take a deep dive on the positive side, then turn back to approach the graphene curve. This dive is deeper for small tubes than for large tubes. Large deviations from the strain of graphene were predicted for the  $3i + 2$  series. The strain for  $(5,0)$  is positive for small positive charges and negative for small negative charges, in contrast to the graphene curve. At large charges, the strain for  $(5,0)$  resumes the usual asymmetric shape but the magnitude is much smaller than for graphene. The deviation from the graphene curve decreases from  $(5,0)$  to  $(8,0)$  and  $(11,0)$  before eventually vanishing for  $(14,0)$ .

**Fig. 5** Calculated strain as a function of SWNT diameter ( $D$ ) for the four types of achiral nanotubes. Strain is calculated with respect to the neutral tubes at  $q = \pm 0.01 e/\text{carbon}$  charge injection level. Solid marks and lines refer to  $q = -0.01 e$ , and empty marks and dashed lines refer to  $q = +0.01 e$  charge injection. The limiting values calculated for graphene (“graph”) are also shown. Strain is defined as percentage change of the translational vector. *Source:* From Ref.<sup>[24]</sup>. © 2003, The American Chemical Society.

The strain–charge behavior of the achiral SWNTs seems complicated, but a much clearer picture emerges in Fig. 5 when the strains for a given charge are plotted against the tube diameters.<sup>[24]</sup> The four types of achiral tubes show different trends. The strains for armchair nanotubes are similar to that of graphene for both  $+0.01 e$  and  $-0.01 e$  charges, even for the ones as small as  $(5,5)$ . For the zigzag nanotubes, the three subgroups have strain values for small diameters that are different from that of graphene, but all three series approach the strain of graphene with increasing diameters.

### ALLOWED STATES IN THE K-SPACE FOR SWNTS

We have shown above that there are four types of achiral nanotubes:  $(n,n)$  armchair nanotubes plus  $(n,0)$  zigzag nanotubes with  $n = 3i$ ,  $3i + 1$ , and  $3i + 2$ . The bond length, length and diameter of the tube, band gap and strain response upon charge injection all have different behavior for each type. The difference in their properties arises from the different electronic structures for each type. As the electronic structures of SWNTs can be obtained, to the first-order approximation, from the allowed states in  $k$ -space,<sup>[5,6]</sup> we relate the observed trends to the allowed  $k$  states. The allowed  $k$  states for  $(6,0)$  are shown as vertical line segments in Fig. 6(A), where the hexagons represent the first Brillouin zone for graphene. The K point is

**Fig. 6** (A) The allowed  $k$ -points for (6,0) zigzag SWNT shown in the Brillouin zone of graphene, and the allowed  $k$ -points closest to the K point for ( $n,0$ ) zigzag SWNTs with (B)  $n = 3i$ , (C)  $n = 3i + 1$  for three consecutive  $i$  values and (D)  $n = 3i + 2$  for three consecutive  $i$  values. Larger tubes have the allowed  $k$ -points closer to the K point.

where the highest occupied  $\pi$  band and the lowest unoccupied  $\pi^*$  band of graphene meet to form its zero band gap. For SWNTs, the allowed  $k$ -point that is closest to the K point gives the corresponding  $\pi$  bands, thus the  $\pi$ - $\pi^*$  gaps of nanotubes are determined by how close to K the closest allowed  $k$ -point can be. For armchair and zigzag nanotubes with  $n = 3i$ , the K point is always allowed, the latter being illustrated in Fig. 6(B), therefore the band gaps for these nanotubes are zero in simple tight-binding theory. For the zigzag nanotubes with  $n = 3i + 1$ , the allowed  $k$ -point closest to the K point is located on the MK line and moves closer to the K point with increasing diameter. In Fig. 6(C) three segments are shown representing the closest  $k$ -points for three different zigzag nanotubes with  $n = 3i + 1$ . As the  $\pi$ - $\pi^*$  separation is smaller when closer to the K point, the  $\pi$ - $\pi^*$  gap in this type of SWNTs decreases with increasing diameter. The  $k$ -point closest to K for  $n = 3i + 2$  is located on the  $\Gamma$ K line and approaches the K point with increasing diameter, as shown in Fig. 6(D). As the  $\pi$ - $\pi^*$  separation is larger along the  $\Gamma$ K line than along the MK line, the  $\pi$ - $\pi^*$  gap for  $n = 3i + 2$  is larger than that for  $n = 3i + 1$ .

This analysis holds true for medium to large zigzag nanotubes where the  $\pi$ - $\pi^*$  gaps are the real band gaps. For small nanotubes, the  $\sigma^*$ - $\pi^*$  hybridization needs to be taken into account, resulting in the reduced band gaps for (7,0) and (8,0), the level crossing in the (6,0) and smaller tubes, and the narrow gaps for (9,0), (12,0), and (15,0) tubes. For chiral nanotubes, general trends cannot be drawn from the limited data available

in the literature. However, electronic behaviors similar to the ones discussed above are expected for chiral nanotubes because, after all, it is the electronic structure that determines the other properties.

## CONCLUSION

Density functional theory in various forms of implementations has been applied to study the geometries, electronic band gaps, and strain-charge response for the isolated single-walled carbon nanotubes by a number of research groups. General consensus on the properties of achiral SWNTs has been reached based on both LDA and GGA calculations. The geometries of the ( $n,n$ ) armchair SWNTs closely follow that of graphene and all armchair SWNTs are metallic, which is consistent with early tight-binding predictions. Large deviations from the tight-binding predictions are shown for small diameter ( $n,0$ ) zigzag nanotubes and for small diameter chiral tubes. Zigzag SWNTs belong to different subgroups corresponding to  $n = 3i$ ,  $3i + 1$ , and  $3i + 2$ . This is related to the remainder of  $(n - m)/3$  values and is a consequence of the  $k$ -space mapping of the graphene and nanotube energy levels closest to the Fermi level. Narrow band gaps are predicted for  $n = 3i$  series having medium diameters, in good agreement with experimental data. Medium band gaps are predicted for medium and large nanotubes with  $n = 3i + 1$  and  $3i + 2$  with the latter having slightly larger band gaps than the former. The geometries of zigzag nanotubes show a triad periodicity similar to their band gaps. All small zigzag nanotubes are metallic because of the strong  $\sigma^*$ - $\pi^*$  hybridization caused by the large curvature. Upon charge injection, the length of large diameter nanotubes changes in a way similar to graphene, whereas significant deviations are again observed for small diameter nanotubes.

Unlike the achiral SWNTs, relatively little *ab initio* work has been done on chiral nanotubes, mostly because of their large repeating units. More studies are needed, especially using *ab initio* quantum mechanical methods, which show results deviating from the ideal tight-binding behavior, e.g., the zero band gaps for small zigzag nanotubes and the much-reduced indirect band gap of (4,2) instead of the large direct band gap predicted by tight-binding theory. More chiral nanotubes need to be included to see if any trend that is similar to those of zigzag nanotubes exists. It would also be interesting to see detailed geometrical analysis for additional chiral nanotubes.

It is worth noting that none of the applied theoretical methods was able to correctly reproduce the bond length alternation in *trans*-polyacetylene, an important parameter in extended conjugated systems.<sup>[26,69]</sup>

Employing methods that give better results for this parameter is desirable in future work for SWNTs. Such methods include post-HF methods such as MP2 and hybrid DFT functionals such as B3LYP.<sup>[70,71]</sup>

The effects of the termini and defects in SWNTs have been studied in the literature, although are not discussed here. However, as these effects have important implications for the electronic properties of SWNTs, more high-level theoretical studies are called for.

## ACKNOWLEDGMENTS

We thank Dr. Jenő Kürti for insightful discussions. G.S. thanks the National Cancer Institute at Frederick for a Visiting Fellowship Award. Financial support from the National Science Foundation (Grant CHEM-9802300) and from the Defense Advanced Research Projects Agency (Grants N00173-99-2000 and MDA 972-02-C-0005) is gratefully acknowledged.

# Single-Walled Carbon Nanotubes: Separation Using Capillary Electrophoresis

Stephen K. Doorn

Chemistry Division, Los Alamos National Laboratory, Los Alamos, New Mexico, U.S.A.

## INTRODUCTION

Fulfilling the promise that carbon nanotubes hold for new lightweight, high-performance materials and nanoscale electronics<sup>[1]</sup> and sensors,<sup>[2]</sup> among other areas, will require production of bulk quantities of pure material. Much progress has been made in production, including electric-arc,<sup>[3]</sup> laser ablation,<sup>[4]</sup> and catalytic gas-phase growth methods,<sup>[5]</sup> which are beginning to prove themselves for large-scale production of raw nanotube material. Initial purification work has focused on breaking up the carbon mat resulting from production and elimination of amorphous carbon and catalyst material from the end product.<sup>[6–15]</sup>

With the increasing availability of relatively pure product, it is becoming feasible to pursue geometry selective separations of carbon nanotubes. Structure-based purification for isolation of specific properties will be an important tool for advancing nanotube science. For example, differences in the geometrical parameters ( $n$ ,  $m$ ) will determine whether the nanotubes are conducting or semiconducting.<sup>[16]</sup> Changes in ( $n$ ,  $m$ ) also result in differences in diameter. A (10, 6) tube will be semiconducting and have diameter of 1.11 nm, while a (10, 10) tube is conducting, with diameter of 1.32 nm. Thus the ability to separate tubes based on geometry will also ultimately provide a degree of selectivity over electronic properties. Field-flow fractionation<sup>[17]</sup> (FFF) and size-exclusion chromatography<sup>[18,19]</sup> have demonstrated some success at length-based separations, but result in fractions with broad length distributions. However, recent work using flow field-flow fractionation demonstrates progress in producing narrower distributions.<sup>[20]</sup> Electrophoretic separations may also be promising. Bulk electrophoresis has been used for alignment of nanotubes and is capable of separating nanotubes from particulate impurities.<sup>[21]</sup> Gel electrophoresis has produced fractions with similar length distributions as found for FFF separations.<sup>[22]</sup>

Capillary electrophoresis (CE) has only been recently investigated for purification of carbon nanotubes. The high-resolution separations available with this method are intrinsically dependent on solute

geometry and may prove valuable in the separation of nanotubes by geometric specification. The first reported use on electric arc produced nanotubes demonstrated its ability to separate nanotubes according to length.<sup>[23]</sup> More recent work has shown that this approach may be capable of producing diameter-specific separations as well.<sup>[24]</sup> These recent studies are described in this entry.

## CAPILLARY ELECTROPHORESIS

Capillary electrophoresis (CE) is a rapid, high-resolution chemical separation method that has found widespread use in applications ranging from DNA separation to chemical speciation. Depending on analyte and separation parameters, typical elution times range from 1 to 20 min.<sup>[25]</sup> CE separations are based on charge- and size-dependent mobility of solution phase species under the influence of an applied electric field. A brief description of the method as applied to separation/purification of carbon nanotubes is given here. More comprehensive treatments can be found in a variety of sources.<sup>[25,26]</sup>

A schematic of a simple CE apparatus is shown in Fig. 1. CE is performed in narrow bore glass capillaries [typically 50–100  $\mu\text{m}$  inner diameter (i.d.)] that are filled with electrolyte/buffer solution. The capillary ends are immersed in electrolyte reservoirs. Separations are driven by a high voltage applied across the capillary after the introduction of sample at one end. For the single-wall carbon nanotube (SWNT) separations described here, a positive potential is applied at the sample inlet, while the effluent end is held at ground. Detection of separated species is performed at some point downstream through a window in the capillary coating. Separations are influenced by two main factors: the electrophoretic and electroosmotic flows (EOF).

## Electrophoretic Basis for Separations

Separation of different species in CE is a result of differences in their electrophoretic mobilities ( $\mu_{\text{ep}}$ ) under

**Fig. 1** Simple schematic of apparatus for performing capillary electrophoresis.

the influence of an applied electric field ( $E$ ). Resultant velocities ( $V_{ep}$ ) are a product of the two [Eq. (1)]:

$$V_{ep} = \mu_{ep}E \quad (1)$$

$$\mu_{ep} = q/6\eta\pi r \quad (2)$$

Mobilities are [Eq. (2)] dependent on the species charge ( $q$ ), solution viscosity ( $\eta$ ), and, for the simplest (spherical) case, species radius ( $r$ ). For more complex geometries, mobility is more correctly determined by overall charge density of the species. Small, highly charged species will be more mobile under the influence of the applied field than large, weakly charged species. This strong dependence on geometric factors makes CE potentially attractive for length- and diameter-based separations of carbon nanotubes.

A number of experimentally controllable factors can influence  $V_{ep}$  through effects on species charge and geometry, as well as on viscosity. Electrolyte pH will influence total charge on a species and may affect geometry through pH-induced conformational changes. Buffer concentration also affects viscosity, as will changes in temperature.

### Electroosmotic Flow

Silica capillaries used in CE are commonly conditioned with NaOH prior to use to convert surface silanol groups (Si-OH) to the negatively charged silanate (Si-O<sup>-</sup>). Introduction of electrolyte subsequently produces a diffuse double layer of buffer cations attracted to the silanate groups. The outer layer is loosely bound

and is mobile in the presence of an applied electric field ( $E$ ). The mobile outer layer moves toward the cathode and effectively drags the bulk solution with it, giving rise to the electroosmotic flow ( $V_{eof}$ ). Electroosmotic flow (EOF) produces a plug flow (rather than hydrodynamic flow) of fractions through the capillary. Plug flow yields sharp narrow fractions. EOF is also largely responsible for the rapid separations available with CE. Finally, EOF makes possible separations of anions, neutrals, and cations in one process.

EOF depends [Eq. (3)] on the zeta potential ( $\zeta$ , proportional to the double layer thickness), applied field ( $E$ ), and buffer viscosity ( $\eta$ ):

$$V_{eof} = \varepsilon\zeta E/4\pi\eta \quad (3)$$

As with  $V_{ep}$ , experimentally controllable parameters have a large effect on  $V_{eof}$ . Changes in buffer concentration and temperature affect the solution viscosity in the same manner as for  $V_{ep}$ . The zeta potential is also directly linked to the buffer concentration: lowering the concentration lowers  $\zeta$ , thus decreasing  $V_{eof}$ . Because  $\zeta$  is proportional to the charge on the capillary wall, pH can also have a significant effect on  $V_{eof}$ . At high pH, most of the silanol groups will be converted to the silanate, resulting in a high charge and  $\zeta$ . Thus  $V_{eof}$  increases as pH is increased. Because pH can also affect  $V_{ep}$  through its influence on the degree of species ionization, pH is generally adjusted to give the best separation, with secondary consideration given to flow velocity.

### CE as Applied to Carbon Nanotubes

The total species velocity ( $V_{tot}$ ) is the sum of  $V_{eof}$  and  $V_{ep}$  [Eq. (4)]. It is possible, as in the case of separations of anions, for these two terms to have opposite signs. As long as the magnitude of

$$V_{tot} = V_{eof} + V_{ep} \quad (4)$$

$V_{eof}$  is greater than  $V_{ep}$  in anionic separations, there will still be net transport of analytes to the cathode, or effluent, end of the capillary. This is an important consideration for nanotube separations, as the solubilized nanotubes are negatively charged. In the absence of an electroosmotic flow, a positive applied voltage (as used in these studies) would simply result in the nanotubes being redeposited at the anode buffer vial. Instead, the EOF results in the passage of nanotubes through the capillary and may be adjusted to optimize separations.

The nanotubes are negatively charged as a result of their dissolution through sonication in aqueous solutions of 0.5% sodium dodecyl sulfate (SDS). This is

slightly above the critical micelle concentration (CMC) for SDS (0.24%), and has been shown to efficiently suspend carbon nanotubes while minimizing their aggregation.<sup>[8,27]</sup> SDS was shown to provide the basis for separation of other carbon materials (fullerenes) in micellar electrokinetic chromatography (MEKC).<sup>[28]</sup> However, for SWNT separations, the use of a micellar medium such as SDS does not have the same significance as in an MEKC application. MEKC relies on partitioning of a neutral solute into the micelle.<sup>[25]</sup> The SWNTs are too large to reside in the spherical intramicellar region. Instead, the hydrophobic SDS tails are expected to specifically interact with the nanotube surface, providing it with a negative charge through the anionic sulfate head groups.<sup>[27]</sup> Modeling of these interactions suggests the resultant geometry to be a nanotube encapsulated in a cylindrical micelle.<sup>[29]</sup> The resultant electrostatic repulsion between encapsulated tubes stabilizes them against van der Waals attraction. Investigations into the phase behavior of the SDS/SWNT/water system show that, for the relative concentration of SDS and SWNTs used here, a stable single phase dispersion of nanotubes results.<sup>[27]</sup>

Typical separation parameters for the studies described here use run buffers of 50 mM Trizma base in 0.5% SDS solution. Separations are carried out in 75  $\mu\text{m}$  i.d., 75- to 100-cm-long glass capillaries. Capillaries are conditioned for 2 min using 0.2–1 M NaOH, followed by flushing with deionized water and buffer solution. Samples are pressure-loaded at 100–500 mbar before applying the separation voltage. The buffer pH of 9 results in relatively rapid separations. Lowering the pH will result in closer matching of  $V_{\text{eof}}$  and  $V_{\text{ep}}$ , which may improve the resolution of the separations, but at the cost of increased separation times. Lowering pH to acidic values may result in decreased charge on the nanotubes through protonation of SDS head-groups. Applied voltage was typically +15 kV in these studies. Higher voltages would result in faster separations but may introduce joule heating that would change buffer viscosity and could induce roping of the nanotubes. The voltages used were kept within the linear range of a voltage-vs.-current plot to minimize joule heating effects.

### Detection Methods

The simplest method of detection used in these studies is ultraviolet/visible (UV/Vis) absorbance at 360 nm. However, this method is limited, in that it is unable to indicate whether a detected fraction is carbon nanotubes, fullerenes, amorphous carbon, or other non-nanotube material. Raman spectroscopic detection has been used to overcome this drawback. The Raman spectra for carbon nanotubes are entirely distinct

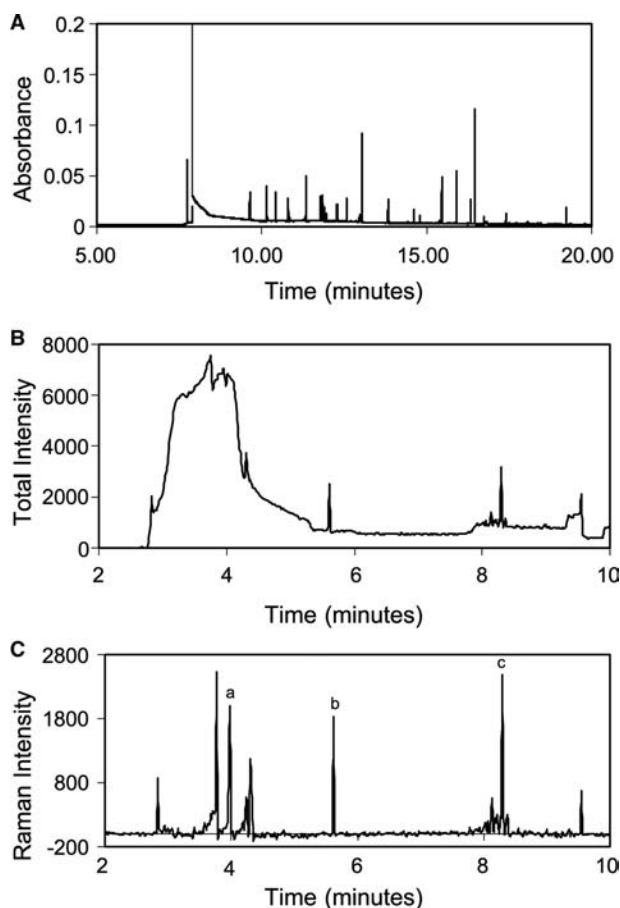

**Fig. 2** Raman spectrum (785 nm excitation, 20 mW, 1 sec integration) of bulk solid HiPco produced nanotubes. Inset: Radial breathing mode region of bulk solid.

(Fig. 2). The two major regions of interest are vibrational modes around  $1590\text{ cm}^{-1}$ , as a result of in-plane carbon–carbon bond deformations, and those at low frequency in the range of  $150\text{--}375\text{ cm}^{-1}$ , which are as a result of the nanotube radial breathing modes (RBM). The frequencies of the RBMs are strongly dependent on nanotube diameter.<sup>[30]</sup>

The key to identification of fractions as nanotubes is the ability to collect Raman spectra in real-time as the separations progress. This is accomplished through the use of high-throughput spectrographs coupled to efficient collection optics and detectors. Excitation at 514.5 or 785 nm is focused onto the sample through a microscope objective [ $20\times$ , 0.5 numerical aperture (NA)]. Scattered light is recollected through the objective and passed (via a confocal microscope or through a fiber optic probehead) through a Kaiser Optical HoloSpec  $f/1.8$  imaging spectrograph. Detection is carried out with a charge-couple device (CCD) camera (red sensitive for the 785-nm excitation case) using 1-sec integration times.

### CE ON ELECTRIC-ARC PRODUCED CARBON NANOTUBES

The first demonstration of CE separations on carbon nanotubes was on single-walled nanotubes prepared using the modified electric-arc method.<sup>[23]</sup> In a typical CE separation using absorbance detection (Fig. 3A), fractions begin to appear around 8 min into the run. From run-to-run, an initial strong sharp peak on top of a broad background followed by a series of sharp (1–2 sec wide) baseline separated peaks is consistently observed. Elution times compare well with what can

**Fig. 3** Capillary electropherograms (+15 kV in 0.5% SDS/50 mM trizma base buffer) of single-walled carbon nanotubes using A) absorbance detection at 360 nm, and capillary electropherograms of single-walled carbon nanotubes using Raman detection (514.5 nm excitation, 5 mW, 1 sec integration). B) Electropherogram showing total intensity (background fluorescence plus Raman scattering) collected at 560.37 nm. C) Electropherogram showing scattered Raman intensity at  $1591\text{ cm}^{-1}$ . *Source:* From Ref.<sup>[23]</sup>.

be obtained for CE on other types of analytes. The sharp peaks in the electropherogram were assigned to nanotube fractions. However, because of the potential presence of other material (such as fullerenes and graphite), unambiguous identification of these peaks requires Raman detection.

A Raman/CE run showing total detected intensity at 560.37 nm (corresponding to the strong nanotube Raman band at  $1591\text{ cm}^{-1}$ ) displays (Fig. 3B) a similar pattern to that seen in the absorbance data.<sup>a</sup> Initial

<sup>a</sup>Although the electropherograms obtained with Raman detection are presented for only one wavelength, it should be emphasized that each point in the electropherogram actually represents a complete Raman spectrum for that segment of sample flowing through the capillary.

sharp bands appear superimposed on a broad fluorescence background, followed by a series of trailing peaks. Subtraction of the background intensity from the peak intensity at  $1591\text{ cm}^{-1}$  results in an electropherogram displaying only the carbon nanotube fractions (Fig. 3C). No Raman bands are associated with the broad fluorescence feature, nor are any observed for any other point in the electropherogram except at the location of the sharp bands. Strong Raman bands, characteristic of carbon nanotubes, are observed for all the sharp features in the electropherogram giving positive identification of these fractions as containing nanotubes.

Raman spectra of three individual fractions (highlighted in Fig. 3C) are compared in Fig. 4. Raman frequencies are identical for all fractions, indicating that each fraction contains tubes of equivalent diameter. The RBM frequency of  $169\text{ cm}^{-1}$  indicates this diameter to be 1.32 nm.<sup>[31]</sup> The arc method primarily produces nanotubes with diameters near 1.3 nm,<sup>[32,33]</sup> so it is not surprising to find that all fractions in the electropherograms consist of tubes of similar diameter.

**Fig. 4** Raman spectra of labeled fractions from capillary electropherogram shown in Fig. 3C. A) 3.98 min fraction, B) 5.62 min fraction, C) 8.30 min fraction. *Source:* From Ref.<sup>[23]</sup>.

This suggests that the difference in mobility between fractions is a result of differences in nanotube lengths.

Further evidence for length-based separation was obtained from atomic force microscopic (AFM) images of composited fractions. Composites were collected by turning off the separation voltage, followed by sectioning the capillary, and then depositing and drying the section contents onto a mica AFM substrate. Each capillary section is composed of a series of individual nanotube fractions occurring progressively later in time. The first composite encompassed sample that included the initial spikes and broad peak (Fig. 3). The second composite included the next 2 min of eluting fractions. Subsequent composites were obtained at approximately 5-min intervals. AFM images (Fig. 5) show the first composite consists of nanotubes ranging in length ranging from 0.2 to 1.2  $\mu\text{m}$ . Amorphous non-nanotube material was found only in the first composite. The second composite consists of longer nanotubes (0.5–2.5  $\mu\text{m}$  in length) with no amorphous material being present. This amorphous material is responsible for the broad background observed at early times in both the Raman and absorbance detection runs. Later composites encompass timeframes that do not show this fluorescence background; nor do they contain amorphous particulates.

The trend toward longer nanotubes continues in composites collected at later times. Some degree of overlap in length range between sequential composites is observed. The significance of the overlap can be evaluated by measuring the distribution of lengths present in each composite (Fig. 6). The length range in which overlap occurs between composites contains a relatively small number of nanotubes compared to the length range into which the majority of tubes in each composite falls. This suggests that length range

overlaps between composites results from a diffusion of nanotubes between composites.

In the latest composites, lengths of up to 10  $\mu\text{m}$  are observed, although tubes longer than 2  $\mu\text{m}$  were not observed in the raw nanotube sample. Bundling of individual tubes can result in the existence of longer structures. Although large-scale aggregation is prevented by the presence of SDS, small bundles are known to occur in these solutions. In addition to providing a pathway for producing longer tubes, bundling may also result in short aggregates with effectively larger diameter than individual tubes. The existence of tubes as short as 2–3  $\mu\text{m}$  in composite 4, although possibly present as a result of diffusion from composite 3, instead may be attributable to bundling of short tubes. Tube bundles of identical length to individual tubes will be expected to elute later because of their larger diameter (see later discussion).

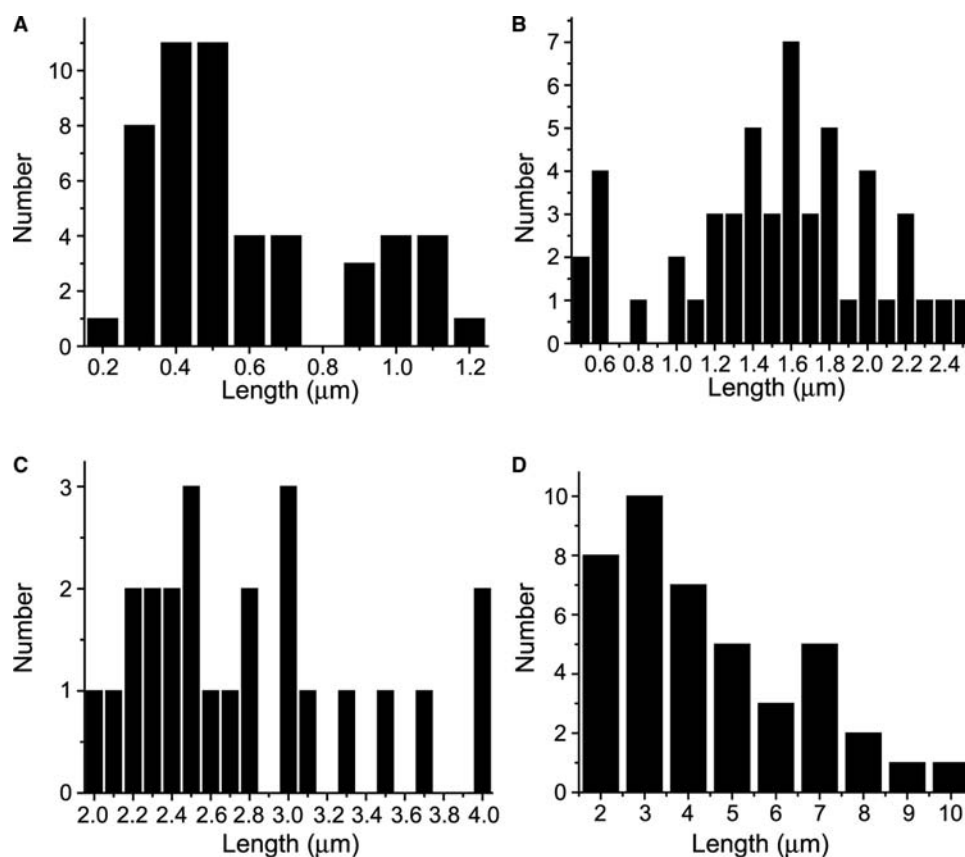

The AFM results on composite fractions demonstrate a length-based separation mechanism that leads to elution of short tubes first, followed by progressively longer tubes. The following mechanism for separation of nanotube fractions was proposed.<sup>[23]</sup> In the case of comparing elution times between individual tubes and tube bundles of the same length, the bundled tubes are expected to have a higher charge per unit length because of their greater diameter. The resultant higher electrophoretic mobility for the bundles is expected to translate to a later elution time than for an individual tube of identical length. However, for the case of nanotubes with uniform diameter, charge-density differences are not expected to be significant and forces other than electrophoretic are responsible for separations.

Under the influence of an electrostatic field ( $E$ ), nanotubes will experience an induced dipole moment ( $p_x$ ). The resultant torque on the nanotubes ( $p_x \times E$ ) aligns the tubes along  $E$ .<sup>[34]</sup> For perfectly aligned tubes

**Fig. 5** A) AFM image (tapping mode on mica substrate) of first (early time) composite of nanotube fractions. B) AFM image of second composite of nanotube fractions. Source: From Ref.<sup>[23]</sup>.

**Fig. 6** Distribution of nanotube lengths observed in each composite as determined from AFM images: (A) composite 1, (B) composite 2, (C) composite 3, (D) composite 4. *Source:* From Ref.<sup>[23]</sup>.

of equal diameter, charge density along  $E$  will be the same, independent of length. However, it has been observed in bulk electrophoresis alignment experiments<sup>[21]</sup> that shorter tubes display a larger deviation from perfect alignment than is observed for longer tubes. This behavior is predicted to occur as a result of opposition to alignment caused by Brownian motion or thermal agitation.<sup>[34]</sup> Shorter tubes are predicted to have a greater deviation from alignment along  $E$ . The resultant “wobble” is expected to effectively create a hydrodynamic resistance to the electrophoretic flow that will increase as tube length decreases. Under a positive applied potential, the negatively charged tubes will be attracted to the anode, or capillary intake, with longer tubes being most strongly attracted because of decreased hydrodynamic resistance resulting from their greater alignment along the applied electric field. EOF produces a net flow toward the capillary outlet (cathode) for all species with shorter tubes eluting first.

### CE ON HIPCO-PRODUCED CARBON NANOTUBES

The separation mechanism described above suggests that, in addition to providing length-based separations,

CE may be capable of producing diameter-dependent separations. However, diameter selectivity in the arc-produced nanotube separations was not apparent because of the limited diameter range present. As seen in Fig. 1, HiPco-produced nanotubes<sup>[5]</sup> have a broad range of observable diameters, making them attractive for investigating the potential of CE for diameter selectivity. RBM frequencies ranging from 169 to 373  $\text{cm}^{-1}$  translate to a diameter distribution of 0.6–1.3 nm for these samples, with the most intense bands corresponding to diameters of 0.88–1.15 nm.

### Behavior of PVP-Stabilized HiPco Nanotubes

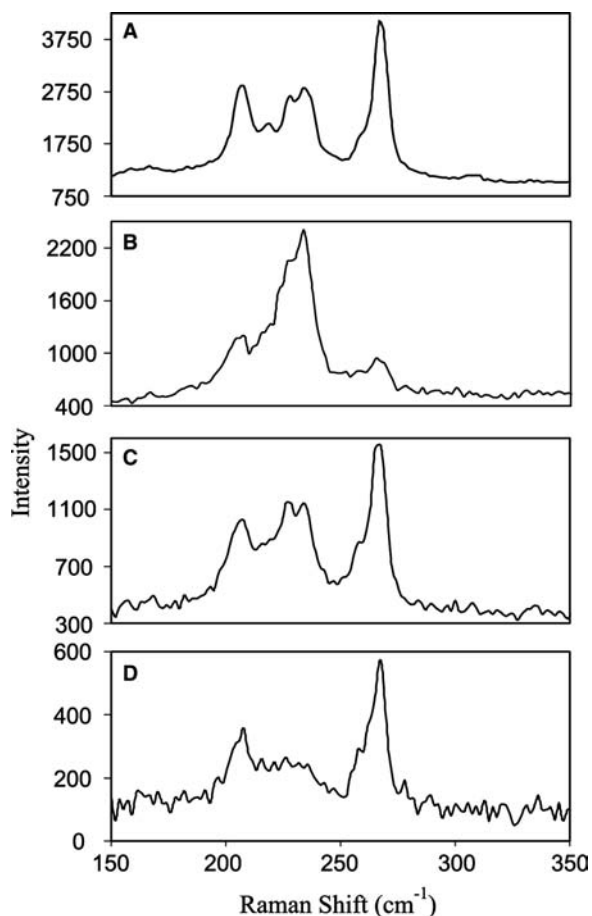

Initial investigations into HiPco separations were performed on nanotubes stabilized with polyvinyl pyrrolidone (PVP).<sup>[22]</sup> These samples contain nanotube bundles with a distribution of composition and bundle size. A representative electropherogram from a separation of PVP suspended sample is shown in Fig. 7A. Nanotubes first appear around 17 min into a separation. The electropherogram is dominated by primarily broad, incompletely resolved fractions. This is in contrast to the behavior observed for the SDS suspensions of arc-produced nanotubes. The presence of

**Fig. 7** Electropherograms of PVP-stabilized nanotubes (+15 kV in 0.5% SDS/50 mM trizma base buffer, 785 nm excitation, 20 mW, 1 sec integration). (A) Monitoring 1591  $\text{cm}^{-1}$  mode intensity, (B) monitoring intensity ratio of 267/234  $\text{cm}^{-1}$  mode, (C) monitoring intensity ratio of 234/207  $\text{cm}^{-1}$  mode.

distinct bands in the electropherogram indicates that some separation process is occurring. Whether this is due only to the previously observed length-based mechanism or combines a diameter-based process requires further analysis of the Raman spectra to determine.

