Hard coatings such as diamond-like carbon layers are widely used as protective coatings on metal substrates, such as steel. Recently, the passivating of silicon surfaces within micro-electromechanical systems using carbon films has been proposed to prevent stiction and to reduce friction. Coatings have industrial applications in many engineering components. Both soft and hard coatings can inhibit adhesion between the substrate and the counterface resulting in decreased wear. They may also make surface defects less harmful by moving crack initiation sites from the surface down to subsurface regions, thus improving the performance of the substrate.

Various techniques such as chemical vapor deposition (CVD) and pulse laser deposition are being used to deposit carbon on to silicon.<sup>[9]</sup> Depending on the technique and conditions, either amorphous carbon films or diamond-like carbon films can be produced, of which the latter exhibit high density, extreme hardness, high thermal conductivity, chemical inertness, and infrared transparency. However, the films often suffer from adhesion problems—partially or totally delaminated at the interface or in the substrate due to high compressive stresses.<sup>[10–21]</sup> For example, Freller et al.<sup>[11]</sup> showed that when the compressive stress in a film exceeds the ultimate tensile strength of the substrate, failure occurs in the substrate. Zehnder et al.<sup>[12]</sup> reported that a film deposited at 20°C showed no evidence of failure in the bulk, but delaminated at the interface, all over the sample. On the other hand, a film grown at 500°C would adhere very well to the silicon substrate, but would delaminate when its thickness exceeds 600 nm. Som et al.<sup>[13]</sup> studied the delamination

of CVD diamond films deposited on silicon and estimated that the biaxial compressive stress to initiate the film buckling was 1.19 GPa.

## DISCUSSION

### Uniaxial and Biaxial Compression of Diamond-Coated Silicon

Buckling delamination of a coating is unwanted in industrial applications. Thus, a fundamental understanding of the stress relief patterns or buckling modes and the stress levels at which buckling occurs is necessary. Some very interesting buckling patterns such as telephone-cord, sinusoidal wave, sinusoidal shape with extra branches, and a strings-of-beads pattern have been reported in Refs.<sup>[15,17,18]</sup>. Gioia and Ortiz<sup>[10]</sup> have compiled most of these patterns in their paper on delamination of compressed thin films. However, the studies to date have been mainly using experimental techniques and continuum mechanics. Although Pailthorpe, Mitchell, and Bordes<sup>[1]</sup>, McKenzie, Muller, and Pailthorpe<sup>[2]</sup>, and Rosenblum et al.<sup>[3]</sup> used atomistic simulation in their studies on coating, they concentrated mainly on the energy diffusion, the structure of films, and the mismatch-induced residual thermal stresses in film substrate systems.

The buckling of a thin film is caused by local compressive stresses on the film, introduced by the coating process. Thornton<sup>[4]</sup> pictured this process as follows: first the incident atoms transfer kinetic energy to the substrate and become loosely bonded “ad atoms.” They then diffuse over the surface exchanging energy with the substrate until they are either desorbed or trapped at low energy sites of the substrate. Thus, the initial kinetic energy transfer to the substrate can induce a tensile stress on the substrate. When the atoms diffuse over the surface, a compressive stress can be induced back to the coated atoms.

In the present molecular dynamics simulation, for convenience but still capturing the nature of the residual stress generation, we apply the tensile stresses on the substrate before placing the coating and then release the stress with the coating on, so that the film will undergo compressions as experienced in experiment. We focus on the deformation of a diamond carbon coating on silicon under various stress levels with different ratios of compressive stresses in two perpendicular directions,  $X$  and  $Y$ , as shown in Fig. 1. A piece of diamond cubic silicon (1 0 0) with the control volume of  $10.3 \times 10.3 \times 3.8 \text{ nm}^3$  (i.e., 19 unit cells  $\times$  19 unit cells  $\times$  7 unit cells), containing 21,516 atoms, was used as a substrate. The outermost layer of the substrate atoms with the exception of the top (1 0 0) surface was thermostated to 300 K. The tensile stresses

**Fig. 1** The simulation model for compression of diamond-coated silicon.

were applied by forced atomic displacements at the boundary of the control volume in the following distinct ways to uncover the effect of stress variation in the film plane: (i) uniaxially (along the  $X$ -direction), i.e. the stress externally applied in  $Y$ -direction would be zero and hence the stress ratio is  $\sigma_y/\sigma_x = 0$ , (ii) biaxially with less displacement along  $Y$ -direction to give the stress ratio of  $\sigma_y/\sigma_x \approx 0.5$ , and (iii) biaxially with equal displacements along both  $X$ - and  $Y$ -directions to give the stress ratio of  $\sigma_y/\sigma_x \approx 1$ . Three atomic layers of diamond coating with dimensions  $9.987 \times 9.987 \times 0.1783 \text{ nm}^3$  having 4817 atoms were placed on the stressed substrate. The coating and substrate were relaxed together for 5Ps and then the stresses on the substrate were released gradually. A three-body Tersoff potential,<sup>[22,23]</sup> which has been used in many successful MD simulation studies,<sup>[24–28]</sup> was used for Si–Si and C–C interactions. A two-body Morse potential was used for C–Si interactions. This potential has been proved to be reliable in describing C–Si, C–Cu, and C–Al interactions.<sup>[27–32]</sup> Since the purpose of this study is to explore the deformation patterns of the film, to facilitate the observation of the buckling deformation, we apply sufficiently large stresses, much higher than the critical buckling stress measured in relevant experiments,<sup>[13,15]</sup> provided that they are within the elastic limit of silicon.

#### Substrate under uniaxial stress ( $\sigma_y/\sigma_x = 0$ )

When subjected to a uniaxial stress  $\sigma_x$ , we find that the substrate of monocrystalline silicon deforms plastically at a Cauchy stress (also known as true stress and defined as force/current area) of 16.0 GPa. Hence, in the present study, the coating was placed on the substrate pretensioned to 12.5 GPa at which the silicon substrate still deforms elastically. Fig. 2A shows a cross-section of part of the substrate and film after releasing the stress on the substrate. The film buckled

**Fig. 2** (A) A cross-section of portion of the film and substrate. (B) Sinusoidal buckling pattern of the top layer of the film in  $X$ -direction, after releasing the uniaxial stress ( $\sigma_y/\sigma_x = 0$ ).

and slightly delaminated in some places at the film–substrate interface. The top layer of the film viewed from the top, at a tilted angle, is shown in Fig. 2B. This presents an interesting buckling pattern with sinusoidal wrinkles mainly in  $X$ -direction along which the stress is applied.

#### Substrate under biaxially unequal stresses ( $\sigma_y/\sigma_x = 0.5$ )

In this case, the substance deforms plastically at a Cauchy stress of 18.32 GPa in the  $X$ -direction and 9.72 GPa in the  $Y$ -direction. Coating was placed on the substrate having the same strain along  $X$  as in case (i) with  $\sigma_x = 15.10$  GPa and  $\sigma_y = 8.86$  GPa, which were well below the above critical stress values. Fig. 3A shows a cross-section of part of the substrate and film after releasing the stress on the substrate. The film buckled and delaminated, but the delamination occurred only at certain places at the interface. The deformation in the topmost layer of the film is shown in Fig. 3B. It is clear that the size of the wrinkles is bigger than that of case (i), but the buckling mode in the present case is no longer uniaxially sinusoidal. The application of  $\sigma_y$  created the wave in  $Y$ -direction as well.

#### Substrate under biaxially equal stresses ( $\sigma_y/\sigma_x = 1$ )

Now the substrate starts to deform plastically at a Cauchy stress of 13.8 GPa in both  $X$ - and  $Y$ -directions.

**Fig. 3** (A) A cross-section of portion of the film and substrate. (B) Wavy buckling pattern of the top layer of the film, after releasing the biaxial stresses ( $\sigma_y/\sigma_x = 0.5$ ).

The coating was placed on the substrate having the same strain along  $X$  as in case (i) with both  $\sigma_x$  and  $\sigma_y = 13.4$  GPa, which were below the above critical values. Again on releasing the stress, the film buckled and delaminated. A cross-section of part of the film and substrate is shown in Fig. 4A and the topmost layer of the film is shown in Fig. 4B. Now, it is interesting to note that the size of the wrinkles becomes larger than those in both cases and the overall buckling pattern approaches a telephone-cord-like structure as observed in many experiments.

In all the three cases, although the delamination occurs at the interface, the film tends to attract a layer of Si atoms. This is because both the C–C interaction ( $348 \text{ kJ mol}^{-1}$ ) and the C–Si interaction ( $285 \text{ kJ mol}^{-1}$ ) are greater than the Si–Si interaction ( $176 \text{ kJ mol}^{-1}$ ),<sup>[38]</sup> so that the Si atoms are attracted toward the C-film when the film possesses a considerable bending rigidity. The results show that within each case, the buckling mode and the size of the wrinkles did not change significantly, but the pattern became more pronounced, on completely releasing the stress. On the other hand, the buckling mode did vary with the  $\sigma_y/\sigma_x$  ratio, from mainly a sinusoidal mode with  $\sigma_y/\sigma_x = 0$  to a telephone-cord-like structure  $\sigma_y/\sigma_x = 1$ .

Thin film buckling does occur on the atomic scale when the compressive stresses in a film are sufficiently high. The buckling mode varies with  $\sigma_y/\sigma_x$ , indicating that the stress ratio is an important factor that

**Fig. 4** (A) A cross-section of portion of the film and substrate. (B) Telephone-cord-like buckling pattern of the top layer of the film, after releasing the biaxial stresses ( $\sigma_y/\sigma_x = 1$ ).

influences the nature of the buckling patterns. It is interesting to note that the pattern of atomic scale buckling of a thin film is similar to that observed in microscale experiments.

## MOLECULAR DYNAMICS SIMULATIONS

Two particular situations are analyzed by molecular dynamics calculations, showing the variations of atomic structures in coating layers and substrate during the indentation and sliding of diamond-coated silicon.

### Indentation of Diamond-Coated Silicon

Simulations of the deformation of diamond carbon-coated silicon under indentation with different coating thicknesses are carried out in this entry. A piece of diamond cubic silicon (1 0 0) with control volume size of  $10.3 \times 10.3 \times 5.5 \text{ nm}^3$ , containing 30 411 atoms, was used as a substrate. The outermost layer of the substrate atoms with the exception of the top (1 0 0) surface was maintained at 300 K by scaling the

velocities of the thermostat atoms. Various atomic layers of diamond carbon coating with top surface area  $9.987 \times 9.987 \text{ nm}^2$  were placed on the substrate. The coating and substrate were then indented with a rigid spherical indenter and the results of the indentation were analyzed. The indentation speed is 300 m/s and the indenter radius is 2 nm.

A three-body Tersoff potential was used for Si–Si and C–C interactions. A two-body Morse potential was used for C–Si interactions.

In a micrometer scale study of indentation of diamond-like carbon coating on steel, Michler and Blank<sup>[33]</sup> found that if the coating thickness is larger than radius of indenter, the coating deforms with increasing indentation load before the substrate experiences plastic deformation. For the cases when coating thickness is comparable with radius of indenter or smaller, coating fracture occurs after plastic deformation of substrate. Five different modes of coating/substrate failure were investigated by Michler and Blank<sup>[33]</sup> by varying the coating thickness and indenter radius ratio ( $h/R$ ). (a) When  $h/R \geq 33$  (infinite coating thickness), the coating layers were found to deform before substrate experiences plastic deformation. Also, circumferential cone cracks are formed close to the contact edge of indenter and top coating layer. In addition, if the contact radius is of the order of the indenter radius subsurface, cracks are also possible. (b) When  $h/R = 3.3$ , coating layer deforms plastically before cracking occurs. It is found that plastic zone extension is slightly larger than the layer thickness. (c) When  $h/R = 0.33$ , the extension of plastic zone in substrate reaches twice the contact radius, approximately. The cracks that nucleate at the interface below the indenter are the dominant failure mechanism. (d) When  $h/R = 0.033$ , the plastic zone extension is found to be identical to the case when  $h/R = 0.33$  and approaches the case of an elastic, fully plastic indentation into a homogeneous unlayered steel solid. Moreover, the layer bent around indentation edge. (e) When  $h/R = 0.0033$  (very thin coating layer), the bending of coating layer is low due to the low bending stiffness of coating layer. Radial and circumferential cracks under the indenter were probable.

Summarizing, three locations for preferential crack initiations were identified with decreasing ratio of layer thickness to indenter radius: (a) at the surface outside the contact area; (b) at the interface close to the symmetry axis; and (c) within the contact area at the surface or interface.<sup>[33]</sup>

On the nanometer scale, plastic deformation of silicon can occur by means of phase transformation and plastic flow without the formation of cracks or dislocations as reported in previous studies.<sup>[34–36]</sup> As such the mechanisms of coating/substrate deformation are very different from its micrometer counterparts.

It is found in this entry that the indentation of diamond carbon-coated silicon also leads to plastic deformation in both the diamond carbon-coating and silicon substrate owing to phase transformation and plastic flow. There is no observable formation of dislocation or cracks. The initiation of plastic deformation and the location of plastic deformation, however, vary with the thickness of the diamond coating.

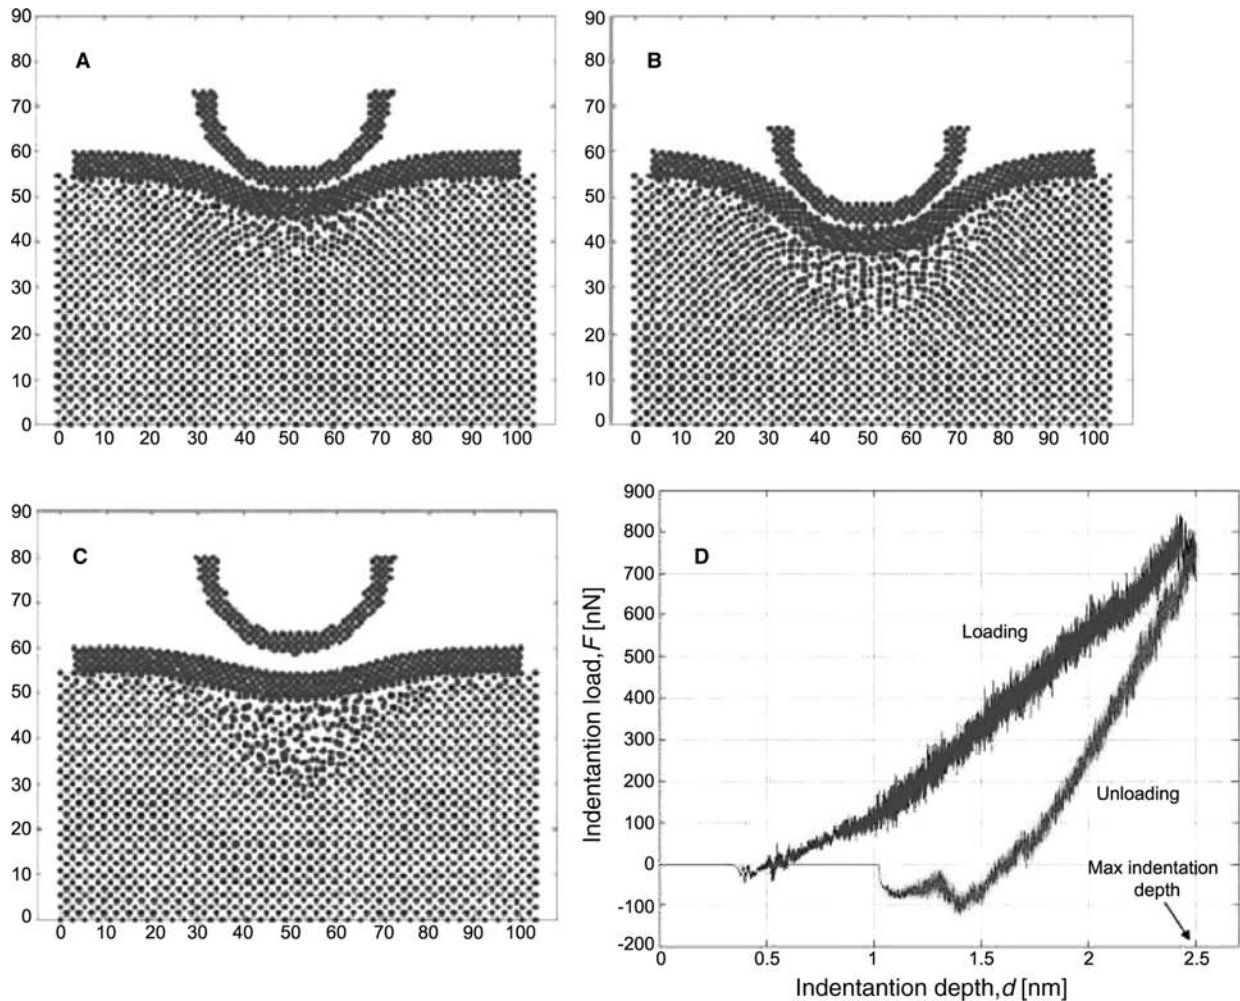

Four distinct failure mechanisms of coating and substrate due to nanoindentation are observed: (i) When the ratio of thickness of coating to indenter radius  $t^*$  ( $=t/R$ ) is 0.35. It is found that the deformation of substrate is almost identical to that in silicon owing to indentation without the carbon coating. (ii) When  $t^* = 0.7$ , it is found that the substrate requires higher indentation load to yield when compared with the case without coating owing to the thicker coating. The substrate experiences plastic deformation before there is any plastic deformation in the coating.

(iii) When  $t^* = 1.4$ , it is found that the coating experiences plastic deformation before the substrate. The substrate also experiences plastic deformation when the indenter is further loaded. (iv) When  $t^* = 2.8$ , it is found that there is no plastic deformation in silicon substrate. The mechanism of plastic deformation for the carbon-coating is similar to the plastic deformation of carbon specimen owing to nanoindentation.

Further elaboration of the four distinct mechanisms of coating–substrate plastic deformation owing to nanoindentation will be given in the following section. The results of molecular simulation calculations demonstrate the variation in deformation mechanism during nanoindentation with different coating thicknesses to asperity radius ratio.

a. Thin coating layer ( $t^* = 0.35$ )

Fig. 5A–C show the deformation of the carbon coating and silicon substrate at various time

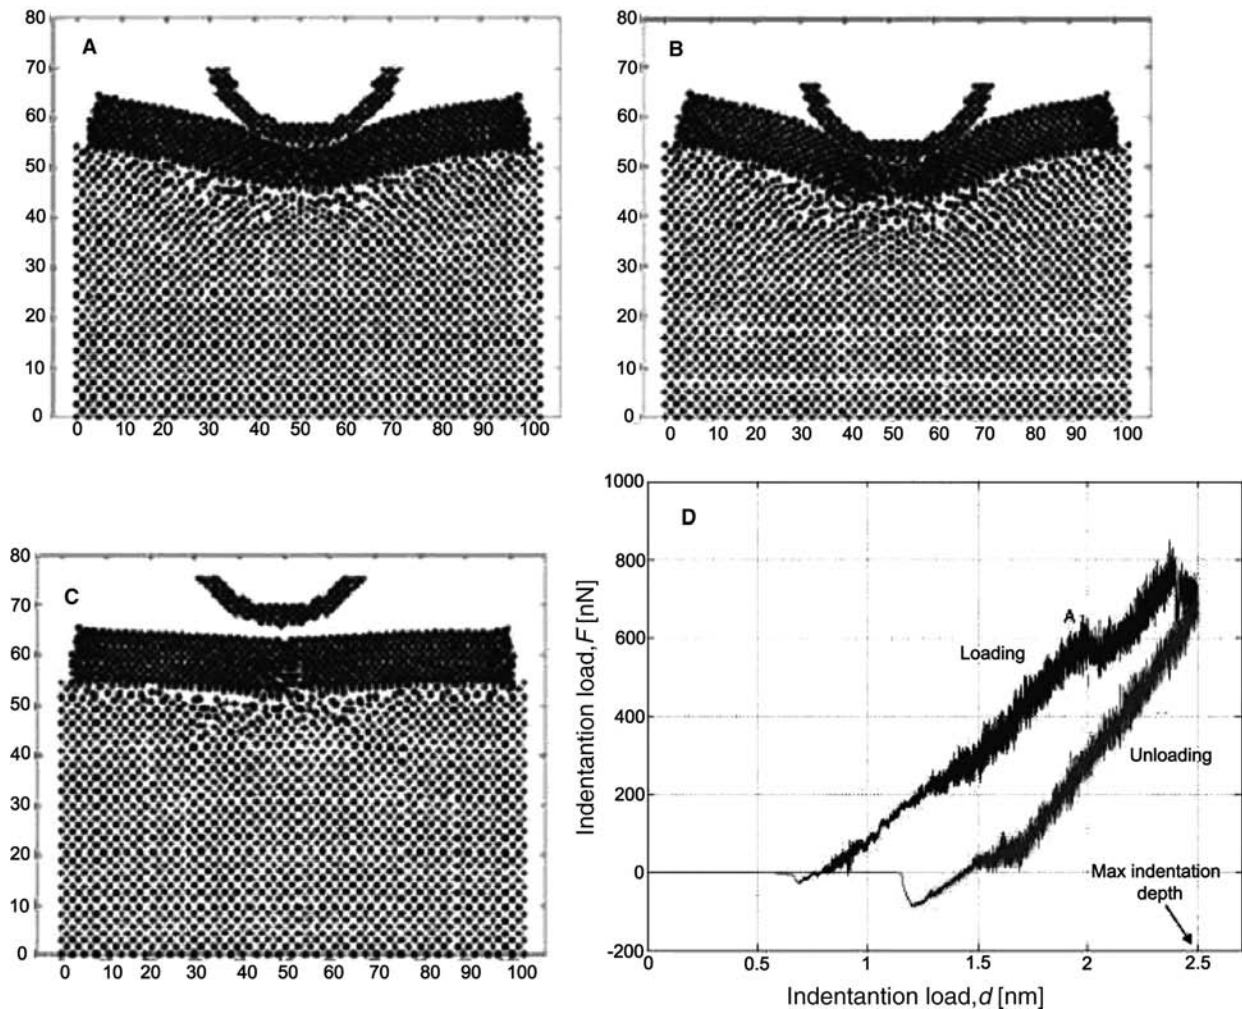

**Fig. 5** Indentation of diamond-coated silicon in case of thin coating layer when compared with the indenter radius ( $t^* = 0.35$ ). Cross-sectional views at different stages for loading and unloading during the indentation (A–C) and load versus displacement curve for indentation (D).

steps when  $t^* = 0.35$ . It is clearly shown that there is no plastic deformation in the coating and the coating recovers in an elastic manner when the indenter is unloaded. Plastic deformation, however, is evident in the silicon substrate even though the coating is intact. The mechanism of plastic deformation for the silicon substrate is similar to that of the plastic deformation of silicon due to indentation without the carbon coating.<sup>[29]</sup> The silicon substrate deforms plastically due to phase transformation and plastic flow. The resultant transformed zone is amorphous. The residual damage zone extends deep below the interface of the coating and the substrate. As a result of plastic deformation in the substrate and elastic recovery in the coating, the substrate delaminates from the coating at the substrate-coating interface below the indenter. Fig. 5D shows the

load-displacement diagram of the indenter due to the indentation. As expected, the load-displacement diagram is similar to the load-displacement diagram due to the direct indentation of silicon with a rigid indenter.<sup>[29]</sup> The main difference is the greater stiffness of the diamond-coated silicon when compared with the silicon specimen without coating.

b. Medium thickness coating layer ( $t^* = 0.7$ )

Fig. 6A–C show the deformation of the carbon coating and silicon substrate at various time steps when  $t^* = 0.7$ . It is clear that plastic deformation occurs in both the carbon coating and the silicon substrate. The damaged zone in the silicon substrate is noticeably smaller when compared with the case when  $t^* = 0.35$ . Plastic deformation of the silicon substrate is confined to the coating-substrate interface directly under the indenter. In addition, plastic deformation of

**Fig. 6** Indentation of diamond-coated silicon in case of medium thickness of coating layer when compared with the indenter radius ( $t^* = 0.70$ ). Cross-sectional views at different stages for loading and unloading during the indentation (A–C) and load versus displacement curve for indentation (D).

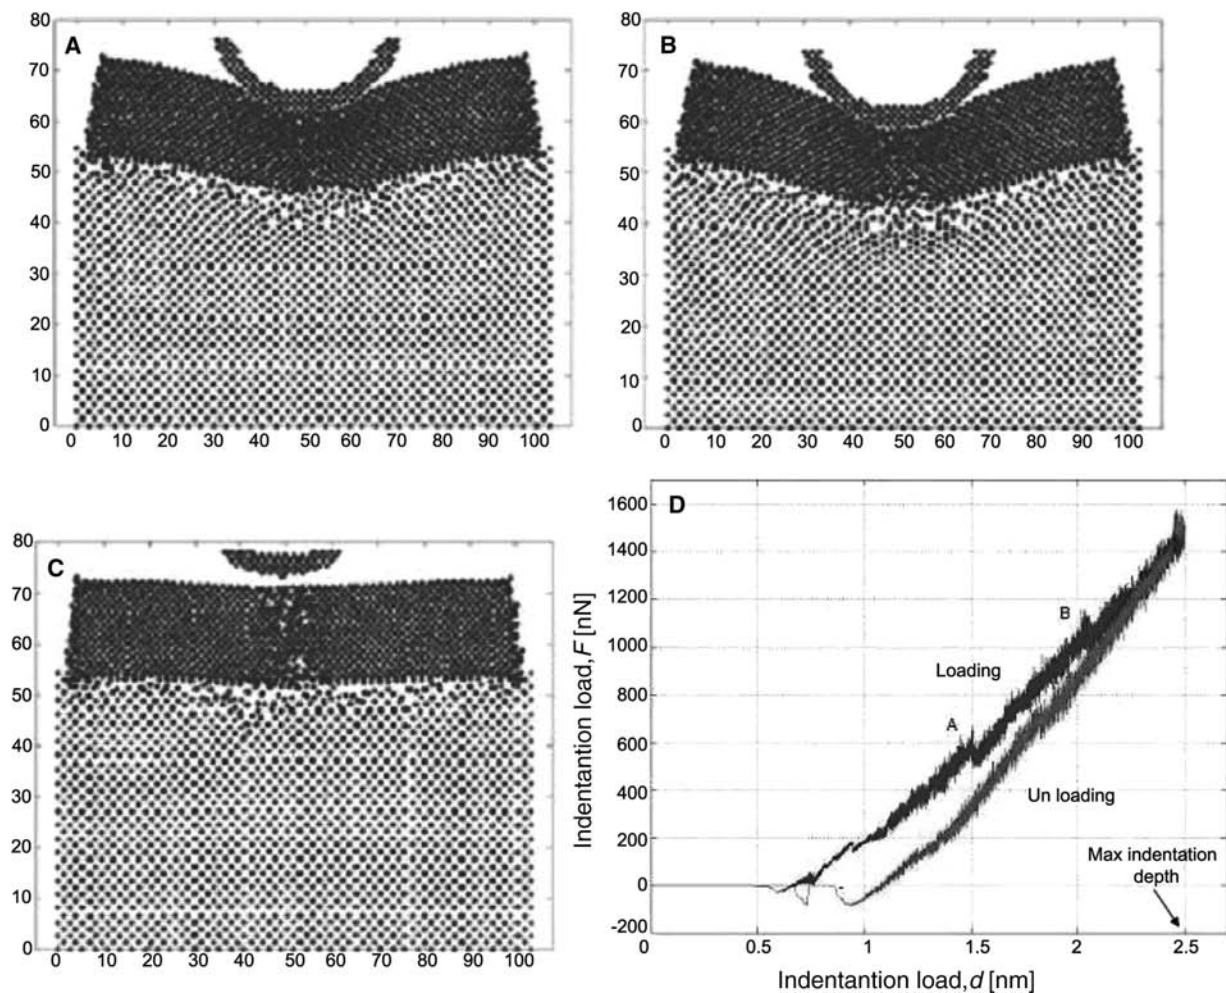

the substrate occurs before plastic deformation of the carbon coating. Delamination between substrate and coating due to plastic deformation of substrate is observed. Fig. 6D shows the force–displacement diagram of the rigid indenter. It can be seen that there is a significant drop of the indenter force at point A. This can be explained by the plastic deformation of the carbon coating. For thickness  $t^* = 0.7$ , the plastic deformation of the coating occurs throughout the entire thickness of the coating in the region directly under the indenter. The substrate experiences plastic deformation when the loading force is 400 nN. On further indentation, the coating also experiences plastic deformation when the loading force reaches 600 nN. From Fig. 6, it is obvious that plastic deformation in the diamond coating initiates from interface of the coating and the substrate

directly beneath the indenter owing to tensile stresses at the bottom surface of the carbon coating. The carbon changes from diamond cubic structure to a disordered amorphous graphitic form as discovered in experiments.<sup>[37]</sup>

c. Thick coating layer ( $t^* = 1.4$ )

Fig. 7A–C show the deformation of the carbon coating and silicon substrate at various time steps when  $t^* = 1.4$ . It can be seen that plastic deformation also occurs in both the carbon coating and the silicon substrate. The damaged zone in the silicon substrate is once again much localized and is confined to the coating–substrate interface directly beneath the indenter. The plastic deformation of the coating when  $t^* = 1.4$ , however, occurs before the plastic deformation of the substrate. Fig. 7D shows the force–displacement diagram of the indenter. The two significant drops in loading force

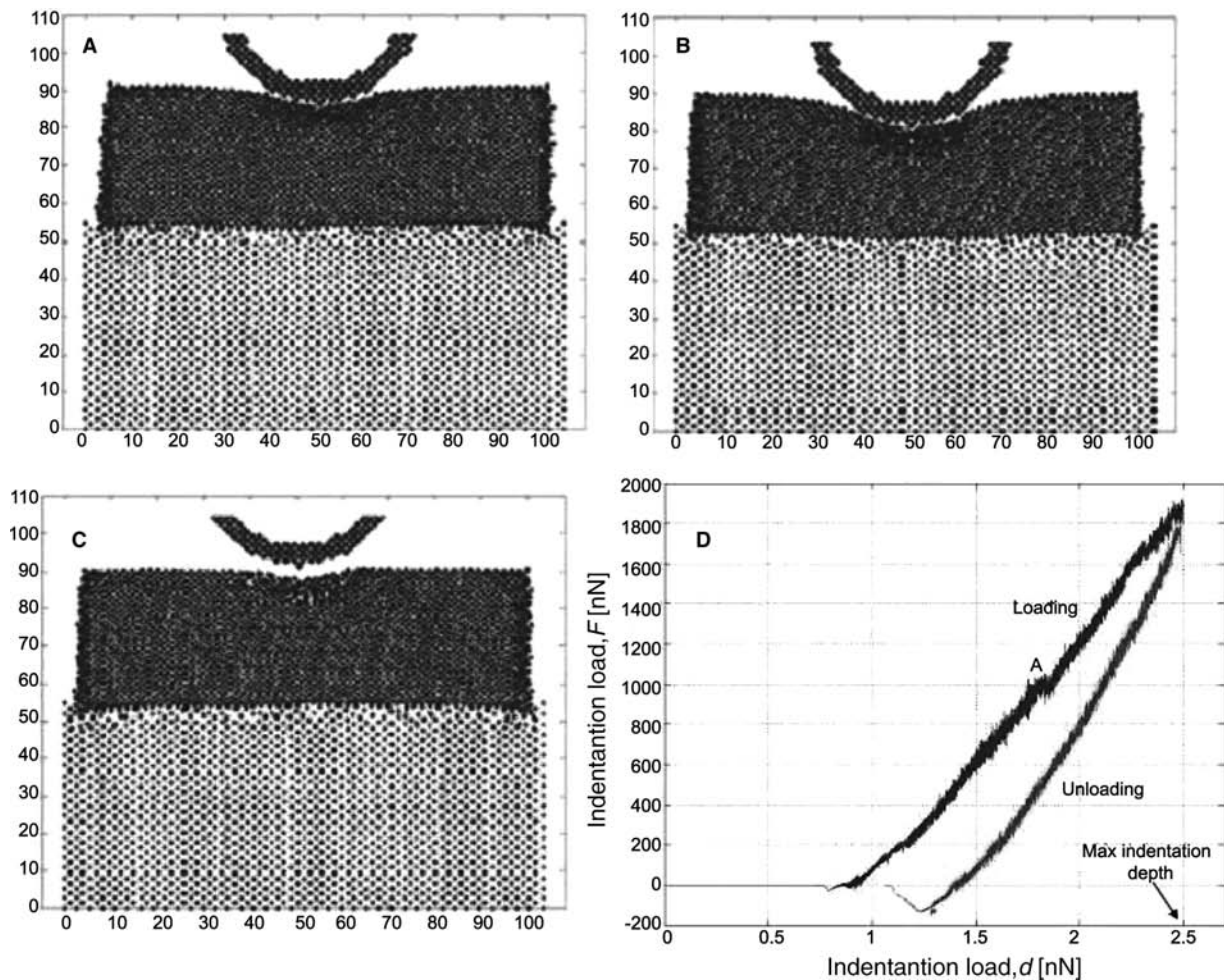

**Fig. 7** Indentation of diamond-coated silicon in case of thick coating layer when compared with the indenter radius ( $t^* = 1.4$ ). Cross-sectional views at different stages for loading and unloading during the indentation (A–C) and load versus displacement curve for indentation (D).

marked A and B are explained by the plastic deformation of the coating first at the top surface of the coating followed by plastic deformation of the coating initiating from the bottom surface of the coating when the force reaches 600 nN. The initial plastic deformation in the carbon is a result of direct contact with the indenter. Phase transformation to a graphitic amorphous phase occurs due to the stresses generated when the indenter indents the coating. The second plastic deformation in the carbon coating occurs due to the significant bending experienced by the coating during indentation. Tensile stresses generated on the bottom surface of the carbon coating due to bending of the coating layer induces a phase transformation of tetrahedral carbon to an amorphous graphitic phase leading to the plastic deformation. This occurs when the loading force reaches 1100 nN. The silicon substrate only experiences plastic

deformation when the loading force reaches 800 nN.

d. Very thick coating layer ( $t^* = 2.8$ )

Fig. 8A–C show the deformation of the carbon coating and silicon substrate at various time steps when  $t^* = 2.8$ . It can be seen that in this case, plastic deformation only occurs in the carbon coating. No observable plastic deformation is seen in the silicon substrate throughout the entire indentation process. The mechanism of plastic deformation in carbon coating is the same as that observed in direct indentation of a carbon specimen with a rigid indenter. Fig. 8D shows the force–displacement diagram of the indenter. Instead of having two drops in the force as in the previous case ( $t^* = 1.4$ ), there is only one drop in the force (pt A). This is consistent with the plastic deformation on the top surface of the carbon coating when the loading force reaches 1000 nN.

**Fig. 8** Indentation of diamond-coated silicon in case of very thick coating layer when compared with the indenter radius ( $t^* = 2.8$ ). Cross-sectional views at different stages for loading and unloading during the indentation (A–C) and load versus displacement curve for indentation (D).

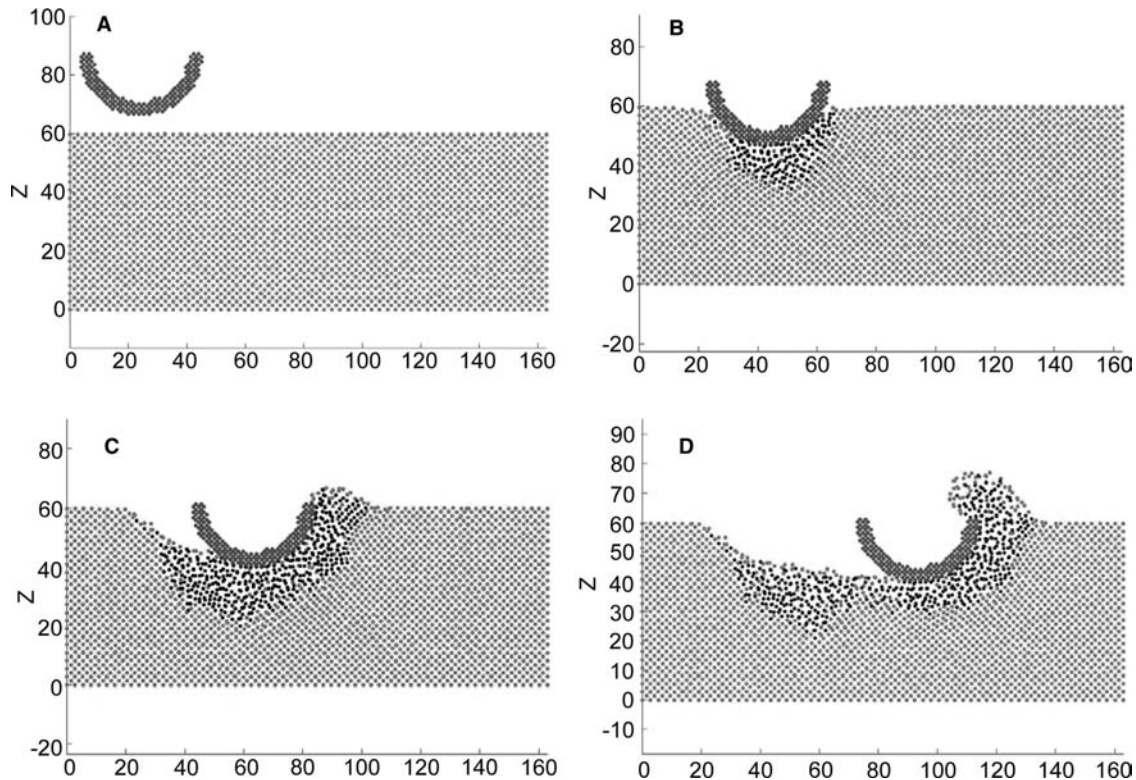

**Fig. 9** Failure map of carbon-coated silicon system owing to nanoindentation.

Noting the force at which the coating and substrate experience plastic deformation, a failure map can be plotted. Fig. 9 shows a plot of the failure map of a carbon-coated monocrystalline silicon obtained using molecular dynamics simulation. Hence, the plastic deformation of a diamond-coated silicon system can

be defined using the failure map, provided the scale of analysis is small enough to ensure that crack formation and dislocations are not initiated.

Hence as a conclusion, no observable formation of dislocations is found throughout the indentations in this present study. The occurrence of plastic

**Fig. 10** Cross-sectional views at different stages for sliding without coating ( $r^* = 0$ ). (A) Snapshot of sliding simulation at 0 time step; (B) Snapshot of sliding simulation at 20,000 time steps; (C) Snapshot of sliding simulation at 40,000 time steps; (D) Snapshot of sliding simulation at 60,000 time steps.

deformation in carbon coating and silicon substrate is solely due to amorphous phase transformation and plastic flow. As observed, the size of residual amorphous zone formed at the end of indentation decreases with the thickness of carbon coating. The initiation and location of plastics deformation, however, varies with the thickness of the carbon coating.

### Sliding of Diamond-Coated Silicon

The simulations of sliding on diamond-coated silicon are discussed in this section. The diamond asperity used is hemispherical and has a radius of 2.14 nm, consists of 1818 atoms with 0.357 nm bond length. The silicon substrate consists of 46,993 atoms, each separated away by 0.543 nm, and the dimension is  $(120 \times 68 \times 44)$  atoms, or  $(16.29 \times 9.23 \times 5.97)$  nm<sup>3</sup>. Four variations of coating thicknesses are used.

The carbon asperity is sliding and subsequent cutting into the diamond-coated silicon substrate is at a sliding speed of 100 m/s and maximum depth of cut 2 nm.

Figs. 10–14 are cross-sections of the four simulations of sliding with four different coating thicknesses.

For the same examples, Fig. 15A–D show the variation of sliding force versus time and Fig. 16A–E show the variation of normal force versus time.

In all four cases of different coating thicknesses, there were no signs of dislocations within the substrate. The inelastic deformation observed under the tool tip and along the sliding path is caused by viscous flow in the amorphous region rather than other failure mechanisms such as dislocations. Such a transformation mechanism is similar to that of nanoindentation.<sup>[29]</sup> Silicon in diamond cubic structure first transforms into a metallic body centered  $\beta$ -silicon, and upon removal of stresses,  $\beta$ -silicon further transforms into amorphous silicon.

The following examples demonstrate the variations in deformation mechanism in nanosliding with different coating thicknesses to asperity radius ratio.

#### a. No coating ( $t^* = 0$ )

The non-coated system shows similar general wear mechanisms as those described by Zhang and Tanaka.<sup>[30]</sup> As the depth of cut of the asperity increases, the mechanism of wear progresses from no-wear to adhering, ploughing,

**Fig. 11** Cross-sectional views at different stages for sliding with very thin coating ( $t^* = 0.17$ ). (A) Snapshot of sliding simulation at 0 time step; (B) Snapshot of sliding simulation at 20,000 time steps; (C) Snapshot of sliding simulation at 40,000 time steps; (D) Snapshot of sliding simulation at 60,000 time steps.

**Fig. 12** Cross-sectional views at different stages for sliding with thin coating ( $t^* = 0.35$ ). (A) Snapshot of sliding simulation at 0 time step; (B) Snapshot of sliding simulation at 20,000 time steps; (C) Snapshot of sliding simulation at 40,000 time steps; (D) Snapshot of sliding simulation at 60,000 time steps.

and finally cutting. Formation of chip is observed when the asperity is cutting the substrate (see Fig. 10).

The sliding force increases linearly from 0 to 0.03 nN as the depth of cut of the asperity increases to and remains constant at that value as the asperity ploughs through it (see Fig. 15A). Observing the normal force on the asperity (see Fig. 16A), it is found that the asperity experiences an initial attractive force when the asperity is first in contact with the silicon surface. The normal force increases linearly to 0.04 nN as the depth of cut of the asperity increases. As the asperity ploughs through the silicon causing the formation of a chip, the normal force stabilizes at 0.02 nN.

b. Very thin coating ( $t^* = 0.17$ )

The plastic deformation mechanism in this case is very similar to that of sliding without coating. The presence of the very thin coating does not change the depth of phase transformation in the silicon substrate. The coating experiences plastic deformation through plastic flow and the silicon substrate experiences plastic

deformation as in the case of sliding without coating. As the asperity slides over the carbon-coated silicon substrate, it begins to plough into the substrate forming a chip (see Fig. 11). The main difference between sliding with coating of this thickness and sliding without coating is the thinner chip formed in the case of sliding with coating. The coating contains the chips formed and hence the chip formed is thinner than that of sliding without coating. The coating fails as the asperity slides over it ploughing into the substrate. No delamination is observed.

Initially, the sliding force remains constant because the contact area is small (Hurtado and Kim). The sliding force increases as the depth of cut increases to 0.06 nN. Stick-slip phenomena are observed as the asperity slides over the coating. However, the stick-slip pattern is irregular because of the damage to the carbon coating as the asperity slides over it. The ploughing force 0.06 nN is much higher in this case than in sliding without coating because the coated chips provide more resistance to the

**Fig. 13** Cross-sectional views at different stages for sliding with medium thickness coating ( $t^* = 0.70$ ). (A) Snapshot of sliding simulation at 0 time step; (B) Snapshot of sliding simulation at 20,000 time steps; (C) Snapshot of sliding simulation at 40,000 time steps; (D) Snapshot of sliding simulation at 60,000 time steps.

asperity. Fig. 15B shows the asperity sliding force versus time steps plot.