Closer inspection of how the RBM region of the Raman spectra changes over the course of a separation will provide information on whether or not diameter-selective separations are occurring superimposed on the length-based mechanism. Electropherograms showing changes in the most prominent bands are shown in Fig. 7B and C. These plots indicate that at early times (1200–1450 sec), the band at 234  $\text{cm}^{-1}$  is the most prominent in this region, with a significant increase in intensity occurring at 1404 sec. At intermediate times, the 267  $\text{cm}^{-1}$  band is strongest. Finally, from around 1600 sec to the end of the separation, the 234  $\text{cm}^{-1}$  mode diminishes in intensity. Representative spectra for selected times in these regions are shown in Fig. 8.

**Fig. 8** (A) Radial breathing mode Raman spectrum of bulk, unseparated PVP-stabilized nanotube solution. Selected Raman spectra from separation shown in Fig. 7: (B) spectrum at 1404 sec, (C) spectrum at 1461 sec, (D) spectrum at 1800 sec.

### Behavior of SDS Suspended HiPco Nanotubes

CE on HiPco SDS suspensions were also investigated for better comparison to the separations on arc-produced samples. A typical electropherogram for the SDS suspended sample is shown in Fig. 9. A series of baseline separated, sharp, and intense spikes are observed throughout the early part of the separation (Fig. 9A). These results are similar to those found for the arc-produced nanotubes. Closer inspection of the electropherogram reveals that the sharp spikes are on top of a broad background (Fig. 9B) that more resembles the results obtained for the PVP suspended tubes.

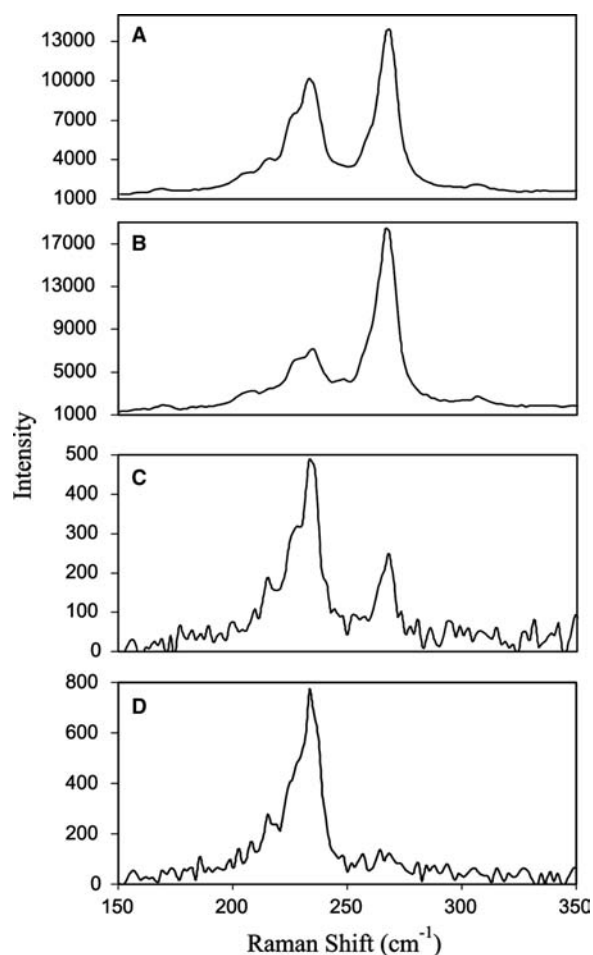

As seen in the ratio electropherogram of 267  $\text{cm}^{-1}$  intensity divided by 234  $\text{cm}^{-1}$  intensity (Fig. 9C), the behavior of the radial breathing modes undergoes large changes over the course of the separation. Three distinct regions of behavior are observed. In the first, ranging from the first appearance of nanotubes to about 500 sec, ratios for both the spikes and broad envelope are seen to be greater than the baseline ratio observed

**Fig. 9** (A) Electropherogram of SDS suspended nanotubes, monitoring  $1591\text{ cm}^{-1}$  intensity (+15 kV in 0.5% SDS/50 mM trizma base buffer, 785 nm excitation, 20 mW, 1 sec integration). (B) Electropherogram showing expansion of y axis. (C) Electropherogram monitoring intensity ratio of  $267/234\text{ cm}^{-1}$  mode.

before appearance of nanotubes. At intermediate times (region 2, 500–677 sec), the intense spikes are still positive going, but the broad envelope begins to trend to values less than the baseline. At longer times (region 3, 678 sec to end), the intense spikes disappear and the broad envelope remains in the region below baseline. This later time region is dominated by the  $234\text{ cm}^{-1}$  mode throughout the broad envelope, as well as for the weak spikes observed in this region.

Representative spectra for these three regions are compared to the bulk solution spectrum in Fig. 10. The spectrum at 482 sec (Fig. 10B) is identical to all spikes observed in the first two regions of the electropherogram, except for variations in intensity. The broad background envelope spectra in this region are also identical to this spike-observed frequencies and relative intensities remain the same. In the second electropherogram region (500–677 sec), the spike spectra also display the same frequencies and relative intensities as are observed in the first region. However, the

**Fig. 10** (A) Radial breathing mode Raman spectrum of bulk unseparated SDS suspended nanotubes. Selected Raman spectra from separation shown in Fig. 9: (B) spectrum at 482 sec, (C) spectrum at 633 sec, (D) spectrum at 918 sec.

background envelope now shifts to spectra that are dominant in the  $234\text{ cm}^{-1}$  mode (Fig. 10C). A further dramatic shift in relative intensities is seen on going into the third region. Here nearly all the RBM intensity is now in the  $234\text{ cm}^{-1}$  mode, (Fig. 10D). Spectra in this region are similar to those observed in the fraction at 1404 sec in the PVP separations (Fig. 8B).

## DISCUSSION

Variations in RBM intensities indicate that diameter-dependent spectral changes occur during a separation. It is tempting to directly relate these intensity changes to changes in relative population of the corresponding diameter tube. However, there are a number of complicating factors that make the analysis more difficult. The PVP samples are known to be bundles that vary in size and composition. Thus the observed behavior is not that for separations of isolated, individual

nanotubes. Furthermore, Raman spectra for nanotubes display strongly diameter-dependent resonance enhancement effects. Spectra for nanotubes of differing diameter will be enhanced to varying degrees for a fixed excitation wavelength. Only radial breathing modes for nanotubes with a van Hove singularity near the 785 nm excitation energy will be significantly enhanced.

These enhancement effects are further perturbed in the PVP samples because of the strong interaction expected among nanotubes in a given bundle, which results in a change in energy spacing of the van Hove singularities.<sup>[35,36]</sup> For semiconducting nanotubes, the absorption maxima are broadened and shifted to lower energy.<sup>[29,36]</sup> This is a particularly strong effect for the  $267\text{ cm}^{-1}$  mode, which can be used as an indicator of the degree of roping. For large enough bundles, the electronic resonance for this mode strongly overlaps the 785-nm excitation energy. As the bundle size decreases, the resonance energy shifts to shorter wavelengths. This shift will result in a decrease in resonance Raman intensity at  $267\text{ cm}^{-1}$  to a minimum when overlap is minimized between the 785-nm excitation energy and the electronic resonance for an individual nanotube. Conversely, the  $234\text{ cm}^{-1}$  mode gains in intensity on going from a roped sample to isolated individuals. Thus enhancement effects and perturbations may result in spectra that do not accurately indicate the dominant nanotube type in a given population, but may be useful in indicating relative nanotube bundle size.

The bundle size/cross section for a collection of nanotubes is defined by the number of nanotubes present and by their individual diameters. The results for the PVP samples demonstrate that they can be separated into fractions of differing composition that exhibit differing electronic resonance behavior. The majority of PVP-stabilized bundles will contain a random distribution of the available tube diameters. Therefore, spectra observed over the course of a separation might be expected to be similar to that observed for the bulk solution. This is observed at intermediate times (Fig. 8C). The dominance of the  $267\text{ cm}^{-1}$  mode for intermediate to late-time spectra (Fig. 8C,D) also suggest that these fractions consist of the largest bundles. Stronger intensity in the  $234\text{ cm}^{-1}$  mode at early times, and especially for the 1404 sec fraction (Figs. 7 and 8B), suggests these fractions consist of much smaller bundles.

The degree to which bundles of different composition exist in a fraction is indicated by its relative intensity and width. The broad fractions observed in Fig. 7A suggests that there is a relatively continuous change in composition for PVP-bundled samples. In addition to broadening from variation in cross section or size distributions, all fractions will be further

broadened because of the superposition of separations based on length differences. This will also cause some overlap of bands that might otherwise represent “pure” compositions. Thus observed spectra will not be pure indicators of composition.

Significant changes in radial breathing mode spectra over the course of a separation are also observed for the SDS suspended samples (Figs. 9C and 10). The presence of three different regions of spectral behavior in these separations demonstrates that nanotube fractions of at least three different electronic behavior are being separated. However, as with the PVP samples, the shift in relative intensities for the different RBMs may not be attributable to a change in absolute population of different diameter nanotubes. Changes in resonance enhancement conditions and interaction effects are also likely.

Changes in relative intensities of the  $267$  and  $234\text{ cm}^{-1}$  modes throughout the separation are likely because of the same effects observed and discussed for the PVP suspended systems. The spectra observed in the first region (Figs. 9C and 10) are likely because of large aggregates/ropes of nanotubes, as the spectra are dominated by the  $267\text{ cm}^{-1}$  “roping” mode. The weaker intensity observed for this mode in the second region (Fig. 10C) suggests that these aggregates are significantly smaller. Finally, near loss of intensity of this mode in the third region (Fig. 10D) suggests that nanotubes present at these times are aggregates of minimum size or are individual, isolated nanotubes exhibiting minimum interaction with other tubes in solution. The Raman intensity observed from the spikes (in some cases, as high as 100 times that observed for the isolated tubes) also supports the conclusion that they are attributable to aggregates. Strong signals may result from a significant number of tubes being present per aggregate. Weaker intensities observed in the second and third separation regions are consistent with these nanotubes being smaller aggregates and individual nanotubes.

Additional evidence for these assignments is found in the complete spectra for the fractions. A comparison of spectra for the three regions (Fig. 11) shows that the late-time spectra (Fig. 10C,D) contain fluorescence features that are absent in the earlier regions. These fluorescence bands occur on either side of the  $1591\text{ cm}^{-1}$  band, with absolute wavelengths for emission of 878 and 915 nm. These emission bands have only recently been discovered for SWNTs and have been assigned as band-gap emission from the first van Hove transitions occurring in semiconducting tubes.<sup>[29]</sup> Emission is only observed for individual, isolated nanotubes as aggregation of tubes quenches fluorescence due to the presence of increased energy decay pathways or through direct interaction with metallic tubes in a given bundle. Fluorescence is not observed at any

**Fig. 11** Full Raman spectra from separation shown in Fig. 9. (A) Spectrum at 482 sec, (B) spectrum at 633 sec, (C) spectrum at 809 sec, (D) spectrum at 918 sec.

point in the separation of the PVP samples, consistent with the above findings that it can only be observed in isolated tubes.

These findings strongly suggest that spectra observed for early-to-intermediate times in Fig. 9 (first two separation regions), particularly in the strong spikes, are from aggregated nanotubes. This suggests that the strong spikes observed for arc-produced tubes are also attributable to aggregates. Observation of fluorescence in the third separation region indicates that it is dominated by isolated individual nanotubes. Spikes observed in this region, although still dominant in the  $234\text{ cm}^{-1}$  RBM, do not contain the fluorescence bands and are therefore assigned as small aggregates. The large number of aggregate fractions observed in the SDS separations is likely a result of the relatively mild sonication conditions used for sample preparation (10 min at 80 W).

The separations observed in the SDS system build on the PVP results. Not only are separate fractions

observed with differing electronic behaviors, but fractions can also be obtained that differ in large-scale geometry. The SDS results demonstrate that bundles of different cross-sectional area can be separated from each other, and also that bundles can be separated from individual isolated nanotubes. However, the fact that the fraction of isolated nanotubes in the SDS separations contains a wide range of diameters suggests that the separations may not strictly be a function of nanotube diameter or bundle cross section. Instead, molecular weight of the species in a fraction may be the important mechanistic factor for separations, although molecular weight will ultimately be dependent on bundle cross section or individual diameter. That separations are dependent on a number of factors is evident in the overlap observed between the three regions in the SDS separations. Large aggregate spikes continue to be observed in the region containing primarily small- to moderate-sized aggregates, while these smaller aggregates continue to appear as spikes throughout the region primarily containing isolated individual nanotubes. The potential for such overlapping behaviors was also recognized in CE of arc-produced nanotubes, and will be an important problem to overcome in future CE work on carbon nanotubes.

## CONCLUSION

These results represent the first applications of CE to purification and geometry-based separations of carbon nanotubes. CE was shown to be effective at separating nanotubes according to length, and also capable of removing nonnanotube material. CE on HiPco-produced nanotubes demonstrated the ability to produce fractions of differing electronic property. Its ability to separate large aggregates from smaller bundles and to produce a relatively pure fraction of individual isolated nanotubes was also demonstrated. These separations may be based on differences in cross section/diameter or diameter-dependent molecular weight.

This initial work has demonstrated that CE may be a promising approach to geometry-dependent separations of carbon nanotubes. However, there is clearly much work yet to be carried out to reach the goal of selectively separating nanotubes by desired electronic or material property. The full potential of CE for diameter-selective separations may best be reached through working with samples of fully isolated individual tubes. Bulk production of these samples is just now becoming feasible.<sup>[29]</sup> A better understanding of the mechanism for separations will also be essential toward reaching this goal.

Geometry-based separations will be important not only for producing samples with a narrow range of geometrical and electronic properties, but will also

make possible the study of pure nanotube properties on isolated individuals without the need to go to the single nanotube level. This capability will be critical to gaining a more complete understanding of nanotube properties and exploiting their unique behavior in real-world applications.

## ACKNOWLEDGMENTS

These studies could not have been accomplished without the contributions of collaborators at Los Alamos National Lab (Robert Fields and Vahid Majidi), University of Kentucky (Prof. John Selegue), University of California Riverside (Hui Hu, Mark Hamon, Prof. Robert Haddon), and Rice University (Michael Strano, Michael O'Connell, Erik Haroz, Kristy Rialon, Robert Hauge, and Prof. Richard Smalley).

## INTRODUCTION

Single-walled carbon nanotubes (SWNTs) represent a novel class of low-dimensional materials exhibiting exceptional electronic properties.<sup>[1-9]</sup> Many of these properties were predicted by theory,<sup>[10-16]</sup> and then confirmed by experiment<sup>[1-3,5-7]</sup> after the successful synthesis of single-walled carbon nanotubes.<sup>[17-19]</sup> In this work, we provide an introduction to the structure and symmetries of SWNTs with emphasis on the use of their helical symmetry. We start by showing how all extended SWNTs can be envisioned by rolling up a single sheet of graphite.<sup>[20]</sup> We then show that all such SWNTs have translational symmetry along the nanotube axis, but often with hundreds, if not thousands, of atoms in the translational unit cell. Next, we show how all SWNTs defined by rolling up a single sheet of graphite have both rotational and helical symmetries that can be used to reduce the number of atoms necessary to generate any SWNT to two.<sup>[15]</sup> (A Fortran program that may be used to calculate the  $x$ ,  $y$ ,  $z$  coordinates for any SWNT defined by rolling up the graphene sheet is provided in Appendix A. This program is based on the helical and rotational symmetries of SWNTs.) We then illustrate some of the uses of helical and rotational symmetries in the calculation of the band structures of SWNTs. Finally, we conclude with brief comments.

## STRUCTURES FROM GRAPHENE

All extended SWNTs can be visualized as a conformal mapping of 2-D graphite (termed graphene) onto the surface of a cylinder. Thus the proper boundary conditions around the cylinder can only be satisfied if the circumference of the cylinder maps onto one of

the Bravais lattice vectors of the graphene sheet.<sup>[11-13]</sup> In addition, each Bravais lattice vector,  $\mathbf{R}$ , can be defined in terms of the two primitive lattice vectors,  $\mathbf{R}_1$  and  $\mathbf{R}_2$ , for graphene depicted in Fig. 1 and a pair of integers, so that

$$\mathbf{R} = n_1 \mathbf{R}_1 + n_2 \mathbf{R}_2. \quad (1)$$

(Note that, if the  $x$  axis in a right-hand coordinate system is oriented along  $\mathbf{R}_1$ , then  $\mathbf{R}_1$  and  $\mathbf{R}_2$  are given by:

$$\mathbf{R}_1 = a \hat{\mathbf{x}} \text{ and } \mathbf{R}_2 = \frac{a}{2} \hat{\mathbf{x}} + \frac{a\sqrt{3}}{2} \hat{\mathbf{y}}, \quad (2)$$

where  $a = \sqrt{3}d$  is the graphene lattice spacing with  $d$  the C-C bond distance, and  $\hat{\mathbf{x}}$  and  $\hat{\mathbf{y}}$  denote the usual unit vectors along the  $x$  and  $y$  axes, respectively.) Thus all unrelaxed SWNTs can be constructed by rolling up a single graphene sheet along one of its 2-D lattice vectors  $\mathbf{R}$  given by Eq. (1) to define an  $[n_1, n_2]$  nanotube with radius,

$$r = \frac{|\mathbf{R}|}{2\pi} = \frac{a}{2\pi} \sqrt{n_1^2 + n_2^2 + n_1 n_2}. \quad (3)$$

The point-group symmetry of the graphene lattice will render many of the SWNTs defined by  $\mathbf{R}$  equivalent. Indeed, this symmetry allows  $\mathbf{R}$  to be restricted to the irreducible wedge of the graphene lattice depicted in Fig. 1, without loss of generality.<sup>[11-13,21]</sup> Each  $\mathbf{R}$  within this wedge defines a different SWNT and all unique SWNTs defined by rolling up the graphene sheet can be generated by this set of  $\mathbf{R}$ 's. Also, within this wedge, only a finite number of SWNTs can be constructed with radii below a given value.

The angle,  $\Theta$ , measured counterclockwise from  $\mathbf{R}_1$  to the roll-up vector,  $\mathbf{R}$ , is usually referred to as the

**Fig. 1** Irreducible wedge of the graphene lattice. Primitive lattice vectors  $\mathbf{R}_1$  and  $\mathbf{R}_2$  are shown and the  $[0,0]$  unit cell at the origin is highlighted in gray. Armchair nanotubes are defined by rollup vectors  $\mathbf{R}$  along the  $[n,n]$  direction corresponding to a chiral angle of  $\pi/6$ . Zigzag SWNTs are defined by rollup vectors  $\mathbf{R}$  along the  $[n,0]$  direction corresponding to chiral angle of 0. Source: From Ref.<sup>[15]</sup>.

chiral angle for the SWNT. In terms of  $n_1$  and  $n_2$ ,  $\Theta$  is given by:

$$\Theta = \arccos\left(\frac{2n_1 + n_2}{2\sqrt{n_1^2 + n_2^2 + n_1n_2}}\right) \quad (4)$$

$$= \arctan\left(\frac{\sqrt{3}n_2}{2n_1 + n_2}\right)$$

for tubes defined based on the irreducible wedge of Fig. 1. The set of possible tubes defined by  $\mathbf{R}$  can be completely decomposed into independent families (subsets) with each family member sharing the same orientation of hexagons with respect to the tube axis and, hence, the same  $\Theta$ . Thus, rather than labeling the SWNTs by  $[n_1, n_2]$ , they could have just as well been labeled by  $M[q_1, q_2]$ , where  $[q_1, q_2]$  denotes the family to which  $[n_1, n_2]$  belongs, and  $N$  is the largest common divisor of  $[n_1, n_2]$ .<sup>[12]</sup> Unless otherwise specified, we will use the  $[n_1, n_2]$  notation to label SWNTs.

The construction of the tubule from a conformal mapping of the graphite sheet shows that each tubule can have up to three inequivalent (by point group symmetry) helical operations derived from the primitive lattice vectors of the graphite sheet. Thus while *all* SWNTs have a helical structure, the two families of tubules defined by rollup vectors with chiral angles  $\Theta = 0^\circ$  or  $30^\circ$  in Fig. 1 (which correspond to lattice translation indices of the form  $[n,0]$  and  $[n,n]$ , respectively) will possess a reflection plane. These high-symmetry SWNTs will therefore be achiral. For convenience, these special structures are given family names based on the shapes made by the most direct continuous path of C–C bonds around the circumference of the tubule. Specifically, the  $[n,0]$ -type structures are referred to as zigzag,<sup>[13]</sup> or sawtooth<sup>[21]</sup> tubes, to reflect the path highlighted in gray for the

$[9,0]$  tube at the top of Fig. 2, and the  $[n,n]$ -type structures are referred to as armchair,<sup>[13]</sup> or serpentine,<sup>[21]</sup> tubes to reflect the path highlighted in gray for the  $[5,5]$  tube at the bottom of Fig. 2. For other values of  $\Theta$ , the tubules are chiral.

## TRANSLATIONAL SYMMETRIES

Regardless of whether they are chiral or achiral, all SWNTs defined by  $\mathbf{R}$  in the graphene lattice have translational symmetry along the tube axis<sup>[11]</sup> with a repeat length given by  $\sqrt{3}|\mathbf{R}|$ , as can be seen by inscribing a hexagon with a side coinciding with  $\mathbf{R}$  in the

**Fig. 2** Sample achiral zigzag (sawtooth) and armchair (serpentine) SWNTs. Highlighted in gray is the most direct continuous path along C–C bonds around the tube. The shape of this path gives these structures their family names. These two examples can be capped with a hemisphere of  $C_{60}$ . Source: From Ref.<sup>[28]</sup>.

lattice prior to rolling up the sheet. An example is given in Fig. 3 for the [4,2] tube. It might be possible that  $\sqrt{3}|\mathbf{R}|$  is not the minimum translational repeat length. Indeed, by constructing a vector

$$\mathbf{T} = -(2n_2 + n_1)\mathbf{R}_1 + (2n_1 + n_2)\mathbf{R}_2 \quad (5)$$

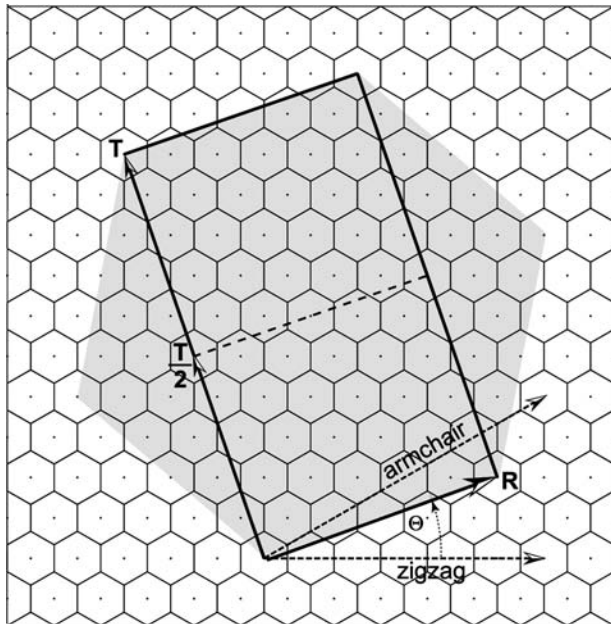

perpendicular to  $\mathbf{R}$  but lying in the honeycomb lattice, it is immediately obvious that the minimum translational repeat length is given by  $\sqrt{3}|\mathbf{R}|/L$ , where  $L$  is the largest common divisor of  $[2n_2 + n_1]$  and  $[2n_1 + n_2]$ . Hence,  $L = N$ , unless there exists an integer  $m$  such that  $(n_1 - n_2)/N = 3m$ , in which case  $L = 3N$ .<sup>[15]</sup>

Although all SWNTs defined by rolling up the graphene sheet have translational symmetry, the minimum number of atoms in a translational unit cell can be large.<sup>[15]</sup> To see this, first note that the unit cell in graphene contains two atoms and has area given by

$$A_g = |\mathbf{R}_1 \times \mathbf{R}_2| = \frac{\sqrt{3}}{2}a^2 \quad (6)$$

Next, note that the area of the strip that is rolled up to form the minimum-sized translational unit cell of the tube is given by:

$$A_T = \frac{\sqrt{3}|\mathbf{R}|^2}{L} = \frac{\sqrt{3}a^2(n_1^2 + n_2^2 + n_1n_2)}{L}. \quad (7)$$

**Fig. 3** The rollup vector  $\mathbf{R}$ , translation vector  $\mathbf{T}$ , and chiral angle  $\theta$  for the [4,2] SWNT. The hexagon highlighted in gray shows that this tube has translational symmetry along the tube axis. For the [4,2],  $L = 2$ , hence the minimum translational repeat length is given by  $|\mathbf{T}|/2$ , which from the properties of the hexagon equals  $\sqrt{3}|\mathbf{R}|/2$ . Source: From Ref.<sup>[28]</sup>.

Hence, the translational unit cell of the SWNT contains  $N_A$  carbon atoms given by:

$$N_A = 2 \frac{A_T}{A_g} = 4 \frac{(n_1^2 + n_2^2 + n_1n_2)}{L}, \quad (8)$$

where

$$L = \begin{cases} 3N & \text{if } (n_1 - n_2)/N = 3m, \text{ with } m \text{ an integer} \\ N & \text{otherwise} \end{cases} \quad (9)$$

and  $N$  is the largest common divisor of  $n_1$  and  $n_2$ . For both the armchair  $[n,n]$  and zigzag  $[n,0]$  tubes, Eq. (9) implies that  $N_A = 4n$ , greatly reducing the number of atoms in the minimum translational unit cell. In these two special cases, Eqs. (3) and (8) show that  $N_A$  scales as the radius,  $r$ , of the tube. It is for this reason that calculations relying on translational symmetry are usually restricted to these two special families of SWNTs.<sup>[12,13]</sup> On the other hand,  $L$  is often 1, so that  $N_A$  scales as  $r^2$ , leading to a large number of atoms in the translational unit cell even for moderate diameter SWNTs. For example, if  $n_1 = 10$  and  $n_2 = 9$ , then the radius of the nanotube is less than 0.7 nm, but from Eq. (8), the translational unit cell contains 1084 carbon atoms. The rapid growth in the number of atoms that can occur in the minimum translational unit cell renders recourse to the helical and any higher point group symmetry of these nanotubes practically mandatory in any comprehensive study of their properties as a function of radius and helicity. As we shall see below, these symmetries can be used to reduce to 2 the number of atoms necessary to generate any nanotube.<sup>[15]</sup>

## HELICAL AND ROTATIONAL SYMMETRIES

The rotational and helical symmetries of a SWNT defined by  $\mathbf{R}$  can be seen by using the corresponding symmetry operators to generate the tubule.<sup>[15]</sup> This is carried out by first introducing a cylinder of radius  $|\mathbf{R}|/2\pi$ . The two carbon atoms located at  $\mathbf{d} \equiv (\mathbf{R}_1 + \mathbf{R}_2)/3$  and  $2\mathbf{d}$  in the [0,0] unit cell of Fig. 1 are then mapped to the surface of this cylinder. The first atom is mapped to an arbitrary point on the cylinder surface, which implies that the position of the second be found by rotating this point by

$$\phi' = 2\pi \frac{\mathbf{d} \cdot \mathbf{R}}{|\mathbf{R}|^2} = \frac{(n_1 + n_2)}{(n_1^2 + n_2^2 + n_1n_2)}\pi \quad (10)$$

about the cylinder axis in conjunction with a translation

$$h' = \frac{|\mathbf{d} \times \mathbf{R}|}{|\mathbf{R}|} = \frac{|n_1 - n_2|}{2\sqrt{3}(n_1^2 + n_2^2 + n_1n_2)^{\frac{1}{2}}}a \quad (11)$$

along this axis. Next, note that the cylinder axis must coincide with a  $C_N$  rotational axis for the tubule, where  $N$  is the largest common divisor of  $n_1$  and  $n_2$ . Thus the positions of these first two atoms can be used to locate  $2(N - 1)$  additional atoms on the cylinder surface by  $(N - 1)$  successive  $2\pi/N$  rotations about the cylinder axis. Altogether, these  $2N$  atoms complete the specification of the helical motif that corresponds to an area on the cylinder surface given by:

$$A_M = N|\mathbf{R}_1 \times \mathbf{R}_2| = \frac{\sqrt{3}}{2}Na^2. \quad (12)$$

This helical motif can then be used to tile the remainder of the tubule by repeated operation of a single-screw operation  $S(h, \phi)$  representing a translation  $h$  units along the cylinder axis in conjunction with a rotation  $\phi$  radians about this axis.

To find  $h$  and  $\phi$  and hence determine  $S(h, \phi)$ , first note that there must exist a real lattice vector

$$\mathbf{H} = p_1\mathbf{R}_1 + p_2\mathbf{R}_2 \quad (13)$$

in the honeycomb lattice that maps to  $S(h, \phi)$  when the sheet is rolled up along  $\mathbf{R}$  to form the tube. In terms of  $\mathbf{H}$  and  $\mathbf{R}$ , the area of the helical motif on the cylinder surface  $A_M$  equals  $|\mathbf{H} \times \mathbf{R}|$ . However,  $A_M$  also equals  $N|\mathbf{R}_1 \times \mathbf{R}_2|$ . Therefore,  $|\mathbf{H} \times \mathbf{R}| = N|\mathbf{R}_1 \times \mathbf{R}_2|$ , or equivalently,<sup>[15]</sup>

$$p_2n_1 - p_1n_2 = \pm N \quad (14)$$

There are no other constraints on  $\mathbf{H}$  and hence on  $S(h, \phi)$ . If a set of integers  $\{p_1, p_2\}$  satisfies Eq. (14), then so too will the sets  $\{p_1 \pm mn_1N, p_2 \pm mn_2N | m \in \text{integers}\}$  and  $\{-p_1, -p_2\}$ . These uncertainties arise because  $\phi$  is defined modulo  $2\pi$  and if  $S(h, \phi)$  generates the tubule, then so will  $S(-h, -\phi)$ . Typically,  $\mathbf{R}$  and  $\mathbf{H}$  are restricted to the irreducible wedge of Fig. 1, the plus sign is chosen in Eq. (14), and then the single solution set is found which yields the minimum value of  $|\mathbf{H} \cdot \mathbf{R}|$  for  $h > 0$ . These choices restrict  $S(h, \phi)$  to a right-handed screw operation along the positive tubule axis that yields a minimum twist angle  $\phi$  around this axis. In contrast to the helical twist angle given by:

$$\begin{aligned} \phi &= 2\pi \frac{\mathbf{H} \cdot \mathbf{R}}{|\mathbf{R}|^2} \\ &= \frac{(2p_1 + p_2)n_1 + (2p_2 + p_1)n_2}{(n_1^2 + n_2^2 + n_1n_2)}\pi \end{aligned} \quad (15)$$

the magnitude of helical translation given by:

$$\begin{aligned} |h| &= \frac{|\mathbf{H} \times \mathbf{R}|}{|\mathbf{R}|} = \frac{N|\mathbf{R}_1 \times \mathbf{R}_2|}{|\mathbf{R}|} \\ &= \frac{\sqrt{3}Na}{2\sqrt{n_1^2 + n_2^2 + n_1n_2}} \end{aligned} \quad (16)$$

is independent of the choice of  $\mathbf{H}$ . These results show that every tubule defined by  $\mathbf{R}$  can be generated by first mapping only two atoms onto the surface of a cylinder of radius  $|\mathbf{R}|/2\pi$ , and then using the rotational and helical symmetry operators to determine the remainder of the tubule.

As an example,<sup>[15]</sup> consider the [6,3] tubule defined by  $\mathbf{R} = 6\mathbf{R}_1 + 3\mathbf{R}_2$ . Then from Eqs. (1), (10), and (11), the first atom of this tubule is mapped to an arbitrary point on the surface of a cylinder of radius  $3a\sqrt{7}/2\pi$ , and the position of the second then found by rotating this point  $\pi/7$  radians around the cylinder axis in conjunction with a translation  $a/(2\sqrt{21})$  units along this axis. Because  $N = 3$ , the cylinder axis must coincide with a  $C_3$  axis for the tubule. Thus the positions of these first two atoms can be used to locate four additional atoms on the cylinder surface by two successive  $2\pi/3$  rotations around this axis. Altogether, these six atoms complete the specification of the helical motif for this tubule. To determine  $S(h, \phi)$  used to generate the remainder of the tubule from this motif, Eq. (14) can be solved subject to the constraints above to find the solution set  $\{1, 1\}$ . Hence  $\mathbf{H} = \mathbf{R}_1 + \mathbf{R}_2$ , which in turn, using Eqs. (15) and (16), implies that  $\phi = 3\pi/7$  and  $h = 3/(2\sqrt{21})$ . If this resultant  $S(h, \phi)$  is applied to only the first two atoms mapped to the cylinder surface, then one third of the tubule is generated as illustrated in Fig. 4 (left). However, if the full helical motif is used, then the entire structure is generated as shown in Fig. 4 (right).

Extended 1-D polymers with both helical and translational symmetries are often labeled as  $N_H^*N_M/N_T$  helices with helical step,  $s$ , where  $N_H$  is the number of

**Fig. 4** Left: One-third of the [6,3] tubule generated by applying  $S(h, \phi)$  with  $\phi = 3\pi/7$  and  $h = 3a/2\sqrt{21}$  to only the first two atoms mapped to the cylinder. Thin dark lines are not bonds but are rather included as a guide to the eye. Right: This same one-third plus the remaining two thirds of the [6,3] tubule generated by applying  $S(h, \phi)$  to the full six-atom helical motif. Source: From Ref.<sup>[15]</sup>.

atoms in the primitive helical motif and  $N_M$  is the number of primitive motifs in the translational unit containing  $N_T$  complete  $2\pi$  helical turns.<sup>[22]</sup> This translational unit need not always correspond to the minimum length translational unit cell because it must contain an integer number of complete helical turns. Also note that the notation  $N_M/N_T$  indicates that any common factors between  $N_M$  and  $N_T$  should be eliminated. Because SWNTs defined by  $\mathbf{R}$  not only have helical, but also translational symmetry, they also can be labeled by using this notation.<sup>[11,15]</sup> In this case,  $N_H = 2N$ ,  $N_M = \sqrt{3}|\mathbf{R}|/|h|$ ,  $N_T = N_M\phi/2\pi$ , and  $s = h$ , where  $N$  is the largest common divisor of  $n_1$  and  $n_2$ , and  $\phi$  and  $h$  are given by Eqs. (15) and (16), respectively. In this notation, for  $h > 0$ , the [6,3] tubule can be labeled as a  $6^*14/3$  helix<sup>[15]</sup> with  $h = 3a/(2\sqrt{21})$ , while the [30,3] tubule can be labeled as a  $6^*222/67$  helix with  $h = \sqrt{3}a/(2\sqrt{111})$ . On the other hand, for  $h < 0$ , the [6,3] tubule can be labeled as a  $6^*42/5$  helix with  $h = -3a/(2\sqrt{21})$ , while the [30,3] tubule can be labeled as a  $6^*222/7$  helix<sup>[11]</sup> with  $h = -\sqrt{3}a/(2\sqrt{111})$ . Assuming  $h > 0$ , the notation is further clarified for the [6,3] tubule in Fig. 5, where the 6 atoms that will form the primitive helical motif ( $\bullet$ ), the 14 successive applications of  $S(h,\phi)$  (represented by  $\mathbf{H}$  in the plane) necessary to generate the translational unit cell (Arabic numerals), and the 3 complete helical turns in this repeat unit (Roman numerals) are all depicted.

Actual SWNTs should relax somewhat from the geometry expected from rolling up a graphene sheet. Indeed, there is no clear reason to assume that after relaxation, they should possess translational symmetry. However, first-principles local density functional

(LDF) calculations have shown that the geometry predicted by rolling up the graphene sheet is quite close to the actual optimized tube geometry for SWNTs that are typically studied experimentally.<sup>[16]</sup> Furthermore, the techniques described below for calculating the electronic structure of an extended SWNT do not rest on the assumption of translational symmetry.

## USE OF HELICAL AND ROTATIONAL SYMMETRIES

The first use of the helical and rotational symmetries of SWNTs is to generate the geometries of an arbitrary  $[n_1, n_2]$  tube defined by rolling up the graphene sheet as a starting point to additional studies. A Fortran computer program that may be used for this purpose is provided in Appendix A. This program implements the procedure outlined in the section ‘‘Helical and Rotational Symmetries’’ and Ref.<sup>[15]</sup> to calculate the  $x, y, z$  coordinates for either a user-defined number of helical motifs or number of translational unit cells in the SWNT. It also returns the tube’s radius,  $r$ , the chiral angle,  $\Theta$ , the number of atoms in the primitive helical motif,  $2N$ , and minimum length translational unit cell,  $N_A$ , and classifies the SWNT as an  $N_H^*N_M/N_T$  helix with helical step  $h$  assumed greater than zero.

The helical and rotational symmetries of SWNTs are, of course, much more broadly useful in studies of their properties. For example, they were used in the earliest band structure calculations of both armchair and chiral SWNTs at both the first-principles LDF<sup>[10,16]</sup> and all-valence tight-binding levels<sup>[11,14,16]</sup> to make these calculations manageable. Here we illustrate how these symmetries can reduce the size of the matrices that have to be diagonalized in a calculation of the nanotube’s electronic structure within a tight-binding approach to one no larger than that encountered in a corresponding electronic structure calculation of graphene.<sup>[15]</sup>

To understand how this is carried out, first assume that each carbon atom in a tubule is described by  $j$  atomic-centered basis functions. Next, let  $(m, \ell)$  denote a cell in the tubule generated by first mapping the [0,0] unit cell of Fig. 1 to the surface of the cylinder, and then translating and rotating this cell by  $m$  applications of the screw operator  $S(h, \phi)$ , followed by  $\ell$  applications of the rotational operator  $C_N$ . Like the helical motif, these cells tile the tubule, but contain 2 instead of  $2N$  carbon atoms. In this notation, a cell labeled by  $(m, \ell)$  in the  $[n_1, n_2]$  tubule corresponds to the unit cell in the graphene plane located at

$$\mathbf{r}_{q_1q_2} = q_1\mathbf{R}_1 + q_2\mathbf{R}_2, \quad (17)$$

**Fig. 5** Six-atom helical motif ( $\bullet$ ), fourteen helical steps (arabic numerals), and three full twists (roman numerals) used to generate the minimum translational repeat unit for the [6,3] tubule. The light dotted lines illustrate the  $C_3$  axis for this tubule. Source: From Ref.<sup>[15]</sup>.

where from the definitions of  $\mathbf{R}$  and  $\mathbf{H}$  and with the help of Eq. (14),

$$\begin{aligned} m &= (q_2 n_1 - q_1 n_2)/N \text{ and } \ell \\ &= q_1 p_2 - q_2 p_1, \end{aligned} \quad (18)$$

with  $\ell$  defined modulo  $N$ . Now, in a short-hand notation, let  $|m, \ell\rangle$  denote the set of basis functions centered on the two carbon atoms contained in the tubule cell labeled by  $(m, \ell)$ . This set contains  $2j$  elements. Then, because  $S(h, \phi)$  and  $C_N$  commute, symmetry adapted generalized Bloch sums given by:

$$\begin{aligned} |\kappa, n\rangle &= \lim_{M \rightarrow \infty} \frac{1}{\sqrt{2NM}} \\ &\times \sum_{m=-M}^M \sum_{\ell=0}^{N-1} e^{-i\kappa m} e^{-2\pi i n \ell / N} |m, \ell\rangle \end{aligned} \quad (19)$$

can be constructed such that

$$\begin{aligned} C_N |\kappa, n\rangle &= e^{2\pi i n / N} |\kappa, n\rangle \text{ with } n \\ &= 0, \dots, N-1 \end{aligned} \quad (20)$$

and

$$S(h, \phi) |\kappa, n\rangle = e^{i\kappa} |\kappa, n\rangle \text{ with } -\pi < \kappa \leq \pi. \quad (21)$$

Just as  $\mathbf{H}$  maps to  $S(h, \phi)$  when graphene is rolled up along  $\mathbf{R}$  to form the tube, the scalar product  $\mathbf{k} \cdot \mathbf{H}$  maps to  $\kappa$  of the SWNT, where  $\mathbf{k}$  denotes the usual 2-D crystalline momentum of the sheet, i.e.,

$$\kappa = \mathbf{k} \cdot \mathbf{H}. \quad (22)$$

Next, note that the matrix elements of the Hamiltonian,  $H$ , between these generalized Bloch functions must vanish due to symmetry, unless  $n = n'$  and  $\kappa = \kappa'$ , so that  $H$  can be written as

$$H = \sum_k \sum_{n=0}^{N-1} |\kappa, n\rangle \langle \kappa, n | H | \kappa, n \rangle \langle \kappa, n |. \quad (23)$$

where

$$\begin{aligned} \langle \kappa, n | H | \kappa, n \rangle &= \sum_{m=-\infty}^{\infty} \sum_{\ell=0}^{N-1} e^{-i\kappa m} e^{-2\pi i n \ell / N} \langle 0, 0 | H | m, \ell \rangle. \end{aligned} \quad (24)$$

$$\langle \kappa, n | H | \kappa, n \rangle = V_0 \begin{pmatrix} 0 & 1 + e^{\frac{ikn_1 - 2\pi n p_1}{N}} + e^{-\frac{ikn_2 - 2\pi n p_2}{N}} \\ 1 + e^{-\frac{ikn_1 - 2\pi n p_1}{N}} + e^{\frac{ikn_2 - 2\pi n p_2}{N}} & 0 \end{pmatrix}. \quad (25)$$

$$\varepsilon_0(\kappa) = \pm |V_0| \sqrt{3 + 2 \cos n_1 \kappa + 2 \cos n_2 \kappa + 2 \cos(n_1 + n_2) \kappa}, \quad (28)$$

Eqs. (23) and (24) reduce the matrices to be diagonalized in a tubule band structure calculation to a size no larger than those encountered in a corresponding band structure calculation for graphene.<sup>[15]</sup> For example, if we assume an all-valence carbon  $s$  and  $p$  tight-binding model, then the problem is reduced to the diagonalization of an  $8 \times 8$  matrix for each  $\kappa$  and  $\ell$ . In addition, first-principles LDF calculations indicate<sup>[10]</sup> that the highest occupied and lowest unoccupied valence bands of these tubules should be primarily formed from the set of carbon  $p$  orbitals (one per carbon atom) oriented normal to the tubule surface and denoted by  $p_{\perp}$ . Assuming only this set of valence functions, then the right-hand side of Eq. (24) reduces to a  $2 \times 2$  matrix, which within a constant on-site term is given by Eq. (25) below. In obtaining Eq. (25), only matrix elements,  $V_0$ , between nearest-neighboring  $p_{\perp}$  orbitals were retained and small differences in  $V_0$  that arise because of different C-C bonding directions on the tubule surface were neglected. Eq. (18) was also employed to determine that  $S^{(\mp n_1/N)} C_N^{\pm p_1}$  and  $S^{(\pm n_2/N)} C_N^{\mp p_2}$  can be used to locate the four nearest-neighboring cells to  $(0, 0)$  on the SWNT surface. Eq. (25) can then be diagonalized to yield the one-electron dispersion relations for an  $[n_1, n_2]$  SWNT.<sup>[15]</sup>

$$\varepsilon_n(\kappa) = \pm |V_0| \sqrt{3 + A_n(\kappa)}. \quad (26)$$

where

$$\begin{aligned} A_n(\kappa) &= 2 \cos\left(\frac{n_1 \kappa - 2\pi n p_1}{N}\right) \\ &+ 2 \cos\left(\frac{n_2 \kappa - 2\pi n p_2}{N}\right) \\ &+ 2 \cos\left(\frac{(n_1 + n_2) \kappa - 2\pi n (p_1 + p_2)}{N}\right). \end{aligned} \quad (27)$$

$-\pi < \kappa \leq \pi$ ,  $n = 0 \dots N-1$  ( $N$  is the largest common divisor of  $n_1$  and  $n_2$ ), and  $p_1$  and  $p_2$  are given by Eq. (14).

If  $n_1$  and  $n_2$  are relatively prime, then  $N = 1$ , so that Eq. (26) reduces to Eq. (28) below. Thus as a consequence of screw symmetry, a SWNT such as the  $[10, 9]$  has only a single bonding and a single antibonding band as shown in Fig. 6. This is in marked contrast

**Fig. 6** Band structures of [10,9] SWNT from Eq. (26) as a function of the helical phase factor  $\kappa$  from 0 to  $\pi$ . The bands at  $-\kappa$  are the same as those at  $\kappa$ . Hence, results are plotted over only half of the central 1-D zone. The Fermi level is shown as a horizontal dashed line. *Source:* From Ref.<sup>[28]</sup>.

to the 1084 bands that would be obtained if translational symmetry were used to obtain the band structure of the [10,9] SWNT within the same model. If  $N \neq 1$ , then  $p_1$  and  $p_2$  must be first obtained from Eq. (14) prior to evaluating Eq. (27). Examples are given for the [5,5] SWNT ( $N = 5$ ) in Fig. 7. Although apparently different, Fig. 7A and B depict equally valid band structures for the [5,5] tube obtained from Eq. (26). The differences arise because a twist angle of  $\phi = \pi/5$  ( $p_2 = 1, p_1 = 0$ ) was assumed in obtaining Fig. 7A, while  $\phi = \pi$  ( $p_2 = 3, p_1 = 2$ ) was assumed

in obtaining Fig. 7B. Either choice is allowed by Eq. (14) for the [5,5] SWNT and will yield identical results for any measurable property. Fewer distinct bands are visible in Fig. 7B because  $\phi = \pi$  also makes the bands eigenstates of the symmetry operations of the  $C_{5v}$  point group which include the doubly degenerate  $e_1$  and  $e_2$  representations.

The neglect of curvature (other than a slight reduction in  $V_0$  from its value in the graphene sheet) and the inclusion of only nearest-neighbor C–C interactions in obtaining Eq. (27) make the model identical to the single-parameter graphene sheet model (GSM) of SWNTs. This GSM, which was proposed in the earliest theoretical paper on the electronic structure of extended SWNTs,<sup>[10]</sup> and now supported by many experiments,<sup>[1–9]</sup> has been used in successfully predicting many of the fundamental properties of carbon nanotubes with diameters similar to or greater than  $I_h C_{60}$ .<sup>[10–16]</sup> These properties include the grouping of SWNTs as either metallic or semiconducting,<sup>[2,3,10,12–16]</sup> the linear dispersion relations of the metallic tubes in the vicinity of the Fermi level,  $\epsilon_F$ ,<sup>[5,6,10,16]</sup> the approximate  $1/r$  dependence of the semiconducting band gaps,<sup>[2,3,12–16]</sup> the stability of the metallic tubes against a Peierls distortion,<sup>[1,10]</sup> and robust ballistic transport through metallic tubes.<sup>[8,9,23]</sup> The graphene sheet model has also been used to successfully explain and relate the positions of the first few divergent van Hove singularities observed both in metallic and semiconducting SWNTs in STM experiments.<sup>[24,25]</sup>

The  $\pi$  bands of graphene are described, within the standard GSM, by a tight-binding Hamiltonian characterized by a single Slater–Koster parameter,  $V_{pp\pi}$ , representing the nearest-neighbor hopping matrix element between carbon  $|p\pi\rangle$  orbitals oriented perpendicular to the graphene sheet. Using translational

**Fig. 7** Band structures of the [5,5] SWNT from Eq. (26) as a function of the helical phase factor  $\kappa$  from 0 to  $\pi$ . (A) Results obtained by assuming  $\phi = \pi/5$  ( $p_2 = 1, p_1 = 0$ ). (B) Results obtained by assuming  $\phi = \pi$  ( $p_2 = 3, p_1 = 2$ ). The bands at  $-\kappa$  are the same as those at  $\kappa$ . Hence, results are plotted over only half of the central 1-D zone. The Fermi level is shown as a horizontal dashed line.

**Fig. 8** First-principles LDF results for the band structure of the [5,5] SWNT obtained by assuming  $\phi = \pi$  ( $p_2 = 3$ ,  $p_1 = 2$ ). These results can be compared to the GSM results of Fig. 7(B). The bands at  $-\kappa$  are the same as those at  $\kappa$ . Hence, results are plotted over only half of the central 1-D zone. The Fermi level is shown as a horizontal dashed line. Source: From Ref.<sup>[10]</sup>.

symmetry, this Hamiltonian reduces to a  $2 \times 2$  matrix, which is easily diagonalized to obtain the one-electron dispersion relations of the graphene sheet given by Eq. (28) below, in terms of the 2-D crystalline momentum  $\mathbf{k}$  and the primitive lattice vectors  $\mathbf{R}_1$  and  $\mathbf{R}_2$ . The band structure of the SWNT defined by  $\mathbf{R}$  is then constructed from Eq. (29) by imposing periodic boundary conditions over the rollup vector  $\mathbf{R}$  so that

$$\mathbf{k} \cdot \mathbf{R} = 2\pi m, \quad (30)$$

where  $m$  is an integer.<sup>[10,12,13]</sup> At this point, the discussion usually proceeds in terms of allowed lines in the 2-D central Brillouin zone of graphene and translational symmetry along the SWNT axis—an approach that can lead to thousands of bands for tubes of experimental interest. However, these complexities

can be avoided by first using Eqs. (1), (13), and (14) to show that

$$\begin{aligned} \mathbf{R}_1 &= \pm(p_2\mathbf{R} - n_2\mathbf{H})/N \text{ and} \\ \mathbf{R}_2 &= \pm(n_1\mathbf{H} - p_1\mathbf{R})/N \end{aligned} \quad (31)$$

and then using these results in Eq. (29), in conjunction with Eqs. (22) and (30) to recover Eq. (26), which takes full advantage of the helical and rotational symmetries. Note that, in Eq. (29), the nearest-neighbor C–C matrix element is written as  $V_{pp\pi}$ , while in Eq. (26), the corresponding quantity is written as  $V_0$ . These differences have been maintained to reflect the observation that, for tubes that are typically studied experimentally,  $V_{pp\pi}$  should be reduced from its value in graphene ( $V_{pp\pi} \approx -2.8$  to  $-3.0$  eV) to a slightly smaller value ( $V_0 \approx -2.5$  to  $-2.8$  eV), consistent with both LDF calculations<sup>[16]</sup> and scanning tunneling microscopy (STM) measurements on SWNTs.<sup>[2,3]</sup> Such a reduction is expected because, in contrast to graphene, the nearest-neighbor  $p_{\perp}$  orbitals are no longer exactly parallel in SWNTs.

Finally, note that screw symmetry has also been extensively employed in all-electron, self-consistent LDF band-structure calculations of SWNTs<sup>[10,16,25]</sup> by using a method originally developed to treat chain polymers<sup>[26]</sup> and especially tailored to take advantage of helical symmetry.<sup>[27]</sup> In this approach, the one-electron wavefunctions are first constructed from linear combinations of helically adapted Bloch functions, which in turn are constructed from linear combinations of nuclear centered products of Gaussians and real solid spherical harmonics, and then these wavefunctions are used in solving the self-consistent LDF equations. A sample LDF band structure obtained by using this approach is shown in Fig. 8.<sup>[10]</sup> These results for the [5,5] SWNT can be compared to the corresponding results for this tube obtained from the GSM (Fig. 7B) for bands in the vicinity of  $\epsilon_F$ .

## CONCLUSION

In this review, we have provided an introduction to the use of helical and rotational symmetries in studying the properties of SWNTs. Attention has been focused on basic electronic properties, but these symmetries are also equally useful in the study of vibrational properties. Furthermore, they are essential if one wishes to study,

$$\epsilon_{\pm}(\mathbf{k}) = \pm|V_{pp\pi}|\sqrt{3 + 2 \cos \mathbf{k} \cdot \mathbf{R}_1 + 2 \cos \mathbf{k} \cdot \mathbf{R}_2 + 2 \cos \mathbf{k} \cdot (\mathbf{R}_1 - \mathbf{R}_2)}. \quad (29)$$

for example, the effects of twists in all but the simplest models of SWNTs.

## APPENDIX

Program BUILDTUBE<sup>[28]</sup> calculates the  $x$ ,  $y$ ,  $z$  coordinates in Angstroms of an  $[n_1, n_2]$  SWNT for either a user-defined number of helical motifs or primitive translational unit cells using the procedure given in this entry and Ref.<sup>[15]</sup>. Initial input should only be in the form of a couple integers separated by a space. When using this program to generate the coordinates of atoms in a user-specified number of translational unit cells, keep in mind that if  $n_1$  and  $n_2$  are relatively prime, then a single translational unit cell can contain well over a thousand atoms. This is true even for SWNTs with diameters as small as about a nanometer. Output is in the form of two files. Sample output files are given below following the listing of the source code written in Fortran 77.

# Small Amplitude AFM

**Peter M. Hoffmann**

*Department of Physics, Wayne State University,  
Detroit, Michigan, U.S.A.*

## INTRODUCTION

Small-amplitude atomic force microscopy (AFM) is a dynamic AFM technique, in which the AFM cantilever is vibrated at very small amplitudes, typically less than  $\approx 1 \text{ \AA}$  ( $= 10^{-10} \text{ m} = 0.1 \text{ nm}$ ), and the amplitude, phase, and/or resonance frequency of the lever are measured. Small amplitudes serve to *linearize* measurements of tip–surface interactions. Consequently, measurements can be directly related to interaction stiffness (negative if the force gradient) and energy dissipation. Because of the small amplitudes, the measurement is *local*, and interactions can be mapped point by point. This eliminates ambiguities present in large-amplitude techniques.

Historically, scanning tunneling microscopy (STM)<sup>[1]</sup> was the first “easy” technique to reliably provide atomic resolution images of a variety of *conductive* crystalline surfaces. Early on it was realized that forces play an important role in STM measurements.<sup>[2]</sup> This inspired the invention of the atomic force microscope in 1986.<sup>[3]</sup> In terms of applications, it was hoped that AFM would provide atomic resolution on insulators, which was not possible with STM. This goal was finally achieved in 1995, when true atomic resolution imaging was demonstrated by several groups using dynamic, noncontact AFM at *large* amplitudes.<sup>[4–6]</sup> Researchers also realized early on that AFM can be used to measure forces as a function of tip–surface separation in a variety of environments.<sup>[7–10]</sup> However, issues such as drift, mechanical instabilities,<sup>[11]</sup> low sensitivity, and nonlinearities made the direct, local, and linear measurement of force interactions a difficult prospect in many situations.

Small-amplitude AFM techniques were developed to address the issues of nonlinearity and non-locality that continue to plague large amplitude measurements. Moreover, combined with high-sensitivity deflection sensors, such as fiber interferometry, and the use of tailored lever structures, these techniques were able to overcome sensitivity and instability issues as well. In this entry we will discuss the underlying theory of small-amplitude AFM, conditions and limitations for its use, and recent examples of small-amplitude AFM applied to atomic-scale imaging (Fig. 1),

force–distance measurements, atomic-scale dissipation, and force measurements in liquids.

## THEORY AND BACKGROUND

### Limitations of “Standard” AFM Techniques

Commonly used AFM technologies can be categorized into two broad categories: (1) “d.c.” or “contact” AFM and (2) “a.c.” or “dynamic” AFM. Here, dc is meant to signify a *static* technique, while a.c. is meant to signify a *dynamic* technique, involving modulation of the deflection or force. In d.c. AFM the cantilever is static and the equilibrium position of the cantilever in the force field of the sample is measured. The force can then be determined from Hooke’s law. In a.c. AFM the cantilever is vibrated and, typically, two of the observables amplitude, phase, or resonance frequency are measured to determine the tip–sample interaction.

In the following we want to discuss limitations of d.c. and large-amplitude a.c. techniques, which range from drift, mechanical instabilities, and non-linearity to problems of data interpretation.

### Limitations of d.c. and large-amplitude a.c. AFM techniques

d.c. AFM suffers like any d.c. measuring technique from low signal-to-noise and drift. Therefore, d.c. AFM generally utilizes low stiffness levers to increase sensitivity ( $< 1 \text{ N m}^{-1}$ ). Because of the low stiffness of the lever, it is prone to the snap-to-contact instability close to surface.<sup>[11–13]</sup> Consequently, d.c. AFM is generally known as “contact” AFM. This type of AFM is useful in general-purpose imaging at resolutions typically  $> 10 \text{ nm}$ . It is theoretically able to directly yield quantitative force data (via Hooke’s law). However, this is generally hampered by drift and the snap-in instability.

d.c. AFM also has limitations in imaging. Because imaging is generally done in contact, the image resolution is limited to the tip–surface contact radius, which is typically at least several tens of nanometers. In some

**Fig. 1** Atomic resolution image ( $4 \times 2.5$  nm) of the force gradient across a Si(111)-(7  $\times$  7) surface. Round “bumps” correspond to single atoms. Measured with a subresonance AFM at an ultrasmall lever amplitude of 0.25 Å. Feedback was maintained via the tunneling current.

special cases true atomic resolution has been achieved,<sup>[14]</sup> but, typically, apparent “atomic resolution” seen with contact AFM can be attributed to a Moiré-like effect of dragging two well-ordered surfaces (tip and substrate) across each other.<sup>[15,79]</sup> Another disadvantage is the fact that the tip is moved laterally while in contact and that sometimes relatively large forces need to be applied to get a reasonable signal. This can lead to wear and degradation of the sample and tip,<sup>[16]</sup> and is especially detrimental to soft samples.

To overcome some of the disadvantages of d.c. AFM, a.c. AFM techniques were used almost as soon as the AFM was invented.<sup>[8]</sup> There are two major types of a.c. AFM techniques:<sup>[17]</sup> 1) amplitude-modulated (AM) AFM, which includes “tapping mode” AFM, some types of noncontact AFM, and subresonance AFM, and 2) frequency-modulated (FM) AFM, or frequency-shift AFM, also often confusingly called noncontact AFM.

In AM AFM the lever is vibrated at a *constant* frequency, and the amplitude and/or phase are measured. This is typically done with a lock-in amplifier. In tapping mode AFM,<sup>[18]</sup> the cantilever is brought close to the surface while it is vibrated at (or close to) the free resonance frequency of the lever. As the tip approaches the surface, the resonance frequency shifts due to the interaction force gradients. Because the lever is still vibrated at the free resonance frequency, both the phase and the amplitude of the cantilever decrease and can be used as feedback parameters (slope detection).

Tapping mode AFM typically uses large amplitudes of 10–100 nm. As the tip moves through the non-linear force field close to the surface, the motion of the lever becomes highly non-linear. Typically, the system is bistable, and jumps between a low-amplitude and high-amplitude mode are inherent to the system.<sup>[17,19–22]</sup> In addition, relatively low stiffness cantilevers are

typically used (of the order of a few 10 N/m) to boost sensitivity. As a result, the tip is unstable close to the surface and starts “tapping” the surface, hence the name of the technique. This could be avoided by using stiffer cantilevers,<sup>[23]</sup> but that would reduce the signal unduly. Because of the intermittent contact with the surface, the resolution of this technique is comparable to contact AFM. However, because the tip is not dragged across the surface as in contact AFM, the damage to a fragile sample can be much less than in contact AFM.<sup>[18]</sup> In addition, the phase data contain information about sample-mediated damping and can provide additional information about the mechanical properties of the sample. However, although attempts have been made to interpret the results in a quantitative fashion, it is very difficult to completely reconstruct the force field and the distance-dependent loss processes experienced by the tip, and higher resonance modes need to be considered.<sup>[24,25]</sup>

Noncontact AM AFM<sup>[8]</sup> is essentially the same as tapping mode AFM, with the only difference being that the tip is lifted off the surface far enough to avoid contact. Noncontact AM AFM is typically used to measure long-range forces such as electrostatic forces [electrostatic force microscopy (EFM)] or magnetic forces [magnetic force microscopy (MFM)].

In FM AFM the lever is vibrated at its (shifting) resonance at all times. Typically, (but not always) a feedback loop is used to keep the amplitude constant. The lever is maintained at its resonance frequency by using the lever itself as the frequency-determining element in an oscillator circuit. This is achieved by phase shifting the deflection signal and feeding it back to the dither piezo that oscillates the cantilever. The resonance frequency is then measured by an FM demodulator circuit.<sup>[26]</sup> The resonance frequency can be measured very accurately for high quality factor ( $Q$ ) cantilevers, providing improved signal-to-noise (S/N) ratios. Because a high  $Q$  ( $\approx 10^3$ – $10^4$ ) is needed, FM AFM is most often used in ultrahigh vacuum (UHV). The improved S/N ratio allows for the use of higher stiffness levers of typically about  $50 \text{ N m}^{-1}$ . The use of stiffer levers combined with large amplitudes<sup>[27,28]</sup> avoids the snap-to-contact instability and noncontact operation very close to the surface becomes possible. Indeed, it was this technique that yielded the first true atomic resolution AFM images in 1994<sup>[4]</sup> and 1995.<sup>[5,6]</sup> The problems with this technique are the very involved data interpretation when using large amplitudes,<sup>[24,29,30]</sup> the difficulties in measuring local events (because of the large amplitudes), and the almost complete confinement of this technique to ultrahigh vacuum conditions (because of the need for high  $Q$ ). Recently, using an electronic feedback circuit, attempts have been made to increase the low quality factor ( $Q \approx 2$ – $3$ ) of nc-AFM in water to  $Q \approx 30$ – $40$ .<sup>[31]</sup>

However, these low  $Q$  values are still too low to achieve atomic resolution in liquids, and the used techniques raise additional interpretation issues.

### Theory of Small-Amplitude AFM

Small-amplitude AFM is any dynamic AFM technique in which particular attention is paid to vibrating the cantilever at small amplitudes. This means in practice that amplitudes should be small compared to the range of the measured interaction. How small the amplitude has to be to justifiably speak of *linear* measurements can be explored by solving the equation of motion of the oscillating cantilever in the force field of the sample. In addition, by solving the equation of motion, we can distinguish between several conceivable ways of operating a small-amplitude AFM. These include:

1. On-resonance AM operation (“tapping mode”): AM AFM where we drive the cantilever at small amplitudes at a constant frequency close to or at the free resonance frequency. Amplitude and phase are measured and can, in principle, be related directly to the force gradient and damping coefficient.
2. Subresonance operation: AFM is deliberately operated at a constant frequency well below the first resonance. This eliminates dynamic terms in the equation of motion, and makes it easier to keep the AFM in the small-amplitude regime. Measured amplitude and phase relate directly to the force gradient and damping.
3. Frequency shift (FM) operation: Same as regular FM AFM, but using ultrasmall amplitudes. In this case, the frequency shift can be directly related to the force gradient (see below). The cantilever amplitude (or the excitation amplitude if amplitude is kept constant) can be related to the damping coefficient or quality factor.
4. Force-controlled or force modulation AFM: AFM in which a force rather than a displacement is imposed on the cantilever. Typically, a d.c. and a.c. force are applied, and force and stiffness are measured simultaneously. Often used in the subresonance regime.

Actual examples of these different techniques will be discussed toward the end of the chapter.

#### Small-amplitude AFM

The general equation of motion of AFM is given by:

$$m^*\ddot{z} + C\dot{z} + k_L z = k_L A_0 \exp(i\omega t) + F_{ts}(z + d) \quad (1)$$

Here,  $m^*$  is the effective vibrating mass of cantilever and tip,  $z$  is the cantilever deflection,  $d$  is the average tip-surface separation,  $C$  is the damping coefficient,  $k_L$  is the lever stiffness, and  $A_0$  is the applied amplitude (which is equal to the free amplitude in the off-resonance case). If the AFM is operated in the force-modulated mode, the equation is modified by replacing  $k_L A_0$  on the right-hand side by  $F_0$ , the modulated force.

$F_{ts}$  is the sum of forces acting between the tip and the surface.  $F_{ts}$  generally consists of several forces with different interaction ranges. In vacuum, the forces present include chemical bonding, van der Waals forces, electrostatic forces, or magnetic forces. In liquids, we also encounter forces associated with the medium such as solvation forces and hydrophilic/hydrophobic interactions.<sup>[32]</sup> In ambient, capillary forces can be very important. When writing expressions for  $F_{ts}$ , we also need to be careful that forces act on different portions of the tip depending on their range. Long-range forces, such as electrostatic forces in the presence of an applied voltage, might act on the entire vibrating cantilever, while short-range forces, such as chemical bonding forces act on the outermost atoms of the tip only. Finally, we have to take into account that the tip and surface are not infinitely rigid, but instead deform under the influence of the force field. This leads to a rescaling of the tip-surface separation  $z$ .<sup>[13,33]</sup> However, to simplify the discussion, we will ignore these effects for the time being.

In Eq. (1) the cantilever is being treated as a linear spring, which is a very good approximation for the small amplitudes involved.<sup>[34]</sup> We also assumed that the damping coefficient,  $C$ , is independent of tip position. This is in general not true, but again is a good local approximation if small amplitudes are used.

Generally, because of the nonlinear nature of the force field,  $F_{sr}$ , Eq. (1) can only be solved numerically. In some special cases, analytic solutions can be found. A very special case occurs when the AFM is operated at amplitudes over which the force law can be approximately considered linear. We can then write  $F_{ts} = F_{ts,0} - k_{ts}z$ . For convenience, we rescale the displacement  $z$  to account for the equilibrium position of the cantilever  $z_0 = F_{ts,0}/k_L$ , according to  $z - z_0 \rightarrow z$ . By doing this,  $z$  becomes a measure for the *deviation* from the equilibrium position due to the imposed oscillation. The new *linearized* equation of motion becomes:

$$m^*\ddot{z} + C\dot{z} + (k_L + k_{ts})z = k_L A_0 \exp(i\omega t) \quad (2)$$

Note that the interaction stiffness,  $k_{ts}$ , is the negative of the force gradient,  $\partial F/\partial z$ . The steady-state solution of Eq. (2) is  $z(t) = A \exp(i\omega t)$ , where  $A$  is a complex number that includes the phase information.  $A$  is

given by:

$$A = \frac{k_L A_0}{k_L + k_{ts} - \omega^2 m^* + i\omega C} \quad (3)$$

The resonance frequency in the linear regime is given by  $\omega_0 = \sqrt{(k_L + k_{ts})/m^*}$ . Using this we can find for the absolute value of the amplitude:

$$|A| = \frac{k_L A_0}{\sqrt{(k_L + k_{ts})^2 (1 - (\omega^2/\omega_0^2))^2 + (C\omega)^2}} \quad (4)$$

and the phase angle between the  $A_0$  (the drive) and  $A$  (the cantilever):

$$\tan \phi = -\frac{\omega C}{(k_L + k_{ts})(1 - (\omega^2/\omega_0^2))} \quad (5)$$

### Small-amplitude tapping mode AFM

In the case of tapping mode AFM, the system is driven at or near the free resonance. Because the drive frequency is kept constant, the amplitude and/or phase are measured and used as possible feedback signals. When the lever is driven at the free resonance frequency,  $\omega = \omega_{of} = \sqrt{k_L/m^*}$ , the absolute value of the amplitude is given by [Eqs. (4), (5)]:

$$|A| = \frac{k_L A_0}{k_{ts}} \cos \phi \quad (6)$$

The phase angle is given by:

$$\tan \phi = -\frac{\omega_{of} C}{k_{ts}} \quad (7)$$

It is straightforward to solve these equations for  $k_{ts}$  and  $C$ , and thus, at least in principle, a measurement of the amplitude and the phase are sufficient to determine the interaction stiffness and the damping.

This is to be contrasted from the usually used *large* amplitudes. In this case, the interaction and damping are very difficult to reconstruct from the amplitude and phase, because these are the result of an *integral* over the *entire* motion of the cantilever. Thus, for large amplitudes we are not mapping two observables (amplitude and phase) to two unknowns (the local stiffness and damping coefficient), but instead we are trying to map our two observables to *all* values of interaction stiffness and damping coefficient the tip encounters during its trajectory. This is—without additional information—in principle impossible.

Additional information might come from amplitudes and phases of higher vibration modes<sup>[24,25]</sup> or from multiple measurements at different separations and amplitudes. The interpretation, if not impossible in principle, becomes very involved.