The maximum normal force is much higher at 0.07 nN owing to the carbon coating on top

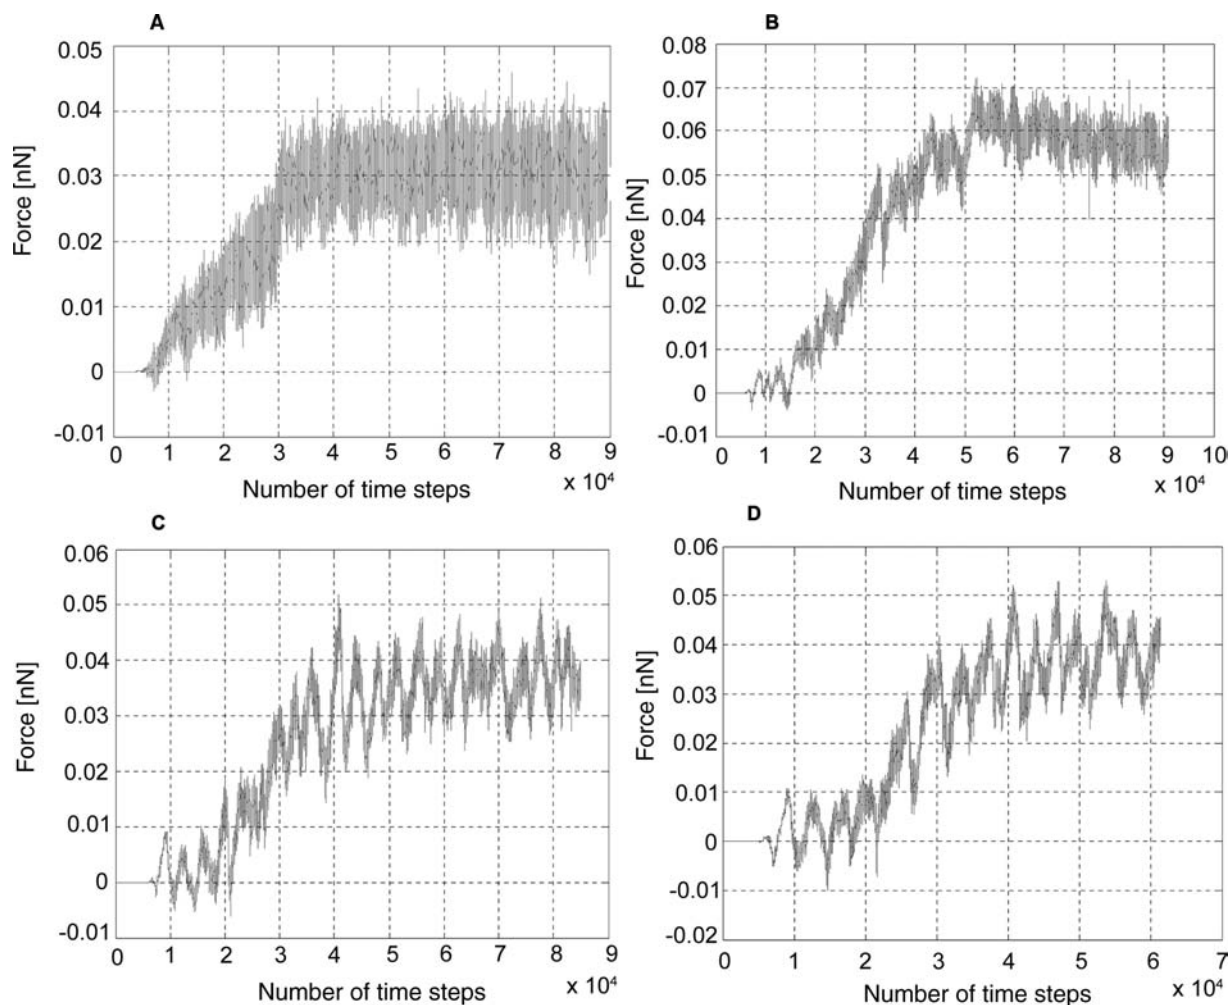

**Fig. 14** Cross-sectional view for sliding with thick coating ( $t^* = 1.4$ ).

of the silicon substrate. There is a large drop in the normal force experienced by the asperity due to failure and tearing of the carbon coating indicated by the point Q in the figure. The normal stress stabilizes at 0.01 nN because the chips formed are still contained by the carbon coating and hence do not exert that much a normal force on the asperity as in the case of sliding with coating. Fig. 16B shows the asperity normal force versus time steps plot.

c. Thin coating ( $t^* = 0.35$ )

As the thickness is increased, no ploughing is observed at the same depth of cut. Contrary to what is expected with a thicker coating, the size of the amorphous region of the substrate is surprisingly larger when  $t^* = 0.35$ , where there is no ploughing, than in the case when  $t^* = 0.17$ , when ploughing occurs. This could be due to the absence of chip formation. In the case of  $t^* = 0.17$ , the formation of chips allows the amorphous silicon to flow out of the substrate, thereby relieving the stresses

**Fig. 15** Sliding force versus number of time steps for coatings of various thicknesses: (A) no coating; (B) very thin coating ( $t^* = 0.17$ ); (C) thin coating ( $t^* = 0.35$ ); (D) moderate thickness coating ( $t^* = 0.7$ ).

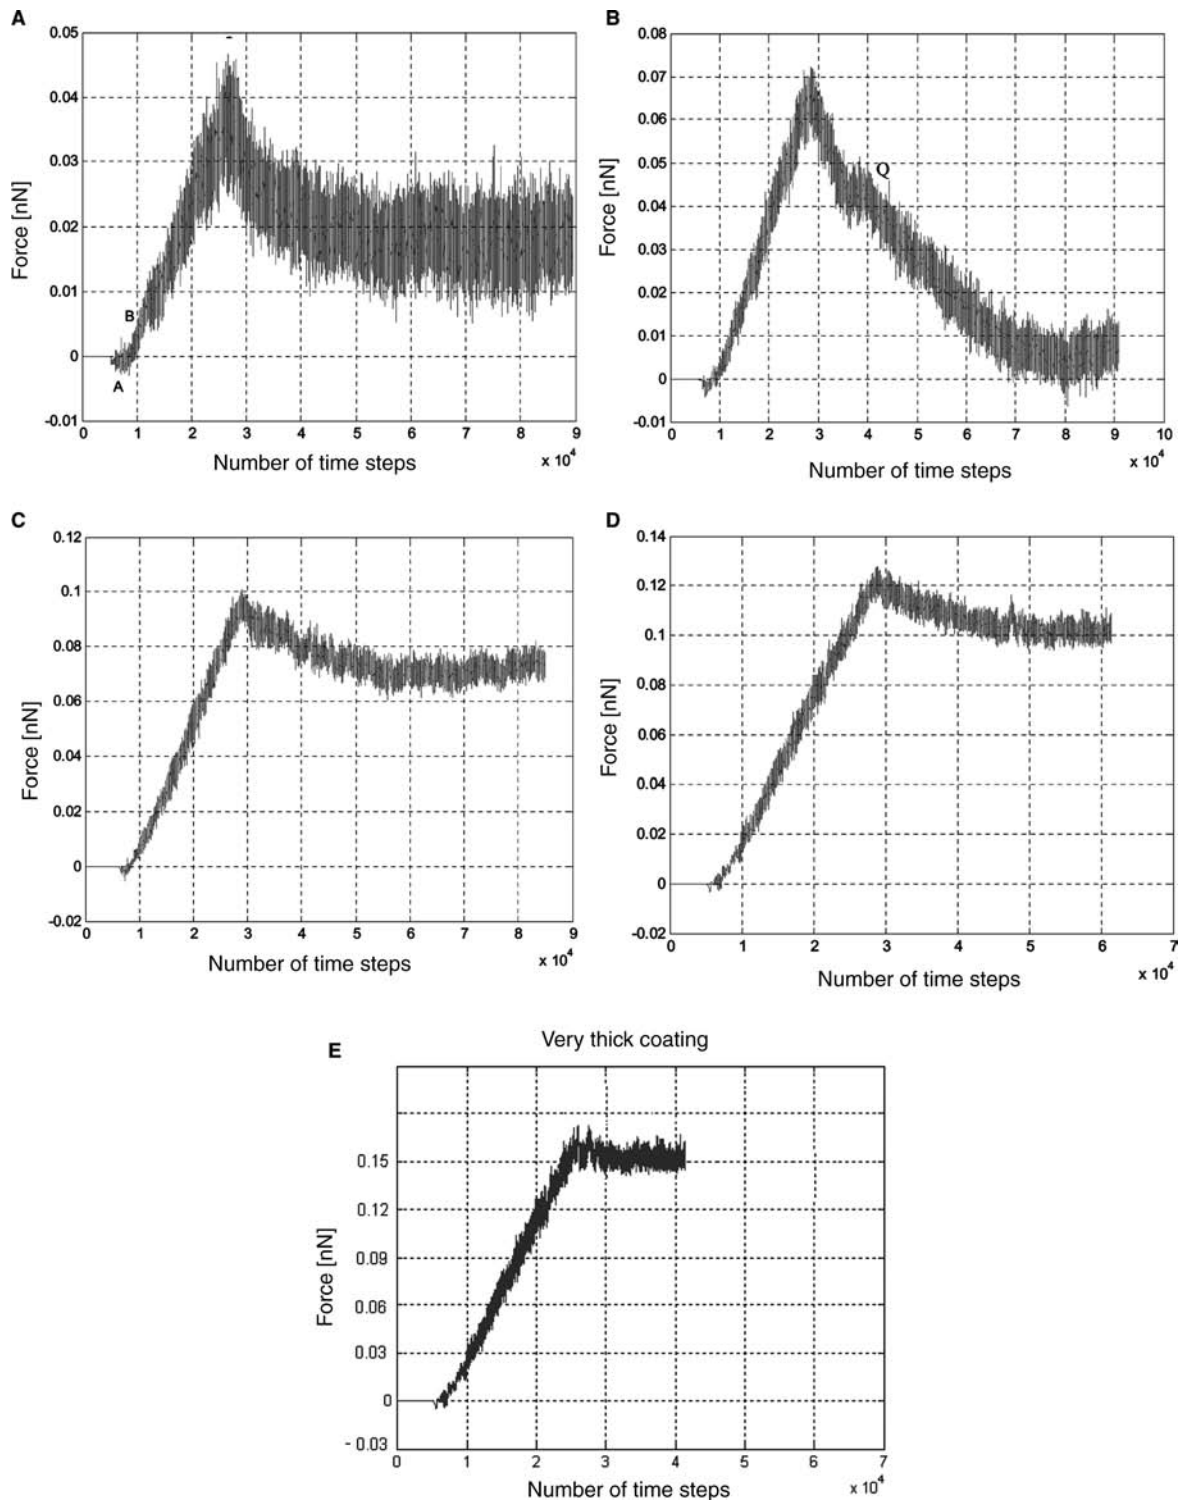

under the asperity. However, in the case of  $t^* = 0.35$ , the thicker coating prevents the formation of chips and hence the higher stresses lead to the formation of a deeper amorphous region under the asperity. Though the coating undergoes plastic deformation, it adheres to the amorphous silicon without tearing or debonding. Fig. 12 shows snap shots of the plastic deformation of diamond-coated silicon due to sliding with  $t^* = 0.35$  at various time steps. The initial sliding force is once again constant because of the initial small contact area in no-wear sliding. The sliding force increases from 0 to 0.03 nN as the depth of cut of the asperity increases. The final sliding force is much lower than the case of coating thickness owing to the absence of ploughing and chipping. The stick-slip pattern is regular because the coating remains intact throughout the entire no-wear sliding process. Fig. 15C

shows the asperity sliding force versus time steps plot.

The maximum normal force reaches 0.1 nN, which is higher than the case of thin coating. This implies that the maximum normal force on the asperity increases with coating thickness. There is little drop in normal force as no chipping occurs and the normal force can be explained by the plastic deformation experienced by the silicon substrate beneath the coating. Fig. 16C shows the asperity normal force versus time steps plot.

d. Medium thickness coating ( $t^* = 0.7$ )

As the thickness is increased further, the thicker coating takes more of the load of the sliding asperity. This results in a smaller amorphous zone in the silicon substrate. There is no plastic deformation in the coating as the coating recovers elastically as the asperity passes. In both this case and the previous one, the silicon

**Fig. 16** Normal force versus number of time steps for coatings of various thicknesses: (A) no coating; (B) very thin coating ( $t^* = 0.17$ ); (C) thin coating ( $t^* = 0.35$ ); (D) moderate thickness coating ( $t^* = 0.7$ ); (E) thick coating ( $t^* = 1.4$ ).

substrate fails before coating. Fig. 13 shows snapshots of the plastic deformation of diamond-coated silicon due to sliding with  $t^* = 0.7$  at various time steps.

It can be seen from the figure that further increases to the coating thickness do not change the sliding force plot. Fig. 15D shows the asperity sliding force versus time steps plot.

The maximum normal force reaches 0.12 nN, which is even higher than the case of thick coating. This is consistent with the observation that the maximum normal force on the asperity increases with coating thickness. This might be explained by the increase in rigidity of the coating with increasing thickness. There is little drop in normal force as no chipping occurs and the normal force stabilizes at 0.1 nN as the asperity slides over the carbon coating. The drop in the normal force can be explained by the plastic deformation experienced by the silicon substrate beneath the coating. Fig. 16D shows the asperity normal force versus time steps plot.

e. Thick coating ( $t^* = 1.4$ )

When  $t^* = 1.4$ , there is no observable plastic deformation in the silicon substrate except for the coating–substrate interface (see Fig. 14). Plastic deformation of the carbon coating occurs in a way similar to that of sliding on a diamond substrate. The sliding force versus time plot is no different from when  $t^* = 0.7$  and  $t^* = 0.35$ , as no chips were formed during sliding.

The normal force stabilizes at the maximum value after the linear increase owing to the increasing depth of cut. There is no drop in the normal force because there is no observable plastic deformation in the substrate (see Fig. 16E).

## CONCLUSIONS

It is very difficult to study the effects of carbon coating on silicon substrate on the nanometer scale experimentally. In this entry, it is shown that molecular dynamics simulation can be used to study the effects of the carbon coating on such scales. The simulation results have shown that thin film buckling does occur on the atomic scale when the compressive stresses in a film are sufficiently high. The buckling mode varies with  $\sigma_y/\sigma_x$ , indicating that the stress ratio is an important factor that influences the nature of the buckling patterns. It is interesting to note that the pattern of atomic scale buckling of a thin film is similar to that observed in microscale experiments.

In the case of indentation on diamond-coated silicon, no observable formation of dislocations is found throughout the indentations or sliding. The occurrence of plastic deformation in carbon coating and silicon substrate is solely due to amorphous phase transformation and plastic flow. As observed, the size of residual amorphous zone formed at the end of indentation decreases with the thickness of carbon coating. The

initiation and location of plastic deformation, however, varies with the thickness of the carbon coating. In the case of sliding, however, even though the occurrence of plastic deformation in carbon coating and silicon substrate is also due to amorphous phase transformation and plastic flow, the size of the residual amorphous zone in the silicon does not necessarily decrease with increasing coating thickness. As discussed in the previous section, a thicker coating restricts the formation of chips and hence inhibits stress relief because of chip formation in the deformation zone, leading to a larger residual amorphous zone.

Hence, using the molecular dynamics simulation, it is possible to observe in real-time, the effects of carbon coating on silicon substrate deformation owing to compression, indentation, and sliding. The results show that the effects of coating on a nanometer scale differ considerably from their larger micrometer scale counterparts.

# Nanolithography: Length Scale Limitations

Takashi Ito

Akiruno Technology Center, Fujitsu Ltd., Tokyo, Japan

## INTRODUCTION

Lithography is one of the fundamental technologies by which nanoscale patterns required for the fabrication and integration of nanodevices are generated. Lithographic requirements are becoming increasingly severe. In the semiconductor industry, the past three decades have seen the critical length-scales of component devices decrease by several orders of magnitude, from 15  $\mu\text{m}$  in the case of the first integrated circuit, to less than 130 nm routinely obtained today. The phenomenal rate of decrease in size seems to reach the limitation of conventional optical lithography. The exposure wavelength, photoresist performance, and equipment determine the lithography limitation. The size of the constituent atoms imposes a fundamental limit on the minimum length scale that can be ultimately attained. This entry first provides an overview of the fundamentals of optical lithography. It is shown how minimum attainable device dimensions are intimately related to the wavelength of light used. Then, several techniques under investigation for further enhancing the resolution of this workhorse of the microelectronics industry are described. As the options available to industry are not all “optical,” the discussions cover the various non-optical lithographic techniques currently being explored.

## TECHNOLOGY OVERVIEW OF LITHOGRAPHY

Fig. 1 illustrates how the lithographic options vary as the critical device dimension decreases, and provides estimates of the timescales on which decisions may need to be made regarding which options to adopt.<sup>[1]</sup> Optical lithography technology has been traditionally used by reducing wavelengths of light sources from mercury lamps to excimer lasers such as KrF and ArF excimer lasers, and probably F<sub>2</sub> and Ar<sub>2</sub> lasers in the future. Phase shift masks (PSM) and immersion configuration can extend the resolution limit for each optical lithography. Extreme ultraviolet (EUV) of wavelengths ranging from 11 to 14 nm is used as extension of the optical method. Non-optical lithography with proximity X-ray

(PXL), electron beam (EBL), and ion beam (IPL) have a potential for finer patterns (as opposed to those produced via optical methods) because of their shorter wavelengths. Electron-beam projection lithography (EPL), which uses mask projection technique, projects to be most promising. However, electron beam direct writing (EBDW) has a drawback on its throughput. Nanoimprint is a simple technique just like paper printing. A shift by the microelectronics industry to any non-optical lithographic technique will require the introduction of a new infrastructure of tools, materials, and processing technologies, resulting in huge research and development costs.

## PROJECTION OPTICAL LITHOGRAPHY

Key elements of a practical lithographic system are essentially the same for all technologies—optical and non-optical. As shown in Fig. 2, they include the following: 1) A set of “masks” containing the patterns of components to be fabricated in and/or on the substrate, the tools for making the masks, and the metrology for ensuring precise dimensions and pattern overlay. 2) An energy source (e.g., a light source) for transferring the pattern from a mask to the substrate. 3) A medium—known as a “photoresist” or “resist”—for recording the pattern on the substrate following exposure to the source, and which allows subsequent processing of material in and/or on the underlying substrate. 4) Procedures for reliable detection of pattern defects, which clearly becomes more challenging as the critical dimensions decrease. The lithographic process—especially projection optical lithography—is closely related to the developing process in print photography, where the photographic negative plays the role of the mask, and the photographic emulsion on the print is the resist.

## Resolution Limits

The resolution limit in conventional projection optical lithography is largely determined by the well-known Rayleigh’s equation. The resolution (minimum resolvable feature)  $R$  and the corresponding depth of focus

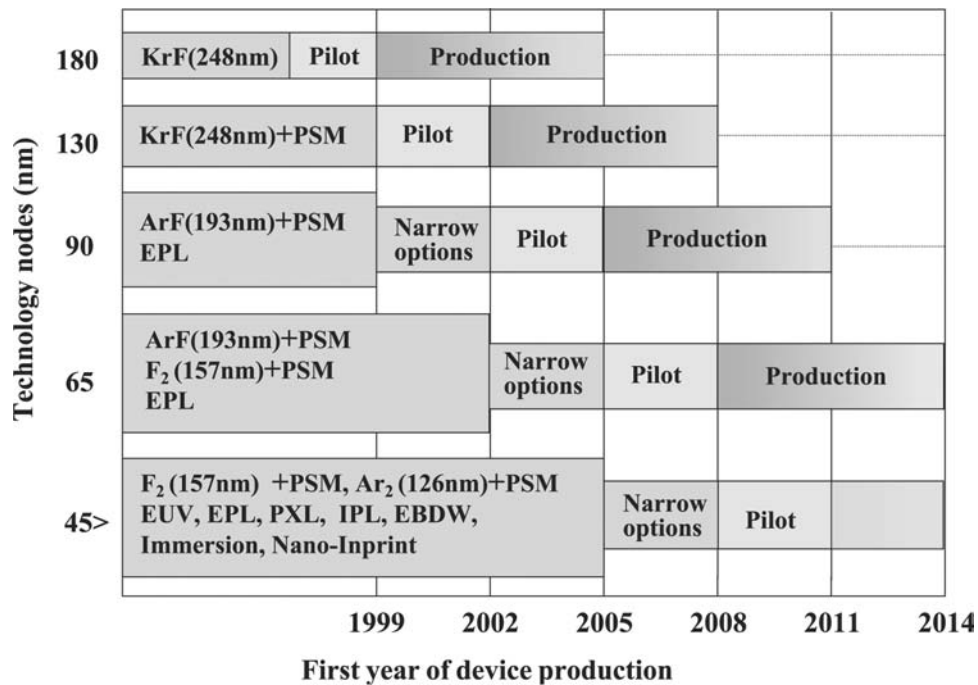

Fig. 1 Technology options of lithography.

(DOF) are given by the following:<sup>[2]</sup>

$$R = k_1 \lambda / NA$$

$$DOF = k_2 \lambda / NA^2$$

Here  $\lambda$  is the exposure wavelength, NA is the numerical aperture of the optical system, and  $k_1$  and  $k_2$  are

constants that depend on the specific resist material, process technology, and image-formation technique used. Fig. 3 shows the evolution of projection optical lithography. It compares the required minimum feature size and the wavelength of the exposure light. At the beginning of the introduction of the projection system, the required minimum feature size was relatively large compared to

Fig. 2 Principle of lithography.

**Fig. 3** Trend minimum feature size and exposure wavelength of optical lithography. Practical resolution limit is reduced to approximately half of wavelength with extremely higher NA and resolution enhancement techniques. Miniaturization exceeds the wavelength reduction trend for ULSI manufacturing.

the wavelength of the exposure light. Then low-NA lens system was used. However, as the miniaturization requirement of the semiconductor devices is faster than the reduction rate of the wavelength of exposure light, higher resolution was required. Therefore, to obtain higher resolutions, shorter-wavelength light and lens systems with larger numerical apertures are required. In general, the minimum feature size that can be obtained is almost the same as (or slightly smaller than) the wavelength of light used for the exposure, for which one needs a relatively large numerical aperture (typically  $\geq 0.5$ ). In such high-NA lens systems, the depth of focus becomes very small, and so the exposure process becomes sensitive to slight variations in the thickness and absolute position of the resist layer.<sup>[3]</sup> The smaller the depth of focus, the more rapidly a focused beam diverges on moving away from the focal point. With the recent introduction of a “chemical mechanical polishing” technology, the topographic variations of substrate surfaces have been reduced, making it possible to use extremely large NA systems; however, the margin for error becomes extremely small under such high-NA exposure conditions.

## Resolution Enhancement

To improve the resolution of an optical lithography system without introducing other impractical

constraints (on, e.g., wafer smoothness), several resolution-enhancement strategies were proposed.<sup>[4–6]</sup> Fig. 4 shows a schematic view of a typical projection optical-exposure system. Such a system consists of several subsystems, and resolution-enhancement ideas can be applied at various points. These may take the form of modified illumination at the light source, phase shifting of the wave front in the mask plane, and/or filtering with an aperture (pupil) at the projection lens. Some basic ideas of resolution enhancement are illustrated in Fig. 5, which compares image formation in: a) the conventional setup with b) phase shifting and c) modified illumination.

Consider the case when the image on the mask is a simple grating. In the conventional system (a), several diffracted light rays are generated by the grating. Zero-th order light proceeds straight through the system, and several rays of higher order are generated with diffraction angles of  $\theta$  (first order),  $2\theta$  (second order),  $3\theta$  (third order) and so on, with  $\theta \sim \lambda/a$  for small  $\theta$  (where  $a$  is the grating periodicity). Near the resolution limit, only the zero-th order and first-order rays pass through the lens pupil. Now consider case (b), where the phase of the light passing through the grating mask is modified to have a periodicity twice that of the grating itself. (Phase shifting also requires a higher degree of coherency in the source light compared to the conventional case.) The transmitted wave front is in turn modified, such that the zero-th order light is canceled out and the diffraction angle of the first-order rays halved to  $0.5\theta$ . As a result, the spatial frequency of the patterns that can be imaged is doubled (or, put in another way, the resolvable grating periodicity is halved). Although both the opaque pattern and the phase modifications on a real mask will be considerably more complex than a simple grating, this example nevertheless serves to illustrate the substantial improvement in resolution that can be achieved by this approach. Fig. 6 shows an example of resist patterns formed by using KrF (248 nm) light and a phase shift mask: structures having half the wavelength of the exposure light are clearly visible.

Next, we consider oblique (or off-axis) illumination, as shown in (c). Zero-th order light no longer passes through the center of the pupil, but at an angle to the vertical. The first-order rays again emerge at angles of  $\pm\theta$  with respect to the zero-th order ray. And at the resolution limit, one of these passes through the side of the lens pupil opposite to that of the zero-th order ray, while the other diffracted ray is blocked. Therefore the result is geometrically equivalent to the phase-shifted case (b), and again leads to a doubling of the spatial frequency of the images that can be resolved. At present, the most advanced mass-produced LSI circuits have a critical dimension of 90 nm. This is achieved by using partially coherent light from ArF excimer laser

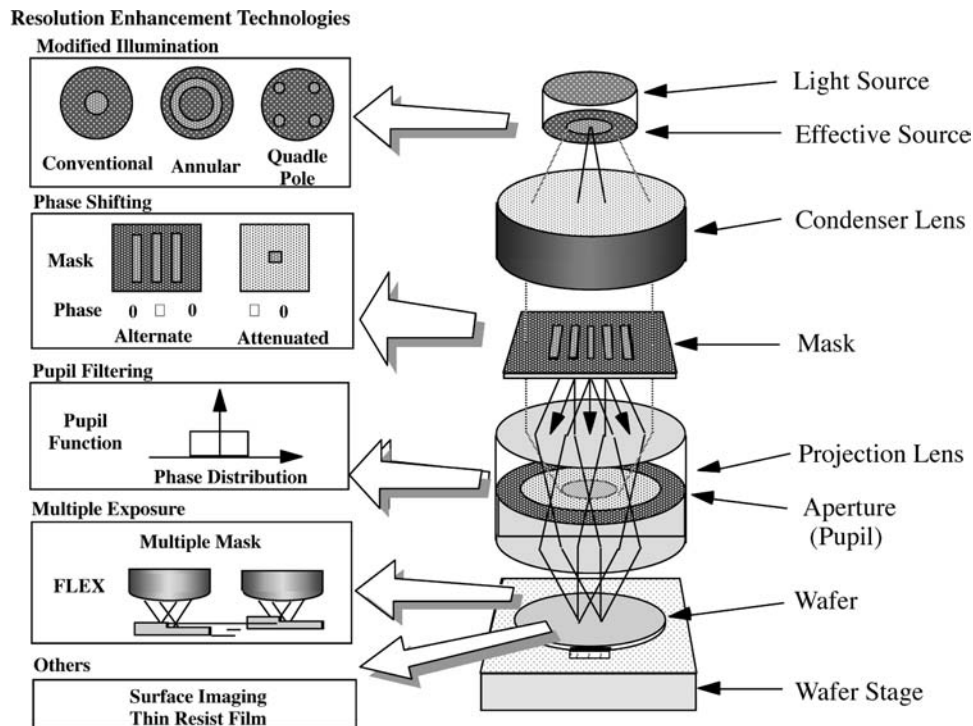

Fig. 4 Schematic view of exposure optical system and various resolution enhancement technologies for each stage of the system.

with a wavelength of 193 nm, in combination with some resolution-enhancement techniques such as off-axis illumination, phase shift mask, and optical proximity correction, as well as advanced resist systems. To further reduce the critical dimension, wavelength reduction is being actively pursued using F<sub>2</sub> and Ar<sub>2</sub> excimer lasers (wavelengths of 157 and 126 nm, respectively). The combination of shorter-wavelength light and resolution-enhancement techniques may ensure optical lithography's position as the most productive lithographic technology for nanofabrication of length-scale of even less than 50 nm.

### ELECTRON BEAM LITHOGRAPHY

Electron beam lithography—in which a beam of electrons, rather than photons, is used as the exposure source—has extremely high-resolution capabilities combined with a large depth of focus. To date, it has been mainly used in the production of masks and reticles for optical lithography. But it has also been used in the fabrication of very fine-scale devices for fundamental and device-verification studies, and also in the small-scale production of the specialized very high frequency devices. However, in the context of mass-produced

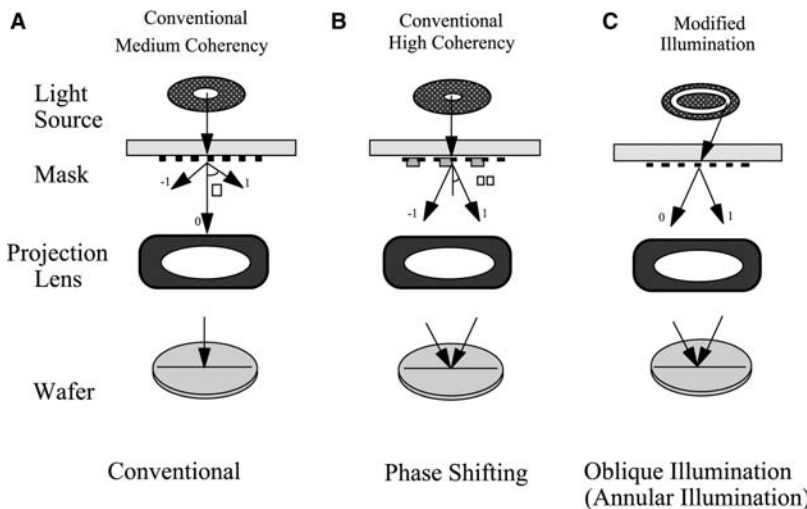

Fig. 5 Grating pattern image formation.

**Fig. 6** An example of resolution enhancement technology and the effect of phase shifting technology.

integration circuitry, the greatest problem of electron beam lithography is the low throughput capability of the system. While using a finely focused electron beam makes it possible to delineate extraordinarily fine patterns, writing of chip-scale patterns with a single electron beam is a slow process. According to the pattern complexity, the exposure time for the mask writing also becomes very long. Accordingly, there has been considerable interest in developing techniques to expand the throughput of electron beam lithography, and these have generally involved finding ways to enlarge and make the electron beam parallel. Fig. 7 shows various electron-beam writing procedures.

The electron projection lithography (EPL), such as cell projection or chip projection, is one such approach that makes use of parallel exposure. Specifically, in a conventional variable-shaped beam system, the maximum size of the electron beam is sufficient to encompass a mask containing the pattern of several memory cells, which have a repetitive structure. So if such a mask is used in place of the second aperture of the shaped beam system, the pattern can be projected on the substrate in a single exposure. Fig. 8

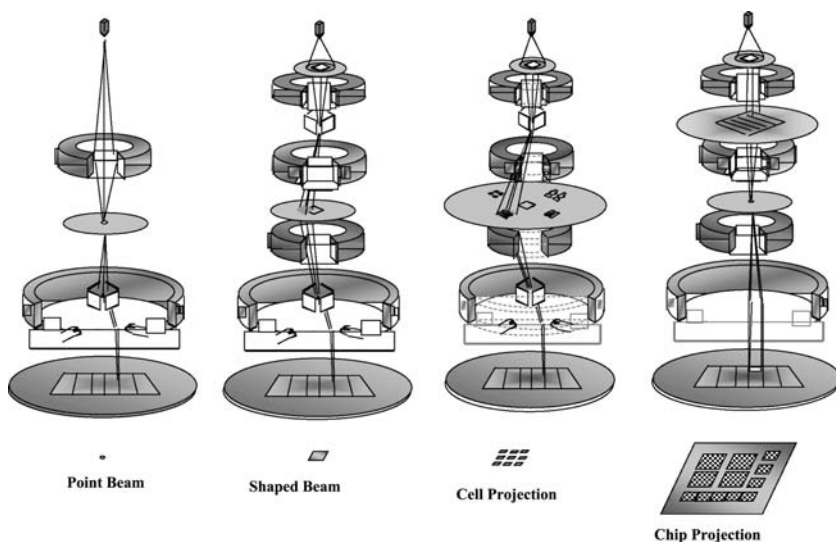

shows a resist pattern produced by this approach: the periodically arrayed patterns at the top are produced by exposure using a cell-projection aperture, whereas the random wiring patterns at the bottom were written by using a variable-shape aperture. But even with this system, throughput remains a critical issue.

A more promising approach to improve throughput is to use a projection optical setup, geometrically equivalent to that used in optical lithography: an image of the desired pattern is projected from a mask. Most notable of the recent attempts to utilize projection are scattering angular limited projection electron beam lithography (SCALPEL), developed by Bell Laboratories; projection reduction exposure with variable axis immersion lenses (PREVAIL), developed by IBM; and low-energy electron beam proximity projection lithography (LEEPL) (see Refs.<sup>[7]</sup> and<sup>[8]</sup>). These approaches will be used in conjunction with optical lithography.

**PROXIMITY X-RAY LITHOGRAPHY**

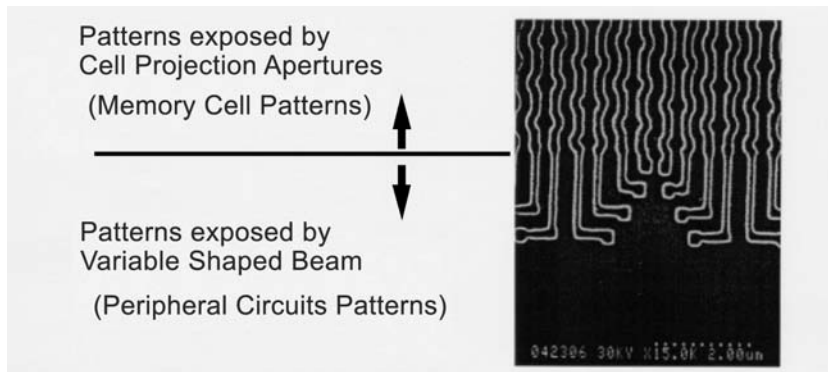

Proximity X-ray lithography is essentially a form of “shadow printing”—a mask is held in close proximity to the substrate surface, and the image is simply produced on exposure by the shadow of the mask on the surface. Proximity techniques were used in the early days of optical lithography, but have long since been superseded by projection techniques: the former are more susceptible to resolution-limiting diffraction effects. Resolution is less of an issue with proximity printing using X-rays, as the wavelengths used are so much smaller.

The exposure system of the PXL is shown in Fig. 9. A synchrotron is used as the source of X-ray radiation; recently, sources of synchrotron radiation have been developed that can store currents as high as 500 mA

**Fig. 7** Various electron beam writing systems; simple point electron beam, shaped electron beam, patterned cell projection, and chip pattern projection.

Nanodiamonds – Nanolithography

**Fig. 8** Resist patterns delineated by cell projection system.

with electron folding lifetimes longer than 10 hr, which should be stable enough for practical usage. The X-ray is first collimated by using a silicon carbide mirror, before passing through a transparent window of beryllium into a chamber containing the mask and wafer. Alignment of the sample uses a vertical X–Y stage, in contrast to the horizontal stages used in most other lithographic techniques. The X-ray used has a wavelength of about 1 nm. The mask is prepared on a membrane of silicon carbide or diamond, and a layer of Ta (patterned by direct-write electron beam lithography) serves to absorb the X-rays and so generate the shadow on the semiconductor wafer. The final image exposed by PXL is limited by the electron-beam-made mask.

Fig. 10 shows a series of typical patterns produced in the resist layer following X-ray exposure and subsequent development.<sup>[9]</sup> The patterns shown were formed on stepped substrates, and exhibited critical dimensions as small as 150 nm with a distribution of less than 10 nm ( $3\sigma$ ). Fig. 11 shows poly silicon patterns transferred from resist patterns with PXL. Dry etching technique was inevitably used to transfer the resist patterns to poly silicon ones.

## EXTREME ULTRAVIOLET LITHOGRAPHY

Extreme ultraviolet (EUVL) lithography is a promising candidate for achieving critical dimensions of 50 nm and below.<sup>[10]</sup> This approach utilizes the same principle of conventional optical projection lithography and also obeys Rayleigh's equation (shown earlier). But now, the exposure wavelength is in the range 11–13 nm, which introduces its own problems. Fig. 12 shows the concept of EUV optics. First, as the absorption of light in this short-wavelength regime is very strong, lens-based refractive optics cannot be used in this lithographic system: an all-reflective optic system must therefore be employed. A second difficulty relates to the mirrors themselves. A conventional mirror surface cannot be used at these wavelengths, so one must resort to multilayer structures that rely on interference effects to achieve reflectivity. And even then, the resulting reflectivities are rather low, typically 60–70% at 13 nm. Accordingly, the number of mirror surfaces in the system needs to be kept as low as possible—6 or fewer—to avoid significant reductions in the light intensity level.

In the case of multilayer mirror optics, the requirement of fewer optical elements means that aspherical

**Fig. 9** System of proximity X-ray lithography. X-ray is generated from a synchrotron ring, reflects on a collimating mirror, and irradiates a wafer through a mask. The mask is made of SiC membrane or diamond and absorption pattern.

Fig. 10 Resist patterns on different substrates. Source: NTT-AT.

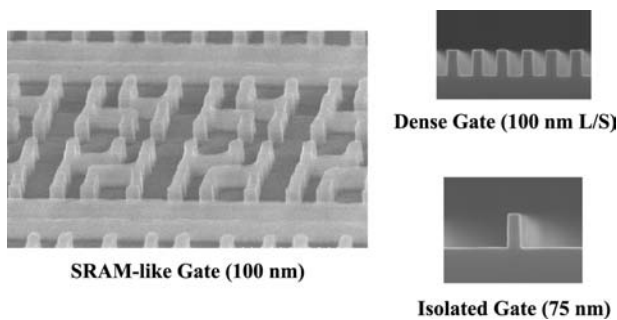

Fig. 11 Examples of polysilicon patterns transferred with X-ray lithography. SRAM-like gate, dense gate, and isolated gate patterns are shown.

mirrors must be introduced to achieve such capabilities. Such aspherical mirrors need to be extremely precise, with figure errors and surface roughness less than 0.1–0.2 nm. As such, an extremely high precision metrology system needs to be developed if this approach to lithography is to become viable.

The source of EUV light is another problematic issue.<sup>[11]</sup> At present, the best candidate is a laser-produced plasma of xenon gas. But the energy

Fig. 12 Concept of EUVL optics.

conversion ratio of laser light (from a YAG laser) to EUV light is so small that lasers of enormous power are required to achieve practical EUV exposure intensities. Therefore, different strategies, such as the use of electrical discharge lamps, are being explored for providing practical light sources for EUV lithography.<sup>[12]</sup> Fig. 13 shows an example of resist line-space patterns of 40 nm delineated by an experimental EUV exposure system. The result features its promising lithographic candidate for nanofabrication.

### EMERGING TECHNOLOGIES

Several other approaches are proposed for delineating patterns below 100 nm. The configuration of the ion beam projection lithography (IPL) is schematically shown in Fig. 14. The ion beam can be used to avoid deep penetration of the incident ions because of their

Fig. 13 40-nm line-and-space resist patterns delineated by EUV exposure system.

Nanodiamonds – Nanolithography

weight compared to electrons. The principle of the nanoimprint lithography is schematically shown in Fig. 15. It is just a printing of patterns. The near-field optical lithography recently appearing is shown in Fig. 16. The technique uses evanescent light. Direct writing with a near-field probe and exposure with proximity printing with a mask are realized to limited applications. Limitations of those technologies to fine patterns are currently under investigation. IPL is one of the candidates of the next-generation lithography for production. Whereas the latter two approaches are good techniques to delineate nanostructures for the investigation of nanometer devices.

## CONCLUSION

Optical lithography is a fundamental process in the manufacture of highly integrated microelectronic circuitry. But with the relentless commercial drive for ever smaller, faster, and cheaper components, the existing technology are rapidly being pushed to their limits. However, optical lithography has far from reached the end of the road, and will continue to be used for some years, adopting light sources of smaller wavelengths (such as F<sub>2</sub> or Ar<sub>2</sub> excimer lasers) and optical techniques for further enhancing resolution. Depending on requirements for images and costs, possible next-generation lithographic technologies using non-optical sources are being actively explored. Whether the future of lithography lies with X-rays, electron beams or extreme ultraviolet light is far from clear at present. Critical issues remain to be solved with all of these alternative approaches. It is the time of length-scale limitation when those developments are abandoned. The requirement of nanoscale patterning will make those emerging technologies practical ones.

## INTRODUCTION

The emerging field of Nanotechnology, including nanomaterials, nanoscale devices, and nanobiotechnology, has been purported to impact every aspect of our life in the decades to come. The race to capitalize on Nanotechnology, “the next big thing,” began in the wake of the abating Internet mania in the year 2000, although basic and applied research on various aspects of this field has been intensely pursued since the early 1990s. For a comprehensive review of scientific advances in this field during the 1990s, the reader is referred to the World Technology Evaluation Center Report.<sup>[1]</sup> We should all remember that studies in catalysis and small metal particles began more than a century ago and represents one of the most significant applications of nanomaterials to date. In many instances, Nanotechnology has been referred to as a “disruptive technology,” the elegant and pithy phrase coined by Harvard professor, Clayton Christensen.<sup>[2]</sup> With the rapid influx of venture capital into the up-and-coming Nanotechnology industry (although it is a far cry from the investment activity that was seen in the mid-1990s with the then emerging internet industry), start-ups are realizing the need for sustainable competitive advantage in what is now becoming a crowded space. Given the scientific evidence so far, the potential for Nanotechnology to beneficially impact various aspects of our life and society exists, but attempting to predict them all at this stage is futile.

To put this field in perspective to the uninitiated, it has often been mentioned that Nanotechnology today is in the same state computers were in the 1960s.<sup>[1]</sup> Perhaps, a more apt comparison should be to the Industrial Revolution that began in the late eighteenth century. The Industrial Revolution enabled products that were already in use to be made cheaper, faster, and of uniform and of predictable quality.<sup>[3,4]</sup> The Nanotechnology Revolution underway has the potential to impact the performance of existing products, but not so much in terms of cost. At the same time, Nanotechnology has the potential to make possible new products that would otherwise not be possible. All of this has spawned the growth of Nanotechnology

as an industrial sector, while in reality it is an aggregate of several different industries brought together in ways never seen before. Accordingly, it is helpful to compare this new industrial sector to the several industries that came into existence during and after the Industrial Revolution: railroad, automobile, commercial aviation, and most recently, internet. Several hundreds of companies came into existence in the initial stages of each of these industries: there was a time when there was a large number of companies with *motor works* being the common suffix for a majority of them.<sup>[4]</sup> This is much the same today with the word *nano* being the prefix in the name of the company. Based on information garnered by market research entities such as CMP Cientifica,<sup>[5]</sup> Business Communication Company,<sup>[6]</sup> and Nanobusiness Alliance,<sup>[7]</sup> the number of companies worldwide that are active in nanotechnology at the present time can be estimated to be in excess of 400. As it has happened in all of these industries, the initial flurry of activity fades in a few years as the companies come to grips with the realities of the market forces. The start-ups burn through the invested capital, and either close shop or morph into a company with a different objective. The stage had been set by the year 2001 for this story line to be repeated in the Nanotechnology industry, except that the financial climate has been dismal since that time, with investment capital becoming a scarce commodity.

Just as it is said that beauty lies in the eyes of the beholder, an objective definition for Nanotechnology depends on the aspect of the field that the person is involved with. To an oncologist working with nanotechnology, it could mean targeted drug delivery to cure certain specific types of cancer, while to a scientist involved with computing, Nanotechnology could refer to molecular switches. The purpose of this entry is to look at technological and commercial advances made to date in the area of Nanomaterials either enabling new products or improving existing products. The focus is on products having the potential to beneficially impact present markets, as opposed to a number of markets that may emerge in the future. Moreover, special emphasis is given on applications where the presence of nanoscale features adds certain

functionality, instead of simply providing a high-surface-area template.

## OVERVIEW

In a broad sense, Nanomaterials include nanoscale particles (metal/ceramic/metalloid/organic particles or composites thereof, nanotubes, and buckyballs), nanoparticles dispersed (or suspended) in a liquid, or nanoparticles dispersed in a polymeric material, either as a coating or a bulk material. A distinction between functional and non-functional nanoscale features needs to be drawn: by nonfunctional nanoscale features, we mean that the nanoparticle simply acts as a high surface area support for a second-phase material, and does not possess any intrinsic functionality. A good example is a ceramic catalyst support, such as a honeycomb structure, in which catalytically active metallic nanoparticles are embedded in the high-surface-area ceramic material. As alluded to earlier, such high-surface-area materials have been in existence for decades. On the other hand, functional nanoparticles are those where the nanoparticles themselves perform a certain function, as a result of their particular crystalline structure, or the lack thereof; e.g., particles having gas sensing capabilities because of their ability to undergo redox reactions.

A few nanomaterials companies made rapid progress (measured in terms of the ability to raise capital and build substantial manufacturing capability) in the mid- to late 1990s, with the anticipation that they will be ready if and when the market emerges. Most of them have found out that either the anticipated markets never materialized, or the products they envisioned did not meet the cost requirement of the targeted industry. A case in point was a company that was initially funded by a U.S. government small business innovative research (SBIR) initiative. The company's manufacturing technology was unique, and the nanopowder product had a sufficient number of distinguishing features from the state-of-the-art, especially with respect to performance. The company attracted investment (initially backed by venture capital and later by large corporations in the same market sector), and a full-scale production facility was commissioned within 5 years of obtaining seed capital. However, the well-funded company failed to make any impact on the market because the market was driven by cost, and not by performance. The company's product was superior and more expensive, but the market had no need for a better product, as the available product at that time more than met what the majority of customers desired. The metrics of comparison had shifted from performance to cost. It was too late by the time management realized the market forces

in play, and the company had to close down its production facility by the start of the new millennium, and abandon its forays into nanomaterials, at least for the moment. The lesson here is that while nanotechnology can lead to a better product, it may not necessarily lead to a "business" because the mass market is not ready to pay a higher price for an improved product. To extend this thought further, it may so happen that, while a particular product developed by a company is superior in performance to an existing product, the sales volume generated may be too small to support a large-scale manufacturing infrastructure. It appears that the maximum potential exists for products that are just not improved, but enabled solely by the use of nanomaterials.