### Subresonance AFM

Combining Eqs. (4) and (5), we find that the measured interaction stiffness,  $k_{ts}$ , can be determined directly from the measured amplitude and phase via:

$$k_{ts} = k_L \left( \frac{A_0 \cos \phi}{|A|(1 - (\omega^2/\omega_0^2))} - 1 \right) \quad (8)$$

If we keep the drive frequency,  $\omega$ , well below the first resonance we can use this equation to find the following simple expression for the interaction stiffness:

$$k_{ts} = k_L \left( \frac{A_0}{|A|} \cos \phi - 1 \right) \quad (9)$$

If the AFM is operated reasonably far below the resonance, the phase angle typically is very small, and the  $\cos \phi$  term can in many cases be replaced by unity, resulting in:

$$k_{ts} = k_L \left( \frac{A_0}{|A|} - 1 \right) \quad (10)$$

The same result can be obtained if we realize that by operating the AFM in the subresonance regime, the measurement becomes *quasi-static*. Close to the surface, the cantilever and interaction stiffnesses can be considered as two “springs” in series. Thus the forces in each spring are identical and we can write:  $F = k_{ts}|A| = k_L(A_0 - |A|)$ , which leads to the same result [Eq. (10)].

The damping coefficient can be calculated from:

$$C = \frac{k_L A_0}{|A|\omega} \sin \phi \quad (11)$$

Thus again a measurement of the amplitude and phase are sufficient to determine both the interaction stiffness and the damping coefficient.

### Frequency shift AFM

In frequency shift AFM, the excitation frequency of the cantilever is altered to keep the lever at its resonance at all times. Therefore the frequency becomes an observable in the measurement. At very small

amplitudes,<sup>[35]</sup> the resonance frequency is directly related to  $k_{ts}$ , since  $\omega_0 = \sqrt{(k_L + k_{ts})/m^*}$  (see Eq. (2) and Ref.<sup>[26]</sup>). In terms of the *free* resonance frequency,  $\omega_{0f}$ , the interaction stiffness can be found from:

$$k_{ts} = k_L \left( \frac{\omega_0^2}{\omega_{0f}^2} - 1 \right) \quad (12)$$

This can be approximately written in terms of the frequency shift,  $\Delta f = 1/2\pi (\omega_0 - \omega_{0f})$  as:

$$k_{ts} = 2k_L \frac{\Delta f}{f_{0f}} \quad (13)$$

The amplitude can be calculated from Eq. (4). Introducing the quality factor  $Q = \omega_{0f}m^*/C$ , we find<sup>[36]</sup>

$$|A| = \frac{QA_0}{\sqrt{(k_L + k_{ts})/k_L}} \approx QA_0 \left( 1 - \frac{k_{ts}}{2k_L} \right) \quad (14)$$

In FM AFM, the amplitude is often held constant by a feedback loop, and the excitation amplitude needed to keep a certain constant lever amplitude is measured and related to the damping.<sup>[37]</sup>

In conclusion, by measuring the amplitude and the *frequency*, the interaction stiffness and the damping coefficient (or quality factor) can be determined. At larger amplitudes, the frequency shift is determined by an integral over the entire tip trajectory, and interpretation of the frequency shift data becomes much more involved.<sup>[24,27–30]</sup>

### Force modulation AFM

In the case of force modulation AFM, Eqs. (4) and (5) still hold if we replace  $k_L A_0$  by the modulated force  $F_0$ .<sup>[15]</sup> If a small *subresonance* force modulation is applied to the cantilever and the displacement response is measured, these equations simplify to:

$$k_{ts} = \frac{F_0}{|A|} - k_L \quad (15)$$

which for small phase angles is simply an expression of Hooke's law; that is, the total effective stiffness  $k_{ts} + k_L$  is given by  $F_0/|A|$ . Note that in the case of force-modulated AFM, the cantilever and interaction stiffnesses are to be considered *in parallel*, whereas in "usual" displacement-modulated AFM, they are to be taken to be *in series*. The reason is that in force-modulated AFM, both the sample and the

cantilever base are held fixed, and thus the *amplitudes* of the base–tip and tip–surface separations are identical, while the forces are different. In "usual" AFM it is the *forces* between base and tip and tip and surface that are identical, while the amplitudes are different ( $A_0$  vs.  $|A|$ ).

The damping coefficient in force-modulated AFM can be found from:

$$C = -\frac{F_0}{|A|\omega} \sin \phi \quad (16)$$

### Practical considerations

As we have seen above, the interpretation of the data becomes greatly simplified if amplitudes are small enough to consider the force field to be linear over the range of motion of the cantilever. In all four cases (tapping mode, off-resonance AM AFM, FM AFM, and force modulation AFM), both the interaction stiffness and the damping can in principle be directly measured. In all cases, two parameters are needed: In AM and force-modulated AFM we need amplitude and phase, and in FM AFM amplitude and frequency shift.

In reality, quantitative small amplitude measurements have been used quite frequently in off-resonance measurements (both displacement and force modulated), less frequently in FM AFM, and hardly in tapping mode experiments. The main reasons for this are problems of phase and amplitude stability in tapping mode. Because the drive frequency enters the equations, but is not explicitly measured as in FM AFM, a shift in the drive frequency can greatly affect the obtained results. Indeed a shift to higher or lower frequency than the free amplitude can lead to a bistable behavior of the oscillator if the amplitude is not small enough. Keeping the amplitude small enough, on the other hand, is difficult if the cantilever is operated near its resonance. In subresonance AFM, this problem is avoided by staying far below the resonance, and, as a result, the frequency does not enter into the equations and the amplitude can be kept low.

In FM AFM the lever is deliberately run at resonance, and the frequency should be quite stable if the  $Q$  of the lever is sufficiently high. The needed high  $Q$ , however, results in larger amplitudes, thus violating the small-amplitude condition. If the amplitudes are deliberately kept small, thermal noise can greatly influence the measurements because most of the thermal vibration energy is centered around the lever resonance. For a lever of 40 N/m stiffness, which is typical for FM AFM, the thermal vibration amplitude is of the order of  $\sqrt{k_B T/k_L} = 0.1 \text{ \AA}$ , which is of the same order as the amplitude needed to linearize

measurements of atomic bonding forces. This particular problem can be alleviated by increasing the lever stiffness and sensitivity of the system as recently demonstrated by Giessibl.<sup>[38]</sup>

### Operating Conditions of Small-Amplitude AFM

Limits of linearity or how small is small enough?

As shown above, the linearized equation of motion [Eq. (2)] can be solved in a variety of situations and leads to the simple relation [Eq. (9)] for the interaction stiffness in the case of an AFM operated at small amplitudes and subresonance frequencies, and to Eq. (13) in the case of a small amplitude, frequency shift AFM. However, an important question remains unanswered: Under what circumstances can the system be regarded linear? Or, in other words: When is the amplitude small enough?

This question cannot be answered in general because it strongly depends on the nature of the force law that the tip encounters. Long-range forces, such as electrostatic, magnetic, and van der Waals forces can generally be explored with somewhat larger amplitudes. Short-range forces, such as chemical bonding and solvation forces associated with small molecules, require significantly smaller amplitudes. We might also expect that it depends on the particular AFM technique used, but, at least as a rule of thumb, the results seem to be quite similar for different a.c. AFM techniques.

In the case of frequency shift (FM) AFM and short-range forces, Hölcher, Schwarz, and Wiesendanger<sup>[35]</sup> showed that the frequency shift is determined by the force gradient only if the amplitudes used are in the sub-Angstrom range, typically of the order of a few tenths of an Angstrom. Similar results can be obtained for subresonance AM AFM.<sup>[33]</sup> In a recent simulation<sup>[33]</sup> of a vibrating lever in a short-range force field (with a decay parameter of 0.54 Å), it was found that the error of the measurement was negligible for a lever amplitude of 0.1 Å, very small for an amplitude of 0.25 Å, and about 10% for an amplitude of 0.5 Å, i.e., for an amplitude of the order of the decay parameter. For large amplitudes, e.g., 1 Å, the error was quite significant. This is shown in Fig. 2. For comparison, typical lever amplitudes in tapping mode are of the order of 100–1000 Å, and in FM AFM of the order of 10–100 Å. In the case of subresonance AFM, we also have the added question of the influence of the frequency, i.e., how far below the resonance we need to be to avoid resonance enhancement of the amplitude. It was found that very clean subresonance operation could be achieved up to about one-eighth of the resonance frequency, but acceptable error rates (<10%) could be achieved up to frequencies of one-third of

**Fig. 2** Simulation of the measured interaction stiffness–displacement curve for different cantilever amplitudes in a subresonance AM AFM. For  $A_0 = 0.1$  Å the measurement does not visibly deviate from the theoretical curve, at 0.25 Å there is a small error around the minimum, at 0.5 Å this error is about 10%, while at an amplitude of 1.0 Å the error has become quite large. *Source:* From Ref.<sup>[33]</sup>.

the free resonance. Beyond these values, the amplitude has a tendency to become too large because of resonance enhancement, complicating the interpretation of the data.

### Limits of stability

Even if small drive amplitudes are used, there is no guarantee that the actual lever amplitude remains small. One reason for this is resonance enhancement, as discussed above. The other reason is the use of low-stiffness cantilevers. Low-stiffness cantilevers not only exhibit larger deflections in an attractive force field than higher stiffness ones, but, moreover, they can become unstable and “snap” to the surface (“snap-to-contact”).<sup>[11]</sup>

In d.c. AFM there is a straightforward criterion that must be satisfied if snap-to-contact is to be avoided. As long as the *effective* stiffness of the cantilever is positive, no snap-in occurs:

$$k_L + k_{ts} > 0 \quad (17)$$

This means that snap-in occurs when the interaction stiffness is negative (“attractive”) and its absolute value exceeds the lever stiffness.

In a.c. AFM snap-in can still be avoided *even* if condition (17) is violated. The reason is that in order for snap-in to occur the total force (cantilever + interaction) must be negative (attractive).<sup>[27]</sup> In a.c. AFM, the cantilever deflects beyond its equilibrium point and therefore the restoring force can overwhelm

the attractive force between the tip and the surface. The second criterion for snap-in to be avoided can thus be written as:

$$k_L A + F_{ts} > 0 \quad (18)$$

This is one of the reasons for the stability of large-amplitude FM AFM. In these techniques relatively low stiffness cantilevers can be used, which boost sensitivity, but because of the large amplitudes the snap-in instability can be avoided. In small-amplitude methods, we need to mostly rely on criterion (17) and thus high-stiffness cantilevers need to be used. This necessitates high-sensitivity deflection sensing as discussed in the next subsection.

### Sensitivity

Small-amplitude AFM requires higher sensitivity of the deflection sensor than regular AFM. The reason is not only that small amplitudes are more difficult to measure, but also, as we have seen above, the stability criterion demands that high-stiffness levers are used, which reduce the signals even further. There are many ways of sensing the deflection of the cantilever,<sup>[39]</sup> from tunneling as used in the original AFM<sup>[3]</sup> to the now most commonly used optical techniques. For each of these methods, a theoretical sensitivity limit can be calculated.<sup>[40]</sup> However, in reality the experimental sensitivity is typically lower due to nonideal experimental conditions.

Because small-amplitude AM AFM needs to operate preferably at amplitudes of a few tenths of an Angstrom, the deflection sensor needs to be able to sense changes in the amplitude of the order of 0.01 Å (i.e., 1 pm) or better. This is difficult to achieve with commonly used laser-deflection systems. Theoretically, highly optimized laser-deflection systems might be able reach similar sensitivity than interferometer-based systems,<sup>[41]</sup> however, in practice, most cannot sense changes in amplitude much smaller than 0.1 Å. Experimentally, it has been demonstrated that fiber interferometers<sup>[42]</sup> can have at least 10–20 times higher sensitivity than laser-deflection systems and are thus the method of choice in small-amplitude AM AFM.

In FM AFM, when high-stiffness cantilevers are used, the frequency shift is reduced and a high sensitivity frequency measurement becomes essential. A very high  $Q$  cantilever is needed to achieve the needed sensitivity. High  $Q$ , however, leads to increased resonance enhancement of the amplitude, and thus drive amplitudes need to be extremely small. Fortunately, high-stiffness cantilevers also help to reduce the thermal noise at resonance, and measurements at sub-Angstrom lever amplitudes can be achieved.

### Thermal noise

When we deal with cantilever amplitudes of the order of 0.1 Å, we immediately face the question of how this compares with the average amplitude of the thermal excitation of the cantilever. It can be shown<sup>[43]</sup> that the power spectral density of the oscillator amplitude due to thermal excitation is given by:

$$\langle P^2(\omega) \rangle = \frac{4k_B T C}{(k_L + k_{ts} - m\omega^2)^2 + C^2\omega^2} \quad (19)$$

Note that  $\langle P^2 \rangle$  has units of  $\text{m}^2 \text{Hz}^{-1}$ , i.e., it needs to be multiplied with the measurement bandwidth,  $B$ , to calculate the rms amplitude due to the thermal motion of the cantilever. The rms amplitude is given by  $\delta x_{\text{rms}} = \sqrt{B \langle P^2 \rangle}$ . At the resonance frequency, i.e., in FM AFM, the power spectral density reduces to:

$$\langle P^2 \rangle = \frac{4k_B T}{C\omega_0^2} \approx Q \frac{4k_B T}{k_L \omega_{0f}} \quad (20)$$

where we used  $Q = \omega_{0f} m / C$  as the quality factor of the free cantilever, and assumed  $k_{ts} \ll k_L$  and  $\omega_0 \approx \omega_{0f}$  to obtain the approximate result on the right-hand side.

In subresonance AM AFM, the formula (19) instead reduces to:

$$\langle P^2 \rangle = \frac{4k_B T C}{(k_L + k_{ts})^2} \approx \frac{1}{Q} \frac{4k_B T}{k_L \omega_{0f}} \quad (21)$$

Comparing the approximate results [Eqs. (20) and (21)], the thermal noise *increases* with increasing quality factor  $Q$  if the lever is driven at its resonance (as in FM AFM), and *decreases* in the case of subresonance AFM. What does this mean in practice? In order to reliably measure the frequency or amplitude of a cantilever with a 0.1 Å = 10 pm free amplitude, the rms amplitude of the thermal noise needs to be less than 1 pm. At room temperature, for a lever with a  $Q$  of 1000, a resonance frequency of  $\omega_{0f} = 2\pi \times 200$  kHz, kHz, and a measurement bandwidth of 100 Hz, the cantilever stiffness would need to be about 1300 N/m in the case of FM AFM, and  $1.3 \times 10^{-3}$  N/m in the case of subresonance AM AFM. A cantilever of 1300 N/m would provide a frequency shift of 7.7 Hz for an interaction stiffness of 0.1 N/m. The thermal frequency noise can be calculated from:<sup>[26,44]</sup>

$$\delta f_{\text{rms}} = \sqrt{\frac{k_B T B f_{0f}}{k_L A_0^2 \pi Q}} \quad (22)$$

This gives a thermal frequency noise of 14 Hz for a lever of 1300 N/m. The lever amplitude therefore

would need to be somewhat increased beyond this value to get a force gradient sensitivity of 0.1 N/m. A cantilever of such high stiffness may sound difficult to implement, but a lever stiffness of 1800 N/m has recently been used by Giessibl to achieve unprecedented high resolution on Si  $7 \times 7$  surfaces.<sup>[38,45]</sup>

In the case of subresonance AM AFM, the lever stiffness would have to be increased far beyond the thermal noise limit of  $1.3 \times 10^{-3}$  N/m to about 100 N/m to avoid snap-to-contact. In this case, the rms amplitude of the thermal noise would reduce to 3.6 fm, which is more than sufficient for even the most stringent requirements. At a lever stiffness of 100 N/m, a force gradient of 0.1 N/m would result in a change of the lever amplitude of about 10 fm assuming a free lever amplitude of 0.1 Å = 10 pm; that is, the signal would be a factor of three above the thermal noise limit. Of course, measuring 10 fm even with an interferometric sensor is not an easy task. Measurements of this order have been demonstrated recently.<sup>[42,46,47]</sup> Theoretically, much higher sensitivity is possible if more elaborate interferometric methods are used (see, e.g., in gravitational wave detection: Ref.<sup>[48]</sup>).

Thermal noise can of course also be reduced by lowering the temperature of the instrument.<sup>[49]</sup> However, the rms amplitude only scales with the square root of the temperature, and thus the expected reduction in thermal noise is “only” of the order of about 10. On the other hand, there are many additional advantages of low-temperature operation, such as limiting drift and surface diffusion, and low-temperature operation can provide a significant advantage over room-temperature methods.

## A SHORT HISTORY OF SMALL-AMPLITUDE AFM

### Nanoindentation and Force-Controlled AFM

Nanoindentation<sup>[50]</sup> is a technique to measure contact-mechanical properties on the nanoscale. It essentially operates by indenting a very sharp diamond tip into a surface while monitoring the displacement and the applied load. In 1987, Pethica and Oliver<sup>[15]</sup> improved this technique by additionally applying a force modulation. This force modulation was small enough ( $\approx 10^{-8}$  N) such that, at the observed contact stiffnesses, sub-Angstrom tip amplitudes were generated. Such small amplitudes allowed the simultaneous linear measurement of the contact stiffness in addition to the load–displacement curve. From the contact stiffness the size of the contact area could be determined. In their paper, the authors also suggested to operate an AFM in a similar fashion, by applying a small a.c. force to the cantilever via a magnetic transducer.

In 1993, Jarvis et al. demonstrated a force-controlled AFM<sup>[51]</sup> that used a cantilever with an attached magnet and an electromagnet to apply a d.c. and small subresonance a.c. force to the cantilever. The small, applied a.c. force resulted in a very small amplitude ( $\approx 0.3$  Å) of the cantilever, giving a direct measure of the stiffness of the cantilever–surface system via Eq. (9). The amplitude was measured with a heterodyne interferometer. The AFM was able to detect a negative stiffness region under ambient condition, which is difficult to achieve with conventional AFM because of the snap-in instability. This device was subsequently implemented in ultrahigh vacuum,<sup>[52]</sup> resulting in the first direct measurement of the interaction stiffness between clean surfaces.<sup>[53]</sup> Imaging with the force-controlled AFM was also demonstrated.<sup>[54]</sup> This technique was also used in liquids, where O’Shea et al. have successfully used the force-controlled AFM to measure solvation forces<sup>[55,56]</sup> in several organic solvents. They used amplitudes of a few Angstroms, which were appropriate for the relatively large molecules they studied.

### On-Resonance AM AFM

In usual AM or tapping mode AFM, a displacement rather than a force is applied to the cantilever. If the applied displacement is small enough, the at-resonance amplitude of the lever can be kept in the Angstrom regime, depending on the  $Q$  and  $k_L$  of the lever (see our discussion of thermal noise above).

Olsson, Wigren, and Erlandsson demonstrated an on-resonance AM AFM technique<sup>[57]</sup> with small free amplitudes of  $< 10$  Å. The needed sensitivity was provided by the use of a fiber interferometer.<sup>[58]</sup> During imaging the amplitude was reduced by 20–90% of the free value due to the shift of the resonance frequency. Using this technique, true atomic resolution on silicon (111)-(7 × 7) surfaces<sup>[59]</sup> was achieved. However, because of the use of an on-resonance technique and the still relatively large amplitudes, the interpretation of the amplitude data proved difficult.<sup>[60]</sup>

### FM AFM

In FM AFM, cantilever stiffnesses of 10–50 N/m and large amplitudes of 10–50 nm<sup>[44]</sup> are generally used. The large amplitudes provide good stability and signal-to-noise and are thus preferred when imaging with atomic resolution.<sup>[28]</sup> There are rather few examples of FM AFM experiments that utilized amplitudes less than 10 nm. Kitamura and Iwatsuki have used amplitudes as low as 1.5 nm to image Si(111).<sup>[61]</sup> Recently, Eguchi and Hasegawa used amplitudes of 2.8 nm to also image Si(111) and were able to resolve

rest atoms.<sup>[62]</sup> The main reason for the low number of small-amplitude experiments is the use of low-stiffness cantilevers, which require large amplitudes to avoid the snap-in instability [see Eq. (18)].

Stable small-amplitude operation at resonance requires very stiff levers in order to avoid the snap-in instability and to reduce thermal noise. Recently, Giessibl designed a novel force sensor based on a quartz tuning fork.<sup>[38]</sup> This sensor has a very high stiffness of 1300–1800 N/m. Using this new device, he was able to achieve very stable atomic resolution imaging at amplitudes of 4 Å, which is very small for FM AFM.

Using the same setup, Giessibl et al. recently achieved subatomic (orbital) resolution of the tip and the Si substrate.<sup>[45,63]</sup> Better-than-atomic resolution had previously been observed only in STM measurements. A tuning-fork-based sensor was found to also provide atomic resolution and atomic-scale friction measurements in a small-amplitude (3 Å) *lateral* mode.<sup>[64]</sup>

Giessibl et al. have argued that in FM AFM measurements, small amplitudes and large cantilever stiffnesses should be able to *improve* signal-to-noise.<sup>[44]</sup> This depends on the exact nature and magnitude of any dissipative processes. Despite the presence of energy dissipation, the advantages of small amplitudes and stiff cantilevers in FM AFM have been experimentally confirmed.<sup>[38,45,63]</sup> A possible reason for the improved S/N of small-amplitude techniques is that the tip will spend most of its time in the regime of *short-range* forces when small amplitudes are used close to the surface.<sup>[65]</sup> These forces are ultimately responsible for atomic resolution imaging. Large-amplitude techniques are more affected by long-range forces (e.g., van der Waals), thus degrading sensitivity to short-range bonding forces. The same reasoning has recently been applied to the room-temperature observation of rest atoms in Si(111)-(7 × 7) at reduced amplitudes of 2.8 nm.<sup>[62]</sup>

### Subresonance AM AFM

Thermal noise and limits of sensitivity are the most important obstacles in reducing the vibration amplitude of the cantilever into the linear regime of a few 0.1 Å. There are essentially two ways to limit thermal noise: high-stiffness cantilevers and subresonance operation. Sensitivity can be improved by using new detection schemes, such as tuning forks for FM detection<sup>[63]</sup> and fiber interferometers for AM detection.<sup>[58]</sup>

Recently, Oral et al.<sup>[66]</sup> constructed a fiber interferometer-based AFM, which was optimized to operate at ultrasmall amplitudes of < 0.25 Å. This instrument has since been successfully used to obtain atomic resolution maps of the force gradient on Si(111)<sup>[46]</sup> and Si(100),<sup>[67,68]</sup> to measure atomic bonding

forces between a W tip and a clean Si(111) surface,<sup>[42]</sup> and to observe atomic-scale energy dissipation at amplitudes as low as 0.13 Å on Cu(100)<sup>[47]</sup> and with slightly larger amplitudes on Si(100).<sup>[67,68]</sup>

Subresonance detection can also be used in liquids. Although the thermal noise increases somewhat because of the decrease in  $Q$  [see Eq. (21)], subresonance AM detection is better suited for liquid-based measurements because there is no need to measure the resonance frequency under low- $Q$  conditions. Recently, subresonance AFM has been used at an amplitude of 0.35 Å for the first *direct* AFM measurement<sup>[69]</sup> of the molecular stiffness variations of confined water layers.<sup>[32]</sup>

### Force gradients of chemical bonds

Few methods allow the direct measurement of the distance-dependent interactions between single atoms. Recently, large-amplitude dynamic AFM has been used to achieve this goal.<sup>[49,70]</sup> However, there are a few remaining questions, especially the difference of the observed interaction length range measured in low-temperature<sup>[49]</sup> vs. room-temperature<sup>[70]</sup> measurements. Part of the problem might be the dissipative interactions that are not always accounted for in the deconvolution schemes used in large amplitude measurements.

Unambiguous measurements of conservative and dissipative interactions can be achieved by low amplitude measurements. Recently, subresonance, ultrasmall ( $\approx 0.2$ – $0.25$  Å) amplitude AFM has been applied to measure atomic interactions between a tungsten tip and a clean Si(111)-(7 × 7) surface at room temperature<sup>[42]</sup> (Fig. 3). No temperature-related broadening of the interaction was observed in contrast to some large amplitude measurements.<sup>[70]</sup> The measured interaction parameters were in agreement with reported theoretical values.<sup>[71]</sup> Atomic bonding stiffnesses have also been measured on Cu(100)<sup>[47]</sup> and Si(100) surfaces.<sup>[67,68]</sup>

### Force gradient atomic resolution imaging

One problem of subresonance, ultrasmall-amplitude AFM is that signals are exceedingly small, whereas the drive frequency can be quite low. This necessitates long integration times for the lock-in detection of the amplitude or phase, which in turn makes it very difficult to use the lock-in signal for feedback during imaging. Imaging has so far been achieved by using the tunneling current for the feedback, while independently imaging the force gradient signal. Using this approach, atomic resolution images of the force gradient have been achieved on Si(111) (Fig. 1),<sup>[46]</sup> Si(100),<sup>[67,68]</sup> and Cu(100).<sup>[80]</sup> The force gradient images showed atomic contrast independent of the

**Fig. 3** Directly measured stiffness of an atomic bond between a tungsten tip and a clean Si(111) surface in UHV.<sup>[42]</sup> The measurement amplitude was 0.24 Å. In addition to the stiffness of the bond, data also include the longer-range van der Waals interaction between the tip and the surface. Long- and short-range forces can be separated by using a suitable fitting procedure.<sup>[42,70]</sup> Also shown is the simultaneously acquired tunneling current.

contrast in the tunneling channel. In the case of Cu(100), atomic contrast was seen in the force gradient image even when no atomic contrast was visible in the tunneling image.

Force gradient feedback is possible by using FM detection<sup>[38]</sup> or by increasing the drive frequency of the lever. The latter can be achieved by increasing the natural resonance frequency of the lever. A higher resonance frequency allows for a higher drive frequency, making imaging possible.

#### Atomic dissipation

A topic of significant interest is the measurement of atomic-scale dissipation in AFM. It has been observed in both large<sup>[37,72,73]</sup> and small-amplitude<sup>[47]</sup> UHV-based AFM that the cantilever loses a few millielectron volts to electron volts of kinetic energy per cycle when it is near the surface. A consensus seems to be that the observed dissipation is related to “slow” stochastic motion of atoms at the tip or the sample surface.<sup>[47,74]</sup>

Small-amplitude AFM is expected to be more sensitive to short-range forces,<sup>[65]</sup> and thus to atomic-scale dissipation.<sup>[75]</sup> Small-amplitude, subresonance AFM is ideally suited to explore dissipation phenomena because any phase difference between drive and lever can be directly related to energy dissipation if the lever is operated in the linear regime far from resonance. Large-amplitude techniques can exhibit phase differences merely because of the inherent nonlinearities of the system.<sup>[76,77]</sup> Recently, subresonance, ultrasmall-amplitude AFM ( $A_0 = 0.13$  Å) has been used to measure atomic dissipation on a Cu(100) surface<sup>[47]</sup> (Fig. 4). It was found that the observed dissipation of a few 10 meV per cycle could be explained by the coupling of the tip motion to the stochastic motion of a

surface atom or defect encountering an energy barrier of the order of 0.5 eV, i.e., of the order of typical surface diffusion barriers.

#### Solvation forces—subresonance AFM in liquids

Subresonance AFM has the distinct advantage of not relying on a measurement of the resonance frequency, which can be exceedingly difficult if the AFM is operated in a highly damping medium, such as water. Exploiting this fact, it was recently shown that subresonance AFM is capable of directly measuring the stiffness oscillations associated with the molecular ordering of water confined between the tip and a flat surface (Fig. 5).<sup>[69]</sup> The advantage of the technique was the unambiguous interpretation of the data and

**Fig. 4** Simultaneously measured interaction stiffness and atomic-scale energy dissipation measured with a tip vibrating with an amplitude of 0.13 Å close to a clean Cu(100) surface in UHV. Note that this measurement was performed close to the noise limit of this particular instrument. *Source:* From Ref.<sup>[47]</sup>

**Fig. 5** Stiffness of a confined water layer measured with a subresonance AFM at a free amplitude of  $0.35 \text{ \AA}$ . Note the regular spacing of higher-stiffness regions, corresponding to positions of the tip that allow the confined water to attain a solidlike structure. Intermediate positions are not commensurate with the molecule size of water, and thus result in a low-stiffness, disordered layer.

the easy separability of conservative and dissipative terms. This was not possible in earlier large-amplitude AFM measurements of the same phenomenon.<sup>[78]</sup>

## CONCLUSION AND OUTLOOK

Small-amplitude AFM offers distinctive advantages over large-amplitude techniques. These include:

1. Linear measurements.
2. Easy data interpretation.
3. Point-by-point, local measurements.
4. Higher sensitivity to short-range forces and potentially better S/N.
5. Easy separation of conservative and dissipative forces, especially when subresonance methods are used.
6. Easier transfer to different environments, especially liquids.

The downside of the techniques is the inherently low signals that need to be measured. However, as we have seen, high-stiffness cantilevers can reduce thermal noise and high-sensitivity displacement sensors are now available that can push amplitude sensitivity into the femtometer regime.

The two most significant developments in this field are the use of subresonance techniques and small-amplitude FM detection schemes. The subresonance techniques offer simple data interpretation, low thermal noise, the possibility of using lower-stiffness levers (as long as the snap-in is avoided), and the easy

transfer of the technique into liquid environments. Recent experiments using FM detection at small amplitudes are also very encouraging, as they combine the advantages of small amplitudes with the high signal-to-noise of FM detection. The very high stiffness levers used in the technique can keep  $Q$  values high even in liquids. This opens up the use of FM detection in liquid environments without the need of  $Q$  control techniques, which raise additional interpretation issues.

In the future, it is anticipated that small-amplitude techniques will play an ever-increasing role in *quantitative* AFM measurements. As they operate in virtually *any* environment, the impact on diverse fields, from atomic and molecular manipulation to the nanomechanics of biomolecules, could be enormous. If the widely heralded nanotechnology industry is to become a reality, methods that can reliably measure forces, stiffnesses, and dissipation at the nanoscale will be essential. Small-amplitude AFM might well be the technique of choice to put hard numbers on the workings of the molecular machinery of future nanodevices.

## Abstract

It is well known that nanoparticles are not rigid structures and may undergo structural/shape changes when exposed to elevated temperatures, reaction environment, or after the absorption of photons. For example, a catalytic active site may change its structure to form a transition state to accommodate the reactant molecules and reaction intermediates. On the other hand, the absorption of light photons may trigger selective vibrations or transient structural changes, affecting the reactivity. Consequently, selective optical excitation of the nanoparticles or nanoparticle–molecule complexes with laser pulses optimized in both time and wavelength domain opens entirely new ways of control of mode-selective photophysics and photochemistry.

Since surface reactions occur on active sites consisting of a handful of atoms only, small metal clusters and organometallic molecules are ideal models for studies of the basic phenomena governing chemical and photochemical processes. In this entry, we explore various schemes to manipulate photoinduced dynamics in the smallest size regime by using tailor-made ultrafast laser pulses. The efficacy of the implemented control approaches will be illustrated on several examples: 1) manipulation of the population of the bound B and X states of the sodium trimer by using linearly chirped laser pulses; 2) control of the ionization and fragmentation pathways of the photoexcited NaK and Na<sub>2</sub>K clusters by shaped laser pulses; and 3) control of branching the photodissociation in CpMn(CO)<sub>3</sub>. The optimum pulse shapes navigating the molecular dynamics are found by employing a feedback loop algorithm based on evolutionary strategies. These pulse shapes contain rich and detailed information about the involved molecular processes.

## INTRODUCTION

With the discovery of the lasers almost half a century ago, an old dream of chemists seemed to get into reach: selective bond breaking and making, which would allow an ultimate control over the outcome of a chemical reaction by using photons with energies corresponding, for example, to the vibration frequencies of the targeted bond. However, it soon became evident that this approach did not bring the highly expected results due to the fast and efficient energy dissipation in the targeted molecules via internal vibrational redistribution (IVR). The advent of tunable femtosecond laser sources, however, has re-opened this fascinating perspective since it allows one to obtain an insight into elementary intramolecular processes like bond shaking, breaking, and making<sup>[1]</sup> and getting ahead of IVR.<sup>[2–8]</sup> Using transient pump&probe spectroscopy, such processes can now be analyzed in real time<sup>[9,10]</sup> and described theoretically.<sup>[11,12]</sup> Also, considerable theoretical effort has been made in various control scenarios to be performed in the time or wavelength domain that would drive the chemical reaction to the desired product state.<sup>[13–33]</sup> The

feasibility of the theoretical models was first verified experimentally on small particles consisting of only a few atoms like monomers, dimers, and trimers.<sup>[1,16,34–36]</sup> In the case of larger and more complex systems, the adaptive laser pulse control strategy has become very attractive.<sup>[37]</sup> The advantage of this method is that it does not require an a priori knowledge of the potential energy surfaces involved in the differently branching reaction pathways. Instead, the employed optimization algorithm “teaches” the light field to maximize the yield of the selected product. This is achieved in an iterative closed-loop experiment in which the genetic algorithm creates an optimal laser pulse that prepares the desired target. Coherent control on larger molecular systems was first confirmed experimentally in a photophysical experiment, where the fluorescence of the iodine molecule was optimized with phase-modulated (chirped) laser pulses.<sup>[38]</sup> Later, it was employed for manipulating a large variety of photophysical and photochemical processes in more complex molecules and nanoparticles: selective fragmentation of the CpFe(CO)<sub>2</sub>Cl molecule,<sup>[39]</sup> selective excitation of solvated dye molecules,<sup>[40]</sup> control of the photodissociation process in CsCl,<sup>[41]</sup> strong-field control of reactivity channels in organic molecules<sup>[42,43]</sup>

**Fig. 1** The principle of pump&probe spectroscopy illustrated in the example of transient two-photon ionization: The first femtosecond laser pulse (pump) electronically excites the particle into an ensemble of vibrational states, creating a wavepacket in the excited state. The temporal evolution of the wavepacket is probed by a second (probe) pulse, which ionizes the excited particle as a function of the time-dependent Franck Condon-window. (A) Shows the scheme for a bound–bound transition, where an oscillatory behavior of the wavepacket reflecting the vibrations in the excited molecule will appear. (B) Illustrates the pump&probe principle for monitoring a bound-free transition exhibiting an exponential decay. (C) Cartoon of the process of predissociation, when a fraction of the oscillating wavepacket leaks into the repulsive state at every passage through the curve-crossing region.

and liquids,<sup>[44]</sup> control of vibrational motion in room temperature molecular gases,<sup>[45]</sup> control of vibrational Raman scattering in liquids,<sup>[46]</sup> control of wavepacket dynamics, population of electronic states, and fragmentation processes,<sup>[47]</sup> control of non-linear processes in liquids by multi-photon intrapulse interference,<sup>[48]</sup> control of photoisomerization in solutions,<sup>[49]</sup> control of the ground-state vibrational dynamics via a Raman process is demonstrated in polydiacetylene,<sup>[50]</sup> control in biological systems,<sup>[51,52]</sup> quantum control of energy flow in light harvesting systems,<sup>[53]</sup> control of ionization processes in aligned  $I_2$  molecule by optimally polarized femtosecond pulses,<sup>[54]</sup> local field enhancement of electron emission from nanoparticles,<sup>[55]</sup> optical control of ground-state atomic orbital alignment in the chlorine atom for orientation-dependent collision studies,<sup>[56]</sup> control of the population transfer in complex solvated molecules,<sup>[57]</sup> weak-field coherent control of retinal isomerization in bacteriorhodopsin,<sup>[58]</sup> control of electronic energy redistribution pathways in molecules by coupling of molecular electronic states with tunable surface plasmon resonances,<sup>[59]</sup> just to name a few.

This entry is not an exhaustive and detailed overview of the field of laser-controlled chemistry and physics but aims to give basic insight into this exciting and rapidly developing area. We will explain the fundamentals of optical control using ultrashort laser pulses, followed by a discussion of the applied

optimal control scenario. We will then explore various schemes to manipulate photoinduced molecular dynamics, and show several examples. This entry presents selected results of the research performed at the Freie Universität Berlin on the control of light-induced processes by employing optimally shaped laser pulses on systems with well-known dynamics from time-resolved pump&probe experiments and from theoretical calculations. The systems and processes addressed are different in many aspects, but there is a common line unifying them throughout this work, namely the particle size, which determines their basic chemical and photophysical properties. The change in the cluster size gives rise to a large variety of ultrafast photoinduced processes like bound–bound transitions, dissociation, and predissociation. The coupling of various electronic states and excitation of different vibrational modes can lead to extensive structural rearrangements and, thus, create substantial changes in chemical reactivity by means of passages through conical intersections<sup>[60–63]</sup> or as an effect of internal vibrational redistribution.<sup>[64–67]</sup> By the proper choice of the size and composition of the molecular system, the type and number of photoinduced processes evolving from rather different pathways and leaking into different product channels can be systematically varied. The time-evolution of the photoexcited system can be monitored in real time by using ultrafast

**Fig. 2** Schematic of the experimental setup consisting of a molecular beam machine, laser systems, and laser pulse characterization equipment.

spectroscopy (Fig. 1). Moreover, the molecular dynamics can be manipulated as well when employing a control experiment searching for an optimally shaped laser pulse, which navigates the evolution of the molecular system on the involved potential energy surface(s) towards the desired product channel. The most important output of the optimization experiments is the very rich information content coded in the obtained pulse shapes. In a joint effort with theoretical calculations and pump&probe experiments, system-specific information about the involved electronic states and reaction pathways can be withdrawn.

Metal clusters are excellent model systems for time-resolved investigations and control scenarios: They exhibit pronounced absorption bands, which are located within the tuning range of the commercially available femtosecond laser sources; their photoionization energies are also well within their reach, and the vibrational frequencies can well be resolved in the time domain with the available sub-100 fs pulses. Further, the influence of internal vibrational redistribution

processes, which depend on the amount of internal degrees of freedom, can simply be adapted to the experimental requirements by the right choice of cluster size and its temperature. For this reason, we have first performed extensive systematic pump&probe experiments on alkaline dimers, trimers, etc. to study the evolution of wavepacket dynamics, vibronic coupling, geometrical rearrangement, fragmentation, etc., as a function of cluster size and excitation energy. Later, we extended our investigations to more complex systems, including organometallic molecules.

## EXPERIMENTAL

The experimental setup (Fig. 2), consisting of molecular beam apparatus, has been described in details elsewhere<sup>[68]</sup> and only its brief description is given here. The beam of clusters or molecules is generated in the first vacuum chamber, by an adiabatic coexpansion of a carrier gas and alkali metal vapor or sublimated molecular substances from a heated oven through a 70–100  $\mu\text{m}$  nozzle into vacuum. The emerging beam is collimated by using a skimmer of 1 mm orifice, which enters into the second differentially pumped vacuum chamber. There, the beam passes between the electrical lenses of a quadrupole mass spectrometer (Pfeiffer Balzers QMG 420). The lenses of the quadrupole are oriented perpendicularly to both the molecular beam and the laser beam(s) to extract the produced photoions for mass analysis.

The femtosecond laser pulses covering the ultraviolet, visible, and infrared wavelength regions were generated by using four different laser setups. In the  $\text{Na}_3$  experiments, a Ti:Sa-OPO laser system (Spectra Physics Tsunami 3960 and OPO, pumped by a 15 W argon ion laser) was used, which produced 100–120 fs laser pulses centered at 620 nm after frequency doubling. In the NaK/Na<sub>2</sub>K experiments, a Nd:YLF laser pumped Ti:Sa laser was used (Spectra Physics Millennia X and Tsunami 3960), which produced pulses of about 80 fs duration at a central wavelength of 770 nm. In the experiments on  $\text{CpMn}(\text{CO})_3$ , two Ti:Sa amplifier systems were used. The first consisted of a Ti:Sa Spectra Physics Tsunami seed laser, which was pumped by a Nd:YLF Millennia V laser and produced 70 fs seed pulses at 800 nm central wavelength for a Quantronix multi-pass regenerative amplifier. The amplifier produced 87 fs pulses of up to 1.5 mJ pulse energy at a repetition rate of 1 kHz. The second Ti:Sa amplifier system consisted of a Kapteyn–Murnane oscillator, which was pumped by a 5 W Coherent Verdi laser and produced sub-40 fs seed pulses for the multi-pass amplifier (Quantronix Odin). This amplifier produced sub-40 fs pulses at the central wavelength of 805 nm and repetition rate of 1 kHz.

**Fig. 3** Scheme of the experimental setup for generating linearly chirped pulses. The transform limited input pulse passes through the grating pair. On the output, the shorter wavelength spectral components of the pulse are followed by the longer spectral components. The relative time shift of the spectral components and the related duration of the generated pulse can be tuned by changing the separation between the gratings. The insert shows the intensity and wavelength/frequency profile of a typical output pulse as a function of time.

In the control experiments on the sodium trimer, the pulses were shaped with a grating pair with manually adjustable separation between the two gratings, generating linearly chirped laser pulses. When an unchirped input pulse of 120 fs duration with a central wavelength of 620 nm was employed, chirped pulses of 200 fs to 2000 fs duration could be routinely generated (Fig. 3).

For an effective control of multi-photon driven processes, rather complex pulse forms are needed. Such pulse forms were generated by applying voltages to the individual pixels of a liquid crystal spatial light modulator,<sup>[69]</sup> allowing phase and amplitude modulation. We used a double-mask modulator of Cambridge Research Instruments with  $2 \times 128$  pixels positioned between two gratings and two lenses in a 4f arrangement (Fig. 4).<sup>[70]</sup> By computer control, arbitrary pulse forms, such as linearly chirped pulses or pulse trains can be generated, as illustrated in the inserts of Fig. 4. However, the design of such large sets of arbitrary tailored pulses is not straightforward for applications on real molecular systems when pulse forms cannot be predicted by theory or when detailed experimental knowledge of the involved electronic states and the underlying dynamics is not available. In such cases, the optimal pulse shape, which will navigate the molecular system into the desired product channel, can be found in a self-learning closed-loop experiment consisting of a laser, pulse shaper, detector of reaction products and a computer executing an iterative optimization algorithm.<sup>[37]</sup> In the experiments described here, the modulated pulse is focused on the molecular beam and the desired product ion current is monitored on a mass spectrometer and is taken as reference feedback signal for the optimization algorithm. The algorithm, which is based on evolutionary strategies, iteratively

alters the settings on the pulse-shaper until the maximum yield of the selected product ions is achieved. The closed-loop experiment is shown schematically in Fig. 5.

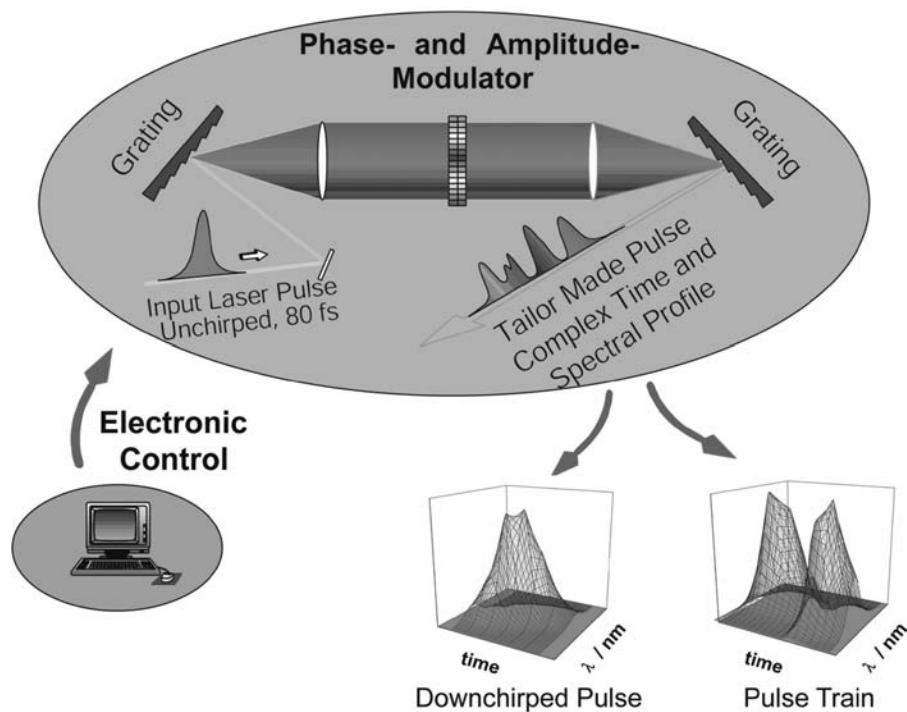

The laser pulses were characterized in both time and wavelength domain by using a Jobin–Yvon monochromator, Spectra Physics autocorrelators for Ti:Sa oscillators, autocorrelator for OPO built by Harald Ruppe,<sup>[71]</sup> single-shot autocorrelator for sub-40 fs pulse characterization constructed by Marcel Krenz,<sup>[72]</sup> second harmonic generation frequency-resolved optical gating (SHG-FROG, Polytec Femtos) and time- and wavelength-resolved sum-frequency cross-correlation (SFG-CC) built by Patrick Wetzel.<sup>[73]</sup>

## RESULTS AND DISCUSSION

### Homogeneous Clusters: Bound–Bound Transitions in $\text{Na}_3$

The time-resolved spectrum of the sodium trimer reflects the vibrations in its bound B-state when excited with a femtosecond pulse with a central wavelength of 620 nm (Fig. 6). In this experiment, a wavepacket in the B-state is populated via one-photon excitation (pump) and the time evolution of the excited state is monitored by one-photon ionization (probe). The observed vibration period of 320 fs is in excellent agreement with the data previously reported in the literature.<sup>[74,75]</sup> Gerber and coworkers<sup>[76]</sup> used amplified laser pulses to study the dynamics in  $\text{Na}_3$  and, in addition to the  $\text{Na}_3$  B-state dynamics, they resolved an additional vibrational component in their pump&probe spectra, which reflected the propagation of the wavepacket in the ground state of  $\text{Na}_3$  as well.

## Laser Pulse Modulation

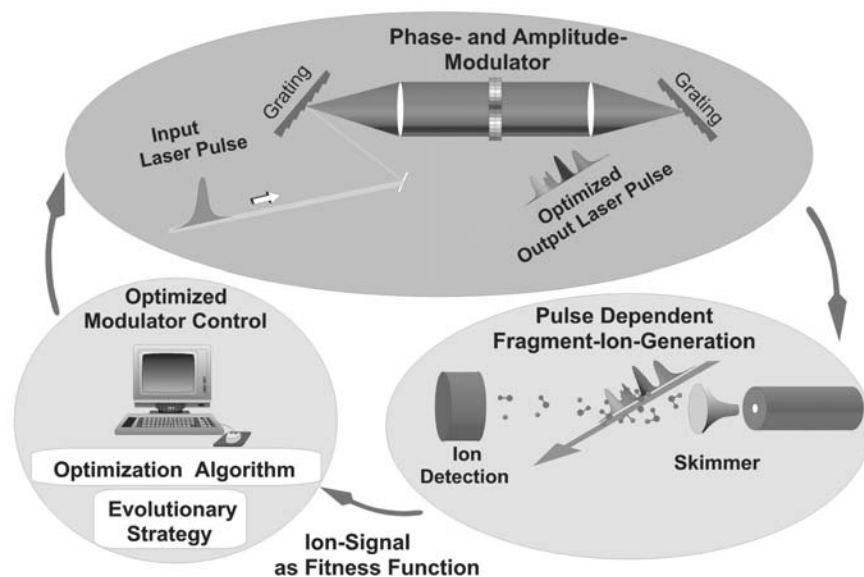

**Fig. 4** Scheme of the setup for generation of phase- and amplitude-modulated pulses. The description of the setup is given in the main text. Shown are two tailor-made pulse forms generated from a 120 fs laser pulse ( $\lambda = 620$  nm) and characterized by time and spectrally resolved cross-correlation technique employing an 80 fs reference pulse ( $\lambda_{\text{ref}} = 775$  nm): a linearly chirped pulse of 300 fs duration and a double-pulse (pulse train).

To achieve control of population of different bound electronic states of the sodium trimer ( $\text{Na}_3\text{-B}$  and  $\text{Na}_3\text{-X}$ ), a series of experiments employing linearly chirped pump&control pulses and an unchirped 120 fs probe pulse was performed. The chirped pulses were characterized by employing SFG-CC using an unchirped 80 fs laser pulse with a central wavelength of 775 nm as reference pulse. When applying down-chirped pulses of

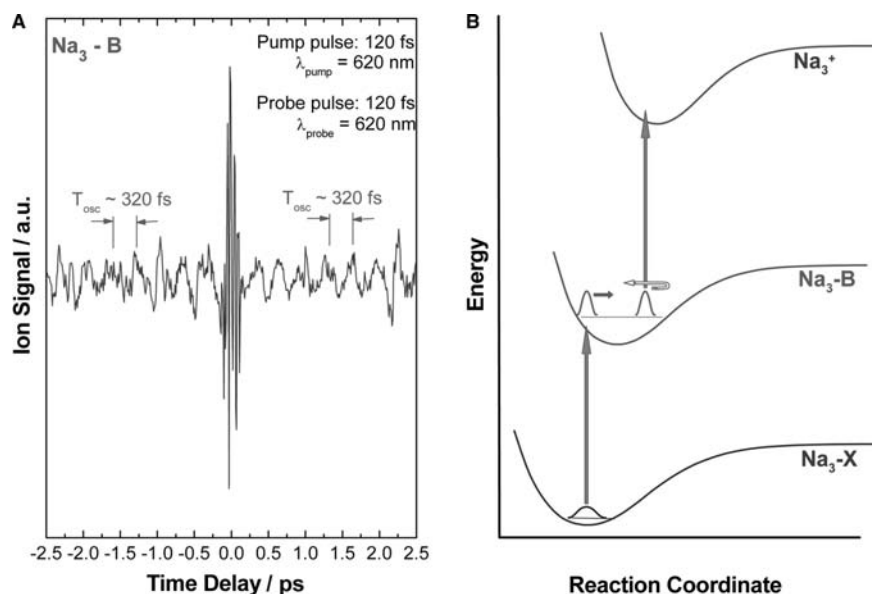

up to 350 fs duration (FWHM, full width at half maximum), the feature of the transient  $\text{Na}_3^+$  signal remained unchanged—reflecting the 320 fs vibration period of the B-state. However, the pump&probe signal changed dramatically when a down-chirped pump&control pulse of 400 fs duration was employed: the period of the oscillatory signal changed abruptly to 230 fs with the pump&control pulse arriving first

## Control of the Fragmentation of Small Clusters & Molecules

**Fig. 5** Schematic cartoon of the self-learning optimization setup searching for optimal pulse shape, which produces the highest ion yield of the desired ionic product in a multi-step multi-photon process. The description of the setup is given in the main text. *Source:* Reprinted with permission from Ref.<sup>[42]</sup>.

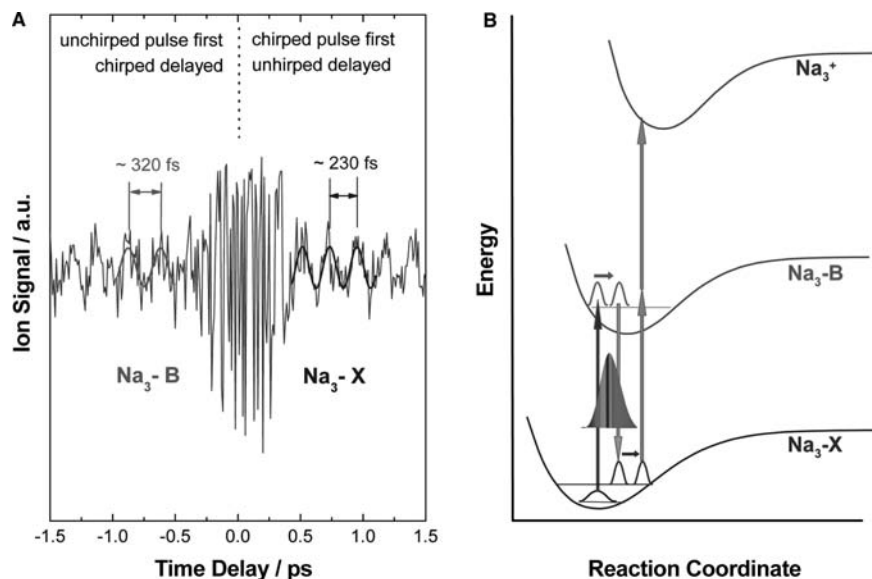

**Fig. 6** Transient two-photon ionization spectrum of  $\text{Na}_3$  recorded with transform-limited 120 fs pulses with a central wavelength of 620 nm (A). The progression exhibits oscillations with a period of 320 fs reflecting the symmetric stretch mode of the electronically excited B-state ( $\text{Na}_3\text{-B}$ ). (B) Illustrates the involved one-photon pump, one-photon probe scheme. Part (A) is compiled with permission from Ref.<sup>[42]</sup>.

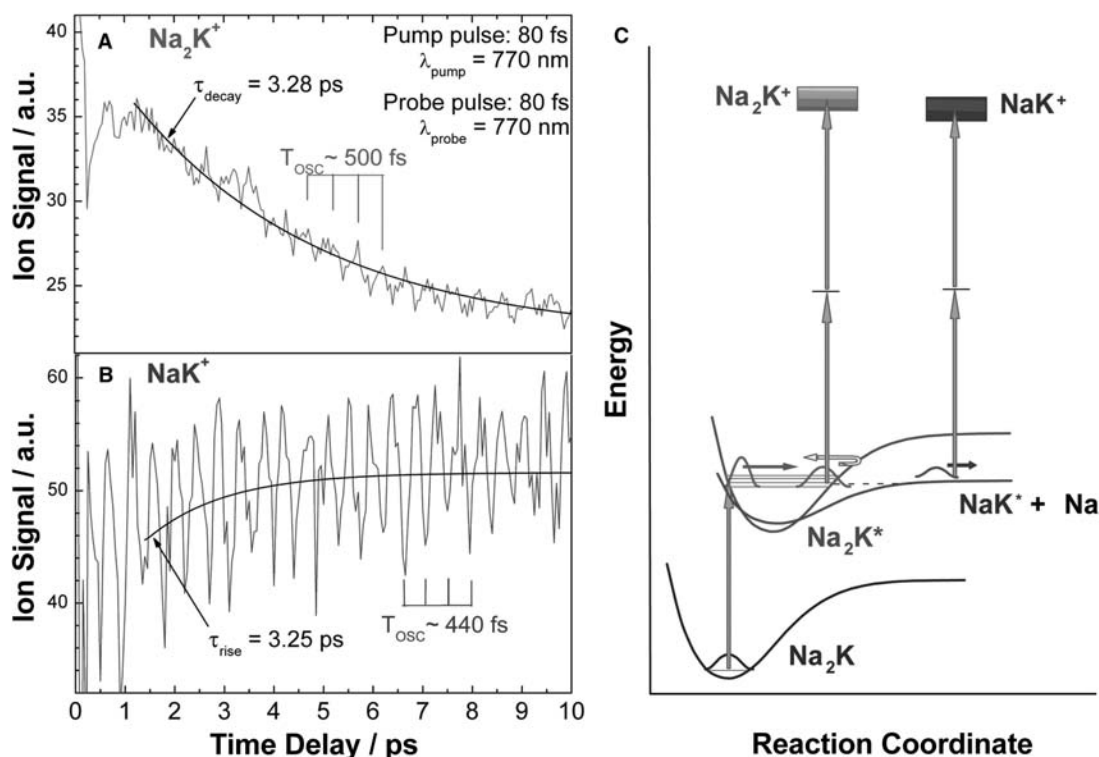

(Fig. 7A). This vibrational period reflects the propagation of the wavepacket created in the ground state of  $\text{Na}_3$ . The action of the pump&control pulse is illustrated in Fig. 7B: the initial shorter wavelength components of this pulse first create a wavepacket in the electronically excited B-state of  $\text{Na}_3$ . Then, the evolving wavepacket is transferred into the vibrationally excited, electronic ground state of the trimer (X-state) by the following longer wavelength components of the same pulse. The vibrational dynamics of the ground state is then monitored by two-photon ionization with the unchirped probe pulse. At negative delay times (when the unchirped pulse precedes the chirped pulse), the transient signal still reflects the vibrations in the B-state, thus providing a direct proof of the suggested control scheme.

### Heterogeneous Dimers and Trimers: Bound NaK and Photofragmenting $\text{Na}_2\text{K}$

The vibration dynamics of the electronically excited NaK dimer has been described in detail in several studies,<sup>[77,78]</sup> revealing the 440 fs vibration period of the  $A(2) \ ^1\Sigma^+$  state.<sup>[79]</sup> Pump&probe experiments performed on  $\text{Na}_n\text{K}_m$  ( $n = 0\text{--}2$ ,  $m = 1\text{--}3$ ,  $n + m = 3$ ) trimers with variable laser wavelength in the 730–840 nm region<sup>[80]</sup> revealed strongly wavelength-dependent fragmentation times, as well as NaK fragments emerging from  $\text{Na}_2\text{K}$  on excitation. When employing laser pulses with a central wavelength of 770 nm (Fig. 8), not only the decay time of the fragmenting  $\text{Na}_2\text{K}^*$  trimer and its vibration dynamics

**Fig. 7** (A) Pump&probe spectrum of  $\text{Na}_3$  obtained under identical experimental conditions, as in Fig. 6 with the only exception that the employed pump pulse was a linearly down-chirped 400 fs one. The resulting oscillation time of 230 fs corresponds to the symmetric stretch vibration of the electronic ground state of  $\text{Na}_3$  ( $\text{Na}_3\text{-X}$ ). (B) Schematic of the pump-control-probe scheme. Source: Compiled with permission from Ref.<sup>[42]</sup>.

**Fig. 8** Temporal evolution of a transient three-photon ionization signal of the decaying  $\text{Na}_2\text{K}$  (A) and its fragment  $\text{NaK}$  (B). The decay time of the fragmenting trimer matches well with the rise time of its diatomic fragment. The superposed oscillations indicate wavepacket oscillations in the coherently excited system. (C) Shows the schematic view of the investigated three-photon fragmentation and ionization process. *Source:* Figure (A) and (B) compiled with permission from Ref.<sup>[42]</sup>.

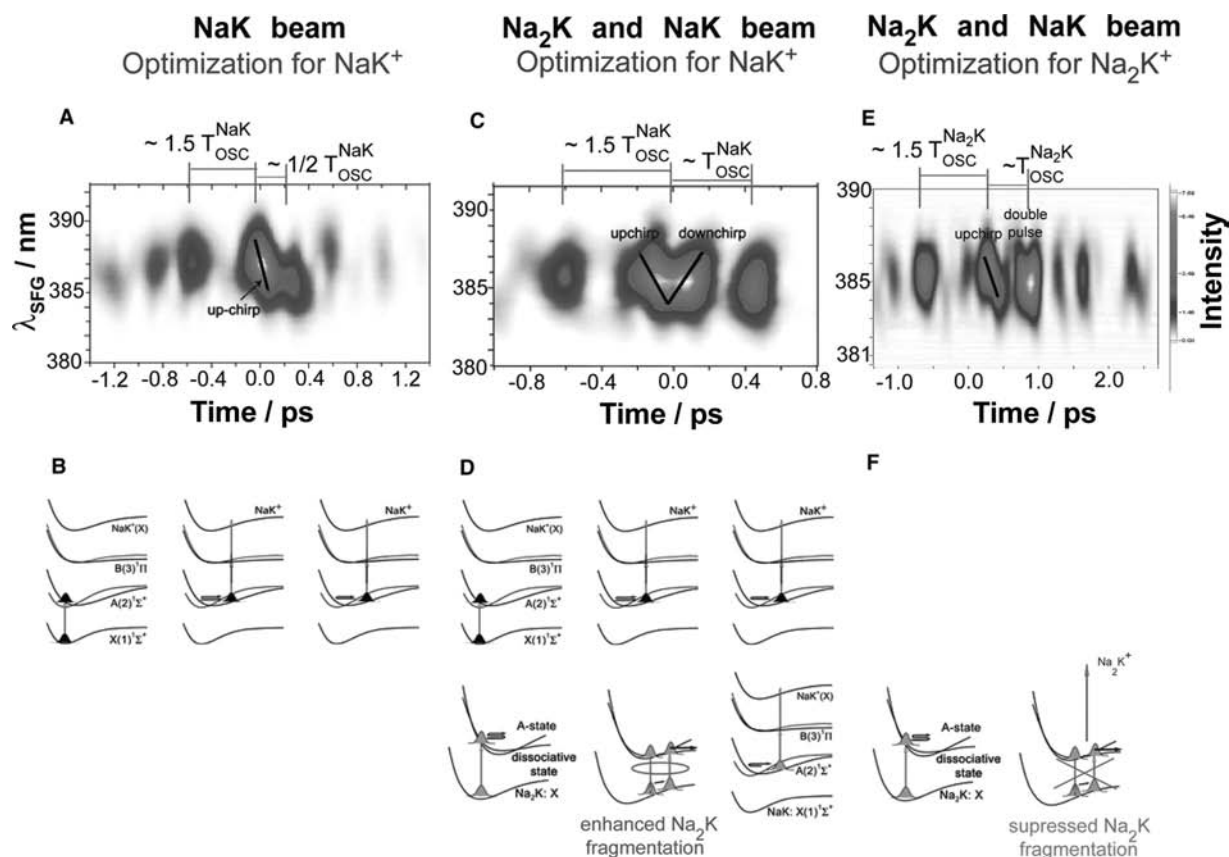

with a vibration period of 500 fs could be clearly resolved, but also the identical rise time of the emerging  $\text{NaK}$  fragment exhibiting the distinct vibrational dynamics of the  $\text{NaK}$  dimer. Most importantly, these experiments helped to identify the first suitable candidates for coherent control experiments, namely the fragmenting  $\text{Na}_2\text{K}$  trimer and its fragment dimer  $\text{NaK}$ ; the dynamics of both species observable with the scheme experimental scheme involving one-photon excitation and two-photon ionization at identical laser wavelength.

The results of three optimal control experiments on the  $\text{NaK}/\text{Na}_2\text{K}$  system will be presented in this section, namely the optimization for the maximum yield of  $\text{NaK}^+$  in a cluster beam without trimers and larger aggregates (aimed to optimize the excitation and ionization step in  $\text{NaK}$  only); for the maximum yield of  $\text{NaK}^+$  in the presence of  $\text{Na}_2\text{K}$  and  $\text{NaK}$  in the cluster beam (with the goal to enhance fragmentation of  $\text{Na}_2\text{K}$ ); and optimization for the maximum ion yield of  $\text{Na}_2\text{K}^+$  (with the goal to suppress fragmentation). The focus will be on the interpretation of the optimal pulse shapes with regard to the controlled molecular dynamics.

The optimal pulse producing the highest  $\text{NaK}^+$  yield via optimization of the excitation and ionization

step is shown in Fig. 9A. The enhancement of the ion yield with respect to an unchirped 80 fs pulse of the same energy was about 60%.<sup>[81]</sup> The optimal pulse consists of three subpulses, with time separations  $\sim 650$  fs ( $\sim 1.5 T_{\text{OSC}}^{\text{NaK}}$ ) and  $\sim 220$  fs ( $\sim 0.5 T_{\text{OSC}}^{\text{NaK}}$ ). The explanation of this optimal pulse form can be given based on known transient behavior of the  $\text{NaK}$  dimer.<sup>[78,82]</sup> The first subpulse act as a probe pulse in a one-photon transition and prepares a wavepacket in the  $A(2) \ ^1\Sigma^+$  state (see Fig. 9B). The generated wavepacket evolves and as it reaches the optimal Franck–Condon window for ionization at the outer turning point on the potential surface, it will be ionized with the second subpulse.<sup>[81,83,84]</sup> The high intensity of the second subpulse reflects the two-photon ionization step. The third subpulse serves as an additional ionization pulse via resonant ionization involving most probably the  $B(3) \ ^1\Pi$  state. The up-chirp superimposed on the second subpulse can be understood as it provides a compensation for a defocused wavepacket.

The pulse form producing the highest yield of  $\text{NaK}^+$  in the presence of  $\text{Na}_2\text{K}$  is depicted in Fig. 9C. The increase in the ion yield was about 80% in comparison with the ion yield achieved by a single unchirped 80 fs pulse of the same energy, thus to a

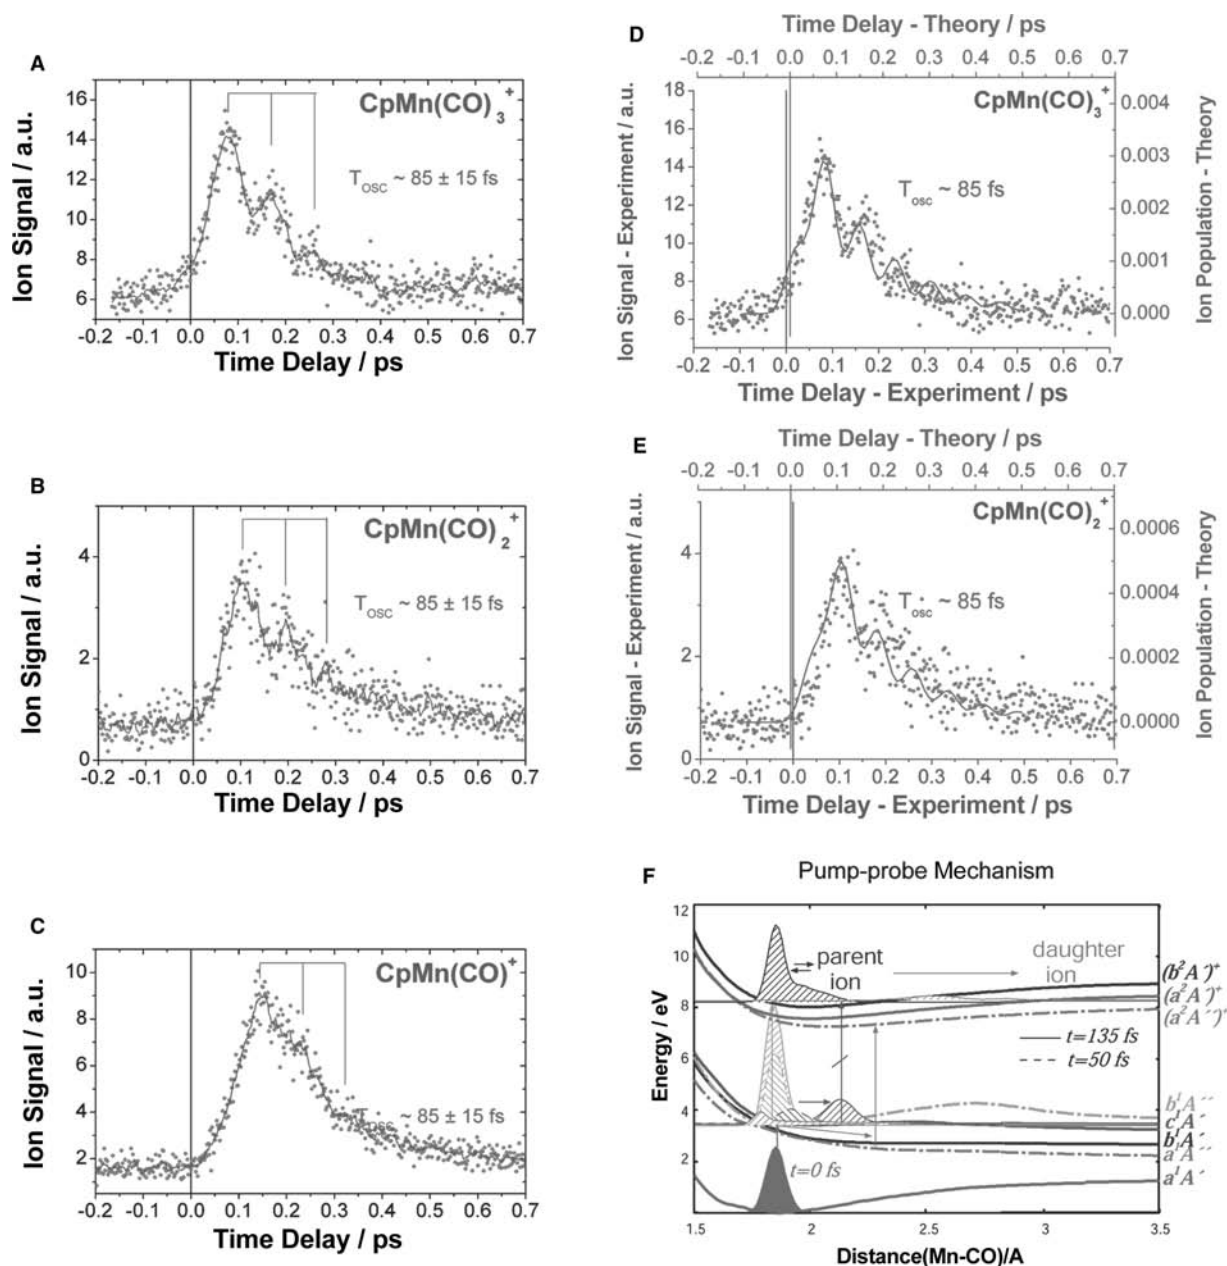

**Fig. 9** SFG-CC traces of the acquired optimal pulse shapes and cartoons of the involved processes for producing maximum yield of NaK<sup>+</sup> in a pure excitation and ionization optimization experiment of the NaK dimer (A, B); maximum ion yield of NaK<sup>+</sup> in the presence of the fragmenting Na<sub>2</sub>K<sup>+</sup> trimer (C, D) maximum ion yield of Na<sub>2</sub>K<sup>+</sup> (E, F). *Source:* Compiled by permissions from Refs.<sup>[25,36]</sup>

20% higher value than in the case of pure NaK ionization.<sup>[47,83]</sup> The optimal pulse shape consists again of three subpulses. The scheme of the control mechanism is shown in Fig. 9D, and first we will focus on the enhancement of the Na<sub>2</sub>K fragmentation by the optimal pulse. The time delay between the first and second subpulse ( $\sim 660$  fs) is the same as in the NaK ionization experiment; however, its structure is different, showing a double-pulse with the opposite chirp superimposed. In this experiment, the first subpulse prepares a propagating wavepacket in the excited trimer. The role of the second up- and then down-chirped subpulse can be explained in the following way. The frontal red-shifted part of the central subpulse stimulates the propagating wavepacket down to the ground state of the trimer, similar to the Na<sub>3</sub> case. The wavepacket continues to move in the same direction in the vibrationally excited electronic ground. The trailing part of the central subpulse then lifts this wavepacket onto the dissociative state leading to NaK\*. In other words, the central pulse navigates the evolving wavepacket into a dissociative channel while avoiding the bottleneck of the conical intersection. Finally, the third subpulse ionizes the

emerging NaK fragments. The excitation and ionization mechanism for NaK dimers already present in the molecular beam can be explained as follows. The first subpulse prepares a wavepacket in the excited state of NaK; the central part of the second subpulse ionizes the NaK\* after 660 fs ( $\sim 1.5 T_{\text{OSC}}^{\text{NaK}}$ ) and the third pulse improves the ionization efficiency after 440 fs ( $\sim 1 T_{\text{OSC}}^{\text{NaK}}$ ). In summary, the 20% rise in the NaK<sup>+</sup> yield when compared with the pure NaK ionization corresponds to NaK<sup>+</sup> gain through enhanced fragmentation of the parent Na<sub>2</sub>K trimer.