The initial part of this article will describe advances made by small and large corporations in producing a variety of nanopowders, because nanopowders provide the all-important building block for forming nanostructured materials. The discussion will be limited to technologies that were successfully developed into, at least, a quasi-commercial operation. As it turns out, the roots of a vast number of nanopowder synthesis processes are either a university or some other research laboratory. However, synthesis processes that are still practiced only in a research environment are excluded from the discussion. Furthermore, the discussion will be restricted to ceramic and metal nanoparticles. Carbon-based materials (e.g., fullerenes/bucky balls, single-wall carbon nanotubes, and multiwall carbon nanotubes) and chalcogenide nanotubes, and organic nanoparticles are beyond the scope of the present discussion.

The second part will describe the activities of companies involved in commercializing nanomaterials for specific applications, where substantial value is added to nanoparticles by way of surface treatment or incorporation into a host matrix. Also included are work performed at corporations that purchase nanoparticles from the open market and incorporate them into an end product. This section will also detail the activities of a few companies that are vertically integrated, i.e., they synthesize their own raw nanomaterials and integrate them into a component or a device. However, such vertical integration is not common in the materials industry.

The final section is a reflection on the past decade of nanomaterials development, and a prognosis of where things are likely to be by the end of the decade.

## PART I: NANOPOWDER PRODUCTION

Two of the pioneers in production of nanopowders of single-phase oxides (e.g.,  $\text{SiO}_2$ ,  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{ZrO}_2$ ) are located on either side of the Atlantic

Ocean: Degussa Corporation, headquartered in Europe, and Cabot Corporation in the United States. Both companies have been in production of nanopowders for several decades now, accounting for much of the “nanopowder sales” figures quoted in reports by some market research analysts. Over the years, Degussa and Cabot have steadily made incremental improvements in particle characteristics, such as reduction in aggregate size and altering surface characteristics to suit specific applications. The Degussa Process, called the AEROSIL<sup>®</sup> process,<sup>[8]</sup> involves hydrolysis of gaseous metallic chlorides under the influence of water, which develops during the oxyhydrogen reaction, which, in turn, leads to a high-temperature reaction zone. Example reactions are as follows:

Nanoparticles of titanium dioxide, produced by Degussa, are sold as Degussa P25, and are an extremely well characterized nanopowder. The powder has a surface area of  $\sim 50 \text{ m}^2/\text{g}$ , with a primary particle size of 21 nm. Fig. 1 shows a transmission electron microscopic (TEM) image of  $\text{TiO}_2$  nanopowders. The purity of the oxides is in general  $>99\%$ , and in some cases, the purity is in excess of 99.9%. The reason for the high purity is that the chloride byproduct is cleaned relatively well through distillation. These nanopowders are used in a number of commercial applications, some of which are: aluminum oxide used in Ink jet papers (smoothing and sealing), cable insulation (improvement in dielectric strength), photo resists for production of integrated circuits (ICs) (rheology); titanium dioxide in ultraviolet (UV) protecting gels (transparent, yet 100% UV protection); zirconium oxide in IC substrate boards (higher resolution), battery separators (filler), and polystyrene (free flow aid).

High-surface-area  $\text{SiO}_2$  has been the flagship product of Cabot Corporation (in addition to carbon black, which itself is a nanostructured powder, given the high surface area of the powder particles). Cab-o-sil<sup>®</sup> is the trade name of Cabot's  $\text{SiO}_2$

nanopowders, an electron micrograph of which is shown in Fig. 2.<sup>[9]</sup> Nanoparticles of  $\text{SiO}_2$  are produced by a flame process, which substantially resembles the Degussa process described above. An experimental grade of aluminum oxide is also produced by Cabot using the same process, with a surface area of  $\sim 55 \text{ m}^2/\text{g}$ . The reported average aggregate length, which is different from the aggregate size measured by a typical instrument, such as Coulter N4 plus or a Horiba LA 920, is 150–170 nm.

Interestingly enough, unlike conventional materials development—where a unique material is often developed in response to either an actual or a perceived need—the above-described oxide nanopowders have largely found use in new markets as soon as they became available in large quantities. For example, the production process for synthesis of nanoparticles of aluminum oxide was developed well before the powders began to be used in inkjet papers. Moreover, nanopowders of aluminum oxide, titanium oxide, and silicon dioxide have been commoditized over the years by the two industry giants mentioned above, thereby leaving little room for nanopowder-producing neophytes to use their approach to penetrate well-established markets. A further discussion on the barrier to entry is presented in the final section of the entry.

**Fig. 1** TEM image of Degussa's P25 titanium dioxide powder.

**Fig. 2** Electron micrograph of nanoparticles of  $\text{SiO}_2$ , produced by Cabot Corporation.

Baikowski International,<sup>[10]</sup> a company based in France with operations in the United States as well as in Japan, also provides nanoparticles of aluminum oxide with exceptional purity:  $\geq 99.99\%$  (in addition to micron- and submicron-size particles). The powders have a high surface area,  $\sim 120 \text{ m}^2/\text{g}$ . Some grades of such high-surface-area powders have an aggregate size as small as  $\sim 0.3\text{--}0.4 \mu\text{m}$ . The company exclusively produces aluminum oxide, and caters largely to the lighting (for producing translucent ceramics) and polishing (chemical mechanical polishing) industries.

The perceived need for spherical nanoparticles, and with a lower degree of aggregation than what was commercially available, prompted extensive research into new synthesis processes at universities and national laboratories. As soon as a basic research showed promise, the technologies were transferred to a private entity [usually with the aid of federal funds in the form of either SBIRs, or its sister program, small business technology transfer (STTRs)], often located near the originating research institution. The start-ups were the so-called “spin-off” nanomaterial companies. Two such companies in the early days of the Nanotechnology industry were Nanophase Technologies Inc. in Illinois, and Nanodyne Inc. in New Brunswick, although Nanophase Technologies Inc. was funded by equity investment very early on in the life of the company. Nanophase Technologies (NASDAQ: NANX), which evolved from research activity at Argonne National Laboratory in the outskirts of Chicago, focused on the production of oxide nanoparticles, including such commonly used oxides as aluminum oxide, titanium dioxide, and zinc oxide, as well as a number of not so commonly used materials, such as yttrium oxide, copper oxide, and cerium oxide. The synthesis process, schematically shown in Fig. 3, is based on high rate evaporation of metals followed by oxidation in the gas phase.<sup>[11]</sup> The process yields nanoparticles on a commercial scale with a spherical morphology (in many cases) and with minimal

aggregation, which was different from the nanopowders available at that time, although the surface areas were comparable. As of the writing of this entry, all of the compositions mentioned above are available in tonnage quantities. The strategy to market these products appears to be to sell the nanopowders to larger chemical manufacturers, as opposed to directly providing it to the end user; e.g., the biggest customer of Nanophase Technologies is BASF.<sup>[12]</sup>

Nanodyne Inc. was a spin-off from Rutgers—The State University of New Jersey, the basis for the technology being intellectual property and prior research that was carried out at Exxon Corporation. The hallmark of the Nanodyne synthesis approach, shown schematically in Fig. 4, was that existing and commercially available processing technologies (e.g., fluidized bed and rotary furnaces) were used to produce nanostructured materials that were protected by a structure of matter patent. The sole focus of the company was to produce ultrafine grained powders of WC/Co. Research had shown that fine-grained WC/Co materials possessed improved hardness without the usual accompanying loss in toughness, and this provided the impetus to commercialize ultrafine grained WC/Co for tool bits.<sup>[13]</sup> A pilot plant was first built in New Brunswick, NJ, with investment from venture capitalists (Ampersand and CMEA). Later, Union Miniere (now Umicore) bought out the interests of all the shareholders, and a semifull-scale production plant was constructed in North Carolina. Unfortunately, the plant was shut down not too long after it was commissioned,<sup>[14]</sup> and Nanodyne Inc. went into the history books as one of the first casualties of the Nanotechnology industry.

Just about the time that nanopowders were coming in vogue in the United States, a company called Advanced Powder Technology (APT) was founded in Australia.<sup>[15]</sup> Unlike the vapor-phase approaches that were being championed by many companies in the United States, APT developed a patented solid state

Fig. 3 Schematic showing the vapor-phase process practiced at Nanophase Corporation.

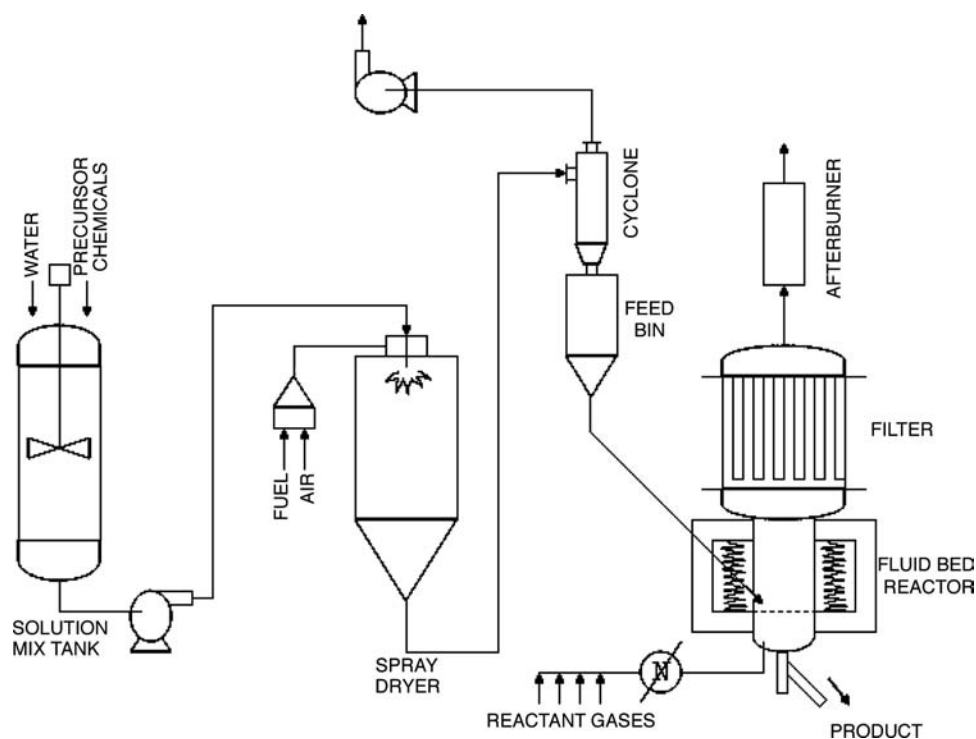

Fig. 4 Schematic of the spray conversion process, developed by Nanodyne Inc.

process that combined a milling operation. Dry milling was used to induce chemical reactions through ball-powder collisions that resulted in nanoparticles forming within a salt matrix. Particle size is defined by the chemistry of the reactant mix, milling, and heat treatment condition. Particle agglomeration is minimized by the salt matrix, which is then removed by a simple washing procedure. While reducing the size of particles by milling had been known for a very long time, APT was among the first to reduce the particle size to the nanoscale. A joint venture with Samsung Corporation was announced in 2001. One of the major products was cerium oxide, which has generally been an expensive material and was scarcely available in a nanopowder form. The technology has also been extended to other compositions, such as zinc oxide.

During the mid- to late 1990s, alternative vapor-phase technologies to what was practiced at Nanophase Technologies was developed by a number of companies, including NEI Corporation, the company that the authors work for. At NEI, a process called combustion flame-chemical vapor condensation (CF-CVC) was developed to produce oxide nanoparticles,<sup>[16]</sup> the origins of which were in a process invented at Rutgers University.<sup>[17,18]</sup> The CF-CVC process, shown schematically in Fig. 5, utilized a flat flame in a reduced pressure environment as the heat source for pyrolyzing vapors of metalorganic precursors. The geometry of the flame insured that the

pyrolysis was uniform, and the condensation of the pyrolyzed species into nanoparticles was rapid. The end result was the formation of high-surface-area nanoparticles with a narrow primary particle size distribution, combined with one of the smallest aggregate sizes among nanopowders available in the market. For example, titanium dioxide nanopowders had a surface area of  $\sim 65\text{--}75\text{ m}^2/\text{g}$  with an aggregate size (as measured by Coulter N4 Plus) of  $\sim 0.1\text{--}0.12\text{ }\mu\text{m}$ . Aluminum oxide nanopowders had a surface area of  $\sim 120\text{ m}^2/\text{g}$  with an aggregate size of only  $\sim 0.125\text{ }\mu\text{m}$ .<sup>[19,20]</sup>

Significant progress in developing new methods of nanopowder synthesis was made at Nanomaterials Research Corporation (NRC) toward the late 1990s. The production system was based on a patented process<sup>[21]</sup> utilizing ultrarapid thermal quenching of high-temperature vapors through a boundary layer converging-diverging nozzle. A suspension of precursor material, which was, for the most part, generated from a fluidized bed of micron size metal particles, was continuously fed to a thermal reaction zone and vaporized under conditions that minimized superheating and favored nucleation of the resulting vapor. The expansion ahead of the nozzle led to rapid condensation, and minimization of nanoparticle coalescence. The process produced metals, intermetallics, single-phase and multicomponent oxides, and even some non-oxides. Subsequently, NRC, which was mostly funded through a number of SBIR programs until

Fig. 5 Schematic layout of the CF-CVC process, developed at NEI Corporation.

then, spun off a separate entity called NanoProducts Inc. A partnership with a major Japanese powder equipment company, Hosokawa Micron Corp., was announced in 2001 for scale-up of the nanopowder synthesis process.<sup>[22]</sup> Production is said to be commencing in Japan, as well as in the United States. NRC has also developed other gas-phase nanopowder synthesis processes, similar to the one described above, some of them utilizing chemical precursors such as acetates and nitrates.

Meanwhile, through the 1990s, the process of spinning off nanopowder- and nanomaterial-producing companies from universities continued in the United States. One such company that came into existence in the mid-1990s was TAL Materials, located in Michigan, which focused on a process based on combustion of precursors in a flame.<sup>[23]</sup> However, unlike many of the processes described above, the TAL Materials technology did not require the precursors to be vaporized. The precursors were pyrolyzed in a tubular reactor, and high-surface-area nanopowders were collected downstream.<sup>[24]</sup> The company, which was still in its infancy at the time this entry was being written, has focused on multicomponent oxide particles for value-added applications in lasers, and of the like.<sup>[25]</sup>

Nanoscale Materials Inc.<sup>[26]</sup> (formerly known as Nantek Inc.), which started operating in 1995, was spun out of Kansas State University—the first commercial spin-off from this university. The company

sells an array of oxide nanoparticles, mostly single phase, under the trade name NanoActive™. The powders are characterized by an extremely small feature size, resulting in enormously high surface areas. Accordingly, applications that can benefit from a very high surface area are ideal users of NanoActive™. According to the company, their oxide powders have shown utility in a variety of applications, including destructive adsorption, purification of air and water, scrubbing of acid gases, and sequestering of odors and toxic gases.

Unlike many of its competitors, which emerged from transitioning of a research activity into a business in nanomaterials, Altair Nanomaterials evolved from being a leaseholder on titanium ore mines in the Tennessee Valley to a manufacturer of oxide (and some nonoxide) nanoparticles, titanium dioxide in particular.<sup>[27]</sup> The Altair process is a solution-based process, wherein particles are precipitated and milled to be reduced to a smaller size while in suspension.<sup>[28]</sup> As of the writing of this entry, initial sales into the thermal spray market had been reported, along with success in animal trials of a phosphate powder for treatment of a kidney disease. Altair is a publicly traded company (NASDAQ: ALTI), and the total sales volume of nanopowders appears to be in the tens of thousands of dollars per quarter.

Nanotechnologies, Inc.,<sup>[29]</sup> based in Texas, and Technanogy<sup>[30]</sup> in California (both backed by venture capital funding), were relative newcomers to the

business of producing nanopowders. Both companies championed vapor phase processes, where a plasma source was used to vaporize metallic materials. The initial emphasis for both companies was on aluminum nanoparticles, with the objective of using them as rocket fuel, and as a component in the primer for bullets. Neither of these two applications seems to have held up to their initial promise, presumably because of cost considerations. Nanotechnologies Inc. has also initiated the development of oxide nanoparticles, and recently announced collaboration with AirProducts Inc. and Essilor, a manufacturer of eyeglasses.

Argonide Corporation<sup>[31]</sup> came into existence in the early 1990s, after transferring nanopowder production technology from Russia. A wire of the desired material is exploded in a continuous manner within a controlled atmosphere. A variety of metals including tungsten, aluminum, and oxide nanopowders are produced by the process.<sup>[32]</sup>

The path followed by a majority of companies has been somewhat self-directed, as opposed to being directed by the needs of the customer. As a result, considerable emphasis has been placed on the production of single-phase oxide nanopowders, such as aluminum oxide, titanium oxide, zinc oxide, and cerium oxide. This has been driven more by what their individual technologies can offer, and less by what the specific needs of an application are. Accordingly, an additional step of converting the single-phase oxide nanopowders into a useful form has become necessary, which reduces the importance of the starting material, which in turn requires it to be relatively inexpensive. Many nanopowder-producing companies have an eventual price target of ~\$10/lb; it remains to be seen if such a low price is attainable, and even if so, to what extent it remains a viable business for small companies.

In contrast to passive or non-functional nanoparticles, i.e., where the internal crystal structure does not contribute to a particular physical phenomenon, functional nanoparticles present significant opportunities for enhancing the properties of a product. Three prominent examples include: 1) multicomponent nanoparticles of electronic oxide ceramics; 2) nanocomposite electrodes for lithium-ion batteries; and 3) active materials for chemical gas sensors and biochemical activity. Processing of these materials is particularly challenging, given the complexity of the material systems, thus it is not surprising that there are very few companies active in these areas, although the market opportunity is immense.

Barium titanate, and variations thereof, is perhaps the most widely used electronic ceramic material. As such, this has prompted the nanomaterials community to investigate the potential benefits of nanostructured barium titanate. It is most commonly used as a sintered high dielectric material (both thick films and bulk).

Accordingly, many companies have made several attempts in developing fine particles of barium titanate. One of the most widely practiced synthesis methods has been the hydrothermal process, where precursors are allowed to react at relatively low temperatures, but at well above ambient pressures. TPL Inc. (Albuquerque, NM) has reportedly scaled a process for producing tonnage quantities of ultrafine multicomponent oxide powders belonging to the titanate family.<sup>[33]</sup>

NEI Corp. has developed processes for producing nanostructured powders of compositions used as electrodes in rechargeable lithium-ion batteries, and related energy storage devices.<sup>[34–36]</sup> Rechargeable lithium-ion batteries present a market opportunity for nanomaterials as three aspects of this class of energy storage device need improvement: energy density, rate capability, and cost. The ability to stabilize structures that are intrinsically of high energy density (example shown below) in a nanoparticle has the potential of inducing improvements in energy density. The rate capabilities of rechargeable batteries can be enhanced by reducing the particle size of electrode materials, because it is well established that the rate capabilities of lithium-ion batteries are limited by solid-state diffusion of lithium ions within the electrode materials.<sup>[37]</sup> Furthermore, compositions that utilize relatively inexpensive compositions (i.e., based on iron rather than cobalt) become viable cathode materials when the particle size is reduced to the nanoscale.

Macrocrystalline layered lithium manganese oxide, which has a theoretical energy density twice that of the presently used lithium cobalt oxide, suffers from structural instability during electrochemical cycling, and as a result, exhibits significant capacity decline. Moreover, the rate capability is less than desirable. NEI Corp. is developing nanostructured and doped layered lithium manganese oxide. Fig. 6 shows the charge/discharge curves of the sample under a low current density. The first charge capacity and discharge capacity were within 15% of the theoretical value. When the current density was raised to 22.5 mA/g during charge and discharge, the discharge capacity dropped, but did not show any capacity fade. Furthermore, development work is underway to increase the discharge capacity at high current densities.

Sensing an opportunity in gas detection instruments needed for industrial health and safety, environmental monitoring, and process control, Nanomaterials Research Corporation spent considerable effort in producing single-phase and doped oxide nanoparticles and integrating them into gas sensors.<sup>[38]</sup> Fig. 7 shows a comparison of the sensitivity of coarse-grained and nanostructured powders. NEI Corp. made initial forays into this market using its low-pressure flame deposition (LPFD) process, which is a high rate

**Fig. 6** A charge/discharge curve of a nano- $\text{LiMn}_x\text{M}_{1-x}\text{O}_2$  cathodes in a Li-test cell at a current density of 2.7 mA/g.

process for depositing and sintering nanoparticles in situ on a substrate.<sup>[39,40]</sup> The process leads to a porous nanoparticulate thick film structure, which is a desired morphology for gas sensor applications. However, the company did not obtain sufficient traction from the end users of such a technology, and has subsequently shelved the process.

## PART II: VALUE-ADDED NANOMATERIALS AND NANOMATERIALS-ENABLED PRODUCTS

In the materials business, the idea of not just producing nanopowders, but also integrating in-house synthesized nanoparticles into a final end product is generally believed to be a good strategy. The argument is that, although nanoparticles have properties that are uniquely distinct from their coarser counterparts, they are still a “raw material,” and so do not carry much more value than a commodity. NanoGram was

**Fig. 7** Data showing the difference in the sensitivity between coarse grained and nanostructured materials.

perhaps the first company to build a business on this concept, and have taken it to the extreme. The company, which was founded in the early 1990s with venture capital backing, concentrated on a laser pyrolysis process as the predominant nanopowder synthesis method. A substantial amount of intellectual property was created in the “use” of nanoparticles for a host of applications, including lithium batteries and chemical mechanical polishing. For example, NanoGram was the first to patent the use of nanoparticles of vanadium oxide as cathode materials for a lithium battery,<sup>[41]</sup> although sol-gel derived vanadium oxide xerogels (which are, by definition, nanostructured materials) have been shown to possess significantly higher capacity than coarse particles of vanadium oxide.<sup>[42]</sup> The laser nanoparticle synthesis process was subsequently modified to directly deposit nanostructured films at high rates on substrates.<sup>[43]</sup> Using this and other nanocomposite technologies, forays were made into the optical waveguide business at the turn of the millennium. The company appears to be deft at changing course as the market evolves. Recently, a new spin-off called NanoGram Devices Corporation has been formed to commercialize energy storage devices for the medical industry.

Another example of a vertically integrated company is Photon-X (Malvern, PA).<sup>[44]</sup> The company was established through a sizable venture capital investment. Among the first products envisioned were optical amplifier modules that support high capacity systems, but consume considerably less power with a smaller footprint than conventional products. These amplifier modules were based on new waveguide materials utilizing optical polymers and their nanocomposites. The company has combined materials innovations with new and improved optical designs that enable a reduction in the number of pump lasers for amplifiers. Reducing the number of pump lasers significantly reduces the electrical power consumption. Right from the start, the company’s goal was to be the provider of amplifier modules, made from building blocks that are all developed and fabricated in-house.

InMat Inc., a New Jersey-based start-up, is among a handful of companies that have released their products in the commercial market.<sup>[45]</sup> The technology and some of the principals of InMat originated from Hoechst Research, which had ceased operations in New Jersey in the mid-1990s. The basic technology is a composite formulation consisting of butyl rubber with a dispersion of exfoliated clay particles. The exfoliated layers of clay have nanometer dimensions along the *c* axis, and hence the material is a nanocomposite, which has the unique feature of reducing permeability of air by as much as 200%, while maintaining the flexibility of butyl rubber. As an example, a coating of the nanocomposite is applied to a tennis ball,<sup>[46]</sup> thereby

increasing its life span. The company is working on establishing its presence into the tire industry and chemically protective gloves, both of which can benefit from rubbers that are less permeable.

Along similar lines, at NEI Corporation, efforts are underway to commercialize transparent polymer nanocomposite coatings that are also hard and scratch-resistant. Innovations have centered on increasing the refractive index, altering the thickness of the coating between 1 and 25  $\mu\text{m}$  (as required by the application), and introducing additional functionalities such as electrical conductivity.<sup>[47]</sup>

There are also several examples of companies where nanomaterials form an integral part of the final product. For example, Konarka Technologies,<sup>[48]</sup> based in Massachusetts, has built upon dye-sensitized solar cells invented by Grätzel more than 10 years ago.<sup>[49]</sup> The core of the dye-sensitized technology consists of nanometer-scale crystals of titanium dioxide semiconductor coated with a monolayer of light-absorbing dye and embedded in an electrolyte between the front and back electrical contacts. The dye absorbs the photon in light. The company claims to be using low-cost raw materials and an inexpensive manufacturing technology to bring this nanomaterial-enabled photovoltaic technology to market.

NanoMagnetics<sup>[50]</sup> (UK) has used nanoparticulate magnetic films to produce a data-recording density of  $\sim 6$  Gbit/in.<sup>2</sup> According to the company, this should eventually lead to a density of several Tbits per square inch. NanoMagnetics realized the importance of a uniform grain size in the film, and has used a protein molecule called ferritin as the cage in which a cobalt-platinum metal alloy is deposited. The advantage in using a protein molecule is that they are always of the same size: a 12-nm-diameter cage with an 8-nm cavity. This way, the size of the alloy nanoparticle is limited to the size of the cavity.

There are also instances where nanomaterials constitute a critical component of the process. A case in point is Reactive Nanotechnologies Inc., which is building upon intellectual property generated at University of Maryland, and claims to have developed a new method of joining that replaces current processes of soldering and brazing, as well as opens up new applications in the areas of metal-to-ceramic joining.<sup>[51]</sup> The principle of joining employed by Reactive Nanotechnologies Inc. is based on a self-propagating exothermic reaction. Two dissimilar components are sandwiched with a stack of alternating layers of elements (with a thickness of several hundred nanometers)—say aluminum and nickel—that undergo an exothermic reaction. The reaction between the two metals is initiated at one end, and propagates rapidly through to the other end. The advantage of the approach is that the components being bonded are

not sensitive to the high temperature. The company envisions opportunities in the microelectronics market for application of its technology. A similar (but not competing) technology has been developed by SusTech Darmstadt in Germany.<sup>[52]</sup> The microwave curable adhesive system works on the principle that nanoparticulate ferrites pick up energy from electromagnetic AC fields, convert it into heat, and pass to the immediate surrounding.

A noticeable trend has emerged, in which large corporations are buying out (or exclusively licensing the intellectual property) small companies that have forayed into areas of interest to the large corporations, although there may not be any significant sales.<sup>[53]</sup> One notable example is the purchase by DuPont Titanium Technologies, a wholly owned subsidiary of DuPont, of a fledging company called NanoSource Technologies in July 2002. NanoSource Technologies Inc., which was founded in 1999, entered into an exclusive licensing agreement with Tekna Plasma Systems Inc. (Sherbrooke, Quebec, Canada) to produce nanoparticles of titanium dioxide. Moreover, the company had announced in January 2001 that it had developed a first-of-its-kind polymer coating for the surface of titanium dioxide nanoparticles that would make it usable in cosmetic applications.<sup>[54]</sup>

### PART III: FUTURE PERSPECTIVES

Given the recent flurry of activity in nanomaterials both in the academia and the industry, one can only conclude that there is still plenty of ground to cover. With the federal governments of advanced and developing nations apportioning increasingly large sums of money each year for research in nanomaterials and nanotechnology, we are most likely still away from seeing the peak in research output. In fact, in our judgment, the biggest breakthroughs are yet to come. In just the past few years, nanomaterials have already penetrated the consumer market, even if the sales volume in dollar terms is only in the tens of millions of dollars. Higher-volume applications requiring larger quantities of nanomaterials take a longer amount of time to be qualified for use, and we can expect to see them incorporated in products over the next several years. At the same time, it is quite difficult to clearly predict where the greatest commercial advances are going to be, and how they will manifest themselves in products. While significant advances in nanotechnology are routinely announced in technical and trade journals, transferring them into applications requires overcoming a number of barriers. Most notable among them are the lack of reproducibility of results reported from various laboratories, and the fact that results are often obtained from non-standardized tests, making

real-life comparisons difficult. To add to all of this, progress in nanomaterials is often at odds with the human nature of inflating what is achievable in the near term, but not envisioning what can be achieved in the distant future.

Interest in specialized nanomaterials and functionalized complex nanoparticles is growing. However, the demand for single-phase and multicomponent oxide powders of commonly used compositions is, at best, tepid. This is because oxide nanopowders, even with excellent particle characteristics such as small primary particle size and small amount of aggregation, do not possess sufficient distinguishing features from the powders that have been available since the latest blitz in this field. In other words, the market has been commoditized, and so does not present new opportunities. Therefore, it is exceptionally difficult for a small company to make much progress as a profitable enterprise.

Another likely scenario is that nanomaterials will be used in a large number of products, where the addition of a relatively small quantity leads to a major change in the properties and performance of the end product. The value-added nanomaterial with functionalized surfaces is likely to possess a unique functionality. Because the additive will impact a large enough market, it will justify the investment in the process technology. The challenge at the hands of companies, particularly the smaller companies in this field, is to identify such applications and team up with the right partners so that it becomes a win-win situation for both parties.

## CONCLUSION

Although the number of small nanomaterials companies throughout the world is quite large, each at various stages of commercialization, only a handful of companies are likely to withstand the test of time 10 years from now. Those without sustainable competitive advantage will lose the support of their investors (including federal sources of funding) and cease to exist. On the other hand, those that are wildly successful in certain segments of the market are likely to become takeover targets of large companies dominating that particular niche of the industry.

The companies cited in this article do not represent ALL the companies working in this area, but to the authors' knowledge, they represent examples of the transition from science to technology.

## INTRODUCTION

The particles with small size in the range from a few to several tens of nanometers are called quasi zero-dimensional mesoscopic system, quantum dots, quantized or Q-particles, etc.<sup>[1]</sup> The reason that nanoscale materials and structures are so interesting is that size constraints often produce qualitatively new behavior. Nanotechnology arises from the exploitation of new properties, phenomena, processes, and functionalities that matter exhibits at intermediate sizes between isolated atoms or molecules ( $\sim 1$  nm) and bulk materials (over 100 nm). As opposed to the microscale, the nanoscale is not just another step toward miniaturization, but is a qualitatively new scale. Hence quantum and size phenomena are allowed to manifest themselves either at a purely quantum level or in a certain admixture of quantum and classical components. At the foundation of nanosystems lie the quantum manifestations of matter that become relevant. Consequently, instead of being a limitation or an elusive frontier, quantum phenomena have become the crucial enabling tool for nanotechnology. Extensive research on semiconductor quantum dots has shown that these particles have properties halfway between macroscopic (bulk) and microscopic (molecular-like) substances and have recently aroused great interest in laser, photochemistry, and non-linear optics.<sup>[2–4]</sup> Bawendi et al.<sup>[3]</sup> have observed a number of discrete electronic transitions and LO-phonon progression which were cleanly resolved for the first time in nanometer-scale cluster in CdSe. Jungnickel and Henneberger<sup>[5]</sup> have described the luminescence properties of semiconductor nanocrystals and the carrier processes that are relevant for the light emission. Their study was concentrated on nanocrystal of size  $\approx 5$  nm, and hence observed strong carrier confinement. A size dependence in the luminescence efficiency of ZnS:Mn nanocrystals has also been observed by Bargava et. al.<sup>[6]</sup> and stated that the  $Mn^{2+}$  ion d-electron states act as efficient luminescent centers while interacting with s-p electronic

states of the host nanocrystals. They showed that this electronic interaction provides an effective energy transfer path and leads to high luminescent efficiencies at room temperature and hence suggested that nanocrystals doped with optically active luminescent centers may create new opportunities in the study and application of nanoscale material structures.

Because nanomaterials possess unique, beneficial chemical, physical, and mechanical properties, they can be used for a wide variety of applications. This review primarily focuses on the synthesis, properties, and applications of nanomaterials. It has been proven that the particles at the nanometer level have improved quality with respect to their potential application that include, but are not limited to, various structural, optical, electrical, mechanical, and catalytic activity, biomedical, next-generation computer chips, kinetic energy (KE) penetrators with enhanced lethality, better insulation materials, low-cost flat-panel displays, elimination of pollutants, tougher and harder cutting tools, high-sensitivity sensors, high-power magnets, future weapon platforms, aerospace, large lasting satellites, longer-lasting medical implants, corrosion resistance, etc. [Figure 1](#) shows the improvements in the final properties of the nanomaterials.

## SYNTHESIS OF NANOMATERIALS

There are several methods that can be used to synthesize solids. Solids can be also prepared in various forms as fibers, films, foams, ceramics, powders, single crystals, and nanoparticles. However, those solids, which are not thermodynamically stable, may be much more difficult to prepare and may require special methods. The oldest and widely used method is the solid-state routing of synthesizing metal oxides. In this traditional technique, the powder reactants are mixed together, pressed into pellets or some other shape, and then heated in a furnace for prolonged periods. However,

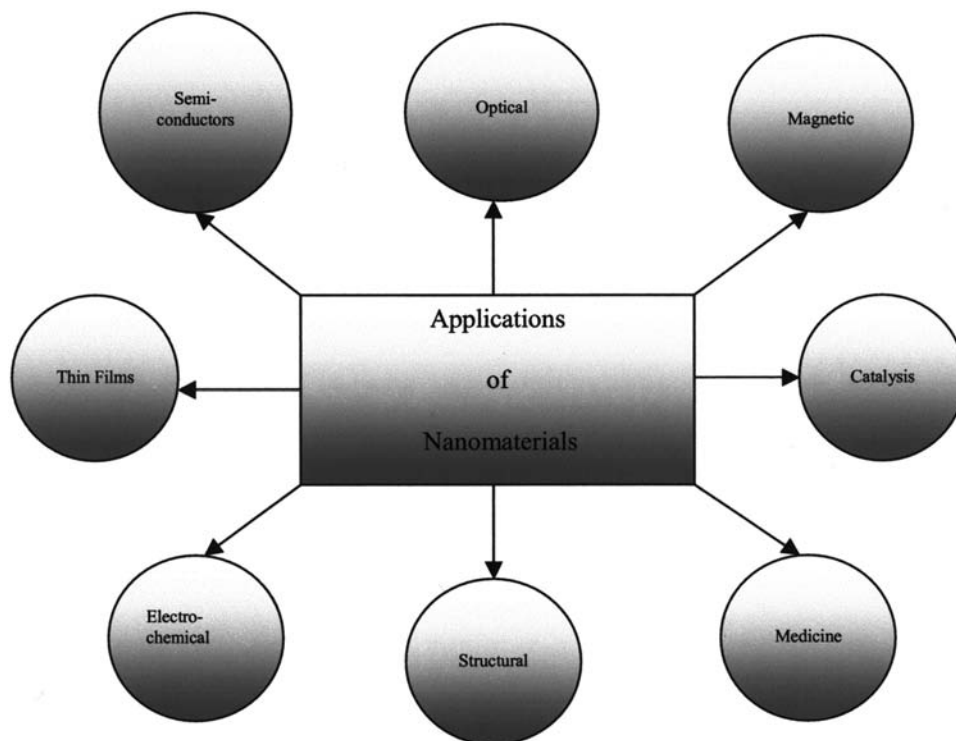

Fig. 1 Applications of nanomaterials.

this method is not very sophisticated because of the following reasons:

- It requires a high temperature to react the reactants.
- Slow diffusion of ions.
- Unhomogenized reaction mixtures.
- Impure final product because of unreacted reactants.
- Large particle size and bimodal particle size distribution.
- Defects, e.g., points/line/twinning.
- Metal oxides with unusual oxidation states cannot be prepared, e.g., vanadates and tungstates.
- Low surface area.

Solids with nanosize particle size cannot be prepared by traditional method simply because the reactants are not mixed on the atomic scale. All the alternative methods, e.g., hydrothermal, sol-gel, Pechini, CVD, and microwave, described in the rest of this section address this problem by achieving atomic scale mixing of reactants, in gas, liquid, or even solid phases. Most of these are low-temperature methods, although finally firing may be required at high temperatures especially for ceramic-type products. These methods enable the final product with the following characteristics:

- Nanosize particles.
- Narrow particle size distribution.

- High surface area.
- Homogenous.
- Pure.
- Improved properties.

### Hydrothermal Synthesis

Hydrothermal methods are becoming a popular technique to precipitate mixed metal oxides directly from either homogeneous or heterogeneous solution. Hydrothermal method utilizes water under pressure and at temperatures above its normal boiling point as a means of speeding up the reactions between solids.<sup>[7]</sup> Water is an excellent solvent because of its high dielectric constant. This decreases with rising temperature and increases with rising pressure, with temperature effect predominating. In addition, the high dielectric constant of water is confirmed to a region of low temperature and high densities (pressure). This property is mainly responsible for increasing the solubility of many sparingly soluble compounds under hydrothermal conditions leading to many useful chemical reactions such as hydrolysis, precipitation, coprecipitation, and crystal growth.

Hydrothermal reactions are usually performed in closed vessels. The pressure-temperature relations of water at constant volume are shown in Fig. 2. The reactants are either dissolved or suspended in a known

**Fig. 2** Pressure–temperature relations for water at constant volume. *Source:* From Basic Solid State Chemistry by A. R. West, John Wiley and Sons, Ltd, NY, 1999.

amount of water and are transferred to acid digestion reactors or autoclaves (Fig. 3). Under hydrothermal conditions, reactants otherwise difficult to dissolve can go into solution and reprecipitate.

Hydrothermal reaction is a single-step process for preparing several oxides and phosphates.<sup>[7–9]</sup> Oguri, Rimen, and Bowen<sup>[10]</sup> obtained narrow size distribution of spherical submicron titanium hydrous oxide, which could be readily transformed into polycrystalline anhydrous anatase with spherical morphology. Fine particles of ferroelectric lead titanate with high Curie temperature were prepared via hydrothermal technique.<sup>[11]</sup> Kutty and Balachandran synthesized

**Fig. 3** Schematic diagram of an autoclave.

lead zirconate titanate (PZT) in better compositional homogeneity and sinterability. This technique was further used for the fabrication of nanocrystalline metal oxides. Sharma et al.<sup>[12]</sup> have synthesized nanosize  $\alpha$ -alumina using hydrothermal method with particle size of 10 nm. Quantum size particles ( $< 10$  nm) of  $Y_2O_3$  could also be achieved by this technique at  $170^\circ C$  using seeds<sup>[12]</sup> and are shown in Fig. 4. This method was further employed for the fabrication of several other metal oxides, e.g., ZnO,  $TiO_2$ , and  $ZrO_2$ , with nanosize particles.<sup>[12–15]</sup>

### Sol–Gel Synthesis

In sol–gel synthesis, the precursors, which are essentially the starting compounds for the preparation of a colloid, consist of a metal or metalloid element surrounded by various links called ligands. These ligands do not include another metal or metalloid atom, but may be inorganic, such as aluminum nitrate [ $Al(NO_3)_3$ ], or organic, such as aluminum butoxide [ $Al(OC_4H_9)_3$ ]. Metal alkoxides are more widely used than any other precursors because metal alkoxides react readily with water. However, for some non-silicates, especially for transition-metal-oxide gels, inorganic precursors are used. The transition-metal-oxide gels are also used for obtaining thin-film ferroelectric materials such as barium titanate, electrochromic  $WO_3$  films, and semiconducting  $V_2O_5$  films.<sup>[16–20]</sup> Fig. 5 is the high-resolution transmission electron microscopy (HRTEM) of  $\alpha$ - $Al_2O_3$  derived by sol–gel method.

A gel can be classified as aquagel, alcogel, xerogel, and aerogel depending on the nature of the medium that is contained within the gel's three-dimensional network of particles. An aquagel is a gel wherein water

**Fig. 4** Hydrothermally prepared nanosize yttria.

**Fig. 5** High-resolution transmission electron microscopy of  $\alpha$ -alumina synthesized by sol-gel process. Source: From Ref.<sup>[29]</sup>.

is contained within its interstices. An alcogel is a gel in which the water is replaced by alcohol substitution. When the gel is in as-dried condition, it is called a xerogel. If the gel is supercritically dried (a drying process in which a medium is replaced, by another medium, under controlled conditions so that the gel structure does not collapse), then the resulting gel is termed an aerogel, where the fluid trapped in the gel interstices is air. The techniques used to preserve the gel structure include freeze-drying. This apparatus is called the freeze-dryer and is used commercially to preserve food-stuffs such as instant coffee powders, dry milk powder, and non-dairy coffee creamer, has been used to synthesize materials, and is available in large sizes. This method has also been used to synthesize dispersion-strengthened alloy and composite systems.<sup>[18]</sup> The rationale behind the preservation of the open structure of the aquagel or alcogel is to facilitate the accelerated expulsion of the fluid trapped at the interstices of the gel, which is made of a continuous, three-dimensional network of nanocrystalline particles, during the metal deposition process in a fluidized-bed reactor. The open structure (greater grain boundary area) of the aerogel lends itself to processing at very low temperatures unlike its commercial counterparts. This method is also useful in the hydrogen reduction, carburization, nitridation, and a host of other surface treatment processes. A schematic of the aerogel is depicted in Fig. 6.

The specific advantages of the sol-gel synthesis technique are as follows:

- Sol-gel synthesis is a very viable alternative method to produce nanocrystalline elemental, alloy, and composite powders in an efficient and cost-effective manner.

**Fig. 6** A schematic of an aerogel structure.

- Almost any combination of materials could be synthesized at very low temperatures.
- Greater control of material chemistry and homogeneity is possible.
- Sol-gel synthesized powders could be processed, such as for coating, carburization, and nitridation, at substantially lower temperatures.
- Nanocrystalline powders could be consolidated at much lower pressures and temperatures.
- Enhanced densification of high-temperature materials without the low-temperature binders, which are detrimental to their performance under extreme conditions, is also possible via sol-gel synthesis of nanocrystalline materials.
- Thermomechanical processing of the components could be accomplished at significantly lower processing conditions.
- Processes, such as infiltration, could be carried out uniformly because of the continuous, three-dimensional network of nanocrystalline particles.

However, there are several factors that affect the sol-gel chemistry, but among them, the pH of the aqueous solution plays important roles in the particle morphology, stability, and the particle size of the final reaction products. During the polymerization process, the three-dimensional networks of particles serve as nuclei for further growth. This growth proceeds by a mechanism called Ostwald ripening whereby particles dissolve and reprecipitate on larger, less-soluble nuclei. Ostwald ripening ceases to exist when the difference in solubility between the smallest and largest particles

becomes negligible. Nevertheless, this growth continues to larger sizes at higher temperatures. Europium-doped yttrium oxide (Eu:Y<sub>2</sub>O<sub>3</sub>) was synthesized by a sol-gel method in the presence of Tween-80 and ε-caprolactam in pH range 4–10. It has been observed that the variation in surface area, pore size, and pore volume of the final product was strongly dependent on the initial pH of the solution. The powder with a large surface area (~230 m<sup>2</sup>/g) and low pore diameter (~16 nm) was obtained when the powder was processed at pH ~ 4. The crystallite sizes of the powders processed at pH ~ 4 and 10 were found to be 35 and 198 nm, respectively.

At low pH, the reaction rate of the hydrolysis is governed by the hydronium ion in solution (H<sub>2</sub>O + H<sup>+</sup> → H<sub>3</sub>O<sup>+</sup>) and is also observed by Sakka and Kamiya<sup>[21]</sup> (described below). In this reaction, the amount of water is small because of the rapid formation of H<sub>3</sub>O<sup>+</sup>. Cagle and Keefer have stated that the hydrolysis/condensation in low pH condition is relatively controlled and selective, thus generating relatively more linear polymers of metal.<sup>[22–24]</sup> Hydrolysis can be represented by the following equation

Condensation can take place by any of the following two equations:

The linear polymerization can be explained by a simple steric argument: monomers (II) are more readily hydrolyzed than dimers (III or IV), which are, in turn, more readily hydrolyzed than middle groups in chains. Therefore the reaction polymerization at low pH is expected to be a linear chain (III or IV) with

low cross-links and is also suggested by Pope and Mackenzie.<sup>[25]</sup>

At high pH, the reaction is governed by the hydroxyl ions (OH<sup>-</sup>). Although the initial growth leads to linear chains, because of the high concentration of OH<sup>-</sup> ions, it results in the cyclization because the probability of intermolecular reaction is higher than intramolecular reaction.<sup>[26]</sup> At high pH value, hydrolysis/condensation is uncontrolled and unselective, which leads to highly branched polymers. It also generates larger interconnected particles.<sup>[26–28]</sup> The polymeric chain at high pH is larger than the one at low pH. At high pH, the most probable metal-oxygen polymeric network formed in the chain is the structure V as shown in Fig. 7. Nevertheless, the larger interstices at pH > 7 result in larger grains, as shown in Fig. 7. Thus the crystallite size of the powder at pH > 7 (198 nm at pH ~ 10) was smaller than the powder at pH < 7 (35 nm at pH ~ 4). At pH ~ 10, a cube-like morphology of the particles is seen in Fig. 8. In contrast, the morphology at pH ~ 4 has totally changed into polygonal shape with size of 40 nm (shown in Fig. 8).

#### Modified sol-gel synthesis: microemulsions as microreactors

Microemulsion-based sol-gel synthesis is a versatile technique to prepare materials with novel microstructures, in particular, ultrafine (nanosize) powders, e.g., TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, ZrO<sub>2</sub>, etc.<sup>[30–32]</sup> A microemulsion may be defined as a thermodynamically stable, optically isotropic solution of two immiscible liquids (e.g., water and oil) consisting of microdomains of one or both liquids stabilized by an interfacial film of surfactants.<sup>[33,34]</sup> The surfactant molecule generally has a polar (hydrophilic) head group and a long chained aliphatic (hydrophobic) tail. Such molecules

Fig. 7 Schematic diagram of polymeric network in different pH range.

**Fig. 8** High-resolution transmission electron microscopy of Eu-doped yttria at pH (A) 4 and (B) 10.

optimize their interactions by residing at the oil / water interface, thereby considerably reducing the interfacial tension. In water-in-oil microemulsion, the aqueous phase is dispersed as microdroplets (typically 10–25 nm in size) surrounded by a monolayer of surfactant molecules in the continuous hydrocarbon phase. The aqueous cores of microemulsions containing soluble metal salts are used as microreactors for the synthesis of nanoparticles. Because of the dynamic nature of the microdroplets, the exchange mechanism involves coalescence and fusion of the droplets upon collision, which then disintegrate into droplets, and this process occurs continuously in the microemulsion.<sup>[35]</sup> If two reactants, A and B, are dissolved in the aqueous core of two identical water-in-oil microemulsions, upon mixing, they will form a precipitate, AB. The growth of these particles in microemulsion is suggested to involve interdrop exchange and nuclei aggregation.<sup>[36,37]</sup> Recently, this method has been applied for the fabrication of cubic BaTiO<sub>3</sub> (please refer to Fig. 9).

### Polymerized Complex Method

Wet chemical method using polymeric precursor based on the Pechini process has been employed to prepare a wide variety of ceramics oxides.<sup>[38]</sup> The process offers several advantages for processing ceramic powders such as direct and precise control of stoichiometry, uniform mixing of multicomponents on a molecular scale, and homogeneity. In this process, an alpha hydroxycarboxylic acid, preferentially citric acid, is used to chelate various cations by forming a polybasic acid. In the presence of a polyhydroxy alcohol, normally ethylene glycol, these chelates react with the alcohol to form ester and water by-products. When the mixture is heated, polyesterification occurs in the

liquid solution and results in a homogenous sol, in which metal ions are uniformly distributed throughout the organic polymeric matrix. When excess solvents are removed, an intermediate resin is formed. This resin gives metal oxides on burning. All the organic matter removes on heat treatment.

In polymerized complex method, several metal ions in a solution could be first chelated to form metal complexes and then polymerized to form a gel, which seems to be one of the most suitable among several other chemical solution processes of nanocrystalline particles because rigidly fixed cations are homogeneously

**Fig. 9** Nanosize metal oxides synthesized by microemulsion-mediated sol-gel.

dispersed in the polymer network and have few chances to segregate even during pyrolysis. This method has been already successfully applied to prepared highly pure samples of various double oxides such as  $\text{BaTiO}_3$ ,<sup>[39]</sup>  $\text{Y}_6\text{WO}_{12}$ ,<sup>[40]</sup> mixed-cation oxides,<sup>[41]</sup> and even for various superconductors<sup>[42]</sup> with multiple cationic compositions.

### Chemical Vapor Deposition

Chemical vapor deposition (CVD) may be defined as the deposition of a solid on a heated surface from a chemical reaction in the vapor phase. It is a versatile process suitable for the manufacturing of coatings, powders, fibers, and monolithic components. It is possible to produce most metals, metal oxides, and non-metallic elements such as carbon and silicon as a large number of compounds including carbides, nitrides, oxides, intermetallics, and many others. The main advantage of CVD is that the deposition rate is high and thick coatings or nanoparticles can be readily obtained. The process is generally competitive and, in some cases, more economical than the physical vapor deposition (PVD). Additionally, it is not restricted to a line of sight deposition, which is a general characteristic of sputtering, evaporation, and other PVD processes. However, two major areas of applications of CVD have rapidly developed the last 20 years or so, namely, in the semiconductor industry and in the metallurgical coating industry which includes cutting tool fabrication. Very recently, the CVD process has been given enormous attention owing to the possibility of mass production of monodisperse nanoscale powders; however, the mechanism of powder synthesis kinetics is still not clear.<sup>[43–46]</sup> Kim, Yu, and Lee<sup>[46]</sup> have synthesized nanosize  $\text{TiO}_2$  powders using CVD. Carbon nanotubes have also synthesized by CVD method using Fe–Mo nanoparticles.<sup>[47]</sup>

### Microwave Synthesis

Recently, there has been a growing interest in heating and sintering of ceramics by the microwave energy.<sup>[48,49]</sup> The interest in the use of microwave processing spans a number of fields from food processing to medical applications to chemical applications. A major area of research in microwave processing of ceramics includes microwave material interaction, dielectric measurement, microwave equipment design, new material development, sintering, joining, and modeling. Therefore the microwave processing of ceramics has emerged as a successful alternative to conventional processing. Nevertheless, microwave method not only offers the advantages of a uniform heating at lower temperature and time than the conventional method, but also provides an economic method of processing. The microwave energy has been already successively utilized in the fabrication of ceramics as well as carbon fibers at low temperature and time. Varadan et al.<sup>[50]</sup> and Sharma, Varadan, and Varadan<sup>[51]</sup> have synthesized various electroceramics such as barium strontium titanate (BST) and lead zirconate titanate (PZT) by microwave. Fig. 10 shows the schematic diagram of a typical domestic microwave unit used by Sharma, Varadan, and Varadan. These materials are observed to have improved mechanical, electrical, and electronic properties. Until recently, microcoiled carbon fibers with large surface area have also been fabricated by using microwave aid.<sup>[52]</sup>

Fig. 11 shows a schematic diagram of a microwave chemical deposition unit used for the fabrication of carbon nanotubes and coils. It consists of microwave magnetron, circulator, four-stub tuner, waveguide, cavity, etc. The microwave power can be adjusted from 0 to 3000 W at a frequency of 2.45 GHz. The function of circulator was to prevent power reflected by the load, thus preventing overheating of the magnetron. The forward and reflected powers were determined

Fig. 10 Schematic diagram of microwave used for the powder.

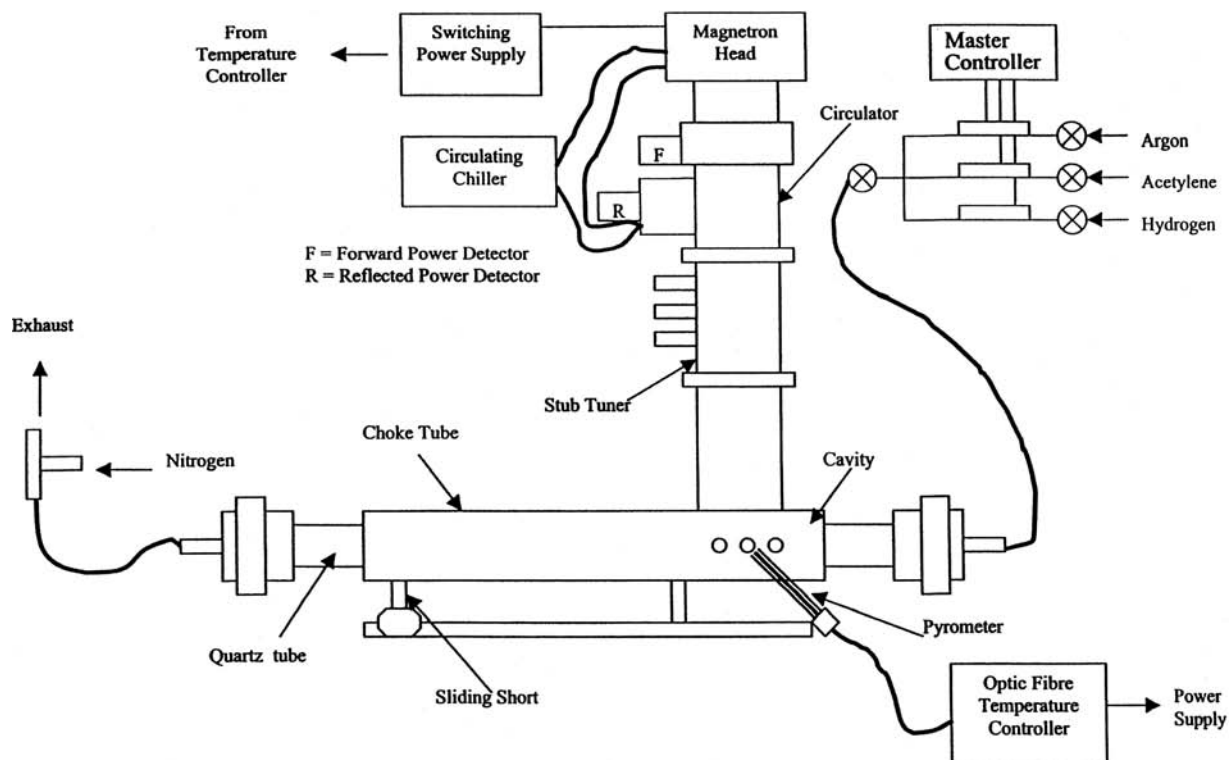

Fig. 11 Schematic diagram of the microwave chemical vapor deposition of carbon nanotubes.

by a power meter that is helpful in determining impedance matching. The four-stub tuner, consisting four threaded stubs spaced at  $3/8$  wavelength apart, was another part to optimize impedance matching. These stubs were adjusted properly, and the four-stub tuner became a matching network which maximized the power transmitted to the load by matching the source impedance to that of the load. As an important part of cavity, sliding short was used to adjust the length of the cavity such that it could resonate at 2.45 GHz. High field intensities could be attained when the cavity resonates. A quartz tube, which was the reaction chamber, passed through the cavity. Reaction gases were introduced from one end of the quartz tube and exhausted at the other end. The flow rates were controlled by a set of flow controller. In this microwave CVD system, SiC was chosen as substrate because of its high loss tangent; thus it could absorb microwave energy effectively. A fibrous morphology with a hollow tube inside was obtained. The diameter of these Multi-wall nanotubes (MWNT) ranges from 20 to 30 nm as shown in Figs. 12–14.

### High-Energy Ball Milling Processes

Ball milling has been utilized in various industries to perform size reduction for a long time. Recently, materials with novel microstructures and properties have

been synthesized successfully via high-energy ball milling processes.<sup>[53,54]</sup> Although different terms have been used to describe the high-energy ball milling processes, three terms are generally used to distinguish powder particle behavior during milling: mechanical alloying (MA), mechanical milling (MM), and mechanochemical synthesis (MS). Mechanical alloying

Fig. 12 Transmission electron microscopy of the CNTs obtained from microwave.

**Fig. 13** High-resolution transmission electron microscopy of MWCNT from microwave CVD.

is referred to when mixtures of powders are milled together. In this case, material transfer is involved to obtain a homogeneous alloy. Mechanical milling describes a milling process when no material transfer is involved; that is, only powder with uniform composition is milled. Mechanochemical synthesis, on the other hand, is a special MA process where chemical reactions between the powders take place during milling. The unique feature of the MS process is that grain refinement and chemical reactions take place at low temperatures under far-from-equilibrium conditions.

**Fig. 14** High-resolution transmission electron microscopy of MWNTs with Encapsulated Co.

A wide variety of nanostructure (grain size in the range of 1–100 nm) materials have been synthesized via MA and MM techniques.<sup>[53–55]</sup> However, MA and MM are not capable of synthesizing nanoscale powders primarily because of cold welding and agglomeration during milling. In other words, individual powders synthesized by MA and MM usually contain many nanosize grains and may show rather low specific surface area values.

It has been shown more recently that the nanocomposite mixtures formed during mechanochemical reactions can be further processed into nanoscale particles.<sup>[56–58]</sup> For instance, nanocomposite of Fe and NaCl was obtained by milling FeCl<sub>3</sub> and sodium metal according to the following reaction:

On dissolution of the soluble NaCl phase by a simple washing process after milling, Fe nanoparticles with relatively narrow particle size distribution can be obtained.<sup>[56]</sup> The synthesis of ultrafine oxide powders with particle size of 10–50 nm has also been reported.<sup>[59,60]</sup>

There are some inherent advantages in processing nanomaterials via high-energy ball milling techniques, such as excellent versatility, scalability, and cost-effectiveness. Therefore high-energy ball milling techniques are well suited for manufacturing large quantity of nanomaterials. A major concern of ball milling techniques is the powder contamination. While the contamination is mainly caused by the wear of milling media and container, the level of contamination depends on factors such as milling time, milling intensity, and milling atmosphere. Attempts have been made in recent years to minimize the powder contamination during ball milling. For example, using the same material for the container and grinding media as the powder being milled will help reduce the contamination.

## PROPERTIES OF NANOMATERIALS

### Optical Properties

It is well known that the yttrium oxide (Y<sub>2</sub>O<sub>3</sub>) has its application in the lighting industry for Eu:Y<sub>2</sub>O<sub>3</sub>, the red phosphor of the trichromatic fluorescent lamps.<sup>[61]</sup> Because of a <sup>5</sup>D<sub>0</sub>→<sup>7</sup>F<sub>2</sub> transition within europium, Eu:Y<sub>2</sub>O<sub>3</sub> shows luminescence properties and emits red light with a wavelength of 611 nm.<sup>[62]</sup> The rare earth ions, such as Eu<sup>3+</sup> and Nd<sup>3+</sup>, show sharp emissions based on electron transitions within the 4f manifold. Furthermore, their emission is found to be highly dependent on the local environment of rare earth ions.

**Fig. 15** Emission spectra of powder with the particle size (A) 6  $\mu\text{m}$ , (B) 1  $\mu\text{m}$ , (C) 0.2  $\mu\text{m}$ , and (D) 0.01  $\mu\text{m}$ .

Therefore the fluorescence of  $\text{Eu}^{3+}$  ions can be used as a probe to investigate the local surrounding in the host, e.g., yttria, alumina, and mullite.

Effect of particle size on fluorescence behavior ( ${}^5\text{D}_0 \rightarrow {}^7\text{F}_2$  transition) of  $\text{Eu}^{3+}$  in the yttria powder was studied by Sharma et al.<sup>[63]</sup> The most noteworthy feature of Fig. 15 is the sensitivity of  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_2$  peak (614 nm) with the particle size. It has been observed that the peak emission intensity of  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_2$  transition increases approximately fivefold as the average particle size decreases from 6  $\mu\text{m}$  to 10 nm. This suggests that the emission intensity of fluorescence varies inversely as the particles size increases. Its behavior was expected from the quantum-confinement model as described by Bawendi et al.<sup>[64]</sup> and Alivisatos et al.<sup>[65]</sup> Goldburt et al.<sup>[66]</sup> have observed high efficiency in Tb-doped  $\text{Y}_2\text{O}_3$  nanocrystals which was measured at 18% as compared with 16% in the bulk and stated that the non-radiative contribution decreases with decrease in particle size. The size dependence of the fluorescence emission intensity can also be demonstrated in terms of number of particles per unit area facing toward the incident light as described by Iwasaki, Ida, and Kimura.<sup>[67]</sup> Increasing surface area of smaller particles (refer Table 1) leads to enhancement in the fluorescence intensity.<sup>[67]</sup> All spectral features were found to be unchanged except the intensity of the peak centered at 395 nm, which was found to be enhanced and shifted to lower wavelength (higher energy level) as the par-

tle size decreased. This shift in excitation spectra with particle size is the evidence of quantum confinement. Gallagher et al.<sup>[68]</sup> have reported a shift of 60 nm in the excitation peak at the maximum emission from  $\text{Mn}^{2+}$  doped in ZnS nanocrystals to shorter wavelength with decrease in particle size because of quantum-confined ZnS.

### Electrochromic devices

An electrochromic device consists of materials in which an optical absorption band can be introduced or an existing band can be altered by the passage of current through the materials or by the application of an electric field. Nanocrystalline materials, such as tungstic oxide ( $\text{WO}_3 \cdot \text{H}_2\text{O}$ ) gel, are used in very large electrochromic display devices. The reaction governing electrochromism (a reversible coloration process under the influence of an electric field) is the double injection of ions (of protons,  $\text{H}^+$ ) and electrons, which combine with the nanocrystalline tungstic acid to form a tungsten bronze. These devices are primarily used in public billboards and ticker boards to convey information. Electrochromic devices are similar to liquid-crystal display (LCD) commonly used in calculators and watches. However, electrochromic devices display information by changing color when a voltage is applied. When the polarity is reversed, the color is bleached. The resolution, brightness, and contrast of these devices greatly depend on the tungstic acid gel's grain size. Hence nanomaterials are being explored for this purpose. Using nanostructure materials, color change will be faster and uniform. Additionally, the number of cycles of coloration and bleaching can be enhanced. Recently, Ntera Inc. has developed an electrochromic display technology called NanoChromics<sup>TM</sup> using nanostructure film electrodes. The nanostructure films are derived from sol-gel precursors and formulated to suit the particular coating application method.

### Catalytic Properties

Some of \$10 trillion worth of chemicals and materials are produced each year through catalytic processes,

**Table 1** Comparison of  $\text{Li-MO}_2$  in microparticle and nanoparticle size

Properties	$\text{LiNiO}_2$ <sup>[74]</sup>		$\text{LiMnO}_2$ <sup>[75]</sup>		$\text{LiCoO}_2$ <sup>[77]</sup>		$\text{Li}[\text{Cu}_{1-x}\text{Fe}_x]\text{O}_2$	
	Micro	Nano	Micro	Nano	Micro	Nano	Micro	Nano
Crystallite size	830 nm	300 nm	$\approx$ microns	5–50 nm <sup>[75]</sup>	1.67 $\mu\text{m}$ <sup>[74]</sup>	60 nm	$\approx$ microns	< 50 nm <sup>[80]</sup>
Capacity (mAh/g)	90 <sup>[1]</sup>	205 <sup>[1]</sup>	130 <sup>[76]</sup>	250	87 <sup>[1]</sup> 140 <sup>[78]</sup> ; 126 <sup>[79]</sup> ;	167 <sup>[1]</sup>	140 <sup>[1]</sup>	230 <sup>[1]</sup>
Potential (V)	4.2	4.2	4.1	3.8	4.1 <sup>[78]</sup> ; 3.9 <sup>[79]</sup>	4.2	4.1	4.2

according to industry estimates and published in Chemical and Engineering News. Most of these processing deal with the microscopic size of the particle with diameters measuring no more than a few billionths of a meter. In catalysis, the goal is to design catalysts with certain features that help boost catalytic performance. It is anticipated that this goal will be more closely approached through tailoring a catalyst particle via nanoparticle synthesis and assembly, so that it performs only specific chemical conversions, performs at high yield, and does so with greater energy efficiency. It has been established that the nanostructures have higher surface area than do conventional materials. The high surface areas can be attained either by fabricating small particles or clusters where the surface-to-volume ratio of each particle is high (category I) or by creating materials where the void surface area (pores) is high compared with the amount of bulk support materials (category II). Materials such as highly dispersed supported metal catalysts and gas phase clusters fall into the first category, and microporous (nanometer-pored) materials such as zeolites, high surface area metal oxides, porous carbon, and amorphous silica fall into category II. The nanostructure approach to high surface area materials may have significant impact in petrochemical process, biosensors, gas sensors, absorption and adsorption phenomena, gas storage, energy storage, battery performance, biological reactions, etc.

### Electrochemical Properties

Lithium-based rechargeable batteries have been proposed for a wide variety of extremely demanding applications. These applications include, but are not limited to, electric vehicle (EV), start-light-ignition (SLI), portable electronics, and personal communications devices. The lithium battery technology can be generally classified as cathode, anode, and electrolyte technology (liquid-electrolyte and solid-electrolyte types). Although variation in cathode materials for lithium has been recognized as a highly flexible and versatile technological approach for the production of high-energy density batteries, none of the existing battery technology is capable of satisfying the energy- and power-density requirements in the aforementioned applications. The widespread use of battery is severely hampered by poor performance of cathode materials of Li-ion battery because of the following characteristics:

- Micron-size particles.
- Small surface area.
- Unstable structure during cycling.
- Inadequate mechanical strength.
- Costly precursors, high-temperature stability.

Furthermore, the aforementioned characteristics are the primary factors that deprive the overall performance of the battery, which include the following

- Inferior electrochemical stability.
- Inferior mechanical properties.
- Greater toxicity.
- Low power-to-energy ratio.
- High costs.
- Low cycle life.
- Low calendar life.
- Poor thermal management capabilities.
- Inferior manufacturability.
- Potential hazards, especially of the liquid electrolytes, because of leakage, deposition, and explosion.

To obviate the aforementioned deficiencies associated with cathode materials, researchers have developed a new class of material using nanoparticles of different cathode materials based on metal oxides, which will exceed, or meet, the above performance requirements.

Furthermore, it is now well established that the limitations in the rate capabilities of Li-ion batteries are caused by slow solid-state diffusion of Li within the electrode materials.<sup>[69–72]</sup> As a result, there is tremendous interest in the development of *nanostructure* Li-ion battery cathode electrodes. These batteries can store two to three times more energy per unit weight and volume than the one with micron-particle-size electrode.<sup>[73]</sup> Table 1 represents the improvement in the Li-ion battery.

### Energy Storage

Recent interest in the use of hydrogen as a multi-purpose fuel has emphasized the necessity of reliable storage system for this element. LaNi<sub>5</sub> alloy stores up to 1.6%, while FeTi stores up to 1 wt.% of hydrogen in the form of metal hydride. The hydrogen capacity in these host materials was quite low, and hence research was focused on the storage of hydrogen in molecular sieves especially in natural and synthetic zeolites.<sup>[81]</sup> CsA-zeolite was found to have hydrogen storage capacity of ~6 wt.%. On the other hand, it is also well known that the carbon nanotubes (CNTs) have the capacity of hydrogen storage.<sup>[81–83]</sup> Dillon et al.<sup>[82]</sup> reported that the SWNTs with low purity could adsorb 5 wt.% of H<sub>2</sub> at 133 K and 0.040 MPa. This value of hydrogen storage was enhanced to 8 wt.% for highly pure Single wall nano tubes (SWNT) in the studies of Ye et al.<sup>[81]</sup> However, temperature was reduced to 80 K and pressure was increased to 7.18 MPa. At room temperature, the hydrogen capacity was only 4 wt.% at 10 MPa.

## Biomedical

Biomolecule/inorganic interactions can be used to produce ceramics with increased toughness. Fundamental studies of biomineralization, in which an organic substance (usually protein or peptide or lipid) interacts with an inorganic phase (e.g., calcium carbonate or hydroxyapatite), have led to the bioinspired synthesis of composite materials. Hydroxyapatite (HAp), a major inorganic component of bone, has been used extensively for biomedical implant applications and bone regeneration because of its bioactive, biodegradable, and osteoconductive properties. However, the application of pure HAp is very limited because of its brittleness. Because the natural bone is a composite mainly consisting of nanosized needlelike HAp crystals and collagen fibers, many efforts have been made to modify by polymers such as polylactic acid, collagen, chitosen, and polyethylene and have received much attention in the field of medical applications because of their excellent biocompatibility and biodegradability.<sup>[84]</sup> Additionally, the following materials are used in various applications of biomedical, biotechnical, and bioengineering.

### Nano-ZnO

1. Biosensor: Nanoparticles of ZnO can sense the toxic and hazardous gas such as H<sub>2</sub>, SF<sub>6</sub>, and gasoline in shorter time because of high surface area.
2. Neutralizes biochemical use in biological weapons because high surface area of nanostructured ZnO is highly reactive and able to degrade toxic biochemical (e.g., naphthalene, anthracene, phenol, chlorophenol, and polyaromatic hydrocarbons) use in biological weapons.

### Nano-MgO and nano-TiO<sub>2</sub>

Nano-MgO and nano-TiO<sub>2</sub> neutralize the biological immune buildings, e.g., bacteria and virus, which are used as biological warfare agents.

### Magnetic nanoparticles of iron

Magnetic particles coated with biocompatible polymers dispersed in water could be used as

- Site-specific drug delivery after being attached with drug molecules to the magnetic particles.
- Magnetic tourniquet. In this case, a person with blood loss because of injury could be injected with the magnetic particles dispersed in water. Then a magnet could be placed on the injury site. The

magnetic particles will agglomerate there and hence would prevent the blood from flowing out.

### Biodegradable nanosilica

Biodegradable nanosilica can be used for drug delivery. It is important for an inorganic material to be used as a drug delivery agent; it should be biodegradable, nanosized, porous, and non-toxic. Nanostructured silica can be a good candidate for a drug delivery agent, which can easily degrade and would not provide any side effect. This kind of drug delivery system will be extremely valuable for the instant wound therapy of any injured person.

### Protein tagging using nanoluminescent particles

Protein tagging is an experimental strategy in which a tag such as a probe (luminescent lanthanides, e.g., Eu, Sm, etc.) is attached to primary sequence of a protein. The size of the tag used for attachment to the loops of a protein must be extremely small.

This strategy can also be used in:

- Cancer therapy: to block interactions such as enzyme substrate interactions or interaction of a toxin with a specific cell or a component of a cell.
- Drug delivery: for delivery of protein drugs to cells.

### CdS and ZnS semiconductor quantum dots

Immunosensor, bioanalytical, and biolabels: Semiconductor quantum dots are highly light-absorbing luminescent nanoparticles, whose absorbance onset and emission maximum shift to higher energy with decreasing particle size because of quantum confinement effect.

Quantum dots can conjugate with antibodies using an engineered adapter protein and are new types of reagents for immunosensors and bioanalytical applications.

### Nanogold particles

1. Labeling of target molecules, especially protein with nanogold particles, has revolutionized the visualization of cellular or tissue components by electron microscopy or atomic force microscopy.
2. As a bioconjugate: with DNA, it can detect the active site of DNA and can be used in disease diagnostics.

### Nanoparticles in gene therapy

Nanoparticles are now also being used as a delivery mechanism in gene therapy. Nanoparticles can be

employed to insert good DNA into specific sites to replace faulty genes in such disorders as cystic fibrosis.

## Textile

Another huge industry that will be impacted by nanotechnology is the textiles industry. Companies are working on “smart” fabrics that can change their physical properties according to surrounding conditions or even monitor vital signs. The incorporation of nanoparticles and capsules in clothing offers some promise, and nanotubes would make extremely light and durable materials. Fabrics are already being marketed that are highly resistant to water, stains, and wrinkling.

## Magnetic Properties

Ferromagnetic nanomaterials have potential advantages over existing materials in numerous applications in soft magnets,<sup>[85]</sup> hard magnets,<sup>[86]</sup> magnetic recording,<sup>[87,88]</sup> etc. The study and exploitation of magnetism at the nanometer scale have been exceptionally active research areas over the past two decades. Ferromagnetic nanoparticles (usually referred to as magnetic nanoparticles) have generated great interest because of their size-dependent magnetic properties. The ferromagnetic interaction leads to parallel spins on adjacent atoms. However, the exchange forces responsible are short range, and magneto static forces dominate at great distances. Magnetic domains arise spontaneously in bulk ferromagnets to minimize their overall energy. The typical sizes of the domains are in nanometer-size range. Below a certain size, which is in the nanometer range, it is energetically favorable for a particle to be monodomain.

The coercivity of magnetic materials has a striking dependence on their size. It increases with the reduction of particle size in the nanometer range going through a maximum at the single domain size, and then decreases again for very small particles because of thermal effects and becomes zero at the superparamagnetic particle size. Iron, which is a soft magnetic material with coercivity about 20 Oe at room temperature, could be made “hard” with a coercivity of 540 Oe when the particle size is reduced to about 12 nm.<sup>[89]</sup> Remarkably low coercivity of the order of a few millioersteds along with high saturation magnetization and permeability has been achieved in  $\text{Fe}_{74}\text{Si}_{15}\text{B}_7\text{Cu}_1\text{Nb}_3$  nanocrystalline magnetic alloy where  $\alpha$ -Fe(Si) nanocrystallites of size  $\sim 10$  nm are embedded in an amorphous matrix.<sup>[90]</sup> These materials were synthesized

by melt spinning followed by annealing. The nanocrystallites, whose dimension is less than the exchange length, are exchange-coupled with randomly oriented easy axes of magnetization. The combination of random orientation and averaging over multiple grains makes the preference for magnetization in a particular direction, and therefore the effective magnetic anisotropy and hence coercivity are small.<sup>[91,92]</sup> Several other nanocrystalline soft magnetic alloys based on Fe(Co)–Si–B have been studied.<sup>[93]</sup>

R–Fe–B (R = Nd, Pr, Dy, Pr) alloys, prepared using melt-spinning, exhibited very high coercivity in the range 10–100 kOe.<sup>[86]</sup> In these permanent or hard magnets, the large coercivity is a result of the highly anisotropic tetragonal  $\text{R}_2\text{Fe}_{14}\text{B}$  phase, which were produced in the nanoscale size during melt spinning or subsequent crystallization. Several other permanent magnets, e.g.,  $\text{SmCo}_5$ ,  $\text{Sm}_2\text{Co}_{17}$ ,  $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.6}$ , etc., with high coercivity have been made with nanosized microstructure.<sup>[86]</sup> Another class of hard magnetic material is called nanocomposite permanent magnet or exchange-coupled magnet where the nanocomposite consisting of a hard magnetic material such as  $\text{Nd}_2\text{Fe}_{14}\text{B}$  and a soft magnetic phase such as  $\alpha$ -Fe are coupled through exchange interaction.<sup>[94,95]</sup> This leads to high coercivity and high remanence to saturation magnetization ratio and hence high maximum energy product values. In these magnets, the crystallite size needs to be less than 20 nm for exchange coupling to occur. Most of these nanocomposite magnets have been prepared by melt spinning and mechanical alloying.<sup>[96,97]</sup> Recently, a chemical synthesis has been proposed with the potential for making three-dimensional magnets with high maximum energy product.<sup>[98]</sup> First,  $\text{Fe}_{58}\text{Pt}_{42}$  and  $\text{Fe}_3\text{O}_4$  nanoparticles of 4-nm size are mixed and allowed to self-assemble. When it was heated and chemically reduced, FePt (hard)– $\text{Fe}_3\text{Pt}$  (soft) nanocomposite is formed. The particles are 5 nm in size. The maximum energy product is 20.1 MGOe compared with 13 MGOe for FePt alone. This is an exciting new development that shows promise for making strong magnets.<sup>[99]</sup> Moreover, 4-nm particles of  $\text{Fe}_{52}\text{Pt}_{48}$  (synthesized by very similar chemical route) that self-assembled into arrays when annealed exhibited a coercivity of 1800 Oe.<sup>[100]</sup> These  $\text{Fe}_{52}\text{Pt}_4$  nanocrystal assemblies are smooth ferromagnetic films, and initial magnetic recording experiments suggested that it could support high-density magnetization reversal transitions or bits. A key requirement for magnetic recording at areal density in the terabits per square inch regime is a medium with nanometer-size, magnetically isolated grains with moderately high writable coercivity.<sup>[87,88]</sup> With these 4-nm  $\text{Fe}_{52}\text{Pt}_{48}$  self-assembled particles, it might be possible to achieve magnetic recording at areal density in the terabits per square inch range.

## CONCLUSION

This review highlighted on the fabrication of nanomaterials by various methods e.g. chemical, physical and mechanophysical. The various properties e.g. chemical, physical, mechanical, magnetic, optical and electrical, of nanomaterials have discussed in detail. Nanostructured materials exhibit novel and technologically attractive properties, which can be exploited for a variety of applications which include, but are not limited to the biomedical, energy, displays, insulations, elimination of pollutants, catalysis, microelectronics, high power magnets, sensors, aerospace, weapons, automobiles etc.

Pohang, South Korea*

## INTRODUCTION

The immense potential of functional nanomaterials in the fields of communication, information storage, materials, and biological sciences has heightened the quest to obtain them. In this quest, the “bottoms-up” approach, with its emphasis on chemical methods, has proven to be of more value than the classical “top-down” approach. Design strategies based on quantum theoretical methods are particularly suited to accelerate the “bottoms-up” approach, because of their ability to predict the properties of these nanomaterials to a high degree of accuracy. In the course of this entry, we show how the pursuit for small, fast, and powerful nanoelectronic and nanomechanical devices, chemical/biochemical sensors/monitors, DNA chips, etc. can be vastly facilitated using an approach based on de novo theoretical design.

The first step in this process is to obtain a detailed insight of intermolecular interactions prevailing in these nanomaterials. This is because most physical phenomena, such as molecular recognition,<sup>[1]</sup> nanorecognition,<sup>[2]</sup> molecular clustering/aggregation,<sup>[2]</sup> self-assembly,<sup>[3,4]</sup> and self-synthesis,<sup>[5]</sup> are the result of competitive and cooperative effects of several types of interatomic, intramolecular, and intermolecular interactions.<sup>[6,7]</sup>

Based on a thorough understanding of various interaction forces and mechanisms, one can design molecular clusters, inorganic/metal clusters, endo-/exo-hedral fullerenes/nanotubes, non-linear optical materials, ionophores/receptors/sensors, polypeptides/membranes/enzymes, organic nanotubes/nanowires, photo/electro-nanodevices, and nanomechanical molecular devices. In the course of this entry, we show how the above strategy helped design novel and experimentally viable ionophores,<sup>[8–12]</sup> organic nanotubes,<sup>[4–6]</sup> nanowires,<sup>[5]</sup> molecular flippers,<sup>[13]</sup> and molecular switches,<sup>[14]</sup> etc.

## INTERMOLECULAR FORCES

The intricacies of most intermolecular interactions can be obtained from the study of molecular clusters.<sup>[15–18]</sup> These diverse intermolecular interactions can broadly be classified as: 1) H-bonding, 2) ionic interactions, 3) intermolecular interactions involving  $\pi$  systems, 4) metallic interactions, and 5) interactions involving quantum species.

## DESIGN AND DEVELOPMENT OF FUNCTIONAL MOLECULES, NANOMATERIALS, AND NANODEVICES

In the following account, we discuss the strategies employed to design nanoclusters, nanowires, ionophores, receptors, sensors, carbon-based nanomaterials, organic nanotubes, encapsulated nanowires, non-linear optical switches, and nanomechanical devices.

### Nanoclusters and Nanowires

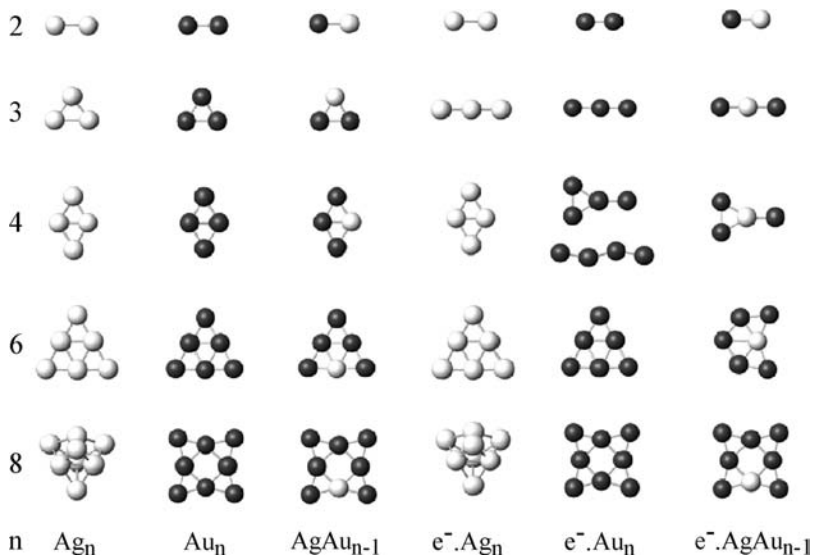

Clusters, in addition to offering several ways of making new materials, are a fundamental subject for understanding the intrinsic nature of materials.<sup>[15,16]</sup> The investigation of H-bonded clusters,<sup>[18–22]</sup> metal clusters,<sup>[23–25]</sup> and clusters containing  $\pi$  systems<sup>[26–29]</sup> not only provides the necessary information for nanomaterial design but also highlights some of the important similarities and differences in their structures and properties. In this discussion, we focus our attention on noble metal clusters and metal nanowires. Theoretical investigations of these noble metal clusters, to a large extent, depend on the ability of the theoretical method to describe metallic interactions. In particular, the ability of the method to accurately describe relativistic effects is vital to the success of the design

strategy. Small noble metal clusters<sup>[23–25,30–33]</sup> are of particular interest because the dominance of quantum effects in such small dimensions alludes to the emergence of several interesting characteristics, such as their catalytic properties, etc. While most studies were concentrated on pure metallic clusters, it has recently been realized that mixed metallic clusters exhibit unique electronic, magnetic, optical, and mechanical properties. For example, mixed clusters of gold and silver have been found to exhibit enhanced optical non-linearity over the corresponding bulk metals. Another advantage of studying these mixed clusters is that they help understand the mechanism of alloying. A recent example of the utility of theoretical methods is illustrated in the case of gold–tungsten clusters, wherein theoretical calculations were able to accurately predict the structures and properties, before they were experimentally identified.<sup>[24,25]</sup>

One of the highlights of neutral and anionic gold and silver clusters is that they exhibit an even–odd oscillation in their stability and electronic properties.<sup>[23]</sup> Owing to the spin pairing, the clusters having an even number of atoms tend to be more stable in the neutral state, while those having an odd number of atoms tend to be more stable in the anionic state. Since the 6s orbital energy of Au is almost as low as 5d orbitals due to the relativistic effect, the strong s–d hybridization in Au favors one-dimensional and two-dimensional structures in the case of the gold clusters. This explains the ductility of small gold clusters. In contrast, silver clusters exhibit a strong preference to exist as three-dimensional structures with spherical coordination because the valence orbitals are predominantly of the s-type. A similar argument can also be employed to explain the low coordination number of the Au atom in the gold clusters as compared to the Ag atom in the silver clusters. This preference in coordination reflects

itself in the location of the Au and Ag atoms in the corresponding binary clusters of gold and silver, with the Au atoms being located on the boundary, while Ag atoms are generally located in the inner side (Fig. 1). In the anionic systems of both pure and mixed clusters, there is a marked tendency to adopt low-dimensional conformations as compared to the corresponding neutral clusters. However, in the mixed clusters, the conformational preferences are strongly correlated to the number of Au and Ag atoms in the cluster. Given the higher energy of the Ag 5s as compared to the Au 6s orbital, electron transfers from Ag to Au atoms are found in the mixed clusters. This together with the predilection for Au atoms to be located on the boundary indicates that the core of the mixed clusters is positively charged, while the surface is negatively charged. The easy formation of the mixed gold–silver clusters and as a consequence their alloys is due to the significant electrostatic stabilization accruing from the charge transfer from Au to Ag atoms.

In order to obtain more insight into the role of dimensionality, we extend the clusters to nanowires, thin-films, and the bulk systems.<sup>[34]</sup> Toward low-dimensional structures, there is a strong sharpening of the d bands, which vastly enhances the corresponding density of states and raises the band edges. This strong preference for lower-dimensional structures is in consonance with the experimental observation that the interatomic interactions progressively become stronger in low-coordinated systems. In our discussion of gold clusters, the presence of an excess charge promotes linearity.<sup>[23]</sup> Interestingly, it was experimentally noted that a wire of at least four gold atoms suspended between two gold electrodes is linear.<sup>[35,36]</sup> However, theoretical calculations of a free-standing, one-dimensional gold wire indicate that a two-dimensional structure is more stable.<sup>[37]</sup> Therefore a subject of

**Fig. 1** Predicted lowest-energy conformers of neutral and anionic clusters of pure silver ( $\text{Ag}_{2-4,6,8}$ ), pure gold ( $\text{Au}_{2-4,6,8}$ ), and gold–silver alloys ( $\text{AgAu}_{1-3,5,7}$ ).

intense interest in the recent past is on methods to obtain one-dimensional gold nanowires. It would be useful to modulate the charge transfer in gold alloy nanowires by injecting *s* electrons into gold wire without distorting its band structure.<sup>[38]</sup> The *s* band of the alloying metal should therefore possess similar energy levels as the 6*s* orbital of gold. Of all the *s* band metals, beryllium, magnesium, zinc, cadmium, and mercury have their valence energy levels closest to that of the 6*s* orbital of gold, and hence can form alloys with gold. Then, density functional calculations were carried out on free-standing, infinite monoatomic gold wires alloyed with both magnesium and zinc. In the alloy chains, the locations of the gold and zinc (or magnesium) atoms were alternated and investigated as both one- and two-dimensional structures. In sharp contrast to pure gold nanowires, the one- and two-dimensional structures of both gold–magnesium and gold–zinc alloys exhibit distinct minima in the plots of the cohesive energy, indicating that both forms are energetically accessible. We note that both zinc 4*s* and magnesium 3*s* bands display *p* character near the Fermi energy. This *sp* hybridization, which is absent in pure gold nanowires, favors a linear structure in the case of these alloyed nanowires.

### Ionophores, Receptors, and Chemical Sensors

The design and synthesis of receptors capable of binding anionic or cationic guests are of crucial importance because of their potential applications in environmental and biological processes. Unlike nanoclusters and nanowires, the theoretical challenge in these systems is to

describe the interactions of an organic system with a charged metal, or another organic cation. Furthermore, one has to take into account the role of the environment in modulating the binding characteristics. The environment could either be solvents, molecules, or other ions.

We begin our discussion of ionophore/receptor design with one of the seemingly intractable problems of contemporary biochemistry: the selective recognition of the ammonium cation ( $\text{NH}_4^+$ ).<sup>[8,39]</sup> Much of the problem is due to the nearly equivalent sizes of  $\text{NH}_4^+$  and the potassium cation ( $\text{K}^+$ ).<sup>[40]</sup> In the following account, we show on how we circumvent the problem and were successful in identifying a series of receptors with improved selectivity and affinity for  $\text{NH}_4^+$ .<sup>[8]</sup> The first step in the receptor design was that high selectivity for  $\text{NH}_4^+$  could be achieved with cation– $\pi$  interactions,<sup>[40–42]</sup> if the receptors have an optimal space to capture  $\text{NH}_4^+$  and exhibit strong interactions toward  $\text{NH}_4^+$ . However, the ionic radius of  $\text{K}^+$  is nearly similar to that of  $\text{NH}_4^+$ , so spatial differentiation is not useful. Therefore we take advantage of the differences in coordination numbers.  $\text{K}^+$  favors a coordination number of six, while  $\text{NH}_4^+$  favors only four. Furthermore, one has also to take into account the directional H-bonds involving  $\text{NH}_4^+$  cations, to describe the higher selectivity for  $\text{NH}_4^+$  over  $\text{K}^+$ . Our initial calculations indicated that a benzene-based tripod system with imidazoline arms (Fig. 2A) possesses vacant sites for the interaction with only one solvent molecule, while the  $\text{K}^+$  ion has three vacant sites for three solvent molecules. In order to maximize the affinity and selectivity of these receptors for  $\text{NH}_4^+$ , it becomes important to maximize the  $\pi$ -electron density of the receptor. Indeed, receptors with enhanced

**Fig. 2** Receptors for  $\text{NH}_4^+$  (A), acetylcholine (B),  $\text{Cl}^-$  (C),  $\text{H}_2\text{PO}_4^-$  (D), and structures of collarenes (E), cyclacenes (F), beltene (G), and  $\text{Rb}^+$ -complexed [8]beltene (H).

$\pi$ -electron density by trimethylated phenyl ring with the strong proton-withdrawing subunits exhibit much higher affinities and selectivities.

Given this background, an extended concept has been applied to the receptor design for a biologically important molecule, acetylcholine.<sup>[9]</sup> The receptor should have higher affinity and selectivity for acetylcholine over  $\text{NH}_4^+$ . This requires enhanced dispersion interactions and diminished ionic interactions, which is met by replacing the imidazole arms of the  $\text{NH}_4^+$  receptors with pyrrole (Fig. 2B). These theoretical inferences were confirmed by experiments.