The optimal pulse generating the highest yield of Na<sub>2</sub>K<sup>+</sup> is plotted in Fig. 9E and it produced  $\sim 150\%$  increase in the Na<sub>2</sub>K<sup>+</sup> yield when compared with the ion yield gained by an unchirped 80 fs pulse of the same energy.<sup>[47,83]</sup> The timing between the subpulses matches exactly the “internal vibrational clock”—the vibrational period of the excited trimer. The individual subpulses exhibit different wavelengths and chirp structure again: the first two subpulses are red-shifted with respect to the third pulse. The short and unchirped (excitation) subpulse is followed by the second intense up-chirped subpulse arriving after

**Fig. 10** Pump&probe trace of CpMn(CO)<sub>3</sub><sup>+</sup> (A) and its fragment ions CpMn(CO)<sub>2</sub><sup>+</sup> (B) and CpMn(CO)<sup>+</sup> (C). Oscillations in the parent molecule signal with a period of ca. 85 fs and the fingerprints of these oscillations in the daughter ion signals are indicated in the plots. The employed wavelengths were 402.5 nm (pump) and 805 nm (probe). Experimental (dots) and theoretical (solid line) femtosecond pump&probe transient spectra for CpMn(CO)<sub>3</sub><sup>+</sup> (D) and for the fragment, CpMn(CO)<sub>2</sub><sup>+</sup> (E). $\sim 750$  fs ( $\sim 1.5 T_{OSC}^{Na_2K}$ ) delay, which ionizes Na<sub>2</sub>K\* via two photons. The third subpulse delayed by additional 500 fs ( $\sim 1 T_{OSC}^{Na_2K}$ ) ionizes the remaining fraction of excited trimers. In this experiment, the second subpulse suppresses the leakage of the wavepacket into the repulsive state of the excited trimer, which leads to a considerable increase in the final Na<sub>2</sub>K<sup>+</sup> yield. Similar ion yield was achieved by a double-pulse sequence as well, with pulse separation of  $1.5 T_{OSC}^{Na_2K}$ <sup>[70]</sup>.

### Organometallic Molecules: Controlled Photolysis of CpMn(CO)<sub>3</sub>

The ultrafast photoinduced fragmentation dynamics of CpMn(CO)<sub>3</sub> was studied in detail in a two-color experiment by employing a 45 fs pump and 35 fs probe pulse with laser wavelengths centered at 402.5 nm and 805 nm, respectively.<sup>[85]</sup> The molecule is first excited by the pump pulse in a one-photon transition, followed

by a delayed probe pulse, which ionizes  $\text{CpMn}(\text{CO})_3^*$  by three photons. The transient spectra of the mother ion  $\text{CpMn}(\text{CO})_3^+$  and its fragments  $\text{CpMn}(\text{CO})_2^+$  and  $\text{CpMn}(\text{CO})^+$  are shown in Fig. 10A–C, respectively. Oscillations with a period of ca. 85 fs are superimposed on the ultrafast decay of the parent ion signal (Fig. 10A). The transients of the emerging fragment ions carry the fingerprints of the parent molecule vibrations as well (Fig. 10B and C). Theoretical studies on these systems were performed by Manz et al.<sup>[86]</sup> These results lead to the  $\text{CpMn}(\text{CO})_3^+$  and  $\text{CpMn}(\text{CO})_2^+$  transients, which are plotted in Fig. 10D and E together with the corresponding experimental pump&probe spectra; both curves show an excellent agreement. The underlying dynamics can be explained by the simultaneous population of two excited states  $b^1A''$  and  $c^1A'$  during the pump step (Fig. 10F). The wavepacket in the  $b^1A''$  state oscillates with an 80 fs period. A fraction of the oscillating wavepacket in the  $b^1A''$  state leaks non-adiabatically into the  $a^1A''$  state every time it passes the point of near-coincidence of the  $b^1A''$  and  $a^1A'$  potential energy surfaces. Both parent and daughter fragments can be probed with the same ionization pulse. In the pump&probe experiment, the wavepacket in the  $c^1A'$  state does not contribute to the ion signal because of off-resonant probe wavelength. (Note: The vibrational dynamics could not be resolved in the first experiments when laser pulses of about 90 fs duration were employed.<sup>[87–89]</sup> The deciphering of the high-resolution pump&probe traces made the detailed understanding of the results of the previous control experiments employed<sup>[87–89]</sup> on  $\text{CpMn}(\text{CO})_3$  with optimized laser fields possible as well.<sup>[86]</sup> First, the optimization experiments will be described, followed by the interpretation of the optimal pulse forms producing the highest ion yield.

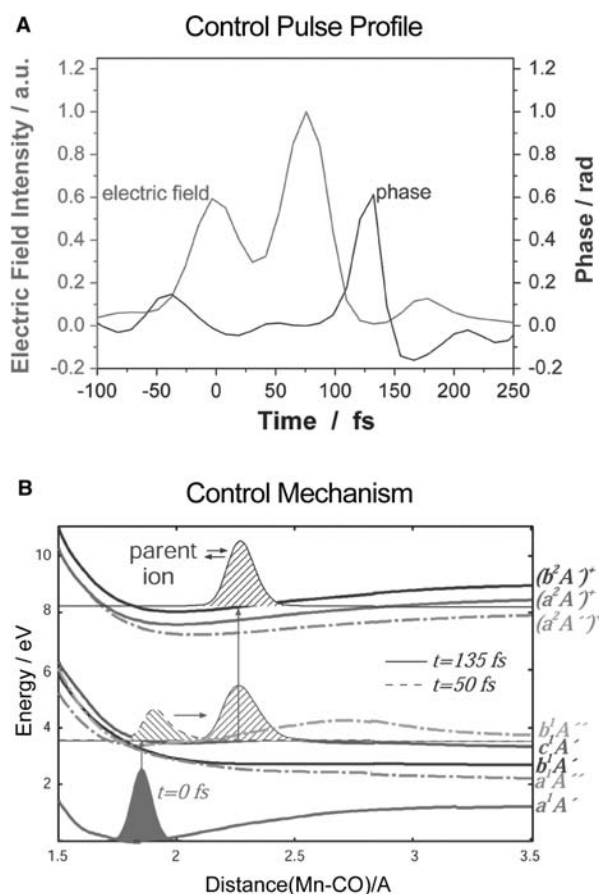

In the optimization experiments, an 80 fs laser pulse centered at a wavelength of 800 nm passed through the optimization cycle with the goal to maximize the ion yield of the parent ion  $\text{CpMn}(\text{CO})_3^+$  or the yield of the daughter ion  $\text{CpMn}(\text{CO})^+$ . The relative ion yield  $\text{CpMn}(\text{CO})_3^+ : \text{CpMn}(\text{CO})^+$  gained by employing an 80 fs unchirped pulse was 1 : 13 as determined from the mass spectrum of the ionic products. The optimization for the maximum  $\text{CpMn}(\text{CO})_3^+$  or  $\text{CpMn}(\text{CO})^+$  yield led to 1 : 16 and 1 : 6 product ratios, respectively, to a significant increase in the desired product ion yield. The SHG-FROG traces of the optimal pulses are shown in Fig. 11A and C, the time profiles of the corresponding pulse shapes retrieved from FROG analysis are depicted in Fig. 11B and D. The pulse sequence that produced the highest  $\text{CpMn}(\text{CO})_3^+ : \text{CpMn}(\text{CO})^+$  product ratio consists of three subpulses of 36–40 fs duration shifted by 70–100 fs. The effective duration of the two dominant pulses is about 100 fs, reflecting a prompt ionization after ionization, which

**Fig. 11** SHG-FROG traces of the optimized pulses acquired from the feedback optimization experiment for  $\text{CpMn}(\text{CO})_3^+$  (A) and the  $\text{CpMn}(\text{CO})^+$  (C). Optimized pulse shapes resulting from the analysis of the FROG traces shown in (A) and (C) for the maximum yield of  $\text{CpMn}(\text{CO})_3^+$  (B) and the  $\text{CpMn}(\text{CO})^+$  (D), respectively. Source: Compiled with permission from Ref.<sup>[42]</sup>.

prevents excessive fragmentation of the excited parent molecule. Moreover, the two-photon excitation and three-photon ionization is reflected in the relative intensities of the first two subpulses. The double-pulse producing the highest  $\text{CpMn}(\text{CO})^+ : \text{CpMn}(\text{CO})_3^+$  consists of longer pulses of 60–70 fs duration shifted by 80 fs. The effective duration of the double pulse is about 150 fs, which reflects the time-window of the maximal  $\text{CpMn}(\text{CO})^*$  population—the time needed for the excited parent molecule to lose two CO ligands. But, is it only the timing and duration of the subpulses that determine the outcome of the controlled reaction? Theoretical investigations show that in the case of  $\text{CpMn}(\text{CO})_3^+$ , the phase change between the two subpulses causing a blue shift (Fig. 12A) plays a decisive role.<sup>[86]</sup> The first subpulse has to increase the  $\text{CpMn}(\text{CO})_3^+$  signal, and the solution is demonstrated in Fig. 12B.<sup>[86]</sup> To maximize the  $\text{CpMn}(\text{CO})_3^+$  product formation, the first subpulse must avoid the population of the predissociative  $b^1A''$  state, which would at the end lead to the production of both parent and

**Fig. 12** Intensity and phase profiles of the optimal pulse that maximizes the ion yield of  $\text{CpMn}(\text{CO})_3^+$  (A). The pathway selected by the optimal control field (B). Detailed description is given in the main text. *Source:* Compiled by permission from Ref.<sup>[40]</sup>, Science, AAAS.

daughter ions during ionization by the second pulse. Instead, the first subpulse should preferentially populate the bound  $c^1A'$  state, which lies slightly above the predissociative  $b^1A''$  state. This is achieved by the wavelength components of the first subpulse centered at 798.7 nm. The second subpulse (800.09 nm) can readily transfer the population of the neutral  $c^1A'$  into the parent ion. In addition to pure ionization, the second subpulse can excite a fraction of molecules into the neutral  $c^1A'$  state as well, which will be ionized by the third subpulse (801.12 nm).

Follow-up studies on sodium–potassium clusters clearly showed that even in the case of the smallest particles consisting of two or three atoms only, because of the large number of electronic states, there are various pathways (thus various pulse forms), which can lead to comparable product yields. The optimal pulse shapes were dominantly consisting of a sequence of subpulses variably delayed with respect to the first subpulse, possessing various peak intensities, time duration, and central wavelength, as well as chirp superimposed

to them. Thus, several ways opened in simplifying the search process for the optimum pulse shape by, for example, limiting the search for pulse sequences consisting of subpulses with equidistant time separation.<sup>[90]</sup> The optimization results obtained with such periodic pulse structures—pulse trains—lead to comparable product yields as in the case of fully optimized pulses; however, now at considerably faster convergence.<sup>[81,91]</sup> An additional chirp superimposed on the pulse trains could lead to further improved product yields.<sup>[81,92]</sup> As shown earlier, in the case of the sodium–potassium aggregates, the interpretation of the obtained optimal pulse shapes was often possible in terms of the molecular dynamics known from pump&probe experiments and theoretical calculations.<sup>[79]</sup> The robustness of the optimization algorithm was demonstrated in the case of mixtures containing  $\text{Na}_m\text{K}_n$  of various particle compositions, when highly complex non-intuitive pulse forms were needed to maximize the yield of the desired photodissociation products.<sup>[83,93]</sup>

The high fidelity of the feedback pulse optimization was illustrated on the isotope selective fragmentation of  $^{39,39}\text{K}_2$  vs.  $^{39,41}\text{K}_2$ ,<sup>[94]</sup> isotope selective separation of  $\text{NaK}$  ( $^{23}\text{Na}^{39}\text{K}$  vs.  $^{23}\text{Na}^{41}\text{K}$ ),<sup>[95,96]</sup> and isotopomer-selective ionization in  $^{124}\text{KRb}/^{126}\text{KRb}$ .<sup>[97]</sup>

Several optimization experiments led to comparable ionic yields even with non-intuitive pulse forms, underlining the role of the phase and increasing demand for detailed theoretical calculations.<sup>[82,98,99]</sup> The obtained control pulses are very rich in information in the time and wavelength domain; they reflect the wavepacket propagation or transient consecutive propagation of states during a multi-step process, as well as the cross-sections of the multi-photon processes.

## CONCLUSION

The results summarized in this entry demonstrate the capability of a feedback optimization loop to actively control the branching between different pathways of the involved photoinduced processes. By employing an evolutionary algorithm for tailoring the applied laser field in the amplitude and phase domain, the yield of the desired products could be controlled with very high selectivity, thus opening new ways of controlling bond-specific chemistry at the nanoscale.

## ACKNOWLEDGMENTS

The authors thank Prof. Herschel Rabitz, Dr. Werner Fuß, and Dr. Sergei Trushin for stimulating discussions, Prof. Thomas Feurer and Prof. Thomas Leisner

for their assistance and advises in the early stages of setting up the pulse shaper experiments. The continuous theoretical support of Prof. Vlasta Bonačić-Koutecký and her group members, Dr. Michael Hartmann, Dr. Roland Mitrić, Dr. Jiří Pittner, and Boris Schäfer-Bung, as well as the cooperation with Dr. Chantal Daniel, Prof. Jörn Manz, and his coworkers, Dr. Leticia González, Dr. Jürgen Full, and Dr. Marcus Oppel, is greatly appreciated. This work would not have been accomplished without the enthusiasm of the post-docs, graduate, and undergraduate students involved in the experiments: Dr. Andreas Bartelt, Dr. Porfirio Rosendo-Francisco, Dr. Cosmin Lupulescu, Dr. Albrecht Lindinger, Dr. Shinichirou Minemoto, Dr. Sören Rutz, Bernd Baptist, Filip Budzyn, Jens Heufelder, Cristina Kaposta, Marcel Krenz, Andrea Merli, Harald Ruppe, and Patrick Wetzel. The financial support of this work by the Deutsche Forschungsgemeinschaft within the Sonderforschungsbereich 450 project is gratefully acknowledged.

Gainesville, Florida, U.S.A.*

## INTRODUCTION

Nanoscience is one of the most important research and development frontiers in modern science.<sup>[1]</sup> Nano is a Greek word meaning dwarf, and the nanometer (nm,  $10^{-9}$  m) defines the length scale that is used to measure systems being studied in nanoscience. In the most simplistic sense, nanoscience is the science of small particles of materials. Such small particles are of interest from a fundamental viewpoint because all properties of a material (e.g., melting point, electronic properties, and optical properties) change when the size of the particles that make up the material becomes nanoscopic. With new properties comes new opportunities for technological and commercial development, and the applications of nanoparticles have been demonstrated or proposed in areas as diverse as microelectronics, coatings and paints, and biotechnology.

For example, one application that is currently in the commercial marketplace entails using gold nanoparticles as visual indicators in over-the-counter medical diagnostic kits.<sup>[2]</sup> This application illustrates nicely how the unique properties of a nanoparticle can lead to technological opportunities. Macroscopic samples of pure gold have only one color—gold—but nanoparticles of gold can show essentially all the colors of the rainbow, depending on the size and the shape of the nanoparticle.<sup>[3]</sup> Furthermore, the intensity of the optical absorption of gold nanoparticles is extraordinarily strong, which means that when suspended in a solution or deposited on a surface, the naked eye can detect a very small quantity of these particles. These properties make gold nanoparticles ideally suited as visual indicators.

Other applications of microparticles and nanoparticles in the biomedical sciences and biotechnology include the use as vehicles for enzyme encapsulation,<sup>[4]</sup> DNA transfection,<sup>[5–7]</sup> biosensors,<sup>[8–10]</sup> and drug delivery.<sup>[11–13]</sup> For example, drugs can be incorporated into nanospheres composed of a biodegradable polymer, and this allows for timed release of the drug as the nanospheres degrade.<sup>[11,12]</sup> The circumstances that cause the particle to degrade can be adjusted by varying the nature of the chemical bonding within

the particle. For example, when acid-labile bonds are used, the particles degrade in acidic microenvironments such as would-be extant in tumor cells or around a site of inflammation.<sup>[13]</sup> This allows for site-specific drug delivery. In another recent study, polymeric nanoparticles were labeled on their outer surfaces with a viral peptide sequence that promotes permeation of substances through cell membranes.<sup>[14]</sup> These peptide-derivatized nanoparticles passed through cell membranes, and got incorporated into living cells, at much higher levels than nanoparticles without the surface-bound peptide.

## OVERVIEW

Surface functionalized nanoparticles can also be used to deliver genetic material into living cells, a process called transfection. For example, silica nanospheres labeled on their outer surfaces with cationic ammonium groups were found to bind DNA—a polyanion—via electrostatic interactions.<sup>[5]</sup> These nanoparticles were then used to deliver the surface-bound DNA into cells. That transfection was successful was proven by showing that the cells produced the protein encoded by the DNA. There is also a tremendous interest in using cationic lipid-based nanospheres—liposomes—as DNA transfection agents.<sup>[6,7]</sup> Finally, the gold nanoparticles introduced above have been used extensively in the development of new types of gene sensors.<sup>[8–10]</sup>

Spherical nanoparticles are typically used in such applications, but this only reflects the fact that spheres are easier to make than other shapes. Microtubes and nanotubes—structures that resemble tiny drinking straws (Fig. 1)—are alternatives to spherical nanoparticles. Examples include organosilicon polymer nanotubes,<sup>[15]</sup> self-assembling lipid microtubes,<sup>[16–20]</sup> fullerene carbon nanotubes,<sup>[21–24]</sup> template-synthesized nanotubes,<sup>[25–28]</sup> and peptide nanotubes.<sup>[29–32]</sup> Nanotubes offer some interesting advantages relative to spherical nanoparticles for biotechnological applications. For example, nanotubes have large inner volumes (relative to the dimensions of the tube), which can be filled with any desired chemical or biochemical

**Fig. 1** Scanning electron micrograph of an array of template-synthesized carbon nanotubes. These nanotubes are composed of disordered graphitic carbon.

species ranging in size from proteins to small molecules.<sup>[25,26]</sup> In addition, nanotubes have distinct inner and outer surfaces, which can be differentially chemically or biochemically functionalized.<sup>[25]</sup> This creates the possibility, for example, of loading the inside of a nanotube with a particular biochemical payload but imparting chemical features to the outer surface that render it biocompatible. Finally, nanotubes have open mouths, which makes the inner surface accessible and the incorporation of species within the tubes particularly easy.

We review here some emergent technologies for preparing microtubes and nanotubes, and we give examples of recent biotechnological applications of these tubular systems. This review is not intended to be all encompassing; instead, it discusses recent trends and emphasizes some particularly promising technologies. Systems reviewed include self-assembling lipid microtubes, fullerene carbon nanotubes, cyclic peptide nanotubes, and template-synthesized nanotubes.

## NOMENCLATURE

In the literature, the tubular structures of interest to this review are called by various names including microtubules, microtubes, nanotubules, and nanotubes. This nomenclature can be simplified by noting that in this context, there is no difference between a tube and a tubule; in this entry, we use only the name tube. Nano vs. micro is a more difficult issue because there is no universally accepted dimension scale above which a particle is micro, and below which it is nano. In our research group, we have agreed that if a tube has at least one dimension that is 100 nm or less, it is called a nanotube.

## SELF-ASSEMBLING LIPID MICROTUBES

In 1984, Yager and Schoen<sup>[16]</sup> of the U.S. Naval Research Laboratory showed that chiral lipid molecules of the type shown in Fig. 2 self-assemble in solution to form microtubes. When diacetylenic lipids (Fig. 2) are used, the resulting microtubes have diameters on the order of 500 nm, lengths varying from about 50 to several hundreds of micrometers, and wall thicknesses from 10 to 60 nm or more.<sup>[17]</sup> The theory of this self-assembly process has been discussed by Selinger, Spector, and Schnur<sup>[18]</sup> In the most simplistic interpretation, the lipids self-assemble in solution to form planar bilayer sheets, which then curl up to make microtubes.

One proposed application of lipid microtubes is as vehicles for controlled drug release. For example, Price and Patchan<sup>[19]</sup> coated such tubes with metallic copper (to improve their mechanical strength) and then loaded antibiotics used to prevent marine fouling into these

**Fig. 2** Typical lipids used to make self-assembling lipid microtubes.

tubes. The tubes were then incorporated into a paint, which was applied to fiberglass rods. This microtube-based paint successfully inhibited marine fouling during 6 months testing of these rods in ocean water. Microtubes of this type have also been used for the controlled release of testosterone in living rats.<sup>[20]</sup> While these applications provide proof-of-concept, lipid microtubes are mechanically weak and, as indicated above, must be coated before use. In addition, because the ability to form tubes is connected with the unique chemistry and chirality of the lipids used, it would be difficult to use this approach to make tubes with any desired set of chemical, biochemical, or physical properties.

### FULLERENE CARBON NANOTUBES

In 1985, Kroto et al.<sup>[33]</sup> at Rice University discovered a new form of carbon—buckminsterfullerene or  $C_{60}$ —and this work ultimately led to the awarding of the 1996 Nobel Prize in chemistry to Smalley, Kroto, and Curl. Fullerene molecules of this type can be prepared by a carbon arc discharge method, and, in 1991, Iijima<sup>[21]</sup> discovered nanotubes in the products obtained from such a reactor (Fig. 3). These tubes are, in essence, rolled-up, highly ordered graphene sheets, and they may be single-walled or multiwalled.

**Fig. 3** Transmission electron micrograph of fullerene carbon nanotubes. The three converging objects are each a small bundle (“rope”) of hexagonally close-packed single-wall carbon nanotubes. These ropes are a little more than 10 nm in diameter and so contain ~50–100 nanotubes, each approximately 1.35 nm in diameter. *Source:* From Prof. Andrew Rinzler, University of Florida.

They are typically referred to in the literature as simply carbon nanotubes; however, because there are examples of nanotubes composed of more disordered forms of carbon (Fig. 1),<sup>[34]</sup> the more precise name, fullerene carbon nanotubes, is used here. Diameters for these nanotubes range from 1 to tens of nanometers, and lengths can be from microns to hundreds of microns.<sup>[22]</sup> Since their discovery, there has been a massive international research effort aimed at understanding the properties of fullerene carbon nanotubes and at developing applications for these nanotubes; a number of authoritative reviews have recently appeared.<sup>[22–24]</sup>

One proposed nonbiomedical application is in the area of microelectronics, where the ultimate objective is to make electronic circuit elements that are composed of these nanoscopic carbon tubes.<sup>[24,35–37]</sup> This research effort is driven by the need to further miniaturize electronic circuits so that increasing numbers of circuits can be accommodated on a chip. It is widely believed that the current silicon-based lithographic technology will reach its limit during the next decade. Fullerene nanotubes are interesting alternatives not only because they are small, but also because depending on the way they are rolled up, they can have electronic properties similar to both metals and semiconductors.<sup>[23,35,36]</sup> A number of groups have demonstrated that fullerene nanotubes can be used as components of electronic circuit elements.<sup>[24,36,37]</sup>

There have been a number of recent reports of putting biomolecules onto and into fullerene carbon nanotubes.<sup>[38–42]</sup> For example, Chen et al.<sup>[38]</sup> used a simple non-covalent route to attach a reactive molecule to the sidewalls of single-walled fullerene nanotubes. This reactive molecule could then be used to attach proteins to the walls of these nanotubes. This and related work is of interest to the development of biosensors based on fullerene nanotubes.<sup>[39]</sup>

Lieber et al.’s group<sup>[42,43]</sup> has pioneered the use of single-walled carbon nanotubes (SWNTs) as probe tips for atomic force microscopy (AFM) imaging of biomacromolecules such as antibodies, DNA, and amyloid  $\beta$  protofibrils (a constituent of the amyloid plaques characteristic of Alzheimer’s disease). As discussed in their recent review,<sup>[43]</sup> AFM is a scanning probe microscopy technique that has molecular-level resolution capabilities. They have shown that SWNTs are ideal probe tips for AFM because of their small diameter (which maximizes resolution), high aspect ratio, excellent chemical and mechanical robustness, and extraordinary stiffness.<sup>[43]</sup> In addition, Lieber’s group has attached biomolecules to SWNTs and used them as “molecular-recognition” AFM tips.<sup>[42]</sup> This approach is used to study the chemical forces that exist between molecules. For example, the molecule biotin was attached to a SWNT, and this tip was used to

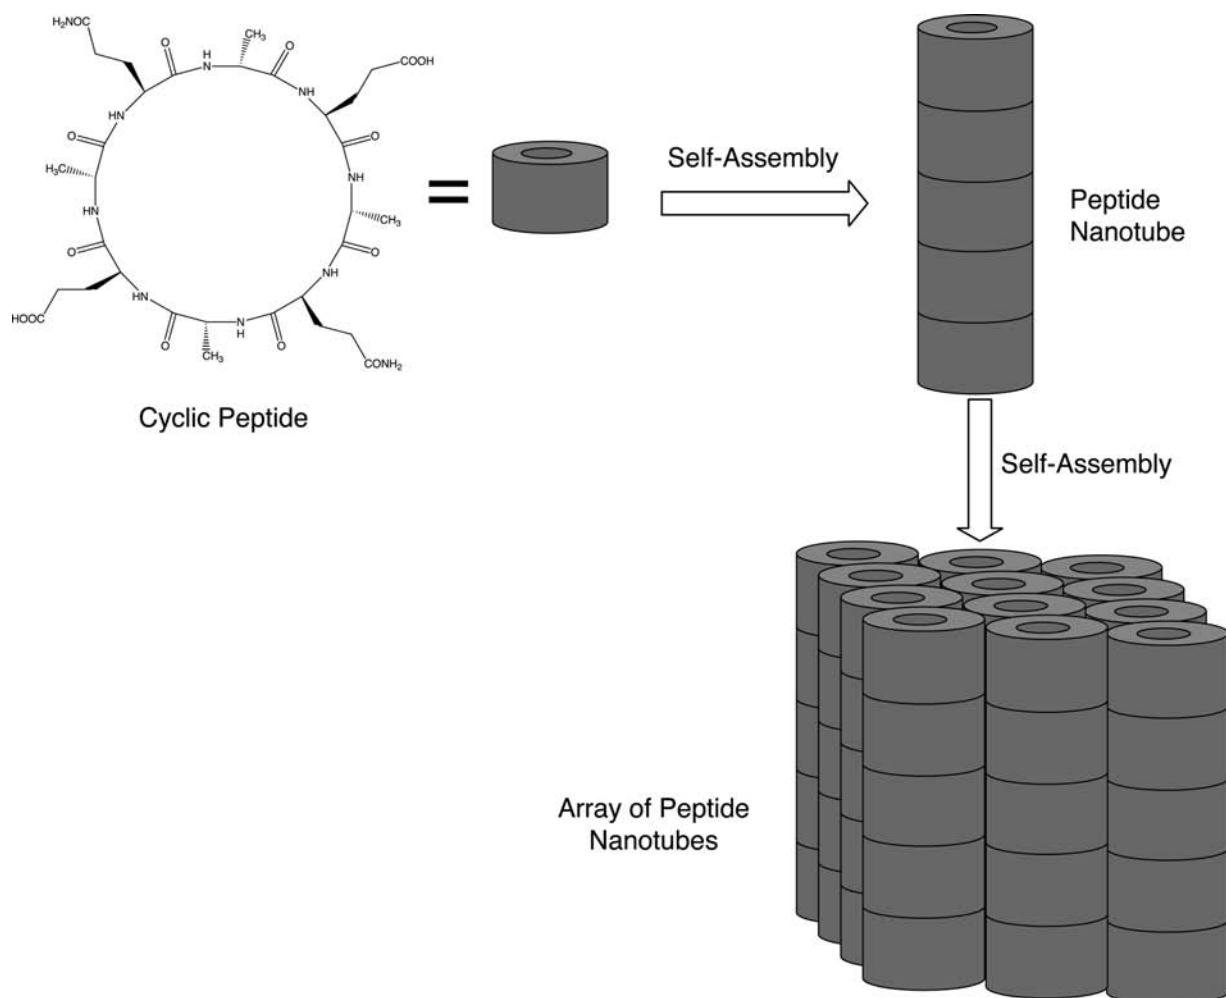

explore the binding interaction between biotin and the protein streptavidin.<sup>[42]</sup>

## PEPTIDE NANOTUBES

In 1993, Ghadiri et al.<sup>[29]</sup> at the Scripps Research Institute described a fascinating class of nanotubes based on cyclic peptide molecules that consists of an even number of alternating D- and L-amino acids (Fig. 4). They showed that these molecules self-assemble via hydrogen-bonding interactions into nanotubes, which, in turn, self-assemble into ordered parallel arrays of these nanotubes. The number of amino acid residues in the ring determines the inside diameter of the nanotubes obtained; as an example, a 12-amino-acid ring gave nanotubes with an inside diameter of 1.3 nm.<sup>[30]</sup> The chemical functional groups on the outside of the walls of these nanotubes can be varied by varying the amino acid composition of the ring.

Ghadiri et al. have demonstrated a number of biomedical/biotechnological applications for these nanotubes. Perhaps the most interesting is as a new class of antibiotics against bacterial pathogens.<sup>[31]</sup> They showed that 6 and 8 amino-acid residue cyclic peptides act preferentially on both Gram-positive and Gram-negative bacterial membranes relative to mammalian cells.<sup>[31]</sup> The data suggest that nanotubes formed from these peptides insert into the cell wall of the bacterium resulting in rapid cell death. They have also shown that these nanotubes can function as artificial ion channels in lipid bilayer membranes by self-assembling across the membrane.<sup>[32]</sup> Ion transport rates comparable to those of naturally occurring ion channels were observed.

These cyclic peptides have also been used as components in stochastic sensors—an elegant new chemical and biochemical sensing technology developed by Bayley et al.'s<sup>[44,45]</sup> group at Texas A&M University. This example raises an interesting fundamental point—*Mother Nature has evolved and routinely uses*

**Fig. 4** Cyclic peptide nanotubes. A typical chemical structure for a cyclic peptide and schematic illustrations of the self-assembly of such peptides into nanotubes and nanotube arrays.

her own brand of nanotubes, called protein channels. The most prevalent examples are the ligand-gated and voltage-gated ion channels that are used for electrical signaling in our brains, nerves, and muscles.<sup>[46]</sup> Another type of protein channel, the  $\alpha$ -hemolysin channel ( $\alpha$ HL) (Fig. 5A), is used as the sensing element in stochastic sensors. In these devices, a lipid bilayer membrane containing a single  $\alpha$ HL channel is mounted between two electrolyte solutions, a constant transmembrane potential is applied, and the resulting transmembrane current is measured. This current is associated with the transport of ions through the  $\alpha$ HL channel.<sup>[44,45]</sup>

In simplest terms, when the chemical species to be sensed (the “analyte”) enters the channel, it acts as a cork and blocks the pathway for ionic conduction through the channel. This results in a transient decrease, or downward pulse, in the measured transmembrane ion current. The term “stochastic” (associated with randomness) is used because the analyte enters and leaves the channel by diffusion,

i.e., a random walk.<sup>[47]</sup> The number of such current pulses is related to the concentration of the analyte, and the duration of the pulse provides clues as to the identity of the analyte. Analytes detected in this way include metal ions, DNA chains, and small organic molecules.<sup>[44,45]</sup>

However, small organic molecules by themselves cannot appreciably block the ion current, and so a larger “molecular adapter” that binds such analytes must be used. Sanchez-Quesada et al.<sup>[44]</sup> demonstrated that cyclic peptides can be used as molecular adapters. In this case, the cyclic peptide gets transiently lodged within the lumen of the channel [Eq. (1), Fig. 5B], and this can be detected as a pulse in the transmembrane ion current. The analyte can, in turn, get transiently bound within the annulus of the cyclic peptide [Eq. (2), Fig. 5B], and these binding/unbinding events produce a second set of current pulses. This is an interesting case where a smaller tube, the cyclic peptide, gets inserted into a larger tube, the  $\alpha$ HL channel.