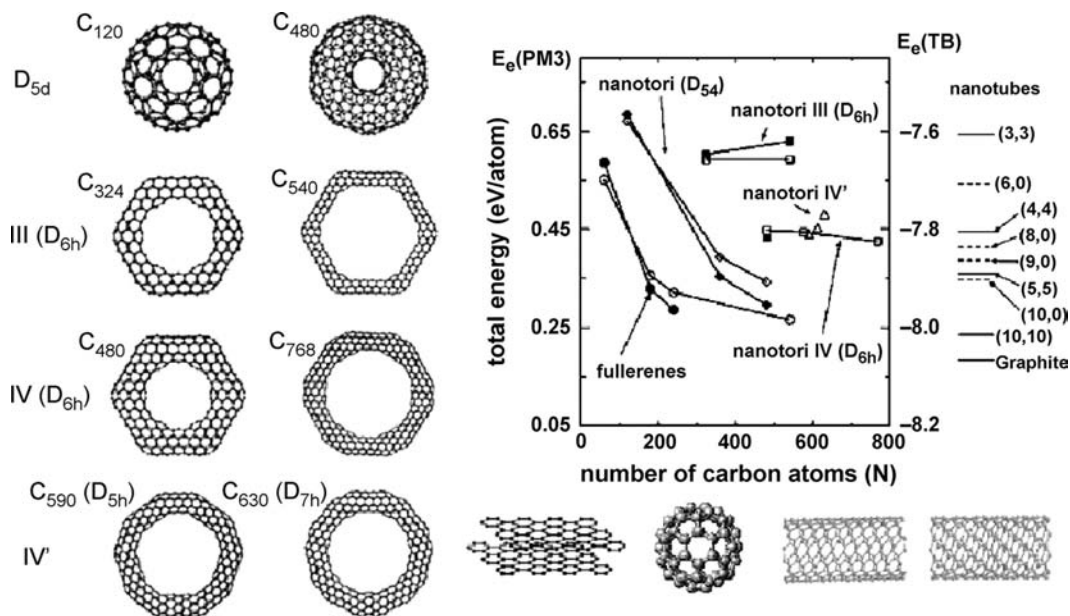

Interactions involving anions are very different from those of cations. As anions are more polarizable and hence more susceptible to polar solvents than cations, it becomes important to take into account solvent effects. Based on molecular dynamics simulations combined with ab initio calculations, highly selective anionophores have been designed.<sup>[10–12]</sup> Enhanced dipole moments (Fig. 2C) were employed by attaching a strategically placed electron-withdrawing group.<sup>[10]</sup> This approach would also aid in the design of novel functional molecular systems and biologically important chemosensors. Utilizing the  $\text{CH}^+ \dots \text{X}^-$  H-bonds, fluorescent photoinduced electron transfer chemosensors for the recognition of  $\text{H}_2\text{PO}_4^-$  have also been designed and synthesized (Fig. 2D). In addition, we have also been successful in designing cyclopeptides as amphi-ionophores.<sup>[43,44]</sup>

It would be appealing to explore the possibility of carbon-based materials being used as ionophores.<sup>[45–47]</sup> Belt-shape carbocyclic-conjugated systems (annulenes, beltene, cyclacenes, and collarenes) are closely related

to other carbon-based systems containing curved surfaces. These include fullerenes and carbon nanotubes. The ion binding characteristics of these carbon materials have been unraveled through ab initio calculations, Monte Carlo, and molecular dynamics simulations of collarenes (benzene rings linked by methylene linkages), cyclacenes (composed only of benzene rings), and beltene (ethene groups linked by methylene linkages), and their complexes with various cations (alkali, alkaline-earth metal, and organic cations) in both the gas and aqueous phases (Fig. 2E–H). Additionally, suitable substituents could also enhance their binding affinities and selectivities. In particular, the designed molecules could be modified to be soluble in polar solvents by adding hydrophilic groups on the edges of the molecules.

### Carbon-Based Nanomaterials

Since the discovery of fullerenes and carbon nanotubes, much effort has gone into the discovery of other interesting allotropes of carbon with unusual structural characteristics and novel physical properties.<sup>[48–50]</sup> Toward this end, the geometries, electronic structures, and energetics of small carbon nanotori were investigated employing both tight-binding and semiempirical quantum chemical methods.<sup>[51]</sup> It should be mentioned here that the very large size of these carbon-based materials precludes the use of high-level quantum methods. One therefore has to take recourse to the use of semiempirical or tight-binding methods. As can be seen from Fig. 3, the structures and electronic

**Fig. 3** Optimized structures of various types of carbon nanotube tori and their stability compared with grapheme, fullerene, and nanotubes. Source: From Ref.<sup>[51]</sup>.

properties of the smallest nanotori exhibit interesting metal, semiconductor, and insulator characteristics depending on nanotube building blocks.

An interesting offshoot in the context of carbon-based nanomaterials is the role of external perturbations in modulating their physical and chemical characteristics. These perturbations can include cations or neutral atoms. In this context, we examined the magnetic properties of exohedral fullerenes of alkali-metal fullerenes ( $A_xC_{60}$ ,  $A = \text{Na, K, Rb, Cs}$ )<sup>[52,53]</sup> and the spin properties of endohedral fullerenes ( $A-C_{60}$ ,  $A = \text{N, P, As, O, S}$ )<sup>[54-57]</sup> (Fig. 4). The most interesting aspect of the experimental investigation of endohedral fullerenes was the fact that the encapsulated nitrogen, which possesses three unpaired electrons and is paramagnetic in nature, is totally inert within  $C_{60}$ . Our calculations, however, indicated that the interaction observed in the case of  $N-C_{60}$  is predominantly dispersive in nature. These systems are interesting because endohedral fullerenes containing paramagnetic atoms could be utilized to design quantum computers.<sup>[58]</sup>

## Organic Nanotubes

There are several advantages in using hydrogen bonds to design nanomaterials,<sup>[4-6,59]</sup> and in particular nanotubes, because these nanotubes have potential applications as artificial biological channels, drug delivery, nanochemical reactors, etc.<sup>[60-63]</sup> One of the spectacular aspects of a recent report on the self-assembly of an organic nanotube from non-tubular units of calix[4]hydroquinone (CHQ) was that the theoretical design preceded the actual experiment of synthesis and investigation of the X-ray structure.<sup>[4-6]</sup> Apart from highlighting the robustness of the theoretical approach, this study also provided several insights into the mechanism of self-assembly of CHQ nanotubes.

In the absence of water, for each CHQ monomer, the number of dangling H atoms is 4, while in the presence of water, these dangling H atoms of CHQs form chains  $HQ-(\text{water}-HQ-HQ)_n\text{water}$ . Although the strength of one-dimensional short H-bonding interaction ( $\sim 10$  kcal/mol) is similar to or slightly stronger

than the strength of the  $\pi-\pi$  stacking interaction, the assembly along the one-dimensional short H-bonds relay should be much more favorable because the number of H-bonds is three times the number of  $\pi-\pi$  stacks. Indeed, in experiments with water, CHQs are assembled to form long tubular structures with four infinitely long, short strong H-bond arrays. The CHQ tubes assemble to form long tubular structures in the presence of water, which in turn, form bundles with intertubular  $\pi-\pi$  stacking interactions (Fig. 5), resulting in crystals with well-ordered two-dimensional arrays of pores. The structures of these pores were utilized for the synthesis of encapsulated nanowires,<sup>[5]</sup> which would be described in the next section. A needle-like nanotube bundle exhibits the infinitely long one-dimensional H-bonding network between hydroxyl groups of CHQs and water molecules and well-ordered intertubular  $\pi-\pi$  stacking pairs (Fig. 5). The geometries of the calculated  $\pi-\pi$  stacks are very close to the  $\pi-\pi$  stacks in the X-ray structure.

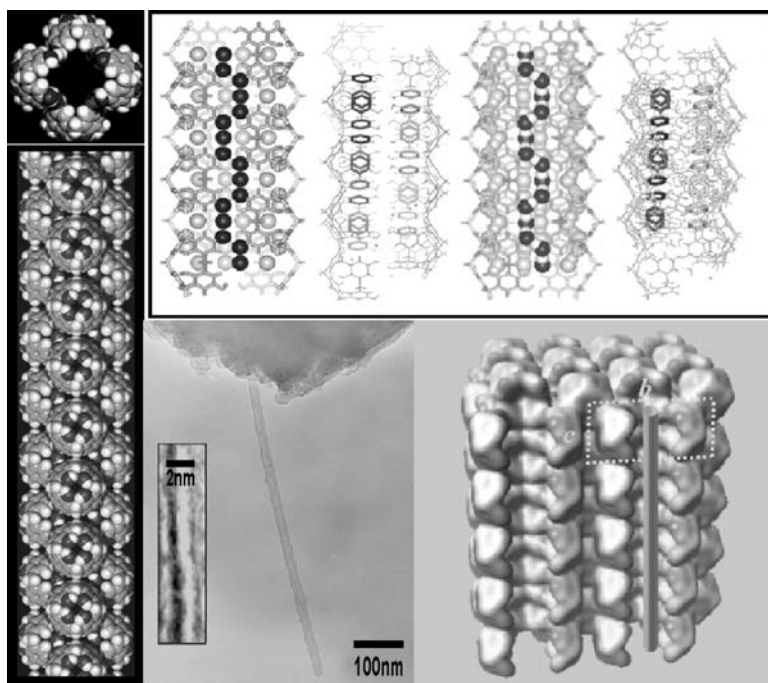

## Encapsulated Metallic Nanowires

As was mentioned earlier, CHQ nanotubes arrays can be utilized in promising templates for nanosynthesis. Redox reaction of the nanotube in the presence of silver nitrate leads to the formation of a silver nanowire arrays in the pores (pore size of  $8 \times 8 \text{ \AA}^2$ ) of the CHQ nanotube. The wires exist as uniformly oriented three-dimensional arrays of ultrahigh density. The driving force for the formation of these nanowires is the free energy gain due to the reduction-oxidation process.<sup>[64,65]</sup> The resulting nanowire is composed of four dumbbells, each of which contains two silver atoms, superimposed on one another and crisscrossed in their length.

The theoretical characterization of the reduced form of the CHQ nanotube was carried out using plane-wave pseudopotential methods.<sup>[66]</sup> Our calculations indicated that upon reduction with silver nitrate, the CHQ nanotubes get transformed to the corresponding calix[4]quinone-hydroquinone (CQHQ) nanotubes, whose band gaps of 0.3 eV indicate that they are semiconducting in nature. The gross structural feature

**Fig. 4** Ground triplet ( $d_{D_{2h}}$ ) and excited singlet ( $s_{C_{2h}}$ ) states of  $(C_{60})_2^{2-}$  with two views (for the alkali cation-doped exohedral fullerenes), and N-containing endohedral fullerene.

**Fig. 5** Calix[4]hydroquinone nanotubes: structure, longitudinal one-dimensional H-bond relay vs. intertubular  $\pi$ - $\pi$  stacking, the HREM image of a single nanotube, and the water-accessible surface of the tubes. Each tube has four pillar frames of short H-bonds, and the pore size is  $8 \times 8 \text{ \AA}^2$ . The unit cell is drawn by the dashed lines. *Source:* From Ref.<sup>[4]</sup>.

of CQHQ nanotubes is similar to that of CHQ nanotubes, with well-ordered H-bond arrays and intertubular  $\pi$ - $\pi$  stacking pairs. In the CQHQ nanotubes, there are only two infinitely long one-dimensional H-bond arrays per nanotube because two hydroxyl groups are transformed to the corresponding reduced forms. Simultaneously, silver cations get transformed to metallic silver. Upon reduction of the CHQ nanotubes, the silver atoms are located within the reduced CQHQ nanotube (Fig. 6). In the case of 2/2 nanowire, the predicted cohesive energy is 2.4 eV, which is 0.9 eV smaller than the bulk value. The encapsulation of a silver nanowire within the

CQHQ nanotube leads to several additional states in the band gap region, which are similar to that of an isolated silver nanowire. In this case two  $s$  channels cross the Fermi energy level, which indicates the existence of quantum conductance.

### Non-linear Optical Switches and Right-/Left-Handed Helices of Polypeptides

We had talked about harnessing the interaction of photons, electrons, protons, or charged species with

**Fig. 6** Top and side views of a silver nanowire inside a calix[4]quinone-hydroquinone (CQHQ) nanotubes (left figures), and the band structures of an isolated silver nanowire (left—first on the right figure), a silver nanowire encapsulated in a CQHQ nanotube (second), a CQHQ nanotube (third), and a calix[4]hydroquinone (CHQ) nanotube (last). *Source:* From Ref.<sup>[66]</sup>.

molecular systems in the design of new nanodevices. While photochemical and electrochemical switching devices have been extensively investigated, most of the photochemical switching devices are limited to the linear regime. However, it would be of interest to use non-linear optical properties for an efficient memory device. In investigations of the interaction of photons with matter, it is essential that the employed theoretical method should be capable of characterizing both open-shells and excited states. The theoretical investigations of 1,2-bis-(3-thienyl)-ethene derivatives indicate that after photoswitching, the resulting  $\pi$ -conjugated closed forms exhibit highly non-linear optical properties.<sup>[67]</sup> The substitution of suitable donors and acceptors on certain strategic positions of these ethene derivatives, however, makes the closed form non-linear optically active and the resulting molecular system behaves as an efficient non-linear optical switch. It should be noted that the above discussion on non-linear optical devices involves the breaking and formation of bonds. It is interesting to explore the possibility of devices, which rely entirely on conformational or enantiomeric changes.

Peptides are well-known biological systems, whose conformational characteristics are well understood. To date, the conventional wisdom was that a polypeptide can exist only as right-handed helix. However, calculations reveal the feasibility of a left-handed helix.<sup>[68]</sup> Most of these calculations on these peptide systems were carried out using molecular dynamic simulations based on empirical potentials. The calculations indicate that the diameter of the left-handed helix is larger than the conventional right-handed helix. The left-handed helix is stabilized when the terminal residues are charged, because the dipole moments of carbonyl groups for the former are aligned opposite to those of the latter. Thus a molecular dynamics simulation of a poly-alanine peptide capped with neutral amino and methyl groups ( $\text{CH}_3\text{-(Ala)}_n\text{-NH}_2$ ) under neutral charge conditions yielded a right-handed  $\alpha$ -helix pattern, in about  $\sim 1.8$  nsec. However, when the terminals are charged ( $\text{NH}_3^+\text{-(Ala)}_{30}\text{-COO}^-$ ), a left-handed  $\lambda$ -helix is formed in about  $\sim 4.0$  nsec. During the formation of the left-handed  $\lambda$ -helix, helix-nucleation first occurs at the terminal sites (in particular, near the N-terminus in the case of the left-handed  $\lambda$ -helix) and it promotes the propagation of the helix pattern along the segment. It should be noted that in both the molecular dynamics simulations, only the terminal composition is different. Therefore the handedness of the final conformation is related to the terminal charge conditions. The propagation of the helix pattern along the segment clearly shows that sequential local interactions determine the nascent folding patterns of the protein. The initial folding in the left-handed  $\lambda$ -helix arises from the electrostatic interactions of the positively charged  $\text{NH}_3^+$  group with

the adjacent carbonyl dipole moiety, followed by the dipole-dipole interactions between two adjacent carbonyl moieties. These results were further confirmed with more accurate calculations using a density functional approach. The preceding discussion implies that a transition between left-handed and right-handed helix motifs can be triggered by the presence of charged species near the end of the helix terminals. Such a possibility holds immense promise in the development of novel chiral switches.

## Nanodevices

Up to now, our discussion was only centered on static systems. However, the quest for nanodevices implies that one has to induce motion in a system using external or internal means. The external means could include changes in pH, radiation, etc. We discuss one such device (a molecular flipper), which has been designed, synthesized, and characterized.<sup>[13]</sup> The flipping/flapping motion, in the case of designed device, is due to the changes in edge-to-face and face-to-face aromatic interactions.<sup>[69,70]</sup> It is interesting to note that this conformational change can be electrochemically controlled by reduction/oxidation of the quinone moiety in the molecular system.

The strategy for the design of nanodevices is to harness the subtle changes in the  $\pi$ -electron densities of a quinone moiety as results of changes in the electronic environment.<sup>[70,71]</sup> Quinones are particularly suited for this endeavor because their electronic characteristics can be electrochemically or photochemically controlled. Based on a theoretical investigation of the conformational characteristics of *p*-benzoquinone-benzene complexes, we found that the energy difference between the

**Fig. 7** Cyclic voltammogram of MHQC(left)/MQC(right) (1 mM) in acetonitrile with tetrabutylammonium dihydrogen phosphate (0.1 M) at 25°C (scan rate 100 mV/sec). *Source:* From Ref.<sup>[13]</sup>.

stacked and edge-to-face conformations of cyclophane molecules (Fig. 7) is substantial. Thus if one could subtly control the conformational characteristics of 2,11-dithio[4,4]metametaquinocyclophane (MQC) (stacked conformer is 7 kcal/mol more stable than the edge-to-face conformer) and 2,11-dithio[4,4]metametahydroquinocyclophane (MHQC) (edge-to-face is 9 kcal/mol more stable than the edge-to-face conformer) by electrochemical and/or photochemical means, we can have a very interesting model of a potential molecular device. The cyclic voltammograms of MQC exhibit two clear reversible redox reactions (Fig. 7). In aprotic media, quinones exhibit two reduction peaks separated by 0.7 V, which corresponds to the formation of a radical anion species and a dianion species of quinones, respectively. This is in agreement with the reduction characteristics of MQC. Two well-separated reduced states of MQC are formed in the aprotic solvent of acetonitrile upon reduction. Therefore the electronic states of MQC and MHQC can be easily transformed into each other by simple electrochemical control of the redox reaction, which results in large conformational flapping motions due to a preference for the stable conformation caused by the change in the electronic state of the quinone moiety.

Thus a cyclophane system composed of quinone and benzene rings exhibits a flapping motion involving squeezing and thrusting motions in the presence of solvent molecules by electrochemical redox process. This case illustrates a promising pathway of harnessing the differences in the relative magnitudes of different kinds of intermolecular interactions to design a nanomechanical device. The large flapping/flipping motion from the edge-to-face and stacked conformations and vice versa is a first step toward a propelling molecular vessel or a molecular flipper that can be electrochemically or photochemically controlled. It could be applied to design molecular hinges, molecular switches, and eventually to design mobile nanomechanical devices.

## CONCLUSION

In the course of this entry, we have illustrated using several examples from our work that knowledge of interaction forces, together with a judicious choice of theoretical methods, can be employed in the de novo design of functional nanomaterials and nanodevices. The knowledge of interaction forces could also be utilized for the development of novel functional molecular systems having the capacity of controlled assembly. We have discussed the design and synthesis of several functional molecular systems such as nanowires/nanotubes, ionophores/receptors/sensors, electron/proton/molecular tweezers, molecular vehicles, and molecular-robots/bio-nanorobots. We expect that

some of the ideas gleaned from our work would find utility in the search for molecular nanoelectronic/mechanical devices, quantum computing devices, biomolecular sensors, and nanosurgery. Although this research field is still in the embryonic stage, the advent of fast computers and extremely powerful programs should revolutionize the design and development of nanomaterials and nanodevices in the near future. One of the advantages of the present work is that it also helps obtain an enhanced understanding of the processes in the macroscopic world.

## INTRODUCTION

The development of semiconductor integrated circuits (IC) and mass-data acquisition and storage systems set in motion the transformation of the human enterprise that will continue shaping world economies as well as political and social systems for at least the next half-century.<sup>[1,2]</sup> However, the end of the technology road map for semiconductors is rapidly approaching, and new technologies will be needed to cross over to a new era in integrated electronic systems.<sup>[3]</sup> Many highly innovative materials and device ideas have been proposed to help the transition, driven by various nanotechnology initiatives.<sup>[4–9]</sup> The realization of these ideas is subject to the availability of cost-efficient materials synthesis and device fabrication capabilities. While new nanofabrication technologies are constantly emerging, the economic reality calls for the adaptation of the vast IC fabrication tool set developed over the past several decades to fabrication at nanoscale.

Ion-beam technologies based on wide-area ion beams, focused ion beams (FIB), and shaped multiple ion beams have generated substantial interest in applications in nanostructured materials and nanodevice fabrication and prototyping.<sup>[10–16]</sup> In this entry, the utilization of ion beams for nanomaterials synthesis and fabrication of nanoscale devices is reviewed. Special emphasis is paid to FIB processing of nanoscale magnetic devices<sup>[17]</sup> because FIB has played a critical role in the successful development of magnetic recording at areal densities beyond 100 Gbit/in<sup>2</sup>, which is one of the very few examples of a fully functional nanotechnology with a significant economical impact.

## ION-BEAM SYNTHESIS OF NANOSTRUCTURED MATERIALS

Ion-beam implantation has been one of the key IC manufacturing tools for controlled incorporation of

impurities (dopants) into predefined regions on semiconductor wafers (matrix).<sup>[18]</sup> A remarkable feature of ion implantation is that nearly any element from the periodic table can be implanted into any matrix, making the technology highly versatile. Well-known examples include implantation of group V elements such as phosphorus or arsenic into silicon used for defining n-type Si regions and implantation of group III elements such as boron used for p-type Si regions. Ion bombardment is used for hardening of steels via formation of nitrides at the metal surface. Energetic processes based on ion-assisted deposition and ion-beam deposition have been used for the synthesis of metastable phases of various materials (e.g., diamond or cubic boron nitride).<sup>[19–21]</sup>

In the applications mentioned above, ion-beam implantation is used for the synthesis of homogenous materials where implanted species form chemical bonds with the host material. Ion implantation is typically followed by the annealing step to heal the ion-induced damage of the crystalline structure of the matrix and to activate the implanted species.

If the dose of ion implant exceeds the miscibility limit in the host materials or if the ion species and the host material are immiscible, the annealing step leads to the precipitation of a new phase in the form of clusters (or nanoclusters) as illustrated in Fig. 1. Such precipitates/nanoclusters can lead to significant modification of the electrical, mechanical, magnetic, and optical properties of the host material. Formation of nanoclusters, which is often referred to as ion-beam synthesis, has been documented for a large variety of ion species and host materials. The examples include elemental metal and semiconductor nanocrystals in inert hosts, compound nanocrystals formed as a result of chemical reaction between the ion implant and the matrix, metal alloys and compound semiconductors (II–VI, III–V, and IV–VI) formed by coimplantation of multiple reactive ion species into the host.<sup>[22–31]</sup>

Among potential applications of nanomaterials formed by ion-beam synthesis are all-optical switching

Fig. 1 A schematic of ion-beam synthesis process flow.

that utilizes highly non-linear optical response of metal nanoclusters embedded into non-conducting matrix, opto-electronic devices based on the unique optical response of semiconducting quantum dots, non-volatile memory, spintronics, and single-electron transistor devices.<sup>[32–38]</sup>

### FOCUSED ION-BEAM FOR RAPID PROTOTYPING OF NANOSCALE DEVICES

The principle of operation of an FIB system is similar to the principle of operation of a typical electron-beam (e-beam) system used in electron microscopy (SEM, TEM) or e-beam lithography. The key difference is the source: FIB systems use a liquid metal ion source (LMIS). In such an ion source, a reservoir of liquid metal is in contact with the dull end of a sharp needle (usually made of tungsten). Metal from the melt flows toward the sharp tip of the needle biased at a relatively high voltage ( $\sim 10$  kV) with respect to the extractor electrode. The source is designed such that the high electric field between the extractor electrode and the needle tip is sufficient for field ion emission. Extracted metal ions travel through the beam shaping/focusing column, which is similar to a typical e-beam column with the main difference being the polarity of the voltages applied to accelerating and focusing components. A typical LMIS uses gallium (Ga), which melts at  $29.78^\circ\text{C}$  (slightly above room temperature); this significantly simplifies the design and reliability issues.

The resolution limits of an FIB system are defined mainly by the tool design (such as finite penumbra due to finite source size and the precision of the beam shaping column) and not by diffraction limits, which are in deep subangstrom range.<sup>[39]</sup> The utilization of ions adds great versatility as compared to e-beam systems:

1. Focused ion beams can be used for direct etching of device patterns on a wafer using physical

sputtering of materials with heavy energetic Ga ions.

2. Focused ion beams can also be used for highly localized material deposition where the ion beam is used as a material carrier. In this application, a vapor source (either gaseous or near-the-melting point solid) is inserted into the ion-beam path.
3. Focused ion beams can be effective for local ion implantation and ion mixing.
4. As in e-beam lithography, a pattern can be written into resist using secondary electrons for resist exposure.
5. An important feature of a typical FIB system is that it allows high-resolution imaging using either secondary electrons or ions.

Owing to the direct write capability, FIB is an ideal fabrication tool for the rapid prototyping of nanoscale devices. For example, with FIB, even in the academic environment, one complete iteration necessary for making a magnetic recording transducer (write/read head) with sub-100 nm features takes less than 1 hr.<sup>[40]</sup> For comparison, with e-beam lithography in the streamlined industrial environment, it takes months to go through one iteration cycle. In practice, it usually takes several iterations to complete the design of a next-generation recording head. Such tremendous time and resource savings with FIB is a critical advantage for prototyping at nanoscale.

An additional advantage resulting from larger ion mass, as compared to the mass of an electron, is the fact that the FIB is much less influenced by stray fields. For example, in the magnetic data storage industry, one of the main obstacles in implementing e-beam lithography in the fabrication of magnetic recording heads suitable for areal densities above  $100\text{ Gbit/in}^2$  is the frequent occurrence of the physical shift in patterned features due to the interaction between the e-beam and magnetic thin films.<sup>[41]</sup> This shift, depending on the properties of a thin film, could be as large as 100 nm (for  $\text{Ni}_{45}/\text{Fe}_{55}$ ). For comparison with FIB, at

Fig. 2 Schematic diagrams showing trajectories of focused (A) electron and (B) ion beams.

equal conditions, this shift could be reduced to an unnoticeable level, as shown in schematic diagrams in Figs. 2A and B, respectively.

The FIB-based fabrication not only has the advantage of using fewer steps than lithography-based processing but also has the potential to pattern magnetic materials with higher resolution than what is achievable with e-beam lithography. The study on magnetic devices at Seagate showed that with 50% reproducibility, e-beam and FIB are capable of feature sizes of 30 and 10 nm, respectively, with individual devices made with FIB in sub-10 nm feature size range.

The FIB is especially attractive for a small research laboratory/an academic environment. Patterns with nanoscale features can be defined without using complex and expensive fabrication facilities. With the FIB's direct etch/write capability (no mask-based lithography is necessary), a university just needs to have one FIB system available to trim relatively large devices into nanoscale devices of different geometries for further experimentation and testing. The ability to rapidly fabricate at nanoscale for further characterization and optimization makes FIB an indispensable

tool for the rapid development of emerging technologies in the field of nanotechnology.

## ION-BEAM LITHOGRAPHY

Proximity and projection ion-beam lithographies (IBL) can be thought of as an extension of the FIB technology discussed above in that multiple ion beams are used to simultaneously write the pattern into resist.<sup>[42,43]</sup> Note, IBL is typically not used for the direct etching of the device patterns. In proximity IBL, illustrated in Fig. 3, a stencil mask is illuminated by a broad beam of energetic ions (e.g., helium) and the transmitted beamlets transfer the mask pattern to resist on a substrate. The theoretical resolution limit imposed by the range of secondary electrons and atom scattering within the resist is 1–2 nm (R. Kubena, unpublished data).<sup>[44–46]</sup> Using a small (a few micrometers) mask-to-wafer gap overcomes the practical limitations of diffraction and penumbra (due to a finite source size). Ion-beam lithography is on a fast track to practical application in the sub-10 nm domain by

Fig. 3 A schematic of IBL: beamlets formed by an aperture plate write a periodic pattern in resist on a scanned substrate.

**Fig. 4**  $M$ - $H$  loops for 50 nm Co films with different Ga<sup>+</sup> implantation doses: as-deposited Co film;  $7 \times 10^{15}$  ions/cm<sup>2</sup>;  $3 \times 10^{16}$  ions/cm<sup>2</sup>.

leveraging the many important developments of membrane mask technology in the proximity x-ray and projection ion and electron programs of the past two decades. It should be noted that it is also possible to generate a beam of neutrals that allows elimination of the negative effects of stray fields onto the beam.

A variation of IBL is projection IBL, which eliminates the need for stencil masks with ultrafine features. In projection IBL, the initial set of relatively wide beams is focused onto a substrate to achieve fine features.<sup>[47,48]</sup>

## ION-BEAM APPLICATIONS IN MAGNETIC DATA STORAGE

### Ion-Beam Modification of Magnetic Materials

Recently, there has been substantial interest in capitalizing on existing semiconductor processing technologies for magnetic thin film device fabrication. For example, e-beam lithography and chemical-mechanical polishing have been firmly accepted as next-generation tools for advanced magnetic recording applications.<sup>[49,50]</sup> Similarly, ion implantation and FIB processing, which are widely used in the semiconductor industry, are steadily gaining ground in magnetic thin film materials processing.<sup>[12,51]</sup> To enable wide commercialization of these techniques in magnetic recording applications, a detailed study of these powerful fabrication tools with respect to their application to magnetic materials processing is necessary.<sup>[52-54]</sup> In this section, the effects of Ga<sup>+</sup> ion implantation on magnetic properties of magnetic thin films and the application of FIB implantation for tailoring of magnetic properties at nanoscale are presented.<sup>[55]</sup>

Fig. 4 compares the  $M$ - $H$  loops of an as-deposited Co film and two Co films with implant doses of  $7 \times 10^{15}$  ions/cm<sup>2</sup> and  $3 \times 10^{16}$  ions/cm<sup>2</sup>. Note, if all Ga<sup>+</sup> ions were implanted into the film,  $7 \times 10^{15}$  ions/cm<sup>2</sup> and  $3 \times 10^{16}$  ions/cm<sup>2</sup> doses would correspond to  $\sim 1.5\%$  (atomic %) and  $\sim 6.6\%$  (atomic %), respectively. Substantial modifications to the magnetic properties can be observed. The coercivity of Ga<sup>+</sup> implanted films increased by factors of 6 and 30 for  $7 \times 10^{15}$  ions/cm<sup>2</sup> and  $3 \times 10^{16}$  ions/cm<sup>2</sup> implant doses, respectively. Also, the  $M$ - $H$  loop squareness,  $S$ , defined as the ratio of the remanent magnetization,  $M_r$ , to the saturation magnetization,  $M_s$ , changed from a perfectly square loop in the case of as-deposited Co film with  $S = 1$  to  $S < 0.9$  in the case of the higher implant dose. Reduced squareness and shearing of the hysteresis loop indicate a reduction in exchange coupling in the Ga<sup>+</sup> ion implanted films. It should be noted that exchange coupling is one of the key parameters controlled during the development of the magnetic recording medium.

Fig. 5 compares atomic force microscopy (AFM) and magnetic force microscopy (MFM) images of the Co film implanted with a Ga dose of  $7 \times 10^{15}$  ions/cm<sup>2</sup>. Magnetization patterns in MFM images can be clearly tracked to the grain structure observed in AFM images. This suggests that ion implantation results in reduced intergranular exchange coupling. This is consistent with the observed shearing of magnetization loops (see Fig. 4). These data are similar to previously reported observations on permalloy thin films where an increase in coercivity was attributed to the introduction of extended defects.<sup>[56]</sup> In the present study such extended effects are represented by Ga-rich grain boundaries.

Local ion implantation can be achieved using FIB. Figs. 6A and B show MFM images of an as-deposited

**Fig. 5** AFM (left)/MFM (right) scans ( $3\ \mu\text{m} \times 3\ \mu\text{m}$ ) of Co films implanted at  $3 \times 10^{16}$  ions/cm<sup>2</sup>.

Co film and a Co film implanted with 50 keV Ga<sup>+</sup> ions at  $1 \times 10^{16}$  ions/cm<sup>2</sup> using FIB implantation, respectively. Similar to the above observations, a clear split of the film into a magnetic multidomain state can be observed in Fig. 6B. At the same time, using AFM, no measurable modification of the film topography could be observed (RMS roughness in both cases was 0.9 nm). As discussed above, a dramatic change in magnetic domain patterns may be attributed to the diffusion of the implanted Ga<sup>+</sup> ions to the intergranular boundaries, thus reducing the exchange coupling between the individual magnetic grains.

Fig. 7 compares the MFM image of four  $300 \times 300$  nm structures defined by FIB etching of the as-deposited Co film and of an intentionally ion implanted material. A transition to a magnetic multiple domain state attributed to ion implantation can be clearly observed.

In summary, ion implantation can be used for the modification of the properties of magnetic materials. For example, Ga ion implantation leads to the reduction of exchange coupling between magnetic grains and the formation of extended domain wall pinning defects. Implantation can be also achieved locally using FIB technology.

## Nanofabrication of Magnetic Transducers

### Magnetic recording heads

Magnetic recording has had very high areal bit density growth rates for the past 10–12 yr.<sup>[57]</sup> The resultant dramatic reduction of the bit size has led to the rapid scaling of the characteristic grain size and to the corresponding shrinkage of the thermal activation volume in conventional polycrystalline media. This, in turn, has led to challenging issues related to long-term data stability. Medium magnetic stability is controlled by the ratio of the magnetic anisotropy energy,  $K_U V$ , to the energy of thermal fluctuations,  $k_B T$ , where  $K_U$  is the recording layer magnetic anisotropy energy density, and  $V$  is the thermal activation volume, which approximately corresponds to the volume of a single grain in a polycrystalline medium. The ratio  $K_U V / k_B T$  is kept at a value of 40–60 to ensure 10–15 yr data stability.<sup>[58]</sup> At the superparamagnetic limit, the scaling of the grain size necessary to maintain the adequate SNR can no longer be compensated by increasing  $K_U$  because of the limited write fields achievable with conventional write heads.<sup>[59,60]</sup> It has been predicted that the superparamagnetic limit for conventional

**Fig. 6** Magnetic force microscopy image of (A) as-deposited Co film and (B) Ga<sup>+</sup> ion implanted section in the Co film.

**Fig. 7** Magnetic force microscopy images of four  $300\text{ nm} \times 300\text{ nm}$  Co squares formed by FIB etching in hcp Co film. Top left square is as-deposited Co; the remaining three squares are locally implanted with a  $\sim 1 \times 10^{16}$  ions/cm<sup>2</sup> dose using a 50 keV beam.

longitudinal recording is an areal bit density of  $\sim 150\text{ Gbit/in}^2$ .<sup>[61]</sup>

A schematic of the conventional (longitudinal) recording paradigm is shown in Fig. 8A. During writing, the magnetic field generated by a write head aligns the magnetization along the track in either a positive or a negative direction. A magnetoresistive sensor detects the bit boundaries during playback. The lateral dimensions of a bit define the areal bit density that such a drive supports. As shown in Fig. 8B, the recording medium has a polycrystalline alloy structure where, to reduce noise, a bit is represented

by the average magnetic moment of 50–100 grains. The SNR is typically 14–16 dB, measured with the autocorrelation SNR of a repetitive pseudorandom bit sequence. The 32-fold increase in bit density over the past 5 yr has been achieved by reducing grain size, while holding the number of grains per bit approximately constant.

A solution to extend the superparamagnetic limit was recently introduced in the form of perpendicular recording, where larger write fields enable the enhancement of the thermal stability ratio.<sup>[62,63]</sup> A schematic diagram of a typical perpendicular recording system is shown in Fig. 8C.<sup>[40]</sup> In this technology, the magnetization of the media is oriented normal to the disk surface and the use of a single-pole write head, mirrored in a soft underlayer, effectively doubles the available write field compared to longitudinal recording.

It should be noted that the transition of a highly competitive multibillion dollar industry such as the magnetic data storage industry to a different technology is not easy. Early demonstrations of ultra-high-density magnetic recording using an FIB fabricated magnetic recording head have played a key role in the process. An FIB image of a nanoscale trackwidth perpendicular magnetic thin film head fabricated of relatively wide (about  $1\ \mu\text{m}$ ) longitudinal ring-type heads using FIB trimming from the air-bearing surface (ABS) is shown in Fig. 9A. As mentioned above, it takes approximately 1 hr to trim one head into the nanoscale dimensions. It would have taken more than several months to make similar changes to the design using conventional lithography-based methods. An MFM image of two 65 nm-wide adjacent tracks recorded with an FIB-made single-pole perpendicular head with a trackwidth of 60 nm is shown in Fig. 9B. At a 4:1 bit cell aspect ratio, such a narrow track corresponds to an areal density of the order of 1 Tbit/in<sup>2</sup>. With a series of follow-up

**Fig. 8** (A) A schematic of a conventional longitudinal recording scheme employed in today's hard drives. (B) A schematic of a single-bit transition in a polycrystalline medium. (C) A schematic of a perpendicular recording system. The soft magnetic underlayer acts as a magnetic mirror, doubling the amplitude of the write field.

**Fig. 9** (A) Micrograph of an FIB-made perpendicular write head with a 60 nm wide write pole. (B) Magnetic force microscopy image of two adjacent 65 nm-wide tracks recorded into Co/Pd multilayer medium using FIB writer.

experiments, this demonstration has resulted in a major shift to perpendicular recording in the entire multibillion dollar magnetic data storage industry today.<sup>[64]</sup>

#### Ultra-high-resolution MFM

As we step into the world of nanodimensions, the importance of high-precision microscopy is evident.<sup>[65]</sup> Scanning probe microscopy (SPM) is generally recognized as one of the most critical and unique techniques utilized for imaging with nanoscale resolution.<sup>[66]</sup> Many important discoveries of the last two decades would have been impossible without SPM. Some examples are carbon nanotube-based applications, new-generation magnetic media for data storage, detection of magnetic flux quanta in superconductors, and others.<sup>[67,68]</sup> With so many important discoveries resulting from the ability to directly see nanoscale objects, innovations for improving the resolution of SPM even further are critical.<sup>[69]</sup>

This section discusses MFM, which is used for measuring a magnetic field emanating from an object with sub-100 nm resolution.<sup>[70]</sup> Today, MFM, unlike some other more popular modes of SPM, such as AFM and scanning tunneling microscopy, does not provide spatial resolution sufficient for study of the intergranular effects in different media. Most of these effects are caused by the quantum-mechanical exchange coupling with the characteristic length of interaction of the order of 1 nm. The best MFM system today provides resolution only of the order of 30–50 nm. Such a relative low resolution is attributed to the long-range magnetostatic interaction between a probe and a sample. However, it is believed that the resolution of MFM can be substantially improved with more advanced nanoscale fabrication methods with more flexible control of the probe geometry at the nanoscale (see Fig. 10). Recently, it was reported how FIB can be used to fabricate MFM probe tips that would provide not only improved resolution but also directional

information about the magnetic field emanating from a sample.<sup>[71]</sup>

#### Magnetic nanotubes

The process and control of the magnetization switching in nanoscale magnetic probes is of critical importance for a number of emerging technologies, including magnetic random access memory (MRAM), magnetic nanoelectromechanical systems (NEMS), magnetic recording at densities beyond 1 Tbit/in<sup>2</sup>, and others. In this case, considering that the magnetic domain wall width in a typical “soft” magnetic material is of the order of 100 nm, controllable switching of the magnetization becomes an issue with the reduction of the characteristic pole tip dimensions into the sub-100 nm range.

In recognition of earlier theoretical conclusions, a rectangular probe with a magnetic void (tube-like structure of the probe tip) at the ABS in the form

**Fig. 10** Electron image of an FIB-made nanoscale probe with a 40 nm × 40 nm × 10 nm apex.

**Fig. 11** Micrographs of a 60 nm × 60 nm magnetic nanotube with a 40 nm flux cavity fabricated using FIB etching of a magnetic recording head.

of a physical cavity, as shown in Fig. 11, was fabricated.<sup>[72]</sup> Magnetic nanoprobes with a rectangular cross section of 60 × 60 nm<sup>2</sup> and a probe length (throat height) that varied in the range of 100–1000 nm were fabricated using FIB trimming of regular magnetic recording heads. Each magnetic nanotube had a 40 nm-deep cavity with a 40 nm diameter created at the ABS of the probe tip via FIB, as shown in Fig. 11. The FIB-made nanotubes were composed of a Ni/Fe (45/55) alloy with saturation magnetization of 1.6 T and with an anisotropy field of approximately 20 Oe. Also, it is clear that the shape of the nanotubes can be easily varied with FIB. These FIB-made nanotubes are perfect prototype devices to study the physics of magnetization switching in different types of MRAM and other magnetic devices.

### Nanomanufacturing of Patterned Magnetic Recording Media

It should be noted that the perpendicular recording discussed above has its own superparamagnetic

limit and is expected to top out of steam at 500–1000 Gbit/in<sup>2</sup>. If no alternative technology is developed to further extend the superparamagnetic limit, the high-areal density growth rate in magnetic recording technology will come to a halt in 2006–2007. Currently, there are two possible approaches to meeting the superparamagnetic challenge. One is thermally assisted recording on high-anisotropy media where local heating is used to temporarily reduce the magnetic anisotropy during writing.<sup>[73]</sup> The other is nanoscale-patterned medium recording (N-PMR), a single-grain-per-bit recording paradigm, where SNR is maintained by eliminating the randomness of the recording medium through lithographic patterning or self-assembly methods. The N-PMR would face a superparamagnetic limit for a bit size of 3–4 nm or a bit density of 20–50 Tbits/in<sup>2</sup>.<sup>[74]</sup>

One of the promising approaches to N-PMR fabrication and prototyping is IBL, which is under development by the team of the University of Houston, Seagate, the National Institute of Standards and Technology, and Lawrence Berkeley National Lab. A stencil mask with an array of open apertures is used to produce trillions of parallel atom beams. These beams create an N-PMR medium pattern as the substrate is scanned across the unit cell. Because the openings of the aperture array are widely spaced, the ultimate resolution of e-beam lithography necessary for writing these masks is in the 5–8 nm range, not the 20–30 nm that would apply for patterning dense media directly.<sup>[75]</sup> The relatively low (e.g., 1%) pattern density on the stencil mask means the mask will be extremely durable and suffer minimal distortion.

## CONCLUSIONS

In summary, ion-beam technologies represent a versatile tool for next generations of material systems and nanoscale devices. Ion beams can be used for synthesis of various nanocomposite materials, materials properties modifications at nanoscale, and fabrication of record setting functional nanometer scale devices.

# Nanomaterials: Trends

Richard Silbergliitt

RAND Corporation, Arlington, Virginia, U.S.A.

## INTRODUCTION

This entry reviews recent trends in the development and characterization of nanomaterials, which we define as materials with a nanoscale component or structure that exerts a significant influence on properties or function. The trends that we discuss are part of a larger trend in technological development toward integration of disciplines such as physics, chemistry, materials science and engineering, and biology, as well as toward the development of multifunctional materials compatible with increasingly complex environments.<sup>[1]</sup> We identify three principal trends that provide the organizational framework for the entry:

1. Integration of organic and biological materials with nanoscale inorganic and polymeric materials (*bionanomaterials*).
2. Incorporation of nanoscale components into materials to improve functionality (*nanocomposites*).
3. Use of “top-down” (e.g., lithography) and “bottom-up” (e.g., self-assembly) processing approaches, sometimes in combination, to produce novel nanoscale structures (*functional-nanostructures*).

Each of these trends is discussed in a separate section, with references to the recent (e.g., since 2000) literature. Considering the continuing rapid evolution of this research area, the references are intended to be illustrative rather than comprehensive. The discussed trends are aimed at developing materials to be used in new devices, components, and products, so while a detailed discussion of these items is outside the scope of this entry, we do examine the possible implications of trends in nanomaterials for applications with potential societal effects.<sup>[2]</sup> Specifically, we examine possible high-growth and low-growth developments and drivers and barriers to achieving each, as well as the possible synergistic influences that these developments might exhibit. In this discussion, we follow the approach described in Ref.<sup>[1]</sup>.

## BIONANOMATERIALS

Fig. 1 schematically illustrates the domain of bionanomaterials. This is the intersection of nanomaterials, which introduces scale effects to influence materials function, and biomaterials, which introduces biology into materials function at a variety of scales. It incorporates concepts, methods, raw materials, and instrumentation from nanoscience and nanotechnology as well as biology and bioengineering to develop new functional materials at the nanoscale. In some cases, the design and assembly of these materials is based on approaches that imitate or build upon phenomena or mechanisms that occur in nature, which is indicated in Fig. 1 by the inverted arrow labeled “biomimetic design/assembly.” These biomimetic approaches are sometimes aimed at developing materials with biological function and application, e.g., an encapsulant for targeted drug delivery. But biomimetics can also be applied to the design and assembly of nanoscale materials for non-biological applications, e.g., electronic or optoelectronic materials, or catalysts.

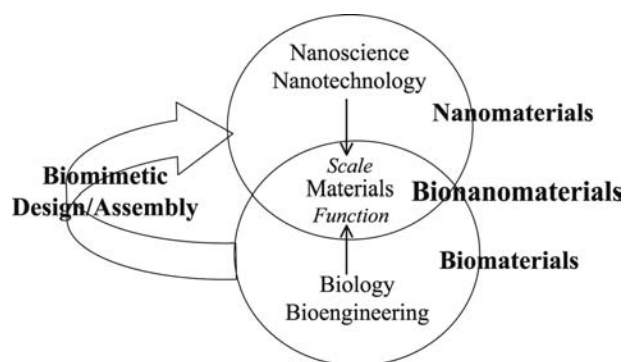

### Biomimetic Approaches

Recent use of biomimetic approaches includes the use of motor proteins to shuttle molecules along bioengineered tracks,<sup>[3]</sup> the use of “sticky-ended” cohesion of complementary DNA molecules to assemble nanostructures,<sup>[4]</sup> the use of block copolymers of polypeptides to form ordered silica structures,<sup>[5]</sup> and the design of self-assembling synthetic substitutes for the collagen proteins that form templates for bone growth.<sup>[6]</sup> A number of recent reviews describe biologically motivated materials design and assembly approaches with a broad range of applications including catalysis, drug design and delivery, tissue engineering, energy collection, storage, conversion and transport, sensing and actuation, bioassays, chemical and biological agent detection, and electronics.<sup>[7–9]</sup>

### Supramolecular Materials

Supramolecular materials (assemblies of molecules that are built up through molecular, non-covalent,

**Fig. 1** Schematic illustration of the domain of bionanomaterials.

forces) have emerged as a key ingredient in achieving function at the nanoscale.<sup>[10]</sup> These materials can be self-assembled into nanoscale structures such as disks, strips, cylinders, and ribbons to which biologically active materials can be attached.<sup>[11]</sup> Selective cleaving of the self-assembling ends can also be used to obtain functionalized nanoporous materials.<sup>[12]</sup> The biological self-assembly process itself has also been adapted for non-biological materials assembly, as molecules based on short peptide sequences taken from fibrinogen (an active ingredient in coagulation) have been used to direct the self-assembly of polyethylene glycol.<sup>[13]</sup> In efforts to link biologically driven assembly to electronic devices, peptides with highly specific binding properties to semiconductor heterostructures have been experimentally demonstrated<sup>[14]</sup> and designed using computational algorithms.<sup>[15]</sup>

Dendrimers (supramolecular materials with a branched tree structure) are being developed and tailored as vehicles for encapsulating drugs for targeted delivery or even strands of DNA for gene therapy, as well as to “harvest” sunlight and transfer the energy into the center of the molecule where it might be used in optoelectronic or photovoltaic applications.<sup>[16]</sup> Dendrimers based on liquid crystals have also been proposed for optoelectronic applications,<sup>[17]</sup> and a liquid crystal phase with a very large unit cell, containing 30 dendrimers, has recently been demonstrated.<sup>[18]</sup>

A possible alternative to dendrimers for encapsulation is afforded by nanocompartments formed from lipid bilayer membranes<sup>[19]</sup> or vesicles formed from copolymers containing hydrophobic and hydrophilic blocks.<sup>[20]</sup> Complexes of closed lipid bilayer membranes and DNA show promise for gene delivery without use of viruses, although much remains to be learned about the relationship between the supramolecular structures formed by these complexes and their efficiency of gene transfer and expression.<sup>[21]</sup>

## Biomaterialization

Living organisms form mineralized crystals of many types, often containing complex multifunctional structures (e.g., mollusk shell, sea urchin skeleton, biogenic silica), sometimes with features that have not been incorporated in synthetic materials.<sup>[22]</sup> The development of such biomaterialized crystals has been shown to depend on both stereochemical recognition of surface step edges by amino acids and resultant changes in free energy of the growing crystal surface,<sup>[23]</sup> linking biological, physical, and chemical interactions in the formation of biomaterials with varied asymmetric structures.<sup>[24]</sup> Biomaterialization principles have recently been used to fabricate a large micropatterned single crystal of calcite from a patterned amorphous calcium carbonate template, with oriented nucleation induced by a self-assembled monolayer of alkanethiol on gold or silver.<sup>[25]</sup>

## Nanoparticle Probes

One of the first successful applications of bionanomaterials is the use of DNA-tagged nanoparticles for bioassays and biosensors. This has been accomplished through the observation of electrical changes due to binding of the target species to oligonucleotides functionalized with gold nanoparticles<sup>[26]</sup> and through the fluorescence of semiconductor nanocrystals linked to oligonucleotides.<sup>[27]</sup>

## Biomedical Applications

Recent bionanomaterials studies aimed at biomedical applications include the development of nanomaterials linking radioactive atoms to monoclonal antibodies for tumor-specific radiation therapy<sup>[28]</sup> and the incorporation of nanoparticles into cement used for orthopedic implants to reduce inflammatory reaction.<sup>[29]</sup> Several university centers in the United States and Europe are focused on biomedical applications such as diagnostics, drug delivery, and implants and prostheses,<sup>[30]</sup> including work on dendrimers, nanomembranes, and biologically driven motors.<sup>[31]</sup> A recent very thoughtful review argues that it is the research effort itself in areas related to nanomedicine that will produce useful results in the near term, rather than the achievement of specific biomedical application objectives.<sup>[32]</sup>

Whether the bionanomaterials trends highlighted above will lead to revolutionary advances in technology or merely to continued incremental improvements is impossible to predict. **Fig. 2** schematically illustrates two possible paths—a high-growth path under which nanomaterials pervasively affect biology

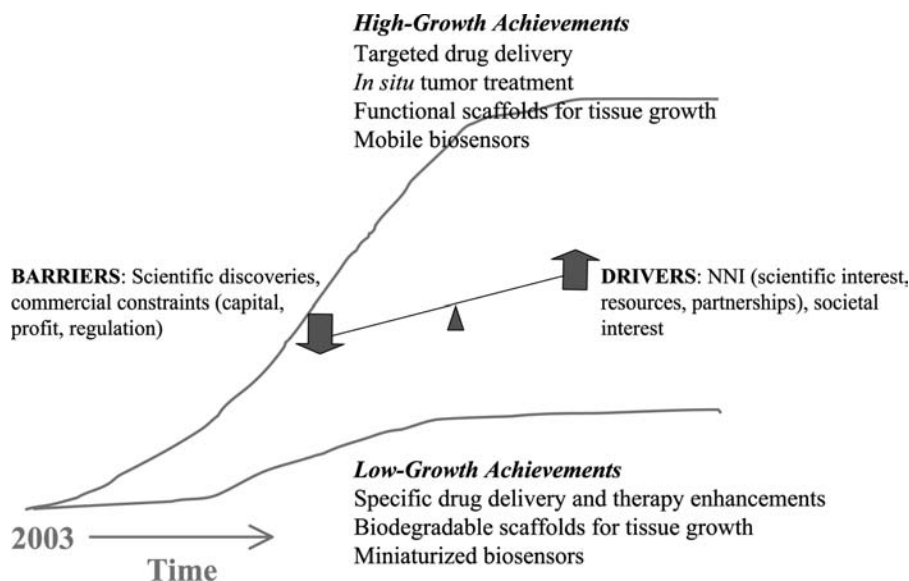

Fig. 2 Possible growth paths for bionanomaterials applications.

and medicine and a low-growth path under which the continued integration of biology, materials, and nanoscience leads to technological advances in specific areas of opportunity. There are currently strong drivers toward the high-growth path, in particular the high level of scientific interest and available resources, including partnerships between academic, governmental, and commercial institutions, resulting from the U.S. National Nanotechnology Initiative (NNI) and similar initiatives in Europe and Japan, as well as strong societal interest in and fascination with nanoscience and nanotechnology. However, there are also strong barriers that, if not overcome, will push toward the low-growth path, in particular the need for major scientific discoveries and commercial constraints such as the availability of capital, the need to show profit, and regulatory requirements.

The following are some of the significant scientific questions that need to be addressed to progress along either path:

- Can integration of functional biological materials into nanoscale materials systems be reproducibly scaled?
- Can biological function be sufficiently retained in synthetic bionanomaterials to allow high-accuracy molecular recognition and targeting?
- Can encapsulation schemes for bionanomaterials be implemented on a cost-effective commercial scale?
- Can short-term or long-term compatibility of synthetic bionanomaterials in the human body be demonstrated?
- Can effective methods for determining unintended side effects of bionanomaterials be developed and implemented?

The rate at which progress is made in addressing these questions will determine the timescale in Fig. 2, in addition to whether progress is toward the high-growth or the low-growth path.

## NANOCOMPOSITES

The incorporation of nanoscale components into materials to improve function is perhaps currently the most advanced area of nanomaterials. A growing number of commercial entities already produce nanoparticles with an estimated world market near \$500 million in 2000 and growth projected in applications such as conductive and magnetic coatings, optical fibers, phosphors, biological labels, orthopedic materials, sunscreens, catalysts, and scratch-resistant coatings.<sup>[33,34]</sup> From the perspective of the chemical industry, nanocomposites can be separated into those that incorporate nanoscale clays, nanoscale oxides or metals, and carbon nanotubes.<sup>[35]</sup> We will adopt a slight generalization of this approach and organize the following discussion around polymer nanocomposites (based on nanoscale silicates including clays); composites incorporating metal, oxide, and semiconductor nanoparticles and nanocrystals; nanoscale coatings and films based on these; and composites incorporating carbon nanotubes or semiconductor nanowires.

### Polymer Nanocomposites

The interest in polymer nanocomposites stems from the fact that the dispersion of a relatively small amount (e.g., <5%) of a layered silicate such as clay can provide significantly improved properties, including strength,

barrier properties, reduced water absorption, and reduced flammability, so long as the clay is exfoliated or intercalated into layers of nanoscale thickness.<sup>[36–38]</sup> Recent experimental work<sup>[39]</sup> demonstrates the positive influence of dispersed silicate nanolayers on both the crystalline morphology and mechanical properties of the nanocomposite, and recent theoretical work<sup>[40]</sup> suggests that the toughening mechanisms may be similar to those postulated for biological structural materials such as spider silk and abalone adhesive. Silicate-based nanocomposites have also been made from aerospace epoxy material and demonstrated both to have improved mechanical properties and appropriate viscosity and cure kinetics to remain suitable for standard composite molding techniques such as resin transfer molding.<sup>[41]</sup>

### Nanoparticle and Nanocrystal Composites

Advances in and approaches to the characterization of the electrical, magnetic, optical, and chemical properties of isolated and assembled nanoscale particles and crystals and attempts to use them to improve materials and device function are described in a recent series of articles.<sup>[42]</sup> Nanomaterials investigated include Co, Ni, Fe, and magnetic alloy nanoparticles for magnetic device applications;<sup>[43]</sup> CdSe<sup>[44]</sup> and Mn-doped ZnS<sup>[45]</sup> nanocrystals for optical and laser applications; nanoscale Au and Ag for optoelectronic applications;<sup>[46]</sup> and nanoparticles capped with organic materials for electronic applications.<sup>[47]</sup>

An alternative approach to incorporating functional Fe nanoparticles into electronic devices consists of introducing Fe<sub>2</sub>O<sub>3</sub> nanoparticles externally produced onto a Si wafer and annealing in ultrahigh vacuum.<sup>[48]</sup> Glass ceramics consisting of SnO<sub>2</sub> nanocrystals dispersed in SiO<sub>2</sub> have also been studied as potential non-linear materials for all-optical switching devices.<sup>[49]</sup>

Mulvaney<sup>[46]</sup> shows that optical properties of Au and Ag nanoparticles depend on shape. Both size and geometric shape of Au and Ag nanoparticles have been shown to be controllable through solution-phase chemistry, yielding Ag nanocubes and Au nanoboxes with a truncated cubic shape.<sup>[50]</sup>

With respect to catalytic applications, capped metallic nanoparticles have been demonstrated to avoid aggregation on electrode surfaces and show catalytic activity on both metal and Pt-doped polymer substrates,<sup>[51]</sup> while semiconductor nanoclusters have been demonstrated to enable the photooxidation of the toxic aromatic organic material pentachlorophenol.<sup>[52]</sup> A novel synthesis route to a porous composite nanostructure including catalytic metal oxide nanoparticles uses aqueous solutions of metal salts together with an aqueous dispersion of synthetic clay and surfactants.<sup>[53]</sup>

### Nanoscale Coatings and Films

All of the nanoparticle and nanocrystal material types mentioned in the previous section have been implemented as nanoscale coatings or films. FePt nanoparticles were synthesized and self-assembled into nanocrystal superlattices and annealed into ferromagnetic films that are mechanically robust and support high-density magnetization reversal transitions required for magnetic data storage.<sup>[54]</sup> Ni nanoparticles were also epitaxially grown on a TiN thin-film matrix and exhibited significantly higher coercivity than randomly oriented Ni particles.<sup>[55]</sup> A quantum-dot light-emitting diode was fabricated by sandwiching a monolayer of CdSe (ZnS) nanocrystals between two organic thin films, using phase separation between these films and the organic materials capping the nanocrystals.<sup>[56]</sup> Films of Au nanoparticles functionalized with aromatic molecules were spin coated onto interdigitated electrode structures and used as vapor sensors.<sup>[57]</sup>

Nanoscale coatings and films have been demonstrated to produce enhancements of a variety of technologically important properties. Nanoporous films of PbZr<sub>x</sub>Ti<sub>1-x</sub>O<sub>3</sub> (PZT) allow tailoring of dielectric properties to increase the figure of merit for piezoelectric applications.<sup>[58]</sup> Thin films of optical polymers with nanoscale corrugated surfaces provide an alternative approach to antireflection coatings.<sup>[59]</sup> Nanostructured hydroxyapatite coatings provide improved adhesion and corrosion resistance for medical implants.<sup>[60]</sup> Nanocrystalline Al<sub>2</sub>O<sub>3</sub> coatings on glass substrates provide increased hardness with no degradation of optical properties.<sup>[61]</sup> Nanoscale coatings also provide the possibility of controlled gradients in mechanical properties that may provide new design options for damage-resistant materials surfaces.<sup>[62]</sup>

### Nanotube and Nanowire Composites

Carbon nanotubes are exceedingly interesting materials both from a scientific viewpoint and because their unique combination of properties (high conductivity, high tensile strength, high temperature capability, plus nanoscale dimensionality) make them suitable, in principle, for many important commercial applications. As described in a recent review,<sup>[63]</sup> carbon nanotubes are already in use as an additive to graphite in a majority of the lithium ion batteries found in cell phones and laptop computers; are anticipated to enter the commercial flat-panel display market as field emitters in 2003; have many additional potential applications including conductive plastics, high-performance fibers for composite materials, and flexible sensors for gas detection; and could be enabling materials for new nanoelectronic technologies. In this entry, we will constrain

our discussion to aspects of nanotube research related to the formation of composite materials in which the nanotubes improve functionality.

The simplest version of the carbon nanotube, a cylindrically rolled sheet of hexagonally arrayed carbon atoms, or single-walled carbon nanotube (SWNT), has been produced in strands of macroscopic length,<sup>[64]</sup> and micrometer-long crystals consisting of ordered arrays of aligned SWNTs have also been produced.<sup>[65]</sup> Composite materials with a nanocrystalline  $\text{Al}_2\text{O}_3$  matrix and reinforcement by ropes of SWNTs that form a network at the grain boundaries have recently been fabricated<sup>[66]</sup> by ball-milling to mix the  $\text{Al}_2\text{O}_3$  powders and nanotubes, followed by consolidation using the low-temperature spark plasma sintering process. The best of these composites, fully dense with 10 vol.% SWNTs, had a fracture toughness of  $9.7 \text{ MPa m}^{1/2}$ , almost three times that of pure  $\text{Al}_2\text{O}_3$  of the same grain size. Peigney<sup>[67]</sup> suggests that the high toughness of these  $\text{Al}_2\text{O}_3$ -carbon nanotube composites results from the combination of high-quality starting materials, homogeneous dispersion without damaging the nanotubes, and the relatively short time and low temperature required for spark plasma sintering. This work demonstrates that carbon nanotubes can be used as reinforcement for ceramic matrix composites. The next steps toward application will include investigation of larger specimens than the  $19 \times 2\text{--}4 \text{ mm}$  disks reported in Ref.<sup>[66]</sup>.

Another type of composite material that can be formed from nanotubes involves the incorporation of fullerenes (e.g.,  $\text{C}_{60}$ ) inside the nanotube<sup>[68]</sup> to form the so-called peapods. It has been demonstrated<sup>[69]</sup> that fullerenes containing metal atoms inside the cage of

carbon atoms that make up the fullerene molecule can also be encapsulated inside single-walled carbon nanotubes in a one-dimensional array of “peapods.” Such an arrangement with Gd atoms inside  $\text{C}_{82}$  molecules, which are then encapsulated inside single-wall carbon nanotubes, has been shown to behave as an array of quantum dots, with proposed potential application for quantum well-based electronic and optoelectronic devices.<sup>[70]</sup> Another composite nanotube material with potential application is a column of liquid Ga inside a carbon nanotube, which is proposed as a nanothermometer based on the increase in height of the Ga meniscus with increasing temperature.<sup>[71]</sup>

Semiconductor nanowires are actively being developed as an alternative to carbon nanotubes for nanoelectronic device applications.<sup>[72]</sup> Superlattice structures have been developed in nanowires, in which the semiconductor material changes along the long axis of the nanowire, allowing designed changes in the electronic properties. Such composite nanomaterials have been produced using GaP, GaAs, and InP;<sup>[73]</sup> Si and SiGe;<sup>[74]</sup> and InAs and InP.<sup>[75]</sup> These materials are proposed for applications including nanobarcodes, LEDs, and thermoelectric devices.

Whether the nanocomposites trends highlighted above will lead to revolutionary advances in technology or merely to continued incremental improvements is impossible to predict. Fig. 3 schematically illustrates two possible paths—a high-growth path under which nanocomposite materials are pervasively applied throughout society and a low-growth path under which the use of nanocomposites leads to incremental improvements in specific technology areas. There are currently strong drivers toward the

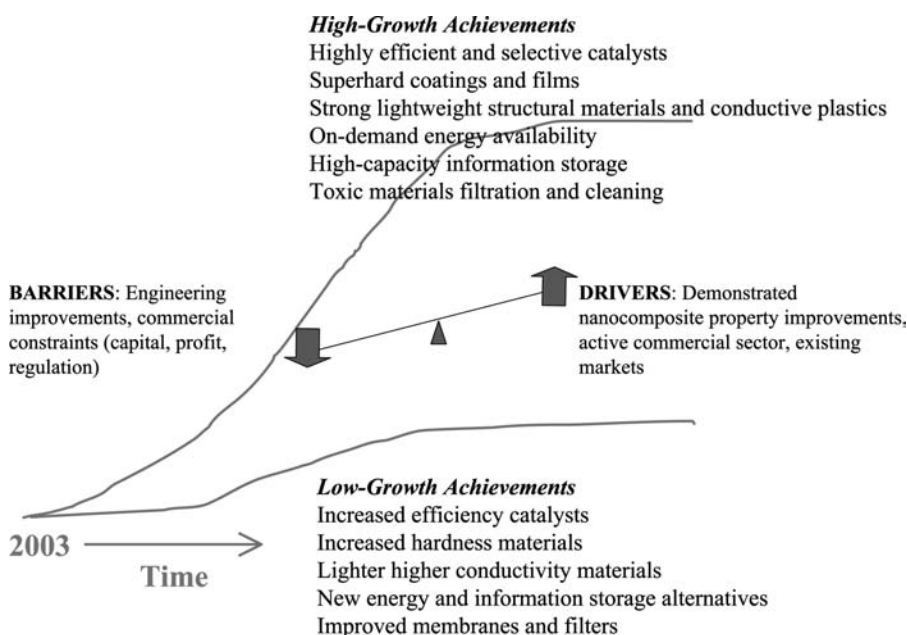

Fig. 3 Possible growth paths for nanocomposites applications.

high-growth path, in particular the demonstrated property improvements already achieved with nanoparticle composites in such areas as catalysis and surface strengthening, as well as the presence of an active commercial sector and existing markets. However, there are also barriers that, if not overcome, will push toward the low-growth path, in particular the need for continuing engineering improvements and commercial constraints such as the availability of capital, the need to show profit, and regulatory requirements.

The following are some of the significant technical issues that need to be addressed to progress along either path:

- Functionalization of nanoscale components and maintenance of that function in the composite material.
- Design and implementation of effective interfaces between the nanoscale components and the composite matrix.
- Demonstration of reproducible composite behavior and long-term stability.
- Scaling up the nanocomposite for cost-effective production while retaining the property improvements.

The rate at which progress is made in addressing these issues will determine the timescale in Fig. 3, in addition to whether progress is toward the high-growth or the low-growth path.

## FUNCTIONAL NANOSTRUCTURES

Perhaps the most fundamental type of functional nanostructure is a microscopic composite with multiple phases formed in situ during processing. As discussed by Ma,<sup>[76]</sup> metal alloys with nanoscale grain size typically have increased strength, but lack plasticity necessary for forming or to avoid catastrophic failure in load-bearing applications, and several different approaches to increasing ductility and toughness in such alloys employ a non-uniform or composite microstructure. He et al.<sup>[77]</sup> described an alloy design and solidification process leading to as-cast Ti-based alloys with an in situ composite microstructure consisting of a nanocrystalline matrix and a ductile dendritic phase. The presence of the dendritic phase is shown to increase the plasticity of the material by preventing the propagation of bands of shear stress that, if allowed to grow, could cause catastrophic failure. Thus this type of microscopic composite combines the increased strength of the nanoscale grain size with good ductility and a high elastic-strain limit, and was produced with conventional casting methods, suggesting that the approach may have more general potential

for strong, yet tough, metal alloys. The combination of nanoscale grains with microscale dendrites in this material emphasizes the fact that useful nanomaterials do not have to be exclusively nanoscale.

## Nanofabrication Methods

A variety of different approaches to fabricate nanostructured materials are described in a recent set of articles,<sup>[78]</sup> including the use of lithographic patterns to induce or guide a self-assembly process,<sup>[79]</sup> applications of lithography using “soft” materials such as organic elastomers,<sup>[80]</sup> and the use of an atomic force microscope tip to “write” nanostructures onto a gold substrate with alkanethiol “ink”, namely, dip-pen nanolithography.<sup>[81]</sup> Another nanofabrication method uses metallic mask membranes fabricated from nanochannel glass (a glass matrix with uniform arrays of hollow channels as small as 20 nm) to produce regular arrays of magnetic dots for magnetic storage application.<sup>[82]</sup> A recent study compared ferroelectric nanostructures fabricated via self-assembly of dispersed nanoparticles synthesized from a microemulsion and via electron beam lithography of a polymer precursor layer,<sup>[83]</sup> with the self-assembly approach producing droplets in the 50–60 nm range (which the authors argued was several times too large for self-assembly), while the lithographic approach produced arrays of 60–70 nm particles with spacing down to 150 nm.

The stability of fabricated nanostructures under application conditions can be an important issue. Nanoscale features produced on a Cu crystal by ion sputtering under ultrahigh vacuum were demonstrated to be stabilized at room temperature in air for a week or more (far longer than needed to serve as a useful process step) by an oxidation treatment.<sup>[84]</sup> The authors noted that without the oxidation treatment, the stability of such nanoscale features is limited by thermally activated diffusion to about 200 K. Feedback-controlled ion beam sputtering has been used to “sculpt” a 5-nm pore in a Si<sub>3</sub>N<sub>4</sub> membrane, which was then used as a detector for a single DNA molecule.<sup>[85]</sup> The authors suggest that this nanofabrication method could be used to fabricate slits, trenches, crosses, and other structures for nanoscale semiconductor devices.

## Nanofabrication via Self-Assembly

Self-assembly phenomena have been used both to form templates for fabricating nanostructures and to assemble the nanostructure itself. Dynospheres (latex particles 0.5 μm in diameter suspended in water) were self-assembled into regular arrays that were used as a mask to deposit arrays of Ni nanoparticles.<sup>[86]</sup>

Polymethylmethacrylate (PMMA) spheres were self-assembled in trenches in Si wafers to form a three-dimensional photonic crystal.<sup>[87]</sup> Nanowires of single-crystal Si that self-align to form a structure suitable for photoemission applications were grown from a thermally evaporated Ni film subjected to magnetron sputtering of Si.<sup>[88]</sup> An Al film deposited on a Si or SiO<sub>2</sub> substrate was anodized to produce a hexagonally ordered nanoporous Al<sub>2</sub>O<sub>3</sub> structure.<sup>[89]</sup> A large variety of topological structures have been produced in mesoporous SiO<sub>2</sub> by combining sol gel and emulsion chemistry with molecular self-assembly.<sup>[90]</sup>

Self-assembled nanostructured films have been shown to possess useful chemical and optical properties. A self-assembled monolayer of hexadecanethiol on a gold surface was shown to block the interaction of the surface with neutral molecules such as water and volatile sulfuric compounds, enhancing its effect as a selective detector of mercury vapor.<sup>[91]</sup> Self-assembled multilayer superlattice films containing chromophoric organic molecules were shown to be useful for optical switching based on their large second-order non-linear optical response.<sup>[92]</sup>

### Self-Assembly with Diblock Copolymers

Films of copolymers consisting of two distinct blocks [e.g., polystyrene (PS) and PMMA] spontaneously assemble into ordered domains with morphology principally depending on the molecular weight ratio of the constituent polymers, allowing the formation of nanoscale tailored polymer dot arrays via chemical removal of one of the blocks. These polymer dot arrays can then be used as templates or masks to form nanoscale dot arrays of metals or insulators on silicon and other

substrates.<sup>[93]</sup> Incorporation of metal nanoclusters synthesized in situ from decomposition of precursors within one of the copolymer blocks was demonstrated to produce patterned structures with selective phase separation and particle confinement.<sup>[94]</sup> Arrays of Co nanowires with application as ultrahigh-density magnetic data storage media have also been fabricated using nanoporous films derived from diblock copolymers.<sup>[95]</sup> Combining a diblock copolymer of polystyrene and polyethylene oxide with a dilute homogeneous solution of a silica precursor leads to a mesostructured silica film that can be calcined to produce closed-cell mesoporous silica films with potential application as low dielectric constant insulators.<sup>[96]</sup> Control of optical energy transfer was demonstrated by embedding semiconducting polymers into the pores of such a silica film, suggesting their potential application in optoelectronics as well.<sup>[97]</sup>

Whether the functional nanostructures trends highlighted above will lead to revolutionary advances in technology or merely to continued incremental improvements is impossible to predict. Fig. 4 schematically illustrates two possible paths—a high-growth path under which advances in functional nanostructure fabrication lead to a broad range of new materials and devices and a low-growth path under which functional nanosystems penetrate existing markets in an incremental fashion. There are currently strong drivers toward the high-growth path, in particular the continuing integration of top-down and bottom-up fabrication approaches and the increasingly interdisciplinary nature of research in this area. However, there are also strong barriers that, if not overcome, will push toward the low-growth path, in particular the need for continuing scientific advances, the need to address

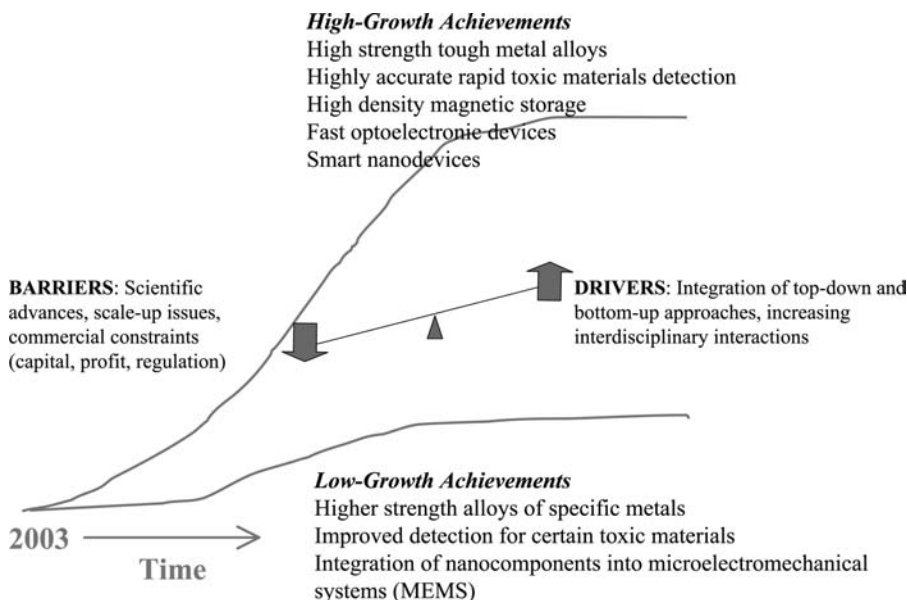

Fig. 4 Possible growth paths for functional nanostructure applications.

**Table 1** Synergisms between nanomaterials applications

	Targeted drug delivery	In situ tumor treatment	Mobile biosensors	Super membranes and catalysts	Superhard coatings and films	Cheap energy storage	High-strength tough metal alloys	Fast precise toxic materials detection	Smart nanodevices

scale-up issues, and commercial constraints such as the availability of capital, the need to show profit, and regulatory requirements.

The following are some of the significant scientific issues that need to be addressed to progress along either path:

- Retention of microscopic nanostructures under application conditions.
- Reproducible, scalable, cost-effective fabrication of designed nanostructures.
- Demonstration of nanostructure function in macroscopic materials and devices.
- Demonstration of long-term nanostructure functional stability.

The rate at which progress is made in addressing these issues will determine the timescale in Fig. 4, in addition to whether progress is toward the high-growth or the low-growth path.

## SYNERGISTIC INFLUENCES

The development of certain nanomaterials trends will in some cases exert a synergistic influence on the development of other trends. Table 1 illustrates some of these potential effects for possible high-growth applications of the nanomaterials trends discussed above. Three application developments are considered for each nanomaterials area. Targeted drug delivery, in situ tumor treatment, and mobile biosensors are the bionanomaterials developments considered. Super membranes and catalysts, superhard coatings and films, and cheap energy storage are the nanocomposites developments considered. High-strength tough alloys, fast precise toxic materials detection, and smart nanodevices are the functional nanostructures developments considered. Where the presence of one development could facilitate the other development, e.g., targeted drug delivery and in situ tumor treatment, the word “facilitates” is shown in the appropriate box. This effect is not always symmetric. For example, the presence of in situ tumor treatment would not facilitate targeted drug delivery. In some cases, synergism between the two developments would improve function, e.g., smart nanodevices together with super membranes and catalysts would lead to improved chemical processes. In other cases, the synergism might lead to an entirely new capability, as for example targeted drug delivery and smart nanodevices would enable smart drug delivery. For the purposes of this analysis, we assumed that the synergisms leading to improved function or new capabilities were symmetric. The boxes in Table 1 with dashes indicate no synergism between the two developments.

The following paragraphs briefly summarize the synergisms listed in Table 1 (symmetric synergisms are only discussed once).

*Targeted drug delivery:* facilitates in situ tumor treatment by providing a mechanism; spurs development of mobile biosensors by providing an application; together with fast precise toxic materials detection could provide detection coupled with treatment for chemical or biological (CB) agents; together with smart nanodevices could provide smart drug delivery.

*In situ tumor treatment:* spurs development of mobile biosensors by providing an application.

*Mobile biosensors:* facilitate targeted drug delivery and in situ tumor treatment by providing locations; together with super membranes and catalysts could provide the basis for blood filters; together with smart nanodevices could provide smart biosensing.

*Super membranes and catalysts:* together with cheap energy storage could provide a means for improved energy conversion; together with fast precise toxic materials detection could provide both for detection and filtering or destruction of CB agents; together with smart nanodevices could provide a means for improving the selectivity and yield of chemical processes that involve separations or catalysis.

*Superhard coatings and films:* could facilitate mobile biosensors and cheap energy storage by providing protection from damaging materials or hostile environments; together with high-strength tough metal alloys could provide long-life structural materials.

*Cheap energy storage:* could facilitate in situ tumor treatment and mobile biosensors by providing cost-effective power sources; could spur development of superhard coatings and films by providing an application; together with fast precise toxic materials detection could provide a means for detection and destruction of CB agents; together with smart nanodevices could provide on-demand portable power sources.

*High-strength tough metal alloys:* can facilitate cheap energy storage, fast precise toxic materials detection, and smart nanodevices by providing functional structural materials.

*Fast precise toxic materials detection:* facilitates mobile biosensors by providing the mechanism for the biosensor.

*Smart nanodevices:* facilitate in situ tumor treatment by providing a means for treatment delivery to the tumor site; facilitate high-strength tough metal alloys by providing a possible means for fabrication.

## ACKNOWLEDGMENTS

The author is extremely grateful to Frank Gac, John Gilman, Eric Landree, Parry Norling, Fyl Pincus,

Stephen Rattien, Ulrich Strom, and Julia Warner for providing reference materials for this entry, and to Philip Antón and Fyl Pincus for their insightful reviews of the draft and several useful suggestions that were incorporated into the final version. The author also acknowledges the financial support of the Rand Corporation for the development of this work.

# Nanomechanical Resonant Devices: Surface Chemistry

Joshua A. Henry  
Debodhonyaa Sengupta  
Melissa A. Hines

Department of Chemistry, Cornell University, Ithaca, New York, U.S.A.

## INTRODUCTION

The sensitivity of nanomechanical resonant sensors to the applied mass or force is determined in part by their quality factor or  $Q$ —a dimensionless quantity that is inversely proportional to the rate of mechanical energy dissipation in the sensor. The  $Q$  of megahertz-range silicon resonators is shown to be surprisingly sensitive to surface chemistry; by changing one monolayer on the surface of a 250 nm-thick device, the rate of mechanical energy dissipation can be increased by at least a factor of 2. The chemical dependence of this effect and possible mechanisms are discussed.

## RESONANT SENSORS AND MECHANICAL ENERGY DISSIPATION: THE ROLE OF $Q$

High-performance nanomechanical sensors based on resonant mechanical motion have been proposed for a wide variety of applications, including mass spectrometry, calorimetry, scanned probe microscopy, electrometry, biological sensing, and, perhaps, even cellular telephony.<sup>[1–6]</sup> By virtue of their small size, nanomechanical structures, such as cantilevers and resonators, are inherently more sensitive to applied forces than their macroscopic counterparts. Importantly, this increased sensitivity is not accompanied by increased fragility. In fact, the opposite is observed. The strength of macroscopic devices is typically limited by bulk defects (e.g., dislocations), not by intrinsic materials properties. In contrast, nanomechanical devices are typically much smaller than the average distance between defects; they are strong, robust, and failure resistant. Having their roots in the microelectronics industry, these devices are also economically viable—they can be mass fabricated and integrated into complex architectures.

At what point, though, will this simple scaling break down? At what length scale will the properties of nanomechanical devices begin to diverge from their macroscopic counterparts? In the following, we show

that the mechanical properties of *micron-scale* devices are sensitive to submonolayer-level changes in surface chemistry. This sensitivity is both exciting and troubling. On the one hand, the increased sensitivity invariably opens up new opportunities in both science and technology. On the other hand, this sensitivity implies that submonolayer control of surface chemistry may be necessary for the production of high-performance devices—a challenge for real-world applications.

In a resonant sensor, a change in mass, temperature, charge, or other applied force induces a small shift in the resonant frequency of a vibrating element. For example, the frequency of a cantilever-based mass sensor will decrease in response to the adsorption of mass. Although many different detection techniques are possible, resonant detectors are all limited by the same fundamental problem—the frequency shift,  $\Delta f$ , induced by the applied force must be detectable. In principle, a frequency shift can be measured with arbitrary precision by simply counting oscillations with respect to a stable time base. In practice, all mechanical devices dissipate energy, and these losses limit the measurement time-scale, and thus the accuracy of the measurement.

To illustrate this process, Fig. 1A compares the displacement of a free resonant structure to one loaded with an applied mass. The applied mass slightly lowers the resonant frequency of the free cantilever,  $f_0$ , to  $f$ , leading to the gradual development of a phase lag,  $\Delta\phi(t)$ , with time, which is given by

$$\Delta\phi = (f - f_0)t \quad (1)$$

In Fig. 1A, the phase lag is readily visible in spite of the slow exponential decay of the vibration because of mechanical energy losses. The Fourier transform of this displacement, which is conveniently measured with a spectrum analyzer in the laboratory, is shown at right. In the frequency domain, the frequency shift,  $\Delta f$ , is directly measured.

The data in Fig. 1B illustrate the deleterious effects of mechanical energy dissipation on resonant sensors. In Fig. 1A and B, the resonant frequencies of the

**Fig. 1** Performance of a mass detector based on a resonant cantilever. (A) A detector with high  $Q$  (low inherent mechanical energy dissipation). The accumulated phase shift,  $\Delta\phi$ , is readily detected, and the narrow line width of the frequency spectrum enables sensitive detection of the frequency shift,  $\Delta f$ . (B) The effects of increased mechanical energy dissipation (low  $Q$ ). Mechanical energy losses prevent long-time measurements; however, the frequency shift is still observable in the Fourier transformed signal. In both, the shaded region indicates a compressed timescale.

loaded and unloaded device,  $f$  and  $f_0$ , are identical; the only difference between the simulations is the rate of mechanical energy dissipation. The resonator in Fig. 1B is more highly damped, making the accumulated phase lag difficult to visualize at long times. In this noise-free (although finite) simulation, the frequency shift remains visible in the frequency domain and neither increases nor decreases in magnitude.

Importantly, the width of the resonance in the frequency domain is determined by the rate of mechanical energy dissipation; this quantity determines the minimum detectable frequency shift. The rate of mechanical energy dissipation in a resonant structure is parametrized by the *quality factor* or  $Q$  of the resonator, a dimensionless quantity. Qualitatively,  $Q$  is the number of free oscillations a device will undergo after an impulsive excitation. For example, a typical musical tuning fork has  $Q \sim 10,000$  ( $= \pi \times 440 \text{ Hz} \times 10 \text{ sec}$ ). Mathematically,

$$Q = \frac{2\pi E}{\delta E} = \frac{f}{\delta f} \quad (2)$$

where  $E$  is the energy stored in the resonator,  $\delta E$  is the energy dissipated per cycle, and  $\delta f$  is the half-power frequency width of the resonator. A detailed analysis of the factors limiting the sensitivity of resonant detectors has been presented by Ekinici, Yang, and Roukes.<sup>[7]</sup> In general, the bottom line is simple: high-sensitivity detectors demand high- $Q$  (low mechanical loss) resonators.

### PUZZLING QUALITY FACTORS IN NANOMECHANICAL DEVICES

As the push towards the development of high-sensitivity nanomechanical structures intensified in the late 1990s,

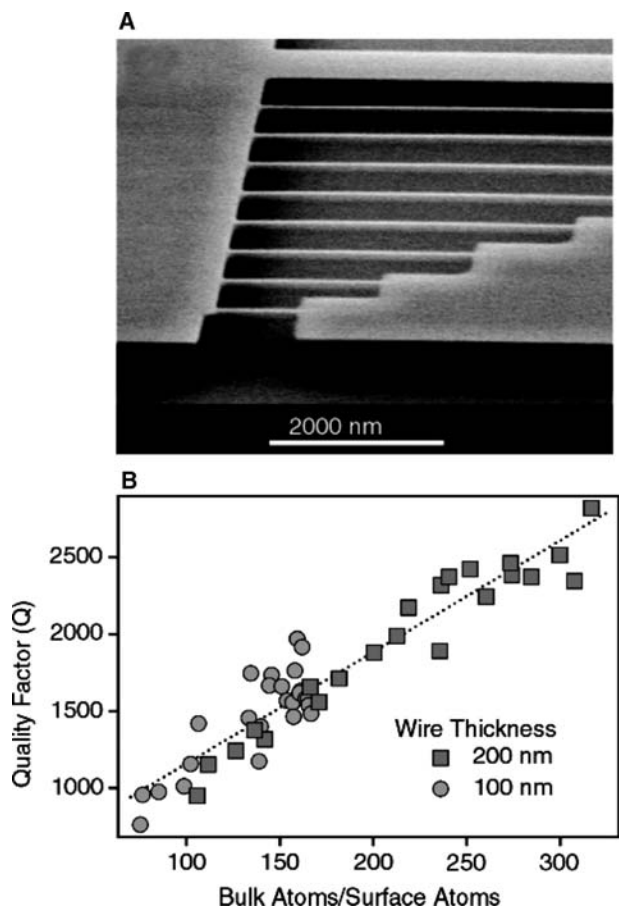

many researchers began to note a puzzling anticorrelation between resonator size and quality factor and hypothesized that these effects were surface related.<sup>[8–11]</sup> This behavior is exemplified by the performance of the 50 nm-wide, 100–200 nm-thick, metal-coated silicon wires with vibrational frequencies in the 100–400 MHz range, displayed in Fig. 2.<sup>[9]</sup> In this case, the rate of mechanical energy dissipation ( $Q^{-1}$ ) had a near-linear dependence on the surface-to-volume ratio of the wires, which strongly suggests that dissipation is occurring at the surface or in the near-surface region.

Studies of scaling behavior are a powerful probe of the fundamental origins of mechanical energy dissipation, because these studies can isolate the effects of different loss mechanisms. For example, the quality factors of macroscopic resonators are often limited by coupling to the supporting structure (so-called clamping losses). In contrast, viscous-drag-induced losses limit the performance of micromechanical devices operated in air or liquid.<sup>[12]</sup> (For this reason, nanomechanical resonators are almost exclusively operated in vacuum.) Mathematically,

$$\frac{1}{Q_{\text{total}}} = \frac{1}{Q_{\text{clamping}}} + \frac{1}{Q_{\text{drag}}} + \frac{1}{Q_{\text{bulk}}} + \dots \quad (3)$$

where each term in the summation represents a distinct energy loss channel.

Importantly, Eq. (3) implies that the performance of mechanical resonators is fundamentally limited by the bulk properties of the resonator material. In insulators, thermoelastic (th) and phonon–phonon scattering (ph) processes lead to intrinsic upper bounds for the  $fQ$

**Fig. 2** The performance of metal-coated, 100–400 MHz silicon nanoresonators. (A) Scanning electron microscopy image of typical nanoresonators. (B) The quality factor displays a near-linear scaling dependence on the volume-to-surface area ratio. *Source:* From Ref.<sup>[9]</sup>.

product of a resonator,<sup>[13]</sup>

$$fQ|_{\text{th}} = 9C^2/\kappa T\alpha^2\rho \quad \text{and} \quad (4)$$

$$fQ|_{\text{ph}} = \rho v^2(1 + f^2\tau^2)/\tau\gamma^2CT$$

respectively, where  $\tau$  is the phonon scattering time, and the other parameters are materials properties.<sup>a</sup> At room temperature, the quality factor of a 1 GHz silicon oscillator is limited to  $\leq 10^5$ . Quartz (and other insulators) should have similar limitations, whereas electronic losses in metals will lead to much poorer intrinsic performance. The performance of today's nanomechanical resonators remains far from this fundamental limit. For example, the  $fQ$  product of our best oscillators is  $8.7 \times 10^{11}$ , one of the highest

<sup>a</sup> $\kappa$  is the thermal conductivity,  $\alpha$  is the thermal expansion coefficient,  $\rho$  is the mass density,  $C$  is the specific heat,  $\gamma$  is the Gruneisen parameter, and  $v$  is the velocity of sound.

reported at room temperature but still two orders of magnitude below the fundamental limit.

The scaling behavior observed by many different groups worldwide have a clear implication—a significant amount of mechanical energy is being dissipated at the surface (or in the near-surface region) of nanomechanical resonators. But is this effect truly surface chemical? Or does it reflect the existence of a damaged or stressed surface layer—an artifact of the processing environment?

The dramatic effect of surface chemistry was conclusively demonstrated and isolated by studying the quality factor of identical micromechanical resonators with chemically controlled surfaces, as shown in Fig. 3A. By replacing 1.3 nm of silicon oxide on the resonator surface with a single atomic layer of H atoms, the quality factor of the functionalized resonators was uniformly increased, as shown by the relative quality factors plotted in Fig. 3B.<sup>[14]</sup> Interestingly, surface chemistry has a much more dramatic effect on large resonators than on small ones—a counterintuitive result. In all cases, H-terminated resonators dissipated significantly less energy than oxide-terminated

**Fig. 3** The effect of oxidation on suspended silicon torsional resonators. (A) Scanning electron micrograph of 5 μm resonator. (B) Relative quality factors of H- and oxide-terminated paddles (points) and best two-parameter global fit (lines) to Eq. (5). The oxide termination was 13 Å thick. *Source:* From Ref.<sup>[14]</sup>.

resonators. More importantly, the observed scaling behavior could be explained by three independent sources of mechanical energy dissipation—dissipation to the supporting structure (which should be constant across the series), dissipation in the bulk silicon of the resonator (which should be proportional to the resonator volume,  $V$ ), and dissipation in the surface oxide layer (which should be proportional to the surface area of the resonator,  $A$ ). From Eq. (3), these mechanisms should lead to scaling behavior of the form

$$\frac{Q^H}{Q^{\text{ox}}} = 1 + \frac{aA}{V + b} \quad (5)$$

where  $a$  and  $b$  are size-independent constants. (In this analysis, possible chemical losses introduced by the H-terminated surface were neglected because of their relatively small contribution).<sup>[14]</sup> The solid lines in Fig. 3B represent the best global fit to this simple model.

Importantly, the fit in Fig. 3B implies that over 50% of the losses in a 7  $\mu\text{m}$ -wide, 190 nm-thick paddle resonator are directly attributable to surface chemistry. In other words, more than half of the mechanical energy dissipation is controlled by less than 1% of the resonator! Moreover, the scaling of Eq. (5) implies that surface-induced mechanical energy losses will become increasingly more severe as we enter the realm of true nanomechanical devices. Why are surface-induced losses dominant? And can these losses be chemically controlled?