**Fig. 5** The  $\alpha$ -hemolysin protein channel, an example of Mother Nature’s nanotubes. (A) Structure (based on a figure from Prof. Hagan Bayley, Texas A&M University). (B) Schematic representation of the use of a cyclic peptide as a “molecular adapter” for stochastic sensing with the  $\alpha$ -hemolysin channel.

## TEMPLATE-SYNTHESIZED NANOTUBES

The template method is a general approach for preparing nanomaterials that entails synthesis or deposition of the desired material within the cylindrical and monodisperse pores of a nanopore membrane or other solid (see, e.g., Fig. 6A).<sup>[3,48]</sup> Cylindrical nanostructures with monodisperse diameters and lengths are obtained, and depending on the membrane and synthetic method used, these may be solid nanowires or hollow nanotubes. This method has been used to prepare nanowires and tubes composed of many different types of materials including metals, polymers, semiconductors, and carbons.<sup>[3,48]</sup> In addition, the template method can be used to prepare composite nanostructures, both concentric tubular composites<sup>[49]</sup> and segmented composite nanowires.<sup>[50]</sup>

How one makes nanotubes within the pores of a template membrane can be illustrated by the carbon nanotubes shown in Fig. 1.<sup>[34]</sup> An alumina template (Fig. 6A) was heated to 670°C, and ethylene gas was passed through the membrane. This causes the ethylene to decompose on the pore walls to yield graphitic carbon nanotubes within the pores. The alumina template membrane can then be dissolved away and the carbon nanotubes can be collected by filtration. These tubes have monodisperse outside diameters determined by the diameter of the pores in the template. The inside diameter is determined by the carbon deposition time. Other synthetic methods we have used include in-pore polymerization to make polymeric nanotubes, electrodeless deposition to make metal nanotubes, and sol-gel chemistry to make nanotubes composed of silica and other inorganic materials.<sup>[3,48]</sup> Templated silica nanotubes<sup>[25,26]</sup> are shown in Fig. 6B. All these nanotubes are of the same length, which is determined by the thickness of the template membrane.

We have used these silica nanotubes as test vehicles to illustrate the power of the template method for preparing nanotubes for biotechnological applications.<sup>[25,26]</sup> Silica nanotubes are ideal for such proof-of-concept experiments because they are easy to make, readily suspendable in aqueous solution, and because silica surfaces can be derivatized with an enormous variety of different chemical functional groups using simple silane chemistry with commercially available reagents.<sup>[25,26]</sup>

### Attaching Different Functional Groups to the Inside vs. Outside Surfaces

As noted above, one of the most important attributes of a nanotube is that it has distinct inner and outer surfaces that can be differentially chemically and biochemically functionalized. The template method

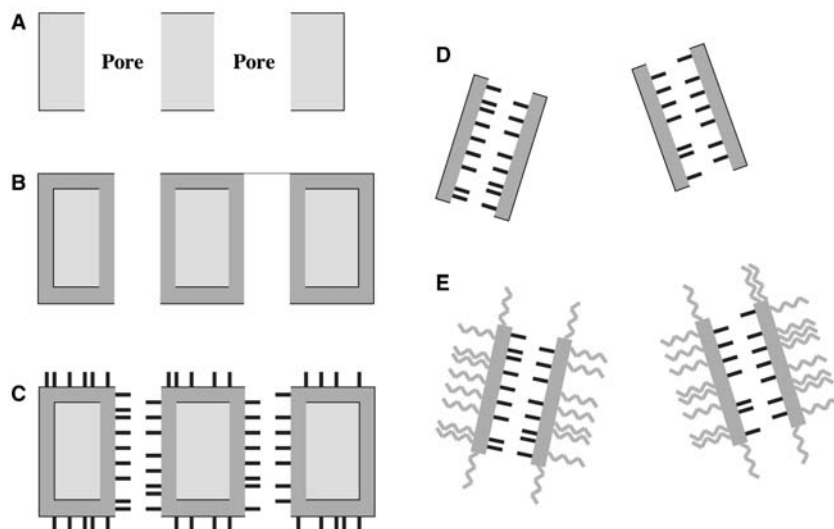

**Fig. 6** Scanning electron micrographs. (A) The surface and cross section of a typical nanopore alumina template membrane prepared in the authors' laboratory. Pores with monodisperse diameters that run like tunnels through the thickness of the membrane are obtained. (B) Silica nanotubes prepared by sol-gel template synthesis within the pores of a template like that shown in (A). After sol-gel synthesis of the nanotubes, the template was dissolved and the nanotubes were collected by filtration.

provides a particularly easy route to accomplish this differential functionalization.<sup>[25]</sup> The silica nanotubes were synthesized within the pores of nanopore alumina template membranes (Fig. 6B) using a sol-gel method described previously.<sup>[25,26]</sup> Templates with pore

diameters of either 60 or 200 nm were used for these studies.<sup>[25,26]</sup>

We have developed the following simple procedure for applying different functional groups to the inner vs. outer surfaces of these nanotubes. Fig. 7A represents schematically a cross section of the alumina template membrane (Fig. 6A) showing two pores. Fig. 7B shows this membrane after sol-gel template synthesis of the silica nanotubes within the pores (blue color). Note that the surfaces of the membrane are coated with thin silica films, which are removed by a brief mechanical polish.<sup>[25]</sup> While still embedded within the pores of the template membrane, the inner nanotube surfaces are reacted with a silane reagent that contains the functional group to be attached to the inner surfaces (green in Fig. 7C). This silane cannot attach to the outer nanotube surfaces because the outer surfaces are in contact with the pore wall and are thus masked. The template is then dissolved to liberate the nanotubes, which unmask the outer nanotube surfaces (Fig. 7D).<sup>[25]</sup> The liberated nanotubes are then exposed to a second silane that contains the functional group to be attached to the outer nanotube surfaces (pink in Fig. 7E).

To demonstrate the concept of differential chemistries inside and outside of the nanotubes, we have used immobilized two different chromophores (green and blue) inside of the nanotubes and making the outside of the nanotubes either lipophilic or lipophobic. A set of nanotubes was prepared with the green fluorescent silane *N*-(triethoxysilylpropyl)dansylamide attached to their inner surfaces and the hydrophobic octadecyl silane (C<sub>18</sub>) attached to their outer surfaces. These nanotubes were added to a vial containing water and the immiscible organic solvent cyclohexane, which were mixed and allowed to separate. Because these nanotubes are hydrophobic on their outer surfaces, they partition into the (upper) cyclohexane phase (Fig. 8B). This may be contrasted to nanotubes that were labeled

**Fig. 7** Schematic of procedure used to attach different chemical functional groups to the inner vs. outer surfaces of template-synthesized nanotubes. (A) Cross section of the template membrane. (B) Membrane after template synthesis of nanotubes within the pores (blue). (C) After attachment of the first functional group (green) to the inner nanotube surfaces. (D) Liberated nanotubes after dissolution of the template membrane. (E) After attachment of the second functional group to the outer nanotube surfaces (pink).

**Fig. 8** Photographs of vials containing nanotubes modified with two different fluorophores in two different solvent medium. (A) Cyclohexane (upper) and water (lower) under UV light excitation after the addition of 10 mg of nanotubes with dansylamide on inner and C<sub>18</sub> on outer surfaces. (B) Quinineurethan on inner and no silane on outer surfaces. (C) Ten milligrams of both A and B nanotubes. Nanotubes, 200 nm in diameter, were used.

on their inner surfaces with the blue fluorescent silane triethoxysilylpropylquinineurethan, but were not labeled with any silane on their outer surfaces. When the same experiment is carried out with these nanotubes, the quinineurethan fluorescence is seen only from the aqueous phase (Fig. 8A). When both sets of nanotubes are added to the solvent mixture in the same vial, the tubes with the C<sub>18</sub> outer surface chemistry go to the cyclohexane and the tubes with the silica outer surface chemistry go to the aqueous phase (Fig. 8C).

### Nanotubes for Chemical and Bioextraction and Biocatalysis

One application for such differentially functionalized nanotubes is as smart nanophase extractors to remove specific molecules from solution.<sup>[25]</sup> Nanotubes with

hydrophilic chemistry on their outer surfaces and hydrophobic chemistry on their inner surfaces are ideal for extracting lipophilic molecules from aqueous solution. The hydrophobic molecule 7,8-benzoquinoline (BQ), which has an octanol/water partition coefficient of  $10^{3.8}$ , was used as a model compound for such nanophase solvent extraction experiments. Five milligrams of the silica-outer/ $C_{18}$ -inner nanotubes was suspended into 5 mL of  $1.0 \times 10^{-5}$  M aqueous BQ. The suspension was stirred for 5 min and then filtered to remove the nanotubes. Ultraviolet spectroscopy showed that 82% of the BQ was removed from the solution. When a second 5-mg batch of these nanotubes was added to the filtrate, >90% of the original amount of BQ was removed from the solution. Control nanotubes that did not contain the hydrophobic  $C_{18}$  inner surface chemistry extracted less than 10% of the BQ.

Nanotubes with the  $C_{18}$  inside will, in principle, extract any lipophilic molecule. This ability to sequester lipophilic molecules can be viewed as a generic type of extraction selectivity, which might be useful in some applications. However, nanotubes that have molecular-recognition capability and extract only one particular molecule from solution might also be useful. We have shown that antibody-functionalized nanotubes can provide the ultimate in extraction selectivity—the extraction of one enantiomer of a chiral drug molecule.

In collaboration with Prof. Hans Soderlund of VTT Biotechnology in Finland, we have been investigating an antibody that selectively binds one enantiomer of the drug FTB (Fig. 9A), an inhibitor of aromatase enzyme activity.<sup>[51]</sup> This molecule has two chiral centers and thus four stereoisomers—RR, SS, SR, and RS. Prof. Soderlund supplied us with the Fab fragment<sup>[52]</sup> of an antibody that selectively binds the RS relative to the SR enantiomer. The antibody was produced against the drug 4-[3-(4-fluorophenyl)-2-hydroxy-1-[1,2,4]triazol-1-yl-propyl]-benzimidazole (FTB, Fig. 9A). The antibody used selectively binds the RS enantiomer, and Fab fragments of this antibody were immobilized to both the inner and outer surfaces of the silica nanotubes. This was accomplished by dissolving the template membrane, collecting the nanotubes, and then dispersing them into a solution of the aldehyde-terminated silane trimethoxysilylbutanal. The nanotubes were then dispersed into a solution of the Fab fragments, which resulted in the attachment of the Fab to the nanotubes via Schiff base reaction between free amino groups on the protein and the surface-bound aldehyde.

The Fab-functionalized nanotubes were added to racemic mixtures of the SR and RS enantiomers of FTB. The tubes were then collected by filtration and the filtrate was assayed for the presence of the two enantiomers using a chiral HPLC method (Fig. 9B).

**Fig. 9** Enantioseparations. (A) 3-D structures of the RS enantiomer (left) and the SR enantiomer (right) of the drug FTB. The black, white, blue, red, and yellow balls are carbon, hydrogen, nitrogen, oxygen, and fluorine, respectively, and \* denotes the chiral centers. The geometry optimization was done by ab initio calculation with minimal basis set in HyperChem 6.03. The drug is in clinical trials by Hormos Medical Corp., Turku, Finland. (B) Chiral HPLC chromatograms for racemic mixtures of FTB before (I) and after (II, III) extraction with 18 mg/mL of 200-nm Fab-containing nanotubes. Solutions were 5% dimethylsulfoxide in sodium phosphate buffer, pH 8.5.

Chromatogram I is from a solution that was  $20 \mu\text{M}$  in both enantiomers, and chromatogram II was obtained for the same solution after exposure to the Fab-functionalized nanotubes; 75% of the RS enantiomer and none of the SR enantiomer was removed by the nanotubes. When the concentration of the racemic mixture was dropped to  $10 \mu\text{M}$ , all of the RS enantiomer was removed (chromatogram III). Nanotubes containing no Fab did not extract measurable quantities of either enantiomer from the  $20\text{-}\mu\text{M}$  solution.

We have also developed a chemistry that allows us to attach the Fab to only the inner surfaces of the nanotubes. While still within the pores of the template membrane, the inner surfaces were treated with amino-propyltrimethoxysilane. The template membrane was then dissolved and the amino sites on the inner surfaces were coupled to free amino groups on the Fab fragment using the well-known glutaraldehyde coupling reaction.<sup>[25]</sup> When 18 mg of these interior-only

Fab-modified nanotubes was incubated with 1 mL of a 10- $\mu$ M racemic mixture of the drug, 80% of the RS (and none of the SR) enantiomer was extracted. This corresponds to 0.44 nmol RS enantiomer/mg tubes, whereas almost double that amount, 0.80 nmol/mg, was extracted by the nanotubes with Fab on both their inner and outer surfaces.

Another example concerns the immobilization of a biocatalyst—the enzyme glucose oxidase (GOD)—to the silica nanotubes.<sup>[25]</sup> Glucose oxidase was immobilized, on both the inside and outside surfaces, via the aldehyde silane route. These GOD nanotubes (60-nm diameter) were dispersed into a solution that was 90 mM in glucose and also contained the components of the standard dianisidine-based assay for GOD activity. A GOD activity of  $0.5 \pm 0.2$  U/mg of nanotubes was obtained. These studies also showed that protein immobilized via the Schiff-base route is not leached from the nanotubes, in that all GOD activity ceased when the nanotubes were filtered from the solution.

### Nanotube Membranes for Bioseparations

In all of the examples cited above, the template membrane was dissolved away and the liberated nanotubes were collected by filtration. The nanotubes may also be left embedded within the pores of the template to yield a freestanding nanotube-containing membrane. We have shown that the nanotubes can act as conduits for highly selective transport of molecules and ions between solutions present on either side of the membrane.<sup>[26–28]</sup> For example, membranes containing gold nanotubes with inside diameters of molecular dimensions (<1 nm) cleanly separate small molecules on the basis of molecular size.<sup>[28]</sup> Gold nanotubes with larger inside diameters (20 to 45 nm) can be used to separate proteins, and here again, rendering the nanotubes biocompatible is essential to prevent protein adsorption.<sup>[53]</sup> Generic chemical transport selectivity (lipophilic vs. hydrophilic) can also be imparted to these gold nanotube membranes.<sup>[55]</sup>

More recently, we have shown that membranes containing the silica nanotubes and the enantioselective FTB antibody Fab fragment discussed above can be used to make membranes for chiral separations.<sup>[26]</sup> In this case, the nanotube membrane separates a feed half-cell containing a racemic mixture of the RS and SR enantiomers of FTB and a permeate half-cell that initially contains only buffer solution. The time course of permeation of the two enantiomers across the membrane was determined by periodically assaying the permeate solution.<sup>[26]</sup> Results for a membrane containing ~15-nm diameter silica nanotubes are shown in Fig. 10 as plots of mole enantiomer transported vs.

**Fig. 10** Enantioseparations using antibody-immobilized membranes. Plots of moles of each enantiomer transported vs. time for a silica nanotube membrane containing the enantioselective antibody Fab fragment. The inside diameter of the nanotubes was ~15 nm.

permeation time. We see that the flux of the RS enantiomer, the one bound by the antibody, is 5 times higher than the flux of the SR enantiomer. Because, in principle, antibodies can be obtained that selectively bind to any desired molecule or enantiomer, this concept might provide a general approach for obtaining selectively permeable membranes for a host of enantio-separations and bioseparations.

Finally, biocompatibility is an important issue for possible *in vivo* applications of nanotube technology. It is well known that materials can be made biocompatible, as evidenced by decreased protein adsorption, by attaching poly(ethylene glycol) (PEG) chains to their surfaces.<sup>[53]</sup> We have shown that when a PEG silane is attached to the silica nanotubes, adsorption of IgG immunoproteins is strongly suppressed relative to nanotubes that did not contain the attached PEG.<sup>[54]</sup>

### CONCLUSION

We believe that nanotubes offer some important advantages for biotechnological applications of nanoparticles. Because of its tremendous versatility in terms of materials that can be used, sizes that can be obtained, and chemistry and biochemistry that can be applied, the template method might prove to be a particularly advantageous approach for preparing nanotubes for such applications. However, this field of nanotube biotechnology is in its infancy, and there is much work to be performed before products based on this technology are brought to the market place. For example, in our applications to date, we have incorporated the payload into the nanotubes by either covalent bonding or other chemical interactions. However, in some applications, it might be useful to simply

fill the nanotube with a payload and then apply caps to the nanotube ends to keep the payload encapsulated. Furthermore, it might be useful to have these caps fall off, thus spilling the payload, when a particular chemical or biochemical signal is detected. We are currently exploring routes for preparing such capped nanotubes. The issues of cost of production and mass production of nanotubes must also be addressed.

Finally, the synthetic nanotubes discussed here can be thought of as mimics of naturally occurring nanotubes—protein channels;<sup>[46]</sup> indeed, the cyclic peptide nanotubes have been used as artificial ion channels.<sup>[32]</sup> Ion channels open and close in response to chemical and electrical stimuli. We are developing synthetic nanotubes with similar voltage<sup>[27,56]</sup> and chemical<sup>[57]</sup> gating characteristics. These nanotubes can be used in smart membranes whose transport properties change in response to an electrical stimulus<sup>[27,56]</sup> and in sensing devices where a chemical stimulus turns on a current that can be measured in an external circuit.<sup>[57]</sup>

## INTRODUCTION

Currently, the dynamical modes of atomic force microscopes (AFM) are commonly used to investigate a large variety of molecular systems and samples. The concept of dynamical modes is based on the oscillation of a tip-cantilever system at or near the resonance frequency where the oscillating behavior changes as the tip is moved toward the surface.<sup>[1–5]</sup>

Dynamical modes were first conceived to minimize the contact between the tip apex and the surface. Thus, images can be recorded with only a slight intermittent contact over a cycle of oscillation or with no contact at all. Therefore, if not totally removed, the shear forces are significantly reduced. The merging of dynamical modes can be seen as a significant breakthrough because its ability to probe minute forces has opened avenues in the imaging of reproducibly soft materials<sup>[5–16]</sup> and in routinely obtaining atomic resolution in ultra-high vacuum conditions.<sup>[17–22]</sup>

This review briefly spans selected experimental images recorded on soft and hard materials and focuses on the capability to discriminate between topographical information and mechanical properties at both nanometer and atomic scales. The manuscript is organized as follows: a short technical introduction giving the basic concepts required to understand the main topics; two sections focusing on the study of soft materials and the procedures to obtain either topographical or mechanical information at the nanometer scale; and a final section dedicated to damping images recorded with contrast at the atomic scale.

## TECHNICAL BACKGROUND

Two modes of operation are used to record the change of the oscillating behavior when the tip interacts with a surface:

1. The amplitude modulation mode (AM),<sup>[1,3,4]</sup> often called *tapping mode* as a commercial name, where the tip-cantilever system is excited

at a fixed-driven frequency and a fixed-amplitude excitation. The main advantage is its ability to image polymers without producing the severe damage caused by contact mode.<sup>[3]</sup> Many works have been dedicated to studies on very soft samples<sup>[5–16]</sup> but, although the AM mode provides a convenient and easy way to image soft materials, quantitative analysis of the experimental data remains uneasy.<sup>[17–36]</sup>

2. The frequency modulation technique (FM), often called non-contact resonant mode.<sup>[2]</sup> The FM mode was first used experimentally under ultra-high vacuum conditions to image semiconductor surfaces. The concept is to use a negative resonant frequency shift at constant oscillation amplitude as the error signal to control the distance between the tip and the surface. The interaction between the tip and the surface remains attractive so that the tip never touches the surface. The key experimental achievement was the demonstration that the FM mode was able to obtain images with contrast at the atomic scale.<sup>[17,18]</sup> The experimental data that depend on the interaction between the tip and the surface are the resonance frequency variation and the damping signal extracted from the energy per cycle needed to supply in order to keep the oscillation amplitude constant. The frequency shift is related only to conservative interaction and the additional damping signal should be uniquely governed by the dissipative interaction.<sup>[21,35]</sup>

## Conservative Interaction

In the harmonic oscillator theory, any variation of the resonant frequency shift corresponds either to a change of the mass of the oscillator or to a change of an effective spring constant. For an AFM oscillator, a mass transfer is not expected; therefore, an effective spring constant taking into account the variation of the force interaction is responsible for the frequency shift. A

very general expression to describe the resonant frequency shift is:<sup>[28,33,36]</sup>

$$\Delta\nu = \nu_0 \left( \sqrt{1 + \frac{k_{\text{int}}^{\text{eff}}}{k_c}} - 1 \right), \quad (1)$$

where  $\nu_0$  is the resonant frequency without any interaction,  $k_{\text{int}}^{\text{eff}}$  is an effective spring constant describing change of the force interaction between the tip and the surface over a cycle, and  $\nu_0$  and  $k_c$  are the resonant frequency and cantilever spring constant respectively. The high sensitivity of commercially available electronics allows easy measurement of a weak effective spring constant. For example, with a cantilever spring constant  $k_c = 10 \text{ N m}^{-1}$ , effective spring constants less than  $k_{\text{int}}^{\text{eff}} \sim 10^{-3} \text{ N m}^{-1}$  can be readily measured.<sup>[4,24,31,36,37,38]</sup>

Only a few analyses were dedicated to the study of interaction when the tip goes inside the materials. This case is significantly more difficult to solve. It is primarily encountered in experimental situations where significant indentation depths occur, particularly studies on soft materials.<sup>[4,16,26,27,30,32,37]</sup>

### Dissipative Interaction: A Straightforward Result for Soft Materials with FM-Mode

In addition to conservative forces of the tip-sample interaction, dissipative interactions must also be considered, giving rise to additional energy losses during each oscillation period. Dissipation manifests itself as a hysteresis of force versus displacement curve. Dissipation mechanisms may involve electrical losses, time delays in viscoelastic materials,<sup>[16,28,33,38]</sup> or mechanical instabilities due to adhesion.<sup>[33,39]</sup>

The total damping coefficient writes:<sup>[25]</sup>

$$\gamma_{\text{tot}} = \gamma_0 + \gamma_{\text{int}}, \quad (2)$$

where  $\gamma_0 = m\omega_0/Q$  is the damping coefficient of the AFM oscillator without interaction between the tip and the surface,  $m$  is the effective mass of the oscillator, and  $Q$  is the quality factor. Typically, in vacuum,  $\gamma_0 = 2.10^{-9} \text{ N s m}^{-1}$ , with a cantilever stiffness  $k_c = 20 \text{ N m}^{-1}$ ,  $\omega_0/2\pi = 175 \text{ kHz}$ , and  $Q = 20,000$ . For an oscillation amplitude,  $A$ , of 10 nm the corresponding dissipated energy per period without interaction is  $\langle E_{\text{diss}}^0 \rangle = k_c \pi A^2 / Q \simeq 10^{-19} \text{ J}$ . In air,  $Q = 500$  and the dissipated energy becomes  $\langle E_{\text{diss}}^0 \rangle = k_c \pi A^2 / Q \approx 10^{-17} \text{ J}$ .

Writing  $\gamma_{\text{int}}/\gamma_0 = \langle E_{\text{diss}}^{\text{int}} \rangle_T / \langle E_{\text{diss}}^0 \rangle_T$ , the additional damping coefficient  $\gamma_{\text{int}}$  can be converted into the power dissipated. Thus, in ambient conditions, a damping increase of about  $10^{-19} \text{ J}$  can be measured

while, in vacuum at room temperature, it can be as low as  $k_B T$ .

### Imaging Soft Materials and the Influence of the Quality Factor

A key objective of the AFM is focused on the capability to record reliable topographic images of soft materials. In that part, we will show that such a goal could be achieved with a high-quality factor of the oscillating cantilever.

At the maximum of the oscillator sensitivity, the rate of the oscillation amplitude is proportional to the quality factor:

$$\frac{dA}{d\omega} \propto Q. \quad (3)$$

Therefore, when the mode with the amplitude variation is used, the sensitivity may simply be proportional to the quality factor. At this stage, it is useful to compare the static and dynamic mode.

In the static mode, when the microcantilever is brought to the surface, the slope of the deflection is (see Fig. 1):

$$p(\delta_c) = \frac{1}{1 + \frac{k_c}{k_s}}, \quad (4)$$

where  $k_s$  is the contact stiffness of the sample. For null-contact stiffness corresponding to a usual liquid, the denominator is infinite and, as expected when the sample does not have a mechanical response, the deflection slope is zero. When the surface is infinitely hard, the slope equals one and the cantilever deflection is strictly equals to the vertical motion. In this case, the image

**Fig. 1** Scheme of the cantilever deflection  $\delta_c$  as a function of the vertical displacement,  $Z$ , of the surface. For dynamic mode the deflection  $\delta_c$  is replaced by the oscillation amplitude,  $A$ , and the slope  $p$  is different (see equation 4 and text below).

**Fig. 2** Drops of poly-isoprene melt deposited on an AFM sample holder. The left drop is a polymer of molecular weight  $M_w = 3.10^6$  Dalton. The right sample corresponds to a molecular weight  $M_w = 5.10^5$  Dalton. The relative low molecular weight has a repetition time sufficiently small that a small basin is required to prevent the flow of the sample.

corresponds to a true topography without containing any mechanical information.

For a soft sample, an evaluation of the sample contact stiffness is readily obtained as the product of the diameter of the contact area,  $\phi$ , between the tip and the sample and the elastic Young's modulus,  $G$ :  $k_s = G\phi$ . With a typical value for soft polymer,  $G = 1$ , MPa =  $10^6$  N m $^{-2}$ , and a contact diameter,  $\phi = 10^{-9}$  m,  $k_s = 10^{-3}$  N m $^{-1}$ . Usual stiffness values of microcantilever used in dynamic mode are

few tens of Newton per meter and, therefore, four orders of magnitude larger than that of a soft contact. This huge difference makes soft materials behave nearly like liquids.

In contrast, imaging soft materials becomes possible when the dynamic mode is used. One reason for this is that the contact sample stiffness is replaced by the product  $Qk_s$  instead of the contact stiffness  $k_s$  alone. The ratio in the denominator of the equation becomes  $k_c/(Qk_s)$ . Thus, for high-value quality factors, the ratio might be close to one and topographical images become easy to record. The quality factor enhances the influence of the repulsive interaction leading to an apparent and much larger contact stiffness. The slope of the variation of the oscillation amplitude  $p(A) = \delta A/\delta D$  becomes close to one, so that the amplitude modulation technique leads to an image of surface topography of a very soft sample.<sup>[15,27]</sup>

The investigation of a polymer melt, poly-isoprene, is a good experimental result showing the influence of the quality factor. Poly-isoprene behaves as a liquid at room temperature (Fig. 2); however, in vacuum, ( $10^{-7}$  Torr) where the contribution of the fluid viscosity goes to zero, giving a large quality factor,  $Q = 23,000$ , the apparent contact stiffness becomes sufficiently high that the soft surface of the polymer appears as hard as a silica surface.<sup>[15]</sup>

In Fig. 3, several approach curves displayed give the variation of the oscillation amplitude as a function of the vertical displacement of the surface. The experiments are made as follows: for a given oscillation

**Fig. 3** Approach curves showing the variation of the amplitude oscillation in AM-AFM as a function of the sample vertical location on a polymer melt: polyisoprene. At atmospheric pressure,  $Q = 530$ ; at 10 mbar (7.5 Torr),  $Q = 2740$ ; and at  $2 \times 10^{-7}$  Torr,  $Q = 23,000$ . The dash line is the location of the surface. The values,  $p(A)$ , are the slopes of the straight sections of the curves. Arrows show a maximum of indentation depth of  $\delta_3 = 8$  and  $\delta_3 = 6$  nm for  $Q = 530$  and  $Q = 2740$ , respectively. The resonance curve at atmospheric pressure and  $2 \times 10^{-7}$  Torr are shown in the right picture. Source: Adapted from EDP Sciences (see Ref.<sup>[15]</sup>).

amplitude, we record an approach curve at a fixed  $(X, Y)$  location on the surface. The approach curve is obtained by moving the sample along the vertical axis,  $Z$ , with a vertical displacement varying between 20 and 40 nm. In Fig. 3, the frontier domain between the polymer and vacuum or air is marked with a red dotted line. The blue part corresponds to the polymer melt domain. When the quality factor is very high ( $Q = 23,000$ ), the slope is equal to one, the tip is unable to penetrate the melt, and the indentation depth,  $\delta_s$ , is close to zero. As a consequence, whatever the reduction of the oscillation amplitude, the true topography of the polymer surface is recorded without any difficulty.

This very important point was the origin of the development of image on soft polymers. For example, among the first works was an investigation showing the surface reconstruction of copolymers.<sup>[5]</sup> In that work, Stocker et al. investigated the surface morphology of a symmetric poly(styrene-*block*-butadiene-*block* methyl methacrylate) triblock copolymer (PS-*b*-PB-*b*-PMMA). The tapping images are compared to the bulk morphology as determined by transmission electron microscopy (TEM). Fig. 4A shows the TEM image of the triblock copolymer. The triblock forms a lamellar morphology with a spatial period of  $42.7 \pm 0.5$  nm. The AFM experiments also show a lamellar morphology but with a spatial period of  $85 \pm 5$  nm, that is a period twice that found in the bulk (Fig. 4B). The AFM image mostly reveals topography information showing a surface reconstruction of the copolymer.

**Fig. 4** (A) Transmission electron micrograph of a triblock copolymer. The system forms a lamellar morphology. The polybutadiene (PB) spheres appear dark in TEM, while the polystyrene (PS) lamellae (gray) show a weak contrast with respect to PMMA lamellae (bright). The long period of the lamellar structure is  $42.7 \pm 0.5$  nm. The diameter of the PB spheres is 9 nm. Adapted from *Macromolecules*. 1996; 29: 7502–7507.<sup>[5]</sup> (B) AM-AFM image of solution cast films of the triblock copolymer. The image of  $1.3 \times 1.3 \mu\text{m}^2$  area shows the lamellar spherical morphology ( $z$  scale 7 nm). Comparison with the bulk morphology (Fig. 4A) illustrates that the surface morphology observed by AFM shows a long period that is doubled from  $42.7 \pm 0.5$  nm in the bulk to  $85 \pm 5$  nm at the surface. *Source*: Adapted from American Chemical Society (see Ref.<sup>[5]</sup>).

Also, dynamic modes were used extensively to investigate crystallization and melting processes.<sup>[13]</sup> In Fig. 5, Reiter et al. took advantage of the huge change of the viscoelastic properties during crystallization and melting of polyethylenoxide in 12 nm spheres of a block copolymer mesophase. The samples are annealed at a high temperature. These annealed samples did not crystallize at ambient conditions. Phase images are recorded for different times at  $-23^\circ\text{C}$ , where the melting happens at the temperature  $+40^\circ\text{C}$ . The phase images show that all the polymer spheres do not crystallize at the same time. The different times needed to develop crystalline spheres indicate that they do not have all the degree of polymer arrangement inside the sphere. In addition not all spheres melted at the same temperature. Therefore, these AFM experiments show that confined crystals have behavior different from those in bulk.

## NANO-RHEOLOGY: EXPERIENCE ON POLYMER MELT AND COPOLYMER

### Polymer Melt

Typical variations of the normalized damping signal versus the tip indentation are shown in Fig. 6A. Note that contrary to AM mode (Fig. 3), the FM mode, under the same vacuum conditions, allows an indentation depth of several nanometers. When the tip dips into the melt, the damping coefficient,  $\gamma_{\text{tot}}$ , becomes the sum of the intrinsic damping coefficient,  $\gamma_0$ , and of the

**Fig. 5** AM-AFM phase images ( $1 \times 1 \mu\text{m}^2$ ) showing the variation in the number and distribution of crystalline cells after crystallization of polyethyleneoxide at  $-23^\circ\text{C}$  for (A) 5 mn and (B) 15 mn. The inset (C) shows, on semilogarithmic scales, the percentage of remaining molten cells as a function of time. The line represents a fit of equation  $n = n_\infty[1 - \exp(-\tau)]$  yielding  $\tau = 35$  min. The sample after 120 min at  $-23^\circ\text{C}$  (D) was split into several pieces that were separately annealed for 2 min at  $39^\circ\text{C}$ , (E)  $42^\circ\text{C}$ , and (F)  $44^\circ\text{C}$ . Source: Adapted from American Physical Society (see Ref.<sup>[13]</sup>).

damping coefficient,  $\gamma_{\text{int}}$ , related to the additional dissipation. The damping coefficient,  $\gamma_{\text{int}}$ , is an explicit function of the indentation depth  $\delta$ ,  $\gamma_{\text{int}} = \gamma_{\text{int}}(\delta)$ . The damping curves show three domains (Fig. 6A). At a small indentation depth, the dissipation shows a smooth increase and then abruptly increases within a few Angströms variation. At a larger indentation depth, the last part of the curve again increases smoothly or exhibits a plateau-like behavior. A qualitative explanation of this irregular behavior is that the lower part of the curve corresponds to dissipation processes that involve only motion of segment chains with lengths smaller than the entanglement length. Then, the abrupt increase corresponds to an indentation that involves entanglements, and the last section includes contributions due to significant di-entanglements of the network.

A simple way to evaluate the time scale of the sample characteristic relaxation time is obtained by multiplying the experimental data by the power laws dependence,  $A^{3/2}$  and  $A^{5/2}$ .<sup>[16]</sup> The results are shown in Fig. 6B and C. When the experimental data are multiplied by  $A^{3/2}$ , the low parts of the curves, corresponding to the small indentations, gather together, showing that the relaxation times of the processes induced in the network are much faster than those of the contact times. When the experimental data are multiplied by  $A^{5/2}$ , all the abrupt increases of the dissipation align. Thus, by increasing the indentation depth a fraction of a nanometer, the relaxation processes switch from fast to slow relaxation times. At large indentation depths, the slow relaxation processes governed by the network prevail.

### Triblock Copolymers

The triblock copolymer is composed of two identical thermoplastic sequences of poly(methyl methacrylate), PMMA, attached to a central sequence of low  $T_g$  poly(isooctylacrylate). Spherical, cylindrical, and lamellar morphologies have been observed for block copolymers of increasing PMMA contents.<sup>[8]</sup> These systems exhibit phase-separation at the nanometer scale with a soft central part.<sup>[5,6,8,10]</sup>

The height image recorded in non-contact (Fig. 7A), or nearly non-contact situations, shows a perfect flat surface, according to previous tapping studies.<sup>[10]</sup> Therefore, the contrast observed on the damping image (Fig. 7B) corresponds only to different rheological properties between the two sequences of block forming the copolymer.