## CHEMICAL CONTROL OF MECHANICAL ENERGY DISSIPATION

Although H-terminated resonators have relatively high quality factors, these devices have little commercial promise because of their relative instability. For example, Fig. 4 follows a single H-terminated resonator over the course of 1 week in high vacuum ( $10^{-8}$  Torr). Two changes during this time are readily apparent. First, adsorption from the gas phase slowly shifted the resonant frequency downward by 0.07%. This shift can be used to accurately quantify the total mass of the adsorbate (but not its identity). As shown in Fig. 4, 1 week in vacuum produced a frequency shift equivalent to that expected from the adsorption of only 1.5 monolayers of  $\text{H}_2\text{O}$ , illustrating the impressive sensitivity of even relatively large resonators. Unfortunately, Fig. 4 also shows that this adsorption led to increased mechanical energy dissipation, as evidenced by the steady increase in linewidth with time. Over this period, mechanical energy dissipation increased by 90%.

**Fig. 4** The response function of a single H-terminated resonator as a function of time in a  $10^{-8}$  Torr vacuum chamber. The frequency shift is attributed to slow adsorption from the gas phase. The increase in mechanical energy dissipation is calculated from the changes in  $Q$ .

These data suggest that a chemically resistant, hydrogen-like monolayer that is directly bonded to the silicon surface (i.e., with no intervening oxide layer) will have improved performance. From a chemical standpoint, the logical choice is a simple alkyl ( $-\text{C}_n\text{H}_{2n+1}$ ) monolayer, which is both dense and exceptionally stable.<sup>[15,16]</sup> These monolayers can be prepared by immersing H-terminated devices in the appropriate pure 1-alkene at an elevated temperature ( $\sim 200^\circ\text{C}$ ). From a mechanical standpoint, though, this choice is highly questionable. Solid hydrocarbons are waxes—highly dissipative materials completely unsuited for resonant applications. (Imagine the behavior of a wax tuning fork!) If surface-induced dissipation is dominant, will alkyl monolayers not exacerbate the problem?

These expectations are seemingly borne out by the data in Fig. 5. Resonators terminated with a dodecyl ( $-\text{C}_{12}\text{H}_{25}$ ) monolayer have significantly poorer performance (i.e., lower  $Q$ ) than freshly H-terminated resonators.<sup>[17]</sup> After approximately 2 days in vacuum ( $10^{-8}$  Torr), though, this ordering reverses because of the poor stability of the H-terminated resonators. Even after 1 week in vacuum, the frequencies and quality factors of the dodecyl-terminated resonators are essentially unchanged, showing that the alkyl-terminated resonators are indeed highly adsorption resistant.<sup>[17]</sup>

The observed stability of dodecyl-terminated resonators is consistent with the known reactivity of alkyl-terminated Si(111) surfaces. Linford and coworkers showed that silicon surfaces protected by alkyl monolayers bonded directly to the surface are remarkably stable to chemical attack.<sup>[15]</sup>  $\text{C}_{18}\text{H}_{37}$ -monolayers not only remain bound to the surface after

**Fig. 5** Decay of the quality factors of resonators with three different surface terminations held in a  $10^{-8}$  Torr vacuum with time. The solid lines represent the best exponential fits. *Source:* From Ref.<sup>[17]</sup>.

extended exposure to boiling strong acids and bases, but XPS measurements showed little oxidation of the underlying surface after weeks of exposure to laboratory air.<sup>[16]</sup>

To test the hypothesis that the intrinsically poor mechanical properties of waxes affect the quality factors of alkyl-terminated resonators, monolayers of varying chain lengths were studied (J. A. Henry, D. Sengupta, and M. A. Hines, in preparation).<sup>[18]</sup> Because chain length has little effect on monolayer packing and density over the range from  $-C_2H_5$  to  $-C_{18}H_{37}$ , chain length is an experimentally tractable

means of controlling monolayer thickness. If intrinsic mechanical energy dissipation in the monolayer dominates, the quality factors of alkyl-terminated resonators should decrease with increasing chain length. In fact, the opposite is observed. As shown by Fig. 6, resonators terminated with  $C_{18}$ -monolayers have nearly identical performance to those terminated by  $C_{12}$ -monolayers.<sup>[17,18]</sup> Similar results were obtained for ethyl-terminated resonators (J. A. Henry, D. Sengupta, and M. A. Hines, in preparation). The conclusion is inescapable—intrinsic dissipation in the monolayer appears to have little effect on the mechanical energy

**Fig. 6** The effect of surface termination on the quality factors of three different sizes of micromechanical silicon torsional resonators. The solid lines are meant to guide the eye. *Source:* From Ref.<sup>[18]</sup>.

dissipation, at least in the relatively large (7  $\mu\text{m}$  wide, 250 nm thick) resonators examined in this study.

Why, then, do H-terminated resonators have significantly better performance than these long-chain alkyl-terminated devices? In this system, long-chain alkyl groups are not a perfect analog of hydrogen, as their 0.42 nm diameter is significantly larger than the 0.38 nm spacing between binding sites on the Si(111) surface. Because of this, only 50% of the surface sites can be alkyl-terminated.<sup>[19]</sup> Presumably, the remaining sites remain H-terminated. There is one exception to this rule—the 0.21 nm diameter of methyl groups allows for complete alkyl termination.

Unfortunately, the simple alkene-based synthesis used for long-chain monolayers cannot be used for methyl termination. Instead, a two-step synthesis is required. First, the surface of a H-terminated resonator must be completely chlorinated, either by immersion in a  $\text{PCl}_5$ -saturated solution using benzoyl peroxide as a radical initiator or by exposure to  $\text{Cl}_2(\text{g})$  during UV illumination.<sup>[20,21]</sup> The latter procedure is clearly preferred for this application, as  $\text{PCl}_5$  severely etches the silicon and structurally damages micromechanical devices.<sup>[18]</sup> After chlorination, the devices are methylated by immersion in a boiling solution of methyl magnesium chloride ( $\text{CH}_3\text{MgCl}$ , methyl Grignard reagent).<sup>[20,21]</sup>

As shown in Fig. 6, methyl-terminated resonators have significantly higher quality factors than either H-terminated or long-chain-alkyl-terminated resonators.<sup>[18]</sup> In contrast to H-terminated devices, methyl-terminated resonators are stable in vacuum. Interestingly, the methyl-terminated resonators are equally stable in air, even at 100% humidity, as long as they are stored in a sealed container (e.g., belljar). If left unprotected in the laboratory, though, a slow degradation of  $Q$  is observed. This degradation is tentatively ascribed to a low flux of reactive species (e.g., radicals) in laboratory air. Importantly, this result shows that methyl-terminated resonators may be suitable for technological applications with suitable packaging.

The difference in the quality factors of methyl-terminated and long-chain-alkyl-terminated resonators cannot be ascribed to differences in the synthetic approach (i.e., alkene-based vs. Grignard-reagent-based), as dodecyl- and octadecyl-terminated resonators prepared by both the approaches showed nearly identical performance (J. A. Henry, D. Sengupta, and M. A. Hines, in preparation). Instead, the differences between  $\text{C}_1$ - and  $\text{C}_n$ -terminated resonators are attributed to differences in monolayer packing density. Resonators terminated by a full monolayer of alkyl groups have higher performance than those terminated by a half monolayer.

Not all alkyl monolayers give equally high performance. For example, chlorosilane-based chemistries

have been successfully used to prepare antistiction coatings on micromechanical devices.<sup>[22,23]</sup> In this case, the alkyl monolayer is not bound directly to the silicon surface; instead, it is bound to a thin chemical oxide on the silicon surface. The oxide layer increases mechanical energy dissipation significantly, as resonators functionalized with the chlorosilane-based syntheses have worse performance than even the oxide-coated resonators discussed earlier.<sup>[17]</sup> Indeed, these resonators have the worst performance of any functionalized resonators tested to date.

In summary, methyl-terminated resonators have the highest quality factors and best stabilities to date. At least for silicon devices, high performance appears to be correlated with two characteristics. First and foremost, the performance of a coating appears to be directly correlated with its ability to resist surface oxidation. Oxidized resonators have uniformly poor performance, even when protected by subsequent alkyl functionalization. Second, a coating that functionalizes every surface site yields better performance than a lower-density coating. Interestingly, the mechanical properties of the surface monolayer have no apparent effect on the performance of the resonator, suggesting that this source of dissipation is too small to be observed in the megahertz-range resonators studied here.

These observations bode well for the production of functionalized resonators of controlled surface chemistry for sensor applications. The past decade has seen tremendous advances in the field of organosilicon surface chemistry, and many different strategies for silicon functionalization have been reported.<sup>[24]</sup> Nevertheless, more research is clearly needed to fully understand the correlation between surface chemistry and mechanical energy dissipation.

### The Mechanism of Surface-Induced Mechanical Energy Dissipation

The coupling of macroscopic mechanical deformations to atomic-scale surface chemistry is at first surprising; however, defect-induced mechanical energy dissipation in *bulk materials* has been understood in a general sense for at least half a century. It is likely, although not proven, that a similar mechanism accounts for the dissipation in micromechanical structures.

When a periodic macroscopic stress is applied to a (imperfect) material, the chemical bonds surrounding the defects will be stressed, usually anisotropically. If the stress puts the defects in a non-equilibrium configuration, the defects will relax to their ground state configuration with a finite relaxation time,  $\tau^*$ . If this relaxation time is much faster or much slower than the vibrational period (i.e., if relaxation is

instantaneous or adiabatic), the defects will have little effect on mechanical energy dissipation. On the other hand, if the relaxation time is comparable to the vibrational period, the material will be anelastic, and relaxation will occur with a significant phase lag to the applied stress. This phase lag inevitably leads to mechanical energy dissipation and “internal friction.”<sup>b</sup> As first discussed by Zener, the quality factor of an anelastic material will obey the relationship<sup>[25]</sup>

$$\frac{1}{Q} = \frac{E_u - E_r}{\bar{E}} \frac{\omega\tau^*}{1 + (\omega\tau^*)^2} \quad (6)$$

where  $E_u$  and  $E_r$  describe the elastic response (Young's modulus) of the solid to instantaneous and adiabatic perturbations, respectively.  $\bar{E}$  is the geometric mean of  $E_u$  and  $E_r$ , and  $\omega$  is the radial frequency of oscillation. Defects are not necessary for dissipation, though. Akhiezer showed that a similar effect occurs when vibrational modes (e.g., phonons) interact with stress fields.<sup>[26]</sup>

Chemically induced mechanical energy dissipation in *bulk* silicon was demonstrated by Mihailovich and Parpia.<sup>[27]</sup> In this case, the quality factors of macroscopic, kilohertz-range silicon resonators were found to be strongly dependent on boron doping density (over the range of  $6 \times 10^{13}$  to  $6 \times 10^{16}$  dopants/cm<sup>3</sup>). Mechanical energy dissipation was therefore attributed to stress-induced shifts of electronic holes occupying energy-split ground states.

The density of surface electronic defect states can be estimated from the charge carrier lifetime. Interestingly, the quality factors and charge carrier lifetimes of functionalized silicon surfaces follow the same (qualitative) trend in initial performance (CH<sub>3</sub> > H > long-chain alkyl monolayers) and relative stability (CH<sub>3</sub> > long-chain alkyl > H-monolayers).<sup>[28,29]</sup>

What is surprising, then, is not the existence of a surface-mediated dissipation channel, but the relative magnitude of the dissipation. For example, by changing a *single monolayer of molecules* on the surface of a 7 μm-wide, 250 nm-thick Si resonator from -C<sub>2</sub>H<sub>5</sub>/H to -CH<sub>3</sub>, less than 0.07% of the total mass, the quality factor of the device can be improved by 95% (J. A. Henry, D. Sengupta, and M. A. Hines, in preparation). Moreover, there is increasing evidence that surface-induced dissipation is primarily related to surface defects (e.g., a small degree of oxidation) and not to the majority sites on the surface.<sup>[17]</sup>

To date, most of the research on chemically induced micromechanical energy losses has focused on silicon

resonators, primarily because of their prevalence. Nevertheless, there is no reason to believe that silicon is the ultimate material in terms of dissipation. Indeed, Eq. (4) predicts that many semiconductors and insulators (e.g., silicon, diamond, and carbon nanotubes) will have comparable intrinsic losses. For this reason, resonators fabricated from materials with relatively unreactive surfaces, such as diamond or carbon nanotubes, may have superior performance.<sup>[30]</sup>

## CONCLUSIONS

The rate of mechanical energy dissipation in micro-mechanical silicon resonators is exquisitely sensitive to the chemical state of the surface. Changes at the monolayer level can increase the rate of dissipation in 250 nm-thick, megahertz-range resonators by at least a factor of 2. This magnitude of surface-induced losses increases as the size (i.e., volume-to-surface ratio) of the resonator decreases, suggesting that submonolayer control of surface chemistry will be necessary for the production of the high-performance nanoscale mechanical resonators necessary for the proposed sensor applications.

## INTRODUCTION

The need for increasing miniaturization of circuitry, as described by Moore's law, requires the reduction of feature size for electronic components, decreasing by an order of magnitude every 10 years. With contemporary minimum feature sizes of  $\sim 0.1 \mu\text{m}$ , circuits with dimensions on the atomic length scale will need to be achieved within the next 30 years<sup>[1]</sup> for this progress to continue.

There are two possible routes to smaller feature sizes: 1) the traditional "top-down" approach, where feature size is simply reduced by scaling of presently used devices; and 2) the more recent "bottom-up" approach based on enlargement, where the self-assembly of macromolecular and colloidal building blocks is used to create larger, functional devices. "Top-down" fabrication processes presently experience a bottleneck because most common lithographic techniques used for the creation of small features are limited to a spatial resolution in the upper nanometer range.<sup>[2]</sup> Feature sizes down to 10 nm have been realized by special techniques, but the small-area and low-throughput properties of these processes are economically challenging. Thus new avenues toward smaller-scale and more densely packed structures need to be explored, and new fabrication methods using the bottom-up approach need to be developed. Two-dimensional and three-dimensional structures can be self-assembled using nanometer-sized objects with the control of feature size in the nanometers to hundreds of nanometer range, bridging the gap between atomic manipulation and modern lithography. The simplicity and low processing costs connected with it make methods based on self-assembly economically interesting. Nanoparticles present ideal building blocks for self-assembly because: 1) they can be synthesized with narrow size distributions ( $\sigma \leq 5\%$ ) from a variety of materials; 2) they come in many different shapes; and 3) their small dimensions lead to a wide functional diversity with respect to their electronic, optical, and catalytic properties, which is usually very different from bulk materials.

This entry reviews recent accomplishments in the fabrication of two-dimensional and three-dimensional

nanoparticle structures using self-assembly, which may be used in electronic applications. Synthetic approaches to monodisperse metallic, semiconducting, insulating, and core-shell structured nanoparticles are briefly reviewed. The basic principles behind two-dimensional and three-dimensional nanoparticle assembly from solutions, by templating and by networking with organic and biological molecules, are presented. Some interesting properties of various nanoparticle arrays and their possible applications in optical and electronic devices are discussed. Finally, recent developments in the self-assembly of nanobuilding blocks other than nanoparticles are briefly mentioned.

## NANOPARTICLE SYNTHESIS

The underlying concept of nanosized particle synthesis is to stabilize small particles by surface derivatization while they are formed in a solution to prevent their coalescence or aggregation.<sup>[3-5]</sup> For most applications, monodisperse nanoparticle solutions with size distributions of  $\sigma \leq 5\%$  are desirable. Nanoparticles are divided into three classes based on their conduction properties: 1) metallic nanoparticles; 2) semiconductor nanoparticles, often referred to as nanocrystallites because of their well-formed crystalline cores and controlled surface chemistry; and 3) nonmetallic nanoparticles. A new class of nanoparticles with core-shell structures, comprising a combination of any of the above, has lately received attention because of their applications in photonic crystals.<sup>[6]</sup>

### Metallic Nanoparticles

Metallic nanoparticles are generally synthesized via the addition of a reducing agent (e.g., sodium citrate) to an aqueous solution of a metal salt under reflux conditions.<sup>[3,7]</sup> Using citrates, nanoparticles with size distributions of  $10 < \sigma < 15\%$  are obtained. Size distribution cannot be narrowed further because of the tendency of nanoparticles to flocculate. The latter can be circumvented by the performance of a two-phase reduction process, which involves the transfer

of metal salt into an organic phase using long-chain alkylammonium surfactants in the first step and the subsequent reduction of the salt in the presence of capping ligands. Monolayer-protected cluster (MPC) molecules in the range of 1–7 nm have been synthesized with size distributions of  $\sigma \sim 5\%$ .<sup>[8]</sup> The advantage of MPCs is that they can be repeatedly isolated from, and redissolved in, common organic solvents without irreversible aggregation and decomposition.<sup>[8]</sup> The gas-phase synthesis of gold MPCs with diameters as small as  $1.9 \pm 0.6$  nm has been reported.<sup>[9]</sup> These clusters are melted and recrystallized in the gas phase prior to deposition, thus yielding clusters that are single face-centered cubic (fcc) crystals. More recent research has focused on controlled production of nanoparticles with shapes other than spherical. For example, disk-shaped cobalt nanoparticles have been synthesized by employing the rapid decomposition of  $\text{Co}_2(\text{CO})_8$  in hot organic solvents in the presence of linear amines and trioctylphosphine oxide (TOPO).<sup>[10]</sup> Anisotropy in growth is induced by TOPO acting as a selective adsorber, altering the relative growth rates of different crystal faces. The effect is enhanced in the presence of linear amines. The disks have average diameters of  $2 \times 4$ ,  $4 \times 35$ , and  $4 \times 90$  nm. They represent high surface area crystals and are also expected to be single magnetic domains (breakup into single magnetic domains occurs at 70–100 nm for cobalt spheres). Furthermore, triangular gold–silver alloy nanoframes<sup>[11]</sup> are obtained when compact silver nanoprisms are etched in  $\text{HAuCl}_4$ . Although these differently shaped particles do not yet exhibit the desirable size distribution of  $\leq 5\%$ , they allow a glimpse at what kind of shape control is possible.

### Semiconductor Nanoparticles

Compound semiconductor nanoparticles, such as CdS, CdSe, PbS, InAs, and ZnSe, can be synthesized by: 1) arrested precipitation in a solution; 2) precipitation in nanostructured templates; or 3) use of molecular precursors.<sup>[3,4]</sup> Arrested precipitation provides a cheap route to many different semiconductor nanoparticles, but because it is performed at low temperatures, the trapping of defects formed during early stages of preparation may cause low crystallinity in the nanoparticles. In contrast, the method based on molecular precursors [e.g.,  $(\text{CH}_3)_2\text{Cd}$  and tri-*n*-octylphosphine selenide (TOPSe)], which are injected into a hot organic ligand such as TOPO, yields organic ligand-capped nanocrystallites (e.g., CdSe) with a size distribution of about 5%. The second advantage of method 3 is that it yields grams of materials. Fig. 1 shows transmission electron microscopy (TEM) images and a small-angle electron diffraction pattern of the  $\langle 101 \rangle_{\text{SL}}$  projection through a three-dimensional superlattice of 4.8-nm CdSe nanocrystals.

**Fig. 1** (A) TEM image showing the  $\langle 101 \rangle_{\text{SL}}$  projection of a superlattice of 4.8-nm CdSe nanocrystals. (B) High magnification shows the lattice imaging of individual nanocrystals. (C) Small-angle electron diffraction demonstrates the perfection of the  $\langle 101 \rangle_{\text{SL}}$  projection of the fcc superlattice. *Source:* From Ref.<sup>[3]</sup>. ### Non-metallic Nanoparticles

Catalyzed hydrolysis and condensation of an alkoxy-metal precursor in a solution are used to prepare monodispersed metal oxide particles.<sup>[5]</sup> In particular, silicon dioxide spheres are usually prepared by the so-called Stöber method, which involves hydrolyzing tetraethyl orthosilicate with ammonium hydroxide in ethanol.<sup>[12]</sup>

### Core–Shell Nanoparticles

Core–shell nanoparticles are synthesized by the coating of nanoparticles with a second material.<sup>[6]</sup> There are four requirements that need to be fulfilled for successful coating: 1) the core particle must be stable under conditions used for the coating step; 2) heterogeneous nucleation (i.e., coating material on core) must be more likely than homogeneous nucleation; 3) the coating and core material should not interdiffuse under coating conditions; and 4) the coating of particles should not lead to

**Fig. 2** (A) A TEM image of silver nanoparticles synthesized using a polyol process. (B, C) Transmission electron microscopy and SEM images of gold nanoshells formed by reacting these silver nanoparticles with an aqueous  $\text{HAuCl}_4$  solution. aggregation of newly formed core-shell particles. The additional surface shell stabilizes the particles toward coalescence, increases their dispersibility, and also allows the tuning of electrical and optical properties.

A subclass of core-shell particles is produced when the core is dissolved after (while) the shell has been (is being) formed.<sup>[13]</sup> For example, hollow, crystalline gold nanoparticles (Fig. 2)<sup>[14]</sup> are produced when crystalline silver templates are exposed to  $\text{HAuCl}_4$ . Owing to the higher standard reduction potential of the  $\text{AuCl}_4^-/\text{Au}$  pair compared to the  $\text{Ag}^+/\text{Ag}$  pair, gold is plated while the silver core dissolves. The procedure is versatile and can be extended to any metal that can be reduced by the template metal.

### NANOPARTICLE ASSEMBLY INTO ORDERED TWO-DIMENSIONAL AND THREE-DIMENSIONAL ARRAYS

The assembly of nanoparticles into functional two-dimensional and three-dimensional arrays requires

excellent control of interparticle as well as particle-surface interactions.<sup>[15–17]</sup> One general prerequisite for the formation of crystalline arrays is a very uniform nanoparticle size distribution. Forces governing self-assembly are static and dynamic in nature. Assuming that nanoparticles act as hard spheres with electrically neutral surfaces, their interaction potential consists of two terms: short-range steric repulsion, and short-range attractive van der Waals force. An additional long-range electrostatic Coulomb repulsion is present in systems with charged particle surfaces. All three potentials are combined in the Derjaguin–Landau–Verwey–Overbeck (DLVO)<sup>[18]</sup> theory. Dynamic forces are at work when particles move through (hydrodynamic) solutions and with respect to each other (steric repulsion). We have divided the assembly methods into three groups: 1) self-assembly of nanoparticles onto planar substrates; 2) self-assembly into structured templates; and 3) self-assembly by coordination with organic and biological linkers. Nanoparticle assembly using the Langmuir–Blodgett (LB) technique is not

included, although close-packed two-dimensional films can be obtained and transferred to solid substrates with the LB technique.<sup>[19,20]</sup>

### Self-Assembly onto Planar Substrates

Convective self-assembly of nanoparticles from solutions onto planar substrates occurs in two stages: 1) onset of array growth (nucleation phase), and 2) array growth. A prerequisite for nucleation is that the nanoparticle suspension forms a wetting film on the substrate. The thickness of the wetting film influences both the nucleation and the growth of the array. The particles move toward each other because of hydrodynamic pressure caused by solvent flux from the bulk suspension toward the drying array (hydrodynamic forces). As the particles start to protrude through the surface of the evaporating film, they experience attractive, lateral capillary immersion forces, which leads to close packing of particles.<sup>[21,22]</sup> In the case of two-dimensional films, the evaporation rate influences the formation of two-dimensional arrays because of competition between solvent dewetting and superlattice formation.

Excessively high rates of evaporation (i.e., when pure solvents are used) lead to dewetting (film thinning) prior to superlattice formation. Particles move away from holes in the wetting film, whereas the convective flow inside wetting droplets drives particles toward the rim of droplets, leading to the formation of ring structures.<sup>[23]</sup> The addition of a nonvolatile liquid to the evaporating solution (e.g., dodecanethiol) reduces the evaporation rate, whereas it increases the time for particle assembly, resulting in better long-range order on the micrometer scale.<sup>[24]</sup> Fig. 3 shows a TEM image of a two-dimensional 5.5-nm gold nanoparticle array with excellent long-range order. Multilayer formation can be induced by higher nanoparticle concentrations because interparticle interactions become more frequent. Murray, Kagan, and Bawendi<sup>[3]</sup> showed that three-dimensional nanocrystal superlattices coherent over hundreds of micrometers are produced when CdSe nanocrystallites capped with long-chain alkyl tail groups are deposited from a low-boiling alkane/high-boiling alcohol mixture. Sedimentation because of gravitational forces can be neglected for very small nanoparticles (<300 nm) because thermal agitation compensates for gravitational forces.

Interestingly, the formation of ordered, stable particles comprising nanoparticles (270–630 nm) was recently reported to occur when an aqueous colloidal suspension was added to fluorinated oil.<sup>[25]</sup> Using mixtures of nanoparticles with largely differing sizes (40 vs. 270 nm) led to an assembly of 40-nm gold nanoparticles in a ring structure on the side of the array in contact with air (Fig. 4).

**Fig. 3** Long-range ordered nanocrystal monolayer formed by 10  $\mu\text{L}$  of colloid in the toluene dodecanethiol mixture, with a thiol volume fraction of  $6.3 \times 10^{-3}$  and a particle concentration of  $1.2 \times 10^{13} \text{ mL}^{-1}$ . Source: From Ref.<sup>[24]</sup>; ©American Chemical Society, 2003.

One disadvantage of the convective assembly described above is that it gives no control over the place of assembly. Therefore it is desirable to develop techniques that allow array positioning using electric fields. Giersing and Mulvaney<sup>[26]</sup> first observed that citrate-stabilized and alkanethiol-stabilized gold colloids (14.1 nm) electrophoretically deposited onto carbon-coated copper grids when a positive voltage was applied (50 mV). Monolayers formed exhibit small domains of hexagonally ordered, close-packed particles. Solomentsev, Böhmer, and Anderson<sup>[27]</sup> developed an electrohydrodynamic (EHD) theory describing the electroosmotic flow around charged particles attached to an electrode leading to clustering of particles. Electrophoresis is also used for the assembly of opals (i.e., highly periodic, ordered arrays of silica spheres with diameters between 300 and 550 nm), which are used as photonic bandgap crystals (see below).<sup>[28]</sup> Dielectrophoresis,<sup>[29]</sup> the a.c. variant of electrophoresis, can be used to create one-dimensional, two-dimensional, and free-standing three-dimensional assemblies of micron-sized particles in between planar electrodes. Electrode shapes and dimensions determine the structure of the final array, but particle type and operating conditions also play a role. The application of a.c. currents to electrodes immersed in metallic nanoparticle suspensions (15–30 nm) leads to the growth of metallic nanoparticle wires between electrodes.<sup>[30]</sup> Interestingly, the wires self-repair after burnout because of high voltage. If a mixture of metallic nanoparticles and polystyrene (PS) spheres is used, conducting wires with a PS shell form. Assembly into a planar

**Fig. 4** Examples of anisotropic particles. (A) Unoriented spherical assemblies incorporating regular (white) and magnetic (brown) latexes. (B) In the presence of a magnetic field originating from below, these particles immediately form an array with the white halves oriented up. If the magnetic field gradient is reversed, the particles flip to form an array with the brown side up. (C, D) Two assemblies of complex shape obtained in the presence of small gold particles, as viewed from opposite faces. A metallic ring is deposited only on the side of the particle that was originally exposed to air. *Source:* Reproduced with permission from Ref.<sup>[25]</sup>. © 2003 American Association for the Advancement of Science.

superlattice is observed when binary colloidal suspensions are exposed to an a.c. electric field.<sup>[31]</sup> The lattice shape is controlled by particle concentration, size, and a.c. frequency. At low frequencies, induced dipole interaction and attractive EHD flow govern superlattice formation, whereas at high frequencies, EHD flow is negligible because dipole–dipole interactions between particles become attractive. Magnetic fields can also be used to improve the monolayer packing of diamagnetic materials (e.g., silver nanoparticles; 6.5 nm).<sup>[32]</sup> Because of interactions with the magnetic field, particles are pulled up in a positive field and pulled down in a negative field. The coating of non-magnetic Al<sub>2</sub>O<sub>3</sub> spheres (47 μm) with a 2- to 3-μm-thick Ni layer by electroless plating yields magnetic microspheres that can be manipulated into two-dimensional and three-dimensional arrays by means of magnetic force from an electromagnet.<sup>[33]</sup>

### Assembly Using Structured Templates

Many applications require particle arrays with more complex patterns than close-packed two-dimensional and three-dimensional arrays obtained by the planar assemblies described above. A very promising approach to complex nanoparticle arrays is the direction and confinement of nanoparticle assembly by substrate structure. For example, two-dimensional particle arrays (300–800 nm) can be obtained using substrates with one-dimensional grating patterns.<sup>[34]</sup> Striped structures as well as hexagonal and centered rectangular lattices with varying lattice spacings are produced by the variation of particle size and grating spacing. The main driving forces for assembly formation are capillary forces and self-shadowing effects.

For three-dimensional arrays, the patterning of surfaces with micrometer features is commonly achieved

by soft lithography.<sup>[35]</sup> The term summarizes a group of microfabrication techniques, which use patterned elastomers as stamps, molds, or masks to generate micropatterns and microstructures. Direct evaporation-induced self-assembly (DEISA)<sup>[36]</sup> of silica nanoparticles (100–500 nm) leads to fcc, close-packed opal crystal architectures. Depending on the substrate pattern, complex forms that offer optical functionality and quality can be obtained. The assembly is directed by colloidal interactions, capillary forces, and surface tension forces between spheres and wall materials. For larger particles (700–2500 nm), sedimentation because of gravitational forces interferes with the assembly and can be circumvented by stirring of the solution during assembly. An interesting variant combines soft lithography and nanoparticle assembly (i.e., a surface pattern is created using one type of nanoparticles, and subsequently filled with nanoparticles of a second type).<sup>[37]</sup>

A very interesting, relatively new three-dimensional nanoparticle structure, the so-called inverse opal,<sup>[28]</sup> is obtained by the infiltration of close-packed three-dimensional microparticle arrays with smaller nanoparticles of a higher refractive index material. The smaller nanoparticles completely occupy the void space of the microparticle array, thereby creating a lattice that is retained when the host microparticles are removed (dissolved). This leaves a collection of micrometric spherical cavities surrounded by a high refractive index nanoparticle material, in which both the cavities and the high refractive material are connected throughout the structure. Inverse opals show even better bandgap properties than opals; however, it is necessary that the photonic properties appear in the transparent region of the material that forms the inverse structure. Defect densities in opals depend on particle monodispersity and size; the more

**Fig. 5** Nanoparticles  $\sim 10$  nm in diameter are deposited into the polymer template. The larger size limits the number of nanoparticles per nanopore. *Source:* Reprinted with permission from Ref.<sup>[39]</sup>.

monodisperse and the smaller the particles are, the lower is the number of defects.

Instead of elastomeric stamps, self-organizing diblock copolymers<sup>[38]</sup> can be employed. They are of great interest to industries because of their compatibility with standard silicon technology. Diblock copolymers consist of two polymers [e.g., PS and poly(methylmethacrylate) (PMMA)], which, under certain conditions, spontaneously self-assemble into patterned structures because of phase separation. Misner et al.<sup>[39]</sup> deposited monolayer-protected nanoparticles ( $\sim 10$  nm) into a mask (Fig. 5) made from a PS/PMMA diblock copolymer by a simple dipping process, allowing the creation of arrays of isolated nanoparticles.

### Assembly Using Organic Linkers and Biological Templates

The third method utilizes organic and biological molecules as linkers and templates for the assembly of nanoparticles into ordered two-dimensional and three-dimensional structures. The assembly is directed by specific interactions of functional groups on the linker molecule or template. For example, a hydrogen bonding network is suggested as the origin of the crystallization of mercaptosuccinic acid-capped gold nanoparticles ( $3.7 \pm 0.5$  nm) into hexagonal closed-packed, colloidal gold crystals from an aqueous solution<sup>[40]</sup> (i.e., mercaptosuccinic acid functions as capping ligand and linker). Furthermore, highly ordered hexagonal and cubic monolayers of Au<sub>55</sub> MPCs have been formed on polymer-coated substrates.<sup>[41]</sup> Double end-functionalized organic linker molecules have been employed in the creation of well-ordered two-dimensional nanoparticle arrays,<sup>[42]</sup>

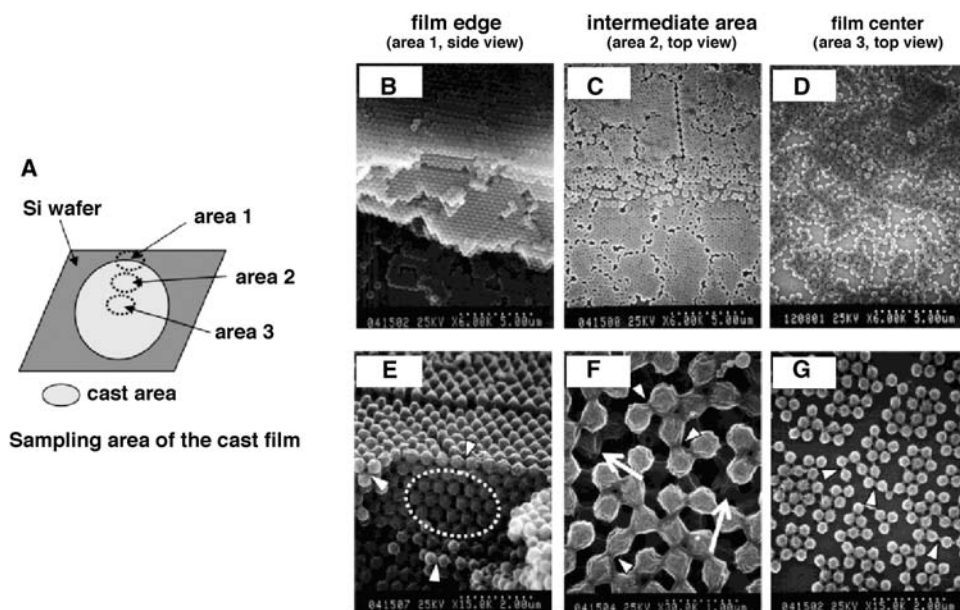

which are extremely important for molecular electronics applications.<sup>[43]</sup>

Biomolecules, with their typical size dimensions in the range of 5–200 nm, are perfectly suited for nanoparticle assembly.<sup>[44]</sup> The utilization of, for example, nucleic acids and proteins as programmable recognition units can modify and improve assembly capacities of nanoparticles and thus allow nanostructured and mesoscopic supramolecular hybrid architectures. The tremendous recognition capabilities of biomolecules and their potential to be addressed through biochemical procedures provide the basis for entirely novel routes to construct advanced materials rationally.<sup>[44]</sup> Recently,<sup>[45]</sup> for example, protein linker units were generated, which directly recognized distinct surfaces of semiconductor materials, whereby no previous functionalization of the linkers was necessary. Thus peptides with semiconductor binding specificity could be used for the controlled placement of structurally related materials in close proximity and the assembly of a variety of practically important materials. Repetitive nanocluster materials can be generated using DNA hybridization. Regular two-dimensional lattices of bacterial cell surface proteins, nanometer-sized and micrometer-sized nucleic acid components, as well as hollow biological compartments have been employed as templates for nanoparticle architectures (e.g., engineered chaperonin proteins<sup>[46]</sup> and hollow tobacco mosaic virus:  $300 \times 18$  nm, inner diameter = 4 nm).<sup>[47]</sup>

The synthesis of hollow three-dimensional arrays of interconnected titania nanospheres<sup>[48]</sup> is achieved by the covering of a mixed latex bead/virus array with an ultrathin layer of titanium alkoxide (Fig. 6). The templates are removed by oxygen plasma, which also converts the titanium alkoxide to titania. In contrast to the infiltration of three-dimensional particle arrays described above, this process leads to a positive copy of the array structure. Biological linkers can also be used in the synthesis of nanoparticles (e.g., immobilized histidine-rich peptide mineralizes gold nanocrystals on template nanotubes with uniform size distribution). Nanocrystal size and packing density are controlled by the adjustment of pH, temperature, and ion concentration.<sup>[49]</sup>

### PROPERTIES AND APPLICATION OF NANOPARTICLE ASSEMBLIES

Ordered colloidal systems<sup>[50]</sup> have lattice spacings ranging from nanometers to micrometers. Their resulting ability to diffract ultraviolet, visible, and near-infrared light makes them useful for sensors, narrow-band optical filters, optical switches, photonic bandgap materials, waveguides, and other types of optical and electrooptical devices.

**Fig. 6** Scanning electron microscopy images of titania-coated multilayers of latex particles. (A) Schematic representation of the sampling area. The series of parts B–D and E–G were obtained before and after the oxygen plasma process, respectively. Images in parts B and E are obtained at the edge of the cast area (area 1). Images in parts C and F are obtained around the intermediate cast area (area 2). Images in parts D and G are obtained in the center of cast area (area 3). *Source:* From Ref.<sup>[48]</sup>; ©American Chemical Society, 2003.

However, the arrangement of metallic nanoparticles (a few nanometers in size) in close-packed structures with  $\sim 1$  nm interparticle spacing leads to the formation of tunneling junctions, which have electrical capacitance values of about  $10^{-19}$  F. Such small capacitances allow single-electron tunneling (i.e., controlled charge transport) at room temperature. This ability has been recognized as a fundamental concept for ultimate miniaturization in electronics.<sup>[51]</sup> Single-electron devices based on single nanoparticles trapped between two electrodes<sup>[52]</sup> and nanoparticles immersed in a polymer matrix<sup>[53]</sup> have been reviewed elsewhere and are therefore not discussed in the following.

### Charge Transfer in Two-Dimensional Nanoparticle Arrays

Langmuir films of hydrocarbon-functionalized silver quantum dots (2–5 nm) show transition from classical behavior to quantum-mechanical coupling when the interparticle distance is reduced to below  $12 \text{ \AA}$ .<sup>[19]</sup> Reversible insulator-to-metal transitions occur when interparticle spacing is decreased to  $< 5 \text{ \AA}$ .<sup>[19]</sup> This tuning capability shows that the electronic band structure of a solid made of quantum dots can be tailored by the adjustment of wave function overlap of adjacent particles. Recently, a theoretical description supporting bandgap modulation by interparticle spacing was

published.<sup>[54]</sup> Compressed hexagonal, closed-packed Langmuir films are transferable to any kind of substrate as Langmuir–Schaeffer films, thus permitting the parallel fabrication of single-electron, solid-state capacitance devices, which show Coulomb blockade as well as step structures reminiscent of Coulomb staircase.<sup>[20]</sup>

One major problem of nanoparticle array formation is the finite distribution of particle sizes in the array, leading to disorder, which in turn affects the charge transport through the arrays.<sup>[55]</sup> Beverly et al. found that the transition temperature between different transport regimes (mobility and hopping) in two-dimensional arrays depends on array disorder. As a result of their study, they predict that a metal–insulator transition will be observed with size distributions  $< 3\%$ . Three types of disorder that can be found in nanoparticle arrays are: 1) global structural disorder; 2) local structural disorder (i.e., interparticle coupling); and 3) charge disorder. Parthasarathy, Lin, and Jaeger<sup>[56]</sup> show that current–voltage characteristics of arrays with long-range order are well fit by single-power law, whereas a sufficiently large amount of disorder leads to distinct deviations from single-power law.

### Nanoparticle Arrays in Photonic Devices

Photonic crystals are spatially periodic arrays of particles arranged within a medium of different dielectric

constants. Their effect on propagation of electromagnetic waves can be compared to that of electrons in semiconductors. They combine the quantum confinement of electronic states with simultaneous phonon confinement in the same structure. Photonic bandgap structures (PBS) were originally proposed in 1993 by Yablonovitch.<sup>[57]</sup> The development of PBS was initiated by the need of a photonic bandgap in quantum optics. The realization of photonic bandgap crystals could lead to miniaturization and high-speed performance of optical integrated circuits. They also have profound applications in telecommunications, lasers, fiber optics, data processing, and display technologies. The size of the photonic gap is determined by: 1) refractive index contrast (refractive index of material vs. surrounding substance), and 2) filling fraction (percentage of volume that is occupied by voids). Wang et al.<sup>[58]</sup> theoretically predict that metal nanoparticles self-assembled into three-dimensional structures could be used as photonic bandgap crystals because of a complete gap below the plasma frequency.

Fig. 7 displays an inverse silicon opal with a complete three-dimensional bandgap near  $1.5\ \mu\text{m}$ .<sup>[59]</sup> Controlling the interactions of light and materials for photonic device application at nanoscale dimensions requires structures that guide electromagnetic energy with a lateral mode confinement at below the diffraction limit of light, the so-called waveguides. Closely spaced silver nanorods have been employed in a plasmon waveguide, which shows electromagnetic energy transport from a source to a detector over distances of  $0.5\ \mu\text{m}$ .<sup>[60]</sup> Numerous applications are possible for light-guiding and light-focusing elements operating below the diffraction limit. A regular gold nanoparticle array deposited on a dielectric waveguide could be utilized for the design of two-dimensional photonic devices in the visible and the infrared (IR), which are relevant for optical communication and microlasers.<sup>[61]</sup>

### Data Storage Media

Magnetic nanoparticle arrays<sup>[62]</sup> can serve as high-density data storage devices, magnetoelectronic devices, and patterned media. Each nanoparticle could store one bit of data, implying densities in the  $150\ \text{Gbit cm}^{-2}$  range for particles in the few nanometers size range. Magnetic logic gates can be realized by manipulation of data through magnetostatic interactions between chains of magnetic elements.

### CONCLUSION

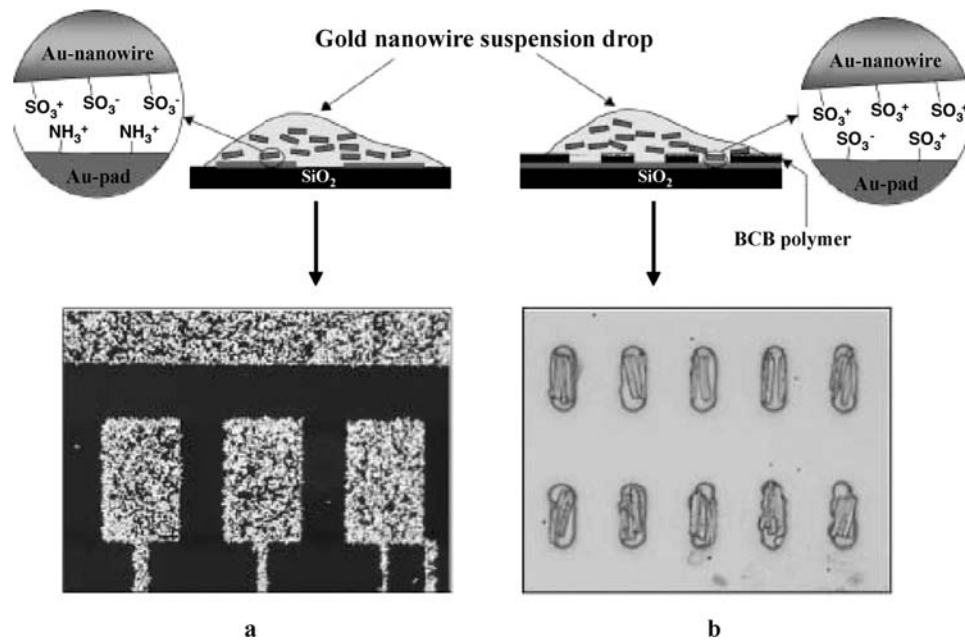

Two-dimensional and three-dimensional arrays of nanoparticles represent a new class of electronic materials with promising properties necessary for their

**Fig. 7** Scanning electron microscopy images of internal facets of silicon inverse opal: (A) [110] facet; (B) [111] facet. *Source:* Reprinted with permission from Ref.<sup>[59]</sup>. ©2000 Nature.

application in small-scale electronic devices. In particular, the fact that their band structures can be engineered by simply changing: 1) the size of nanoparticles comprising the array; 2) the capping and/or spacer ligands in between particles; or 3) the packing order in the array makes them suitable candidates. Despite the fact that considerable research focuses on nanoparticle synthesis and assembly, there are still remaining significant open tasks and questions. One major task emerges—it is desirable to develop new, or to improve existing, syntheses toward even smaller size distributions ( $\sigma \leq 3\%$ ).

Metal nanowires are envisioned as another class of useful building blocks for electronic circuits.<sup>[63]</sup> Their assembly employs the distinct surface chemistry of differently derivatized wires with planar surfaces (Fig. 8, top). The same principle is utilized to interconnect two nanowires in a perpendicular fashion by binding them selectively with bifunctionalized spacers, which opens up the opportunity to construct three-dimensional circuits. High-voltage, anodized, porous aluminum oxide membranes are used as templates to grow wires with sections of alternating materials (i.e., metals, insulators, semiconductors, and/or molecules).

**Fig. 8** Top: Scheme showing the selective adhesion and alignment of negatively charged gold nanowires on lithographically patterned surfaces. Bottom: (A) Dark field optical micrograph ( $500\times$  magnification) of gold nanowires on '2-mercaptoethylamine derivatized gold pads patterned on a  $\text{SiO}_2/\text{Si}$  wafer. (B) Bright field optical micrograph ( $1000\times$  magnification) of gold wires in long wells ( $4\mu\text{m} \times 8\mu\text{m} \times 600\text{nm}$  deep) chemically etched in a divinylsiloxanebis(benzocyclobutene) (BCB) polymer layer on Au. The Au metal at the bottom of the wells is derivatized with '2-mercaptoethanesulfonic acid. Source: Reprinted with permission from Ref.<sup>[63]</sup>.