Typical resonance frequency shift and damping variations are reported in Fig. 8A and B.

In Fig. 8C, the variation of the dissipation contrast is shown as a function of the strength of the tip-sample interaction. The strength of the tip-sample interaction is monitored with the magnitude of the resonance frequency shift (Fig. 8A). The higher the frequency shift, the higher the damping contrast on the image.

### DAMPING IMAGES AT ATOMIC SCALE

In addition to the height and damping images of soft materials, the AFM dynamic modes were also able to produce dissipation maps with contrast at the atomic scale (Fig. 9). Measurements are usually recorded with

**Fig. 6** FM-AFM curves on a polymer melt. (A) Several damping curves recorded at different locations in the  $(X, Y)$  plane for four oscillation amplitudes 25, 40, 50, and 75 nm. In few cases, the curves show a dispersed behavior at the values of the indentation depth where the transition

cantilevers of resonance frequency between 150–300 kHz. Consequently, the experimental time when the oscillating tip interacts with the surface, about a microsecond, is much larger than the characteristic relaxation times expected at the atomic scale. To explain a possible slowing down of the dynamics at such small scales, numerous approaches were considered, such as stochastic resonance, dispersive soft mode of second-order phase transition, adhesion hysteresis, as well as exhaustive analysis of the stability of the AFM oscillator. At this moment, none of these analyses are sufficiently decisive to explain the atomic contrast of a dissipation image.

Leaving aside the numerous works and discussions concerning the experimental results showing damping image with contrast at the atomic scale in UHV conditions,<sup>[20]</sup> the FM mode should be the most convenient way to extract physical quantities. However, because of the use of a feedback loop to keep constant the oscillation amplitude, spurious effects are possible that may affect the damping contrast at the atomic scale or nanometer scale for soft materials.<sup>[10,41]</sup> In order to evaluate the instrumental contributions, two simple equations can be used to evaluate artifact damping and frequency variation. Eq. (5) gives the damping due to an abrupt change of the resonance frequency:

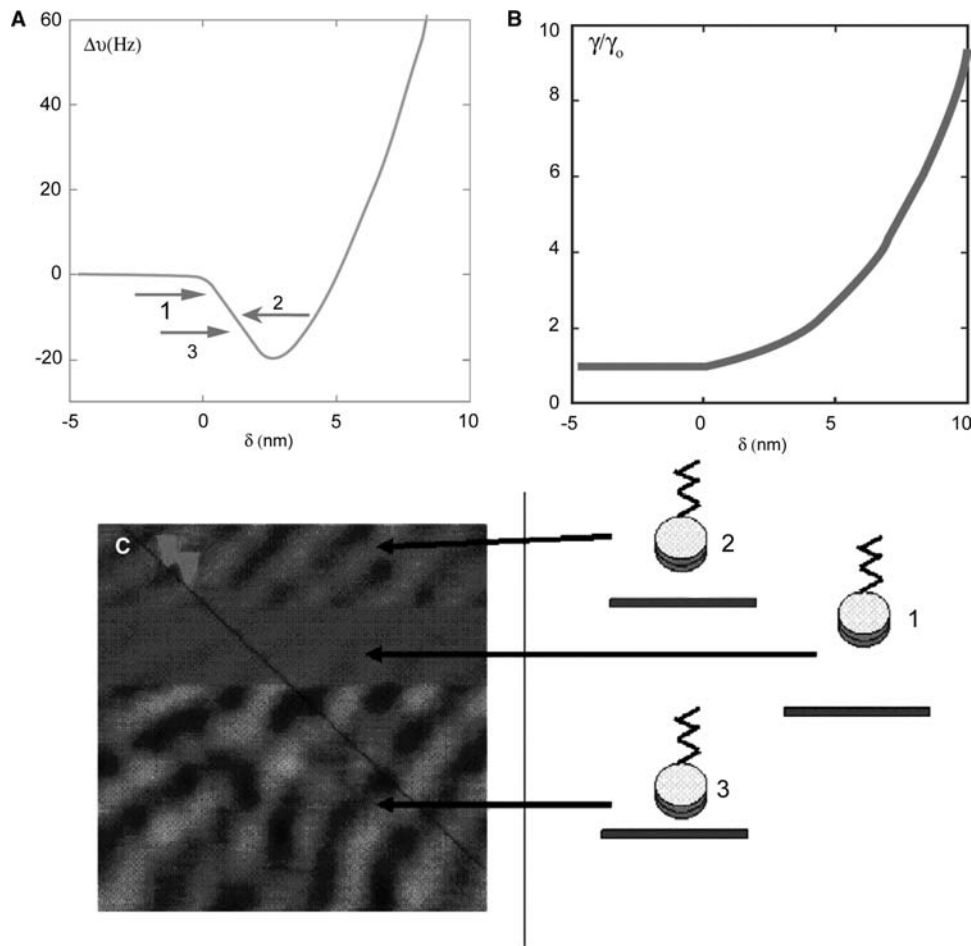

$$D_a \simeq \frac{1}{\omega_0} \left[ \frac{\omega}{Q} + \frac{1}{\omega_0} \frac{d\omega}{dt} \right]. \quad (5)$$

Eq. (5) gives the contribution of the machine to the damping coefficient without the need of the existence of dissipation processes when the tip interacts with the surface. The first term means that the damping coefficient, scaling as  $1/Q$ , is slightly modified because of the frequency shift. Typical relative variation of the frequency shift is  $10^{-4}$  and can be safely ignored. The second term rises when images, or approach retract curves, are nonadiabatically recorded. The damping signal is averaged over a time  $1/B$ , where  $B$  is the bandwidth of the electronic loop.<sup>[10,41]</sup>  $B$  is typically the kilohertz so that, with  $B\Delta t \sim 1$ , the contribution to the damping scales may be written as  $QB\Delta\omega/\omega_0^2$ . Assuming  $\omega_0 = 10^6 \text{ rd s}^{-1}$ , and  $Q = 10^4$ , gives a contribution

between the different regimes occurs. Whatever the location, the general features remains the same. At a given indentation depth, the variation of the oscillation amplitude induces change of the residence time into the polymer. A consequence is that the transition between the two regimes occurs at different indentation depths. (B) Same data as those shown in Fig. 6A with the y-axis multiplied by the power law  $A^{3/2}$ . (C) Same data as those shown in Fig. 6A with the y-axis multiplied by the power law  $A^{5/2}$ . Source: Adapted from *J. Phys.: Condens. Matter.* 2003; 15: 6167–6177. Ref.<sup>[16]</sup>

**Fig. 7** (A) FM-AFM height image recorded on a triblock copolymer composed of a central sequence of polymer melt and two sequences of glassy polymer. The image is recorded with a negative frequency shift.<sup>[10]</sup> (B) Corresponding damping image recorded simultaneously with the height image (Fig. 7A). The damping image shows the nanophase segregation.

**Fig. 8** Frequency modulation data on triblock copolymers. (A and B) Resonance frequency shift (A) and damping (B) curves as a function of the tip indentation depth. The shift of the resonance frequency comes from a pure conservative interaction. The damping should only be issued from dissipative interaction (see paragraph III). The arrows indicate the different level of frequency shifts used to record the damping image in Fig. 8C. (C) Variation of the contrast on a damping image. The numbers refer to the magnitude of the resonance frequency shift shown in Fig. 8A. The larger the frequency shift, the smaller the distance between the tip and the surface. The interaction between the tip and the surface is strongly enhanced by increasing the amount of dissipated energy.

**Fig. 9** Height images of the reconstructed surface  $7 \times 7$  on silicon obtained with STM and FM-AFM apparatus. The third image is the damping image recorded simultaneously with height FM image. <http://www.physik.unibas.ch/>.

$10^{-5} \Delta\omega$ . Therefore, Eq. (5) says that instrumental contributions should always be negligible, provided the FM mode is perfectly set at the resonance frequency. However, as shown recently,<sup>[40]</sup> in a narrow domain of frequencies, the feedback electronic loop can induce unstable behavior. This unstable behavior leads to a strong enhancement of the damping signal, but such an instrumental contribution can be easily removed by varying the scan frequency.

Eq. (6) gives the frequency shift induced by the machine:

$$\frac{\omega - \omega_0}{\omega_0} = \frac{1}{2Q\omega_0} \frac{d \log A}{dt}. \quad (6)$$

Relative fast change of the oscillation amplitude only occurs over the bandwidth  $\omega_0/Q$ . Thus, a typical time interval is  $Q/\omega_0$  and we have  $\omega_0 dt \sim Q$ . In that time interval the relative change of the oscillation amplitude is approximately a few percent and, with  $\Delta\omega/\omega_0 - \Delta A/AQ^2$  for large  $Q$  values, the induced frequency shift remains negligible.

To summarize this section, despite the complexity of the machine, simple expressions are available that provide an unambiguous way to discriminate between contributions from the sample physical properties at the nanometer, or atomic scale, and those rising from the use of the feedback electronic loop.

## SUMMARY

When soft materials are investigated, despite a difference of several orders of magnitude between the sample contact stiffness and the cantilever stiffness, images with a true topography can be recorded with the amplitude modulation technique (tapping mode) and a high-quality factor. Using a high-quality factor is time consuming. Thus, an accurate knowledge of the true topography will always be obtained at the expense of time. However, when the FM mode is used with the same quality factor, the oscillating tip can

deeply penetrate the soft material. Therefore, the FM mode allows study of the mechanical response of the soft material, but is unable to provide accurate information on the topography.

Triblock copolymers provide good samples to illustrate the physical origin of the contrast in height and damping images. Despite the machine's complexity, simple equations are derived extracting the contribution of the AFM electronic so that contrasts at the local scale caused by the mechanical properties are qualitatively understood. However, a more quantitative analysis depends upon the difficult task of obtaining accurate knowledge of the tip size and shape that, in the field of the local probe method, are often poorly known at the nanometer scale.

## INTRODUCTION

Self-assembly of ordered structures, a few nanometers wide, has been observed on many interfaces critical to new nanotechnologies. They are thought to arise because of a delicate balance between long-range strain field interactions and short-range chemical forces that stabilizes these structures. However, a detailed understanding of the driving forces does not exist. In this article, I will show how to identify and control these interactions that have the potential to surpass standard patterning technologies and thus, to lead the way to higher density magnetic storage, more selective catalytic materials, higher sensitivity chemical sensors, and perhaps, quantum computers. Well-ordered networks of misfit dislocations that form in monolayer-high strained metal films can be used as templates to grow two-dimensional nano-arrays of large-scale order and size uniformity in thermal equilibrium. Unique real-time measurements of the dynamics of self-assembled nano-arrays grown on silver and copper films on Ru(0001) and other metal surfaces using a variable-temperature scanning tunneling microscope (STM) will be presented. The results will guide the development of new dynamic models to describe the evolution of nanoscale structures on surfaces.

In particular, vacancy islands formed during room-temperature (RT) exposure to sulfur of a submonolayer Ag film on Ru(0001) order spontaneously to form a triangular lattice at an island area fraction just above 20%. A normal mode decomposition of the thermal vibrations of this vacancy island crystal, measured with time-resolved scanning tunneling microscopy, obtains Lamé coefficients in the range of  $10^8$  (N/m<sup>2</sup>). I will show that these estimates are consistent with stabilizing forces derived from long-range elastic interactions between the islands.

## BACKGROUND

Many observations of self-organized structures at surfaces with well-defined periodicities of 1–10 nm have recently been reported.<sup>[1–10]</sup> Self-assembly of nano-clusters has been seen in a wide variety of systems,

including surface dislocation arrays, surface alloys, metal oxides surfaces, and semiconductor quantum dots and wires. It is expected that these structures find application in higher density magnetic storage,<sup>[11–13]</sup> more selective catalysis and higher-sensitivity chemical sensors,<sup>[14]</sup> and, perhaps, nanoscale computing. It is commonly accepted that a delicate balance between long-range strain field interactions and short-range chemical forces stabilizes these structures. However, an understanding of the fundamental mechanism of self-assembly that is necessary to control the formation and stability of nanostructures does not exist. Novel experiments to identify the ordering forces of self-assembly in strained metal films to advance our basic understanding of this fascinating phenomenon have recently been performed. One particular example is the phonon analysis of the thermal vibrations in nano-arrays that is able to reveal the nanoscale interactions, just as neutron scattering is being used to measure the atomic interactions.

The technological quest for ever smaller, faster, brighter, and longer-lived in the development of electronic, magnetic, and photonic devices imposes increasingly stringent requirements on the quality of heterostructures used in commercial applications. All of these objectives are more or less directly related to an overall device miniaturization, resulting in a growing importance of surfaces, interfaces, and thin films as surface-to-volume ratios increase. Key to the advancement toward new materials is the ability to control atomic-scale growth processes precisely enough to achieve atomically smooth interfaces between dissimilar (mismatched) materials. Lattice and chemical mismatch produces stressed interfaces, significantly altering the growth properties of thin films, causing defect formation at the interface and ultimately, rough growth. Stress is also of central importance in fabricating ordered interface structures. All of this led to an immense amount of information being collected about epitaxial growth over the past decades.<sup>[15,16]</sup> Until recently, the experimental observations of surface dynamics lagged far behind the theoretical understanding. However, the arrival of new microscopes, especially scanning tunneling microscopy (STM) and low-energy electron microscopy (LEEM), which

provide the ability to observe the evolution of individual atoms and nanoscale structures in real-time, finally allowed most of the classical theories to be tested.

The physical and chemical properties of low-dimensional structures depend on their size and shape, and are in general very different from those of bulk matter. If, at least, one dimension of such structures is small enough that quantum-mechanical effects become important, their electronic, magnetic, and catalytic behavior is particularly fascinating and of great technological interest.<sup>[17]</sup> Examples of such nanoscale structures, which lie in size between atoms and solids, are clusters, ultrathin films, macromolecules, and polymers. Most of these structures are grown on crystalline surfaces. However, the controlled fabrication of such nano-arrays with reproducible properties is a serious challenge, and surface physics has to play a key role in the understanding of their formation and their characterization.

Nanofabrication efforts involving mechanical means such as lithography or standard deposition techniques have been consistently inferior to what is typically desired for most applications. Intense interest has been directed toward nanostructures that can fabricate themselves, i.e., self-assemble. There is compelling evidence that natural processes, such as the formation of regular strain-relief structures at surfaces, can be exploited to yield nanostructure arrays of unprecedented regularity. High-technology methods used in reduction of feature sizes may thus be supplanted by simple and elegant patterning techniques.<sup>[18–22]</sup> One illustrative example is the spontaneous organization of three-dimensional (3-D)  $\text{Si}_{0.25}\text{Ge}_{0.75}$  islands on a strained  $\text{Si}(001)$  surface. By observing island nucleation on  $\text{Si}(001)$ , in which  $\text{SiGe}$  islands were imbedded, Tersoff, Teichert, and Lagally<sup>[8]</sup> found strong evidence that the subsequent formation of islands at the surface is determined by the strain due to these buried islands, with nucleation occurring at each local minimum in misfit, i.e., the imbedded islands act as a template for additional island nucleation. In general, growth of a thin film on a dissimilar substrate results in a strained interface as a result of the lattice mismatch between the two materials. The strain is often partially relieved through the formation of well-ordered networks of misfit dislocations. These dislocations networks typically self-assemble into arrays with a 3-to 25-nm spacing.<sup>[23,24]</sup> The herringbone reconstruction of  $\text{Au}(111)$  is an example of how an ordered misfit dislocation network can also form on a clean surface: terminating a  $\text{Au}$  crystal in a  $(111)$  surface leaves the top layer in compression by 4% with respect to the layers below, resulting in this well-known reconstruction.<sup>[25–27]</sup> The  $(111)$  surface of platinum exhibits a similar reconstruction.<sup>[28,29]</sup> Reconstructed surfaces or lattice mismatch systems can serve

as templates for the growth of mesoscopic-scale structures of large-scale order and size uniformity.

In our study on such naturally strained silver films on the  $(0001)$  surface of ruthenium at Sandia National Laboratories, we showed how to combine interfacial stress and corrosion to create a self-ordered nanolattice of unprecedented size and regularity.<sup>[30,31]</sup> A perfectly ordered triangular 2-D lattice of vacancy islands, 25 Å across and 53 Å apart, was formed when a single monolayer of  $\text{Ag}$  on  $\text{Ru}(0001)$  is exposed to

**Fig. 1** Nanoscale self-assembly: (A) STM image of the vacancy island lattice that forms when a monolayer of  $\text{Ag}$  on  $\text{Ru}(0001)$  is exposed to sulfur. (B)  $73 \times 69 \text{ \AA}^2$  STM image of a dislocation array that forms when a strained, two-atom high  $\text{Cu}$  film (dark) on  $\text{Ru}(0001)$  is exposed to sulfur. The individual sulfur atoms appear bright in the image. The Shockley partial dislocations (bright curved regions) form in areas where the  $\text{Cu}$  film is not in registry with the  $\text{Ru}$  substrate.

sulfur at room temperature in ultrahigh vacuum (UHV) Fig. 1A. Another example of our recent work is the formation of self-organized structures of adsorbed sulfur on a dynamically responding strained copper layer, 2 atoms thick, on Ru(0001), shown in Fig. 1B. Highly regular hexagons and equilateral triangles composed of 18 sulfur adatoms are self-assembling at room temperature.<sup>[32]</sup> In both ordered nanosystems, we observed large thermal fluctuations in the arrays from one STM image to the next, taken 1 min apart, which led to the assumption that these structures are in thermodynamic equilibrium.<sup>[31]</sup> For movies of the data, please visit <http://www.nano.unh.edu>.

The great potential of this template approach is that the feature sizes should be tunable according to a basic model for the elastic interaction between vacancy islands. It is generally believed that these structures arise from a balance between short-range attractive forces and long-range repulsive forces.<sup>[33–39]</sup> On surfaces, the short-range chemical interatomic attraction between near neighbors counterbalances the long-range, substrate-mediated elastic repulsion between steps. According to these recent theories, a very important prediction is that the free energy of a surface that is composed of two separate phases can always be lowered by assembling into such patterns. The structure of the pattern depends on the surface area fraction of each phase. We have considered a simple model that can account for the spontaneous formation of the Ag island array and provide a direct connection between the magnitude of the forces and the elastic constants.<sup>[37,38]</sup>

The model has two basic ingredients: 1) The line tension  $\gamma_b$ , i.e., the energy per unit length of the vacancy island edges, expressing the cost of reducing the local coordination of edge atoms. It favors the formation of few large islands. For vacancy islands on Ag(111), one obtains  $\gamma_b \approx 0.1 \text{ eV}/\text{\AA}$ .<sup>[40]</sup> 2) An effective repulsive interaction,  $\gamma_d$ , between neighboring island edges, driven by elastic relaxations in the Ag adlayer and in the Ru substrate. It favors the formation of many small islands. At low area fraction of single vacancies, the lowest energy structure in this model is a hexagonal crystal of near-circular vacancy islands of sharply distributed radius,  $R$ , and repeat distance,  $b$ . These predictions agree qualitatively with our observations. For that model, one readily arrives at the relation

$$\gamma_d = \sqrt{3}(\lambda + \mu)b^2/(\pi R) \quad (1)$$

by assuming that an energy increase due to an isotropic expansion of the lattice unit cell is stored as elastic energy.  $\mu$  and  $\lambda$  are the Lamé constants of the lattice

( $\mu + \lambda$  is the bulk modulus and  $\mu$  is the shear modulus). The complete phase diagram for this model has been analyzed.<sup>[38]</sup> In particular, it predicts the existence of a critical area fraction,  $f_c \approx 0.29$ , at which the hexagonal array of round islands converts to a regular arrangement of parallel stripes and, at  $f_c \approx 0.72$ , transforms back to a hexagonal array but of inverted islands. A beautiful observation of this predicted phase sequence has been recently reported by Plass, Bartelt, and Keliogg<sup>[41]</sup> in a LEEM study of Pb on Cu(111) at elevated temperatures. To assess the feasibility of elastic forces as the root of stable self-organized behavior, one can employ continuum elasticity considerations<sup>[42]</sup> and relate  $\gamma_d$  directly to the stress field around each island as determined by the elastic constants of the substrate and the difference in the surface stress between Ag and Ru regions, ( $\sigma_{\text{Ag}} - \sigma_{\text{Ru}}$ ):

$$\gamma_d \approx (1 - \nu)(\sigma_{\text{Ag}} - \sigma_{\text{Ru}})^2/(2\pi\varepsilon) \quad (2)$$

where  $\nu$  and  $\varepsilon$  are Poisson's ratio and the bulk or Young modulus of the substrate, respectively.

Measurement of the Lamé constants of a 2-D lattice and its feature size and repeat distance yields the strength of the elastic interaction  $\gamma_d$  governing its ordering, by Eq. (1). From this estimate, one can derive the difference in surface stress between the adlayer and the substrate by using Eq. (2), and compare them to independent estimates for other surfaces.<sup>[42]</sup> Therefore, the formation of self-organized pattern could also be used to measure surface stresses.

A main objective of this report is to put these theories to a test, by identifying the forces that form and stabilize self-assembling nanostructures. The experiments described in the following section are designed to measure the dynamics of 2-D nanostructures grown at lattice-mismatched interfaces under various stress conditions. In the next section, I will briefly review the original dynamic approach of determining the Lamé constants of a nano-array by measuring the thermal vibrations of the 2-D lattice of vacancy islands, which allow us to identify the elastic long-range interactions responsible for the observed self-assembly. I will apply this approach to other strained heteroepitaxial interfaces, which may serve as natural templates in the formation of self-assembled nanostructures.

## EXPERIMENTAL APPROACH

The experiments outlined probe the fundamental mechanism of self-assembly of Ag vacancy islands on Ru(0001) by relating the dynamics of the observed

structures to the ordering forces of the ordered nanoscale structure. The approach is unique in the way it uses a combination of *real-time imaging techniques* to study the *elastic properties* of these low-dimensional features, which are otherwise inaccessible.

A clean Ru(0001) surface was prepared in UHV after an initial brief argon sputtering, by repeated oxygen adsorption and flash desorption at 1800 K, and monitored by Auger electron spectroscopy and a room-temperature STM. Micron-wide terraces, separated by monatomic steps, can be typically obtained on this Ru surface. Slightly less than 1 monolayer ( $\sim 0.8$  ML) of Ag was deposited at RT on the prepared Ru surface by evaporation from a resistively heated tungsten basket, at a rate of about  $10^{-2}$  ML/sec as estimated from Auger Electron Spectroscopy (AES) and inspection of STM images. Subsequent flash annealing to 750 K produces a single atomic height film of Ag with the highly ordered equilibrium dislocation pattern shown in Fig. 2A. This structure consists of a network of surface edge dislocations that relieve the local strain induced by the 6.6% lattice mismatch between Ag and Ru.<sup>[43]</sup> In the darker regions in Fig. 2A, Ag atoms reside at bridge sites. These regions nest a pair of surface edge dislocations, the cores of which form a near-square array with a unit cell of about  $40 \times 60 \text{ \AA}$ . In the bright regions, the Ag adlayer is pseudomorphic with the Ru substrate, and thus considerably strained. Presumably, both dark and bright regions are locally highly reactive. We exposed this strained Ag film to sulfur at RT. Sulfur is evaporated from a solid-state electrochemical doser.<sup>[44]</sup> The typical dosing rate was about  $5 \times 10^{-3}$  ML/sec at a background pressure of  $5 \times 10^{-10}$  Torr. Sulfur exposure estimates were based on partial pressure measurements, and S coverages were estimated from Auger spectroscopy and STM images.

In the first stages of the reaction, sulfur etches the region around the cores of the dislocations in the Ag film, forming highly mobile, isolated vacancy islands of monatomic depth, about  $34 \text{ \AA}$  ( $\pm 11 \text{ \AA}$ ) in diameter Fig. 2B. While isolated, these islands are significantly more mobile than has been observed for diffusion of homoepitaxial vacancy islands of similar size on metal(111) surfaces.<sup>[45]</sup> Hopping seems to occur between nearest-neighbor (NN) grid positions defined by the dislocation network, corresponding to an effective island hop rate of about  $0.1 \text{ sec}^{-1}$  at RT. When islands meet, they often form stable clusters of two or more islands, about  $50 \text{ \AA}$  apart, which eventually dissociate, as illustrated in Fig. 2B. Strong short-range repulsions between islands in a cluster seem to prevent them from coalescing. This high mobility suggests that the surface configuration is equilibrated. Atomic resolution images of the islands reveal ordered 2-D sulfur clusters coating the exposed Ru. The sulfur adatoms

**Fig. 2** Dilute gas of vacancy islands: (A)  $400 \times 200 \text{ \AA}^2$  STM image of the misfit dislocation structure of the annealed submonolayer Ag/Ru(0001) film. (B) Sequence of STM images of the same  $500 \times 500 \text{ \AA}^2$  area after exposure to 0.04 ML of sulfur at RT. Dark depressions are 1-atom deep vacancy islands in the Ag film.

form a  $p(2 \times 2)$  structure, as observed in previous sulfur-on-Ru(0001) adsorption experiments. The presence of sulfur covering the Ru regions is not surprising because it lowers their surface free energy and forms a strong S–Ru bond.

With increasing sulfur coverage, the densities of vacancy islands, and self-assembled clusters of islands, increase and the average size of individual islands decreases slightly (to  $2R \approx 24 \text{ \AA}$  average diameter). For sulfur coverages close to 0.1 ML, a highly ordered triangular lattice of vacancy islands forms, with period of  $b \approx 53 \text{ \AA}$  and a feature density of  $10^{14} \text{ cm}^{-2}$  (Fig. 3). The Fourier transform of this 2-D crystal obtains a sharp sixfold diffraction pattern. The distribution of island sizes is also extremely narrow. The width of the distribution of island diameters,  $\pm 4 \text{ \AA}$  (assuming near-circular islands), is comparable to the imaged width of the island edges. We find a few defects in

**Fig. 3** Triangular vacancy island lattice: (A)  $2000 \times 2000 \text{ \AA}^2$  STM image of the 2-D vacancy island crystal. Three ruthenium terraces are shown; again, the holes appear dark. The high order of the lattice can be seen in the sharp diffraction pattern of the image, shown in the inset. (B) Size distribution of the vacancy islands:  $N$  is the number of islands and the solid line is the gaussian fit. The average area is  $(462 \pm 117) \text{ \AA}^2$ .

the crystal, mostly larger vacancy islands ( $\sim 50 \text{ \AA}$  in diameter and density of  $\sim 2 \times 10^{-5}$  islands/ $\text{\AA}^2$ ), which we observed to form by accretion of two or more individual islands during larger amplitude vibrations. The range of perfect ordering is only limited by the terrace width.

Fig. 4(A) and (B) shows another STM image of the vacancy island lattice in Ag film on Ru. Taking a sequence of images 20 sec apart revealed that the holes

**Fig. 4** Thermal vibrations of 2-D nano-array: (A) and (B)  $700 \times 640 \text{ \AA}^2$  STM image of the 2-D vacancy island lattice. (C)  $x$ - and  $y$ -components of the center-of-mass trajectory of four nearest neighbor islands, taken from a sequence of 690 frames, 20 sec apart. About 80 islands were simultaneously tracked.

are moving collectively at room temperature. The trajectories of four hole centers are shown in Fig. 4C. The thermal motion of the holes is clearly correlated and caused by random Ag atom diffusion. These islands vibrate around their equilibrium positions in a manner similar to atomic vibrations, or phonons, in a harmonic crystal. The amplitude of the harmonic hole motion is determined by the force between the holes holding the 2-D lattice together. One can think of the nano-lattice as an elastic solid with a shear and a bulk modulus. These elastic constants of the 2-D lattice can be determined from a normal mode analysis of the  $\mathbf{q}$ -dependence of the vibrations in the same way as performed for bulk phonons for decades. We determined the amplitude of the longitudinal and transversal phonon modes of the 2-D lattice, by thermally averaging the Fourier transform of many images. Nelson and Halperin<sup>[46]</sup> and Huse<sup>[47]</sup> give the expressions that relates these amplitudes to the Lamé constants  $\mu$  and  $\lambda$  :

$$\begin{aligned} \text{longitudinal mode } \langle u_L(q)u_L(-q) \rangle / A &= \frac{k_B T}{q^2 \mu} \\ &\times \left( 1 - \frac{\mu + \lambda}{2\mu + \lambda} \right) \end{aligned} \quad (3)$$

$$\text{transversal mode } \langle u_T(q)u_T(-q) \rangle / A = \frac{k_B T}{q^2 \mu}$$

$u(q)$  is the Fourier transform of the center-of-mass displacements of the vacancy islands that are directly taken from STM movies,  $\langle \dots \rangle$  denotes an ensemble average,  $A$  is the system area,  $T$  is the temperature, and  $k_B$  is the Boltzmann constant. The data showing the thermal vibrations of the Ag/Ru nano-lattice are available electronically at <http://www.nano.unh.edu>.

For a perfectly ordered  $6 \times 6$  vacancy island cell, and the smallest nonzero  $q = 4\pi/(10\sqrt{3}b) \approx 0.14 \text{ nm}^{-1}$ , we estimate  $\lambda/c \approx \mu/c \approx 10^8 \text{ (N/m}^2\text{)}$ . Here,  $c \approx 4 \text{ \AA}$  is the vertical lattice spacing of the Ag/Ru(0001) film, and is introduced to facilitate comparison with bulk values (notwithstanding major

differences in the physics underlying phonon behavior in a crystal of atoms and thermal fluctuations in our island crystal). Typically, one finds significantly larger values for the bulk quantities,  $\lambda_{\text{bulk}} \approx 10^{11}$  (N/m<sup>2</sup>) and  $\mu_{\text{bulk}} \approx 10^{10}$  (N/m<sup>2</sup>), reflecting the fact that the long-ranged ordering forces of the vacancy island lattice are much weaker than the forces ordering atomic crystals (which is no surprise!).

We found that these estimates were consistent with stabilizing forces derived from long-range elastic interactions between islands.<sup>[42]</sup> Putting the just-measured values for  $\mu$  and  $\lambda$  as well as  $b \approx 53$  Å and  $R \approx 12$  Å in Eq. (1), we obtain  $\gamma_d \approx 0.2$  eV/Å. Assuming  $\nu_{\text{Ru}} \approx 0.5$  and  $\varepsilon_{\text{Ru}} \approx 10^{10}$  N/m<sup>2</sup>, similar to those of other elemental metals, the estimate of  $\gamma_d$  according to Eq. (2) implies  $(\sigma_{\text{Ag}} - \sigma_{\text{Ru}}) \approx 0.4$  eV/Å<sup>2</sup>. This is within the range of  $\sigma$  values reported for unreconstructed metal(111) surfaces,<sup>[42]</sup> providing confidence in our central estimate of  $\gamma_d$ . In summary, we were able to quantify the influence of the individual units of the array on each other's positions to probe the strength and physical origin of the underlying interactions and ultimately describe the equation of motion of a self-organized nano-array.

## OUTLOOK

So far, this powerful method has only been applied to this particular system, and we are currently attacking the problem of self-assembly by systematically measuring the phonon spectra in a variety of self-organizing nanostructures and determine their ordering forces. Performing these experiments at various temperatures will enable us to probe the stability and the thermodynamic properties of the 2-D arrays in a way that has not before been achieved.

A just-completed custom-designed, variable-temperature STM is able to operate in a temperature range between 25 and 500 K. In this design, the operator has the unique ability to go back to exactly the same spot on the surface, even after the sample has been removed to another in situ or even ex situ analysis, or modification tool. To operate the STM, the sample is attached to a thermally well-shielded 6-kg aluminum block that serves as the cooling and heating reservoir. The Al mass that is precooled or preheated guarantees a very high temperature stability of the STM. During our measurements, the change in sample temperature is only about 1°/hr, which makes it possible to take very fast image sequences of images over many hours without significant thermal drift of neither tip nor sample. Through improvements to the thermal shielding of our new STM, the sample can

now be imaged down to 25 K by precooling of the Al reservoir via liquid helium transfer.

We are currently growing 2-D lattices on strained interfaces between a bimetallic atomic layer of catalytic active metals such as Cu, Ag, Au, and Co of varying composition and a single-crystal Ru(0001) substrate in ultrahigh vacuum. The amount of interfacial strain will depend on the lattice mismatch and alloy composition. Exposing these strained metal films to sulfur, oxygen, or hydrogen gases is expected to result in the formation of highly ordered vacancy island structures of specific feature densities, as we have previously observed in the Ag/Ru and Cu/Ru system. We will also grow nanostructures on the reconstructed surfaces of Au(111) and Pt(111) by using the network of misfit dislocation as a template. Novel real-time measurements of the lattice dynamics of these nanometer-sized arrays will enable us to study the thermodynamics and kinetics of the formation of these self-assembled nanostructures. The approach is unique in the way it uses a combination of *real-time imaging techniques* to study the *elastic properties* of these low-dimensional features, that would otherwise be inaccessible.

By increasing the sample temperature, we can determine the melting temperature  $T_m$  of the 2-D equilibrium structure and test the theoretical predictions for the conventional melting transition in two dimensions via dislocation unbinding.<sup>[48]</sup> According to Kosterlitz and Thouless,<sup>[49]</sup> the melting temperature should depend on the elastic lattice properties as

$$T_m = (b^2/4\pi)\mu(\mu + \lambda)/(2\mu + \lambda) \quad (4)$$

The nano-array's elastic constants  $\mu$  and  $\lambda$  and the lattice constant  $b$  are now directly measurable through our original experimental approach, outlined above. However, we expect other mechanisms, e.g., an increase in the density of large clusters of coalesced vacancy islands (corresponding to formation of many-fold disclinations), to play a significant role in the melting behavior of our 2-D crystal.

The melting temperature seems to be within the accessible temperature range of the STM, because according to the phenomenological Lindemann criterion, a crystal is expected to melt when the root-mean-square (rms) fluctuations of the constituent particles about their equilibrium positions exceeds approximately 20% of the interparticle separation. At room temperature, we measured vibrational amplitudes of the thermally excited hole oscillations as large as 10 Å, one-fifth of the average separation between nearest-neighbor islands Fig. 4C.