(B) Metal dot grid array on nylon sphere ( $\phi^3$ , 9.5 mm). (C) Metal dot grid array on glass sphere ( $\phi^3$ , 12 mm). Source: Reprinted from Ref.<sup>[65]</sup> with permission from Elsevier.

Wires are released by the chemical etching of the membrane and the bottom electrode. The  $\text{Al}_2\text{O}_3$  membrane can also be removed independently of the bottom electrode, resulting in anchored, free-standing wires, which in a second process step can be coated with additional materials. Silica-coated silver wires with core diameters of 30–40 nm, controlled sheath thicknesses in the range of 2–100 nm, and lengths from 2 to  $\sim 50 \mu\text{m}$  could find use as interconnects in fabricating nanoelectric devices.<sup>[64]</sup>  $\text{SiO}_2/\text{Ag}$  wires form well-dispersed solutions in water, alcohol, and acetone without the need for additional surfactants and their cores can be readily removed by immersion into an aqueous solution of ammonia with  $\text{pH} \sim 11$ . The combination of nanowires, nanoparticles, and nanoparticle arrays presents a powerful tool for circuitry with three-dimensional architectures.

Plating technology allows selective plating of metals where a seed material has been drawn.<sup>[65]</sup> The process is divided into three steps: 1) drawing of amino–silane coupler as seed material; 2) activation of the catalyst; and 3) electroless metal plating. Multilayer circuits with interconnections can be fabricated using this approach. The method can easily be applied to the transfer of structures onto three-dimensional objects such as spheres, enabling the so-called ball semiconductor technology (Fig. 9).

A discovery by Weismüller et al.<sup>[66]</sup> reveals another intriguing area of application for nanoparticles in an area other than electronics or optics. They found that commercially available black Pt with 6 nm grain size sintered into a nanoporous sample displayed charge-induced reversible strain. On application of a voltage, the porous metal composite experienced an unprecedented maximum volume change of  $\sim 0.45\%$ , which is large enough to do mechanical work. Baughman<sup>[67]</sup> suggests using such materials as artificial muscles, and emphasizes that observed volume changes correspond to negative pressure, something that is not easily realized otherwise.

Nanoparticles are versatile building blocks, which can be self-assembled into two-dimensional and three-dimensional structures. Their size-dependent electronic properties make them unique candidates for future electronics and optics applications.

# Nanoparticle Assemblies: Magnetic Properties

Xiangcheng Sun

Center for Materials for Information Technology, University of Alabama,  
Tuscaloosa, Alabama, U.S.A.

## INTRODUCTION

Studies on system of magnetic nanoparticles with sizes in the nanometer scale have been the object of intensive research because of their many technological applications and unique magnetic properties that differ considerably from those of bulk materials.<sup>[1–3]</sup> Nanometer magnetic particles exhibit specific properties such as superparamagnetism<sup>[4]</sup> because of their very small sizes and fundamental change in the coordination, symmetry, and confinement.<sup>[1–3]</sup> Superparamagnetism is regarded as a unique feature of magnetic nanoparticles and has great relevance to modern potential technologies including magnetic resonance imaging contrast agents, data lifetime in high-density information storage, and ferrofluid technology.<sup>[5,6]</sup> However, because of the various contributions (i.e., magnetocrystalline, surface, shape, and dipolar anisotropy), the transition from superparamagnetic state to collective magnetic excitations (i.e., spin-glass) could occur in the interacting magnetic nanoparticles systems.<sup>[7,8]</sup> The study on the mechanism of superparamagnetic properties in the system of fine magnetic particles will facilitate the control of superparamagnetic behavior and be favorable for their technological applications.<sup>[9]</sup>

## OVERVIEW

Following the discovery of the method for the preparation of fullerenes in macroscopic quantities by the so-called Kratschmer–Huffman carbon-arc method,<sup>[10]</sup> some novel magnetic system of carbon-coated ferromagnetic materials, e.g., Fe, Co, and Ni, had successfully been obtained.<sup>[1,4]</sup> Interest was paid not only to the properties of the encapsulated particles, in particular, to those involving novel magnetic properties of ferromagnetic materials.

As an alternative magnetic nanoparticles system, carbon-encapsulated ferromagnetic materials should be considered good candidates for studying the effect of particle size on crystalline structure, magnetization process, magnetic interparticle interaction effect,<sup>[11–14]</sup> superparamagnetism,<sup>[3,4,15]</sup> and quantum relaxation of magnetization.<sup>[16]</sup>

We herein use the modified arc-discharge (carbon-arc) method to generate two types of nickel nanoparticles [Ni(C) and Ni(O)] and iron nanoparticles [Fe(C) and Fe(O)] in methane and in a mixture of H<sub>2</sub> and Ar atmospheres. High-resolution transmission electron microscopy (HRTEM), nanoscale electron diffraction (SAED), and X-ray diffraction (XRD) were used to investigate the remarkable microstructure. Moreover, various magnetic measurements were performed by superconducting quantum interference device magnetometer (SQUID) and Mössbauer magnetometer at different temperature and magnetic fields. Typical and modified superparamagnetic behaviors have been evidenced. The relationships between the microstructure and novel magnetic behavior have also been established.

## EXPERIMENTAL PROCEDURE

The detailed experimental apparatus (modified arc discharge) was fully illustrated elsewhere.<sup>[17]</sup> The pure material (bulk Ni and Fe) to be evaporated was laid on a water-cooled copper stage, which served as the anode. A copper arm that was also water-cooled supports the upper carbon rod, which served as the cathode. After the chamber was evacuated, the desired gas of methane or a mixture of H<sub>2</sub> and Ar were back-filled as a reactant gas to reach the desired pressure; the distance between the two electrodes can be adjusted from outside the chamber, so that the arc can be started and controlled during a continuous operation.

A JEOL-2010EX high-resolution transmission electron microscope (HRTEM) operated at 200 keV was used to reveal the internal structure and morphology of the particle. It also allowed us to record selected area diffraction (SAED) analysis information. X-ray diffraction (XRD) was conducted using CuK $\alpha$  radiation in a Siemens X-ray diffractometer to identify the different nanophases and the crystal structure of nanoparticles.

Mössbauer spectra were recorded at room temperature using an Austin Science Associates Model S-600 spectrometer with a <sup>57</sup>Co/Rh source. The absorption spectra were fitted by using the *NORMOS* program that

used the input parameters as a first approximation to fit the experimental curve.

The magnetization (d.c. susceptibility) measurements were carried out using a quantum design superconducting quantum interference device (SQUID) magnetometer in the temperature range from 2 to 300 K at different applied magnetic fields. For the zero-field-cooled (ZFC) magnetization measurements, the sample was first cooled down to 2 K without the applied field, after which the magnetic field was applied. The sample was then slowly warmed up to 300 K for subsequent measurements of the magnetic moments (ZFC). Thereafter, for the field-cooled (FC) magnetization measurement, the sample was cooled down to 2 K without turning the magnetic field off; measurements of magnetic moment could be obtained at each intermediate temperature (FC). The magnetization as a function of temperature [ $M(T)$ ] reveals some of the main features of a superparamagnetic system. The average blocking temperature ( $T_B$ ), below which the particle moments are blocked, is usually considered an important parameter when characterizing the magnetic behavior of a magnetic nanoparticles system. In general,  $T_B$  can be obtained by analyzing the zero-field-cooled and field-cooled (ZFC/FC) magnetization vs. temperature curve. Above  $T_B$ , thermal fluctuations can flip the direction of the magnetic moment; in addition, no hysteresis is observed in the  $M(H)$  measurement. When the particles interact, magnetic dipole–dipole interactions become significant (stronger). This dipole interaction may be either ferromagnetic or antiferromagnetic depending upon the dipole orientations. In those cases, the superparamagnetic

relaxation process becomes highly blocked and the magnetic dipole–dipole interactions may become important in determining the magnetic state of the nanoparticle system. Thus a system of nanometer particles with disordered magnetic moments may exhibit spin-glass behavior (collective behavior), such as that observed in the  $\gamma$ - $\text{Fe}_2\text{O}_3$  magnetic particle systems.<sup>[18]</sup> In such systems, the irreversible temperature,  $T_{\text{irr}}$ , is defined by the point where the ZFC and FC branches of  $M(T)$  curves separate.

## RESULTS AND DISCUSSION

### The Assemblies of Ni(C) and Ni(O) Particle Systems

Powder X-ray diffraction profiles of Fig. 1A clearly show the presence of a majority of fcc Ni, with a small amount of hexagonal  $\text{Ni}_3\text{C}$  present from carbon-encapsulated Ni nanoparticles. Additionally, that the hexagonal  $\text{Ni}_3\text{C}$  phase is detectable using XRD suggests that the hexagonal  $\text{Ni}_3\text{C}$  most likely is one single phase along with majority of fcc Ni phase in these assemblies of Ni(C) nanoparticles. However, the main reflection peaks of XRD (Fig. 1B) for pure Ni nanoparticles coated with NiO layers are similar to those of the pure fcc Ni phase, except that the peaks are broader. One can infer from such a XRD study that the concentration of NiO oxide on the surface of Ni(O) nanoparticles should be less than a few percent. This is quite similar to the results reported before.<sup>[13]</sup> The average grain size estimated from the XRD

patterns using the Scherrer formula shows that these two kinds of Ni nanoparticles have an average grain size of 10–15 nm, which is consistent with the corresponding HRTEM images (Fig. 2).

High-resolution transmission electron microscopy images and SAED patterns (Fig. 2A and B) also indicate that most of particles are spherical in shape and do not show any well-developed facets. It is worth noting from Fig. 2A that several carbon layers encapsulating the Ni lattice planes are quite visible. The contiguous carbon fringes around the Ni nanocrystal are good evidence for completed encapsulation by carbon layers. Both fcc-Ni (111) and hexagonal Ni<sub>3</sub>C (101) phases are clearly observed from SAED patterns of Ni(C) particles. In addition, the (002) reflection is

also present from those encapsulated carbon layers. However, only fcc-Ni and NiO phases are verified from SAED patterns of Ni(O) particles (Fig. 2B). Nano-energy dispersive spectroscopy (EDS) analysis can further confirm the presence of Ni, O, and carbon phases in these two-kind Ni particles. Those results are in good agreement with the XRD analysis and HRTEM observations.

One significant morphological characteristic to note, from the HRTEM images (Fig. 2A), is that neither gaps nor intermediate phases are observed between the outer carbon layer and the core materials in the Ni(C) carbon cages. These characteristics typically reflect a growth history of these nanoencapsulated Ni particles, in which carbon atoms dissolve into a molten or solid carbon–metal alloy and then graphite precipitate at the surface during carbon-arc discharge plasma process.<sup>[19]</sup> However, Fig. 2B shows some polycrystalline discontinuities in the layers of the Ni(O) nanoparticles.

Fig. 3 shows the magnetization vs. field plots ( $M$  vs.  $H$  hysteresis loops) at 300 K (Fig. 3A) and 2 K (Fig. 3B) for the assemblies of Ni(C) nanoparticles. Figure 3A indicates a rapid increase with increasing applied magnetic field without saturation because of the superparamagnetic relaxation and the noncollinear moment of the surface spins in the smaller particle assembly.<sup>[20]</sup> Hysteresis is absent with a little remanence and coercivity ( $H_C$ ), which suggests the presence of a long-range magnetic dipole–dipole interaction among the assemblies of superparamagnetic Ni(C) particles. With decreasing temperature, the magnetization of the samples increases and exhibits a symmetric hysteresis loop under both ZFC and FC at 2 K, indicating a transition from superparamagnetic to ferromagnetic behavior. Specifically, the temperature dependence of

**Fig. 3** (A–B) Field dependence of magnetization for the assemblies of Ni(C) nanoparticles at 2 and 300 K, respectively. *Source:* From Ref.<sup>[24]</sup>.

**Fig. 4** Temperature dependence of magnetization for the assemblies of Ni(C) nanoparticles at applied field of 1000 Oe; the blocking temperature is about 115 K. *Source:* From Ref.<sup>[24]</sup>.

the magnetization under the ZFC ( $M_{ZFC}$ ) and FC ( $M_{FC}$ ) conditions gives further confirmation of superparamagnetism in the assemblies of Ni(C) nanoparticles, as shown in Fig. 4.

An important feature to note from Fig. 4 is the temperature at which the  $M_{ZFC}$  curve exhibits a cusp that defines as the blocking temperature ( $T_B$ ). Below  $T_B$ , the superparamagnetic transition is blocked; in other words, the magnetization cannot relax during the time of the measurements. In particular, the well-defined  $T_B$  of the  $M_{ZFC}$  at 115 K and broad blocking temperature ranges are consistent with the particle size distribution as observed from HRTEM images. Furthermore, the continued increase of the  $M_{ZFC}$  and the irreversibility occurring below 225 K are also consistent with the presence of superparamagnetic particles.<sup>[20]</sup>

Therefore for the assemblies of Ni(C) nanoparticles above  $T_B$ , the magnetization could be free to align with the fields during the measurement time, and the curves of magnetization vs. applied field should exhibit no hysteresis loop (Fig. 3A). In such a superparamagnetic state, the relative magnetization  $M/M_s$  can be described by the standard Langevin function,<sup>[21–23]</sup>  $L$ , using the relation:

$$M/M_s(T = 0) = \coth(\mu H/kT) - kT/\mu H$$

where  $M_s(T = 0)$  is the 0 K saturation magnetization of the sample, and  $\mu$  is the particle moment given by  $M_s(V)$  where  $M_s$  is the saturation magnetization of the bulk phase and  $\langle V \rangle$  is the average particle volume.

Fig. 5 shows good agreement with Langevin function of the observed magnetization  $M/M_s$  curves as a function of the applied magnetic fields at room temperature for the assemblies of Ni(C) particles.

**Fig. 5** Experimental curves of relative magnetization as a function of applied fields at 300 K for the assemblies of Ni(C) nanoparticles. *Source:* From Ref.<sup>[24]</sup>.

Consequently, below the  $T_B$ , a hysteresis loop response is observed (Fig. 3B) because thermal energy is not enough to allow the alignment of particle moments with the applied fields. Consistent with the theory of superparamagnetism,<sup>[15,24,25]</sup> the coercivity,  $H_C$ , has the temperature dependence of  $H_C = H_{C0}[1 - (T/T_B)^{1/2}]$  at lower temperatures.

Fig. 6 shows the variation of the coercivity with temperature for the assemblies of Ni(C) particles. It is evident from this figure that the coercivity ( $H_C$ ) vs. temperature ( $T$ ) data can be fit to the above expression. It is interesting to note, from Fig. 6, that the zero temperature coercivity ( $H_{C0}$ ) is determined to be  $\sim 425$  Oe and the blocking temperature  $T_B$  is determined to be  $\sim 120$  K. Note that this  $T_B$  value is very close to the one that inferred from the sharp maximum of  $M_{ZFC}$  curves.

**Fig. 6** Plot of  $H_C(T)$  vs.  $T^{1/2}$  for the assemblies of Ni(C) nanoparticles. The  $T_B$  is near 120 K. *Source:* From Ref.<sup>[24]</sup>.

It is known that a small magnetic particle becomes single domain below some critical size because of the interplay between the energy of dipole fields and domain wall creation.<sup>[26]</sup> Consequently, Ni(C) nanoparticles, with an average size of about 10.5 nm, may be considered as having a single magnetic domain, the origin of its magnetic hysteresis being spin rotation. Thus the magnetic behavior is size-dependent and should be considered in conjunction with thermal energy and surface anisotropy aspects.<sup>[27]</sup> In particular, single-domain particles below a certain critical diameter are greatly affected by temperature fluctuations. From Table 1, at 300 K, it is clear that the  $M_r$  and  $H_C$  values of the assemblies of Ni(C) particles are significantly lower than that of microcrystalline Ni. Compared with 300 K, the assemblies of Ni(C) particles show much larger remanent magnetization ( $M_r$ ) and coercivity ( $H_C$ ) at 2 K. This implies that the thermal energy for demagnetizing becomes dominant over spontaneous magnetization at 300 K for the assemblies of Ni(C) nanoparticles. At 2 K, however, the thermal energy effects decrease significantly, so that the interparticle dipole–dipole interaction and surface anisotropy energy may play a significant role in determining the magnetic behavior.<sup>[27]</sup> It can be supposed that such Ni(C) superparamagnetic particle assemblies exhibit modified superparamagnetic behavior. The larger decrease of remanent magnetization ( $M_r$ ) and coercivity ( $H_C$ ) at  $T > T_B$  for the assemblies of Ni(C) particles is a unique characteristic that associated with modified superparamagnetism.

In addition, from Table 1, the saturation magnetization ( $M_s$ ) of the assemblies of Ni(C) nanoparticle is suppressed in magnitude compared to that of the bulk Ni from microstructural analysis (HRTEM) results. We contribute this result to a small amount of carbon solubility in Ni particles. Hwang et al.<sup>[27]</sup> suggest that the decrease in  $M_s$  is a result of the nonmagnetic or weakly magnetic interface that leads to a decrease in the effective magnetic moment per unit mass. So the possibility is that some carbon (which is diamagnetic)

may have remained inside the Ni nanocrystals as a metastable solid solution, thereby reducing the contribution of the effective magnetic moment during magnetization process.<sup>[27]</sup>

On the other hand, one may suggest that the existence of the small amount of metastable hexagonal Ni<sub>3</sub>C phase in the assemblies of Ni(C) nanoparticles has also affected the magnetization process. The metastability Ni<sub>3</sub>C is generally attributed to the low maximum solubility of carbon in nickel (2.7 at.% at 1600 K). The metastable hexagonal Ni<sub>3</sub>C phase, in particular, is expected to be nonferromagnetic because of strong hybridization between Ni and C orbital except that it remains in a disordered state.<sup>[28]</sup> Therefore the saturation magnetization ( $M_s$ ) from the minority of metastable Ni<sub>3</sub>C phase effect should be ruled out of this study. Thus the gradual decrease in  $M_s$  could be attributed to the nanocrystalline nature of the encapsulated particles, coupled with possible carbon solution in Ni nanoparticle.<sup>[27]</sup>

Magnetization vs. temperature measurements at different magnetic fields ( $H = 100, 1000, \text{ and } 10,000 \text{ Oe}$ ), for the assemblies of Ni(O) nanoparticles, are shown in Fig. 7A–C. It seems that this is typical ferromagnetic nanocluster glass behavior (collective behavior) for the assemblies of nanoparticles.<sup>[29,30]</sup> Note the deviation between the zero-field cooling (ZFC) and field cooling (FC) magnetization below the irreversibility temperature ( $T_{irr}$ ). This strong irreversibility is very dependent on the strength of applied magnetic fields. This behavior may be attributed to the random distribution of stronger magnetic dipole–dipole interactions and surface anisotropy effects among those Ni(O) nanoparticles. High-resolution transmission electron microscopy images of Fig. 2B confirm that those Ni(O) nanoparticles are well connected. It is possible that the dipole interaction energy among those Ni(O) nanoparticles is strong to be on the same order of magnitude as the anisotropy energy, kV. Furthermore, it is interesting to observe that the strong irreversibility in curves of Fig. 7A and B disappears when magnetic fields reach 10,000 Oe in Fig. 7C. This means that  $T_{irr}$  decreases with increasing applied fields. This occurred while the anisotropy field and dipole–dipole interaction effects among these Ni(O) nanoparticles are surpassed. In other words, this collective behavior is expected for energy barriers that are reduced by the external field, allowing reorientation of the moments by the thermal fluctuations at lower temperatures. Actually, the above observed magnetic phenomena suggest that those ferromagnetic Ni(O) nanoparticle assemblies can exhibit nanocluster glass behavior depending on external applied fields.<sup>[31–35]</sup>

From a magnetic point of view, the Ni(O) particles are an assembly of nanoclusters together with stronger interparticle interactions. The magnetic dipole interactions in

the overall particle, which, in turn, lead to the magnetic ordered state, resemble cluster glass behavior (collective behavior). Consequently, the  $T_{irr}$  vanishes when the applied field is strong enough to flip the overall cluster moments and destroy the blocking of the interaction behavior.<sup>[31–35]</sup>

Table 2 shows that the assemblies of Ni(O) nanoparticles possess a larger coercivity and remanence magnetization from RT to 2 K compared with the bulk Ni and the assemblies of Ni(C) nanoparticles. These phenomena could be explained by the exchange anisotropy interaction and the spin flip behavior near the interface of the Ni(O) nanoparticles and their oxide layer on the particle surface.<sup>[13]</sup> It is also consistent with the studies of the ordering of the nanocluster magnetic moments in the case of stronger dipole–dipole interaction that cause aggregation and subsequent ferromagnetic-like ordering of the nanoparticles.<sup>[34–36]</sup> This suggests that this magnetic

phenomenon can be interpreted in terms of ordering of the ferromagnetic Ni moments in the ferromagnetic nanocluster glass state below  $T_{irr}$ .<sup>[18,29]</sup>

### The Assemblies of Fe(C) and Fe(O) Particle Systems

Powder X-ray diffraction patterns of both Fe(C) and Fe(O) nanoparticles are shown in Fig. 8A and B, respectively. It is very apparent to reveal that  $\alpha$ -Fe (bcc),  $\gamma$ -Fe (fcc), and  $\text{Fe}_3\text{C}$  (orthorhombic) nanophases are detected from the assemblies of Fe(C) nanoparticles; these three phases are usually found in similarly prepared Fe–C nanocomposites.<sup>[19]</sup> However, dominant  $\alpha$ -Fe nanophases and a small amount of  $\text{Fe}_3\text{O}_4$  phases are examined from the assemblies of Fe(O) nanoparticles. As revealed by high-resolution images (HRTEM) of Figs. 9A,B and 10A,B, these Fe(C) nanoparticles ( $\alpha$ -Fe,  $\gamma$ -Fe, and carbide  $\text{Fe}_3\text{C}$ ) are typically spherical in core-shell shape and completely encapsulated by the wrapping shell carbon layers, which thickness is uniform over the surface of each particle. The size of three core nanocrystals is generally 10 to 15 nm, and note that each core nanocrystal is tightly covered by 10 to 40 carbon layers rather than a single carbon layer only.<sup>[19,37]</sup> Meanwhile, electron diffraction (SAED) patterns of Figs. 9 and 10 further confirm the presence of  $\alpha$ -Fe,  $\gamma$ -Fe, and carbide  $\text{Fe}_3\text{C}$  nanophases that were covered with carbon layers. Especially, X-ray diffraction (XRD) and electron diffraction (SAED) patterns indicate that no intermediate phases are observed between the wrapping carbon

**Fig. 8** (A–B) XRD patterns for Fe(C) nanoparticles (A) and Fe(O) nanoparticles (B). *Source:* From Ref.<sup>[11]</sup>.

layers and three core nanocrystals.<sup>[12]</sup> These striking structural properties are in well agreement with our previous work of other carbon-coated transition metal particles.<sup>[12,15,17,24,25]</sup>

On the other hand, HRTEM images of Fe(O) nanoparticles in Fig. 11 show that the particles are roughly spherical with many structure defects and slight distortion inside the particle's core. The particle size is about

**Fig. 9** (A–B) HRTEM image (A) and SAED patterns (B) for  $\alpha$ -Fe(C) and  $\gamma$ -Fe(C) nanoparticles. Note that arrows indicate the carbon layers. *Source:* From Ref.<sup>[11]</sup>.

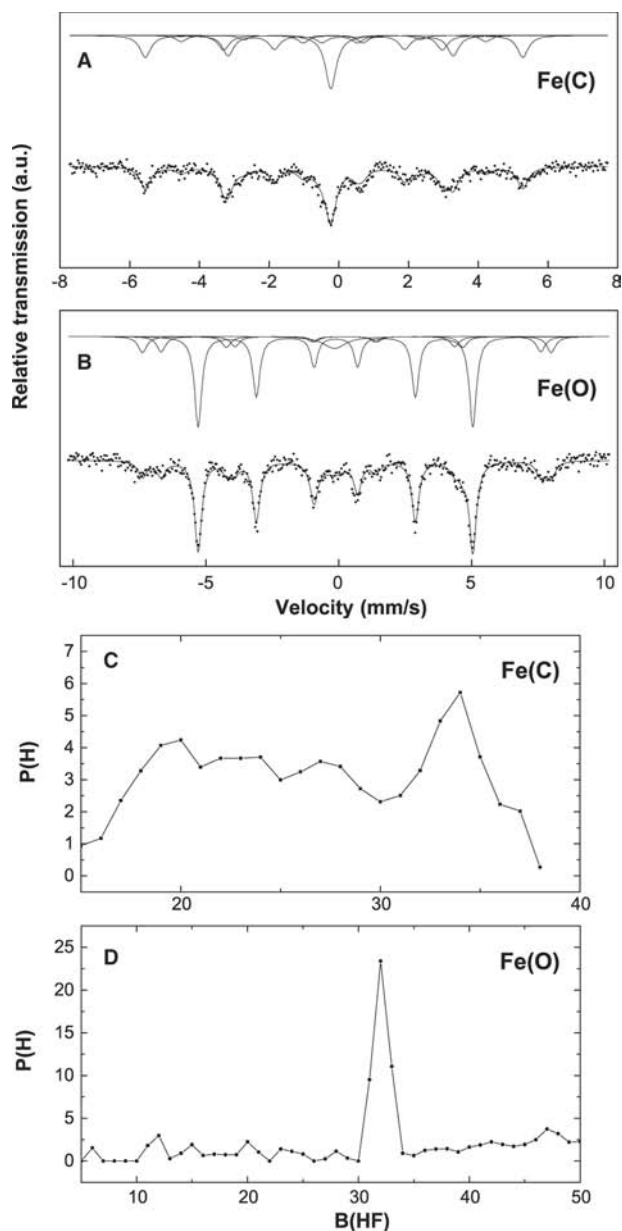

**Fig. 10** (A–B) HRTEM image (A) and SAED patterns (B) for  $\text{Fe}_3\text{C}$  phases in Fe(C) nanoparticles. Note that arrows indicate the carbon layers and structure defects. *Source:* From Ref.<sup>[11]</sup>.

**Fig. 11** (A–B) HRTEM image (A) and SAED patterns (B) for Fe(O) nanoparticles. *Source:* From Ref.<sup>[11]</sup>.

15–20 nm. Electron diffraction patterns (SAED) in Fig. 11 reveal the existence of  $\alpha$ -Fe and  $\text{Fe}_3\text{O}_4$  nanophases; moreover, additional diffuse SAED line patterns could be attributed to a few of spinel-type  $\text{Fe}_3\text{O}_4$  oxide that, surrounding on the surface of these Fe(O) particles, also reflect the presence of structure defect inside the particles.

Typical Mössbauer spectra and hyperfine fields of the assemblies of Fe(C) and Fe(O) nanoparticles at room temperature are shown in Fig. 12A–D. Spectra of Fig. 12A and C are fitted into the following components: the three sextets whose magnetic hyperfine field ( $H_{\text{hyp}}$ ) values of 335, 271, and 200 kOe are assigned to  $\alpha$ -Fe and two carbide  $\text{Fe}_3\text{C}$  nanophases, respectively,<sup>[38–40]</sup> also, the singlet near zero velocity with an isomer shift ( $\text{IS}$ ) =  $-0.126$  mm/sec is assigned to  $\gamma$ -Fe. On the other hand, Fig. 12B and D is decomposed into two phases: the two external sextets of low intensity with a magnetic field of 477 and 444 kOe are

**Fig. 12** (A–D) Mössbauer spectra and hyperfine field distributions for Fe(C) and Fe(O) nanoparticles. *Source:* From Ref.<sup>[11]</sup>.

assigned to the  $\text{Fe}_3\text{O}_4$  structure; the next internal intense sextet with a magnetic field of 320 kOe is assigned to  $\alpha$ -Fe.<sup>[41,42]</sup> Generally speaking, Mössbauer spectra results at room temperature are in well agreement with that of above XRD analysis and HRTEM observations, which confirm these distinct nanophases in both Fe nanoparticles. In addition, the evidence of modified superparamagnetic absorption peaks could be observed at room temperature from Fig. 12A. However, such superparamagnetism can be blocked by interparticle dipole interactions because of the fact that the encapsulated particles are in contact with each other, which suggests that the assemblies of Fe(C)

nanoparticles display modified superparamagnetic relaxation at room temperature.<sup>[39]</sup> Whereas, from Fig. 12B, it can be seen that ferromagnetic properties at room temperature appear in the assemblies of Fe(O) nanoparticles because of the increased magnetocrystalline anisotropy that originated from structure defects and the coupling effects between ferromagnetic  $\alpha$ -Fe core and antiferromagnetic oxide ( $\text{Fe}_3\text{O}_4$ ) shell layer in each particles.<sup>[7,12]</sup> As we know, from the HRTEM images of Fig. 11, these Fe(O) nanoparticles are combined with the aligned necklace structure; thus the magnetic moment of these particles couples with that of adjacent larger particles and becomes stable under thermal fluctuation. Therefore it should not be surprising that the assemblies of Fe(O) nanoparticles display ferromagnetic properties at room temperature.

## CONCLUSION

In summary, two types of nickel (Ni) and iron (Fe) nanoparticles, carbon-coated Ni and Fe nanoparticles [Ni(C) and Fe(C)], as well as pure fcc Ni and  $\alpha$ -Fe nanoparticles that coated with oxide layers [Ni(O) and Fe(O)] have been successfully synthesized using modified graphite arc-discharge method. High-resolution transmission electron microscopy (HRTEM), electron diffraction (SAED), and X-ray diffraction (XRD) analyses have been used to characterize these distinct structural morphologies of Ni and Fe nanoparticles. The presence of the majority of carbon-encapsulated fcc Ni and the minority of  $\text{Ni}_3\text{C}$  phases is confirmed in these Ni(C) particles; meanwhile, the evidence of pure Ni nanocrystal coated with NiO layer is observed from these Ni(O) particles. On the other hand, the presence of carbon-encapsulated  $\alpha$ -Fe,  $\gamma$ -Fe, and  $\text{Fe}_3\text{C}$  phases is also identified in those Fe(C) particles; the evidence of pure  $\alpha$ -Fe surrounded by an Fe oxide layer composed of  $\text{Fe}_3\text{O}_4$  is examined from those Fe(O) particles.

Magnetization measurements [ $M(T)$  and  $M(H)$  curves] for the assemblies of Ni nanoparticles indicate that typical ferromagnetic nanocluster glass behavior (collective behavior) has been observed because of stronger ferromagnetic dipole-dipole interaction effects among the assemblies of Ni(O) particles. However, modified superparamagnetic properties at  $T > T_B$  have been found in the assemblies of Ni(C) particles. The blocking temperature,  $T_B$ , is determined to be near 115 K under a certain applied field. Moreover, a gradual decrease in saturation magnetization ( $M_s$ ) is observed, which is attributed to the nanocrystalline nature of the encapsulated particles, coupled with possible carbon solution in Ni nanocrystals.

Mössbauer spectra and hyperfine magnetic fields at room temperature for the assemblies of Fe(C) and

Fe(O) nanoparticles confirm their distinct nanophases that were detected by XRD analysis and HRTEM observation. Especially, the assemblies of Fe(O) nanoparticles exhibit ferromagnetic properties at room temperature because of the stronger interparticle interaction and bigger magnetocrystalline anisotropy effects among these Fe(O) nanoparticles. Furthermore, modified superparamagnetic relaxation is observed in the assemblies of Fe(C) nanoparticles, which is attributed to the nanocrystalline nature of the carbon-coated nanoparticles. As a matter of fact, it is necessary to perform further studies on magnetization measurements and confirm these specific magnetic properties.

# Nanoparticle Suspensions: Phase Behavior

Subramanian Ramakrishnan

Charles F. Zukoski

*Department of Chemical and Biomolecular Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.*

## INTRODUCTION

The assembly of nanoparticles into interesting and useful structures requires the manipulation of particle interactions at the level of a few times the average thermal energy in the system such that the particles can sample an ensemble of states. When allowed to reach equilibrium, colloidal suspensions display phase behavior similar to that seen in molecular systems. The phases observed can be manipulated through alterations in particle density and particle surface chemistry. The richness of the phase diagram can be expanded by introducing anisotropic interactions, or by working with mixtures of particles. Under some conditions, as the strength of attraction or particle concentration is increased, suspensions fall out of equilibrium and glasses or gels are observed. Here we review links that have been recently made between experimental observations and statistical mechanics of suspension phase behavior and suggest where advances will be made in the future.

## BACKGROUND

Colloidal suspensions display phase behavior similar to that of molecular systems.<sup>[1]</sup> Order/disorder transitions are referred to as fluid/crystal transitions. Suspension phases separate out into dilute and concentrated phases in equilibrium with each other, thus displaying gas/fluid transitions. Dense suspensions form glasses. Although in single-component molecular systems, the thermodynamic variables used to describe phase transitions are density, temperature, and pressure, in colloidal systems, the variables are density, temperature, osmotic pressure, and strength of interaction. The last variable distinguishes colloidal suspensions most strongly from molecular systems. For example, because the strength of interaction can be tuned by solution properties, at fixed temperature, one can map out an entire phase diagram.<sup>[1]</sup>

The connection between descriptions of phase transitions in molecular systems and colloidal systems is based on the use of the effective potential where

solvent-mediated interactions are ascribed to the particle interaction energy. The basis of this mapping goes back to McMillan and Mayer,<sup>[2]</sup> and the treatment of colloidal suspensions containing one type of particle as a pseudo-one-component system has been extensively tested. As the range and strength of attractions and repulsions can be varied over an enormous range with colloidal particles, suspensions of nanoparticles offer a unique test bed for treatments of molecular phase behavior.

The phase behavior of repulsive systems has been extensively studied.<sup>[1,3]</sup> For monotonic repulsive interactions, only order/disorder and glass transitions are observed. The effects of attractions have seen less investigations because of the limited number of experimental systems where the strength of attraction can be varied systematically over a range around the average thermal energy in the system. The limited number of model systems where weak attractions can be modulated arises from the ubiquitous nature of van der Waals interactions and the large magnitudes of these attractions at contact for particles half a micron or larger in size. Realization that the strength of van der Waals forces at contact is limited by the granularity of matter (which limits the distance of closest approach) leads one to conclude that nanoparticles will experience only weak attractions. Indeed, this realization has led to startling connections between the phase behavior of nanoparticles or large molecules, and the simulations and analytical models for the phase behavior of particles experiencing weak, short-range attractions.<sup>[4-6]</sup>

Suspensions containing nanoparticles are widely used in the production of ceramics, consumer products, paints and inks, and quantum dots for optical applications. Nanoparticles are used because of their optical properties, the fact that the electronic states of nanoparticles are altered from their states in the bulk, and because they offer unique chemical and physical properties to the suspensions. Of growing interest in the assembly of nanoparticles are the factors that control the states into which nanoparticles assemble. Key examples can be found in biochemistry, where biological systems are controlled by the

interactions and assembly of nanoparticles whereas the structure of globular macromolecules is often determined by X-ray diffraction derived from crystals. Thus advances in the use of nanoparticles and an understanding of complex biological systems will be tied to a greater understanding of particle interactions and how these alter the state of nanoparticle aggregation.

The fact that many systems of interest interact weakly where the strength of attractions lies on the order of a few times the average thermal energy in the system means that many nanoparticle systems sample an ensemble of states and are subject to undergoing phase transitions. Progress toward unraveling the effects of particle shape, anisotropy of interaction, and details of the spatial extent of the particle interaction as well as the kinetics of the self-assembly process is being made through investigations of systems containing nanoparticle spheres with centrosymmetric interactions. In this entry, we focus attention on these advances while returning to more complex systems at the end as an indication of the opportunities for advancement that lead into the future.

As discussed above, a key feature of suspensions as opposed to pure molecular systems lies in the fact that particle interactions can be tuned based on the composition of the continuous phase. Thus, as a result, small changes in solution variables such as pH, ionic type or composition, and polymer concentration or molecular weight or temperature can give rise to dramatic changes in the state of particle aggregation and the mechanical properties of the suspension.<sup>[1,3]</sup> As a specific example, suspensions of silica particles stabilized with octadecyl chains grafted to their surface and suspended in a near-index matching fluid can be crystallized, gelled, made to separate into two liquid phases, or separated into three equilibrium phases, depending on the amount and size of added non-adsorbing polymer.<sup>[7,8]</sup> The literature abounds in the number of examples in which interactions between various kinds of particles are manipulated to place them into useful structures. Although the details of how these structures are achieved will vary with the chemistry of the solid and fluid phases of interest, the underlying physical chemistry of the colloidal state will be common between different materials, thus offering general guidelines on how to achieve the desired properties.

The complexity of describing the interactions and phase behavior of colloidal suspensions is simplified to a certain extent by treating the suspension as an effective one-component system with the interactions between the particles mediated by the solvent and various additives. This allows the extensive literature developed in the field of molecular thermodynamics to be harvested to advantage. Of key concern to these systems is the particle interaction energy. Here we will

focus on particles with hard cores (i.e., the particles cannot interpenetrate) that experience attractions or repulsions.

## HARD SPHERE BEHAVIOR

Hard spheres represent a model system that contains much of the essential physics for describing behavior in dense systems and has been extensively studied in the thermodynamics and statistical mechanics literature.<sup>[1]</sup> The development of suspensions where particles interact very nearly as hard spheres has advanced the understanding of both fields. A significant advancement was made when links between the order/disorder phase transition in charged stabilized latex particles and computer simulations of the interactions of hard spheres were established. Since this initial connection, advances have been made in understanding the microstructure, thermodynamics, and nonequilibrium behavior of dilute and dense systems of hard spheres.

Hard spheres interact with each other only when they touch with an infinite repulsion at contact representing their impenetrable physical volume. Thus entropy changes because of different packings control suspension equilibrium microstructures. Fig. 1 is the plot of the experimentally measured static structure factor for hard sphere suspensions at different volume fractions.<sup>[9]</sup> The structure factor is an equilibrium property that is indicative of the average spacing between the hard sphere particles and can be determined experimentally by scattering techniques. At a volume fraction ( $\phi$ ) of 0.495, suspensions of Brownian hard spheres arrange in an ordered lattice such that their entropy is maximized. The onset of freezing produces a solid at a volume fraction of 0.545 and the crystal can be further compressed to the closest packing density of 0.74. This phenomenon was first discovered through computer simulations and these predictions were first experimentally tested with colloidal suspensions.<sup>[1,10]</sup> Computer simulations demonstrate that face-centered cubic (FCC) microstructures have the lowest energy, but ground-based experiments and those done under microgravity conditions<sup>[11]</sup> (to reduce the effects of density mismatches) indicate that the particles tend to crystallize as randomly stacked hexagonal close-packed (HCP) structures, although an FCC microstructure slowly emerges if the crystals are allowed to age.

Nucleation rates, crystal growth velocities, and induction times for crystallization in hard sphere suspensions have been the subject of numerous computer simulations and experimental studies (commonly used techniques include light scattering and microscopy). Although the equilibrium states of the suspensions are not impacted by the particles being suspended in

**Fig. 1** Static structure  $S(q)$  of hard sphere colloidal suspensions plotted as a function of the dimensionless wave vector  $qR$ . Here  $R$  is the sphere radius and  $q$  is the scattering vector [ $q = 4\pi/\lambda_1 \sin(\theta/2)$ , where  $\lambda_1$  is the wavelength of incident radiation and  $\theta$  is the scattering angle]. The solid lines are Percus–Yevick calculations of  $S(q)$  for hard spheres. The open symbols are the experimental points as measured by small-angle X-ray scattering on the octadecyl-coated hard sphere silica system. The height of the first peak in the structure factor is indicative of the coherence of the first cage of particles and increases with increasing volume fraction. *Source:* From Ref.<sup>[9]</sup>.

a dissipative continuous phase, all rate processes are influenced to greater or lesser degrees by this continuous phase. Accounting for these hydrodynamic interactions is essential in understanding the mechanical behavior in the low to intermediate volume fraction regime.

At elevated volume fractions approaching the glass transition ( $\phi \sim 0.58$ ), suspension mechanics appears dominated by long-time self-diffusivities, which, once scaled on the infinite solution diffusivity, begin to be well described by models dominated by cage dynamics and cooperative rearrangements where hydrodynamic interactions are less important.<sup>[12]</sup> The approach of the glass transition results in the long-time self-diffusivity dropping to zero and a divergence in the zero shear rate suspension viscosity. Thus a complete description of suspension dynamic behavior requires a transition from regions where suspension mechanics is dominated by hydrodynamic interactions at low  $\phi$  to one where cage dynamics dominates at elevated  $\phi$ .<sup>[13]</sup>

Studies on the crystallization of hard spheres show a characteristic maximum in crystal nucleation rate as volume fraction is raised above 0.495 (Fig. 2).<sup>[14]</sup>

**Fig. 2** Comparisons of predicted (solid line) and literature values of hard sphere nucleation rates as a function of particle volume fraction. The calculations are based on the kinetic model of Dixit and Zukoski. A maximum in the nucleation rate is observed at a volume fraction of 0.56. This is attributed to the competing effects of reduced particle diffusion and the increase in the thermodynamic driving force at elevated volume fractions. *Source:* From Ref.<sup>[14]</sup>.

To understand these observations, two different models have been developed: 1) the application of classical nucleation theory, which employs the combination of thermodynamic and kinetic descriptions that account for changes in self-diffusivity with volume fraction;<sup>[15]</sup> and 2) a completely kinetic description of nucleation,<sup>[16]</sup> which differs significantly from classical theories by making no reference to the solid–liquid surface tension. Both of the approaches predict a maximum in nucleation rate at  $\phi \sim 0.56$ , as measured by experiments. In the classical model, just above  $\phi = 0.495$ , the thermodynamic driving force increases rapidly with volume fraction. The flux of particles to a cluster surface is determined by self-diffusion. As self-diffusivities decrease rapidly as  $\phi$  approaches the glass transition near 0.58, the rate flux of particles to the nucleus surface drops to zero with increasing volume fraction. The competition between these two effects results in a maximum in nucleation rate. In the kinetic model, the flux of particles to a cluster surface is controlled by gradient diffusion. Just above  $\phi = 0.495$ , the flux of particles to a cluster surface increases simply because the bulk concentration increases, whereas the concentration at the cluster surface changes slowly. However, as  $\phi$  further increases, the concentration difference between the bulk and the surface decreases, with the nucleation rate passing through a maximum. In this model, the flux to the surface is governed by

gradient diffusion that has a much weaker dependence on volume fraction than self-diffusivity. A difference in the predictions of these two models lies in the volume fraction dependence of the size of a critical nucleus. Although the kinetic model predicts a minimum in critical nucleus size with increasing volume fraction, the classical approach predicts a monotonic decrease in critical cluster size with increasing volume fraction. There are two experimental data sets reporting volume fraction dependence of the critical nucleus size. In one, the critical nucleus size monotonically decreases, whereas in the second, a minimum in critical nucleus size is reported. Consequently, the differences in these descriptions of hard sphere crystal nucleation will require further experimental and modeling work.

### SOFT REPULSIONS

The addition of “soft” or long-range repulsions to colloidal particles can overcome the attractive van der Waals attraction to render them stable against aggregation. The most common method of electrostatic stabilization is the adsorption of charged species or dissociation of bound surface groups. The range of electrostatic repulsion is characterized by the Debye length ( $\kappa^{-1}$ ) and can be regulated by adding salt to the system.<sup>[1]</sup> The Debye length scales inversely with the square root of the ionic strength of the suspension. Charged particles exhibit an order/disorder phase transition (Fig. 3)<sup>[17]</sup> similar to those seen in hard

**Fig. 3** Optical visualization of 229-nm (diameter) latex particle suspensions at a volume fraction of 0.53 at rest in a transparent shear cell and the resulting small-angle neutron scattering result. The observed iridescence is because of the crystalline packing of the latex particles. The small-angle neutron scattering pattern for the above suspension is given in the form of an isointensity plot where the highest intensity is represented by the lightest color. The spots are indicative of a microstructure with long-range orientational order consisting of HCP planes. *Source:* From Ref.<sup>[17]</sup>.

sphere systems, but at quite low volume fractions. The phase transition can be achieved by two means: by increasing the particle volume fraction, or by increasing the range of repulsion (decreasing the ionic strength). The FCC-ordered phase prevails at higher concentrations, or with shorter-range repulsions. As the range of repulsion is increased (say, by the removal of screening species in solution, thereby increasing the Debye length), a lower-density, body-centered cubic (BCC) packing forms the lowest free-energy ordered phase. BCC and FCC phases coexist under certain conditions in charged colloids as observed by the experiments of Chaikin et al.<sup>[18]</sup> The BCC–FCC–liquid triple point occurs when the interparticle spacing is 4.9 times the Debye length.

The equilibrium thermodynamics of the phase transitions in electrostatically stabilized suspensions is well captured by treating the particles as effective hard spheres where the effective hard sphere diameter is determined by the range and strength of the repulsion through self-consistent ways. More sophisticated approaches use one-component plasma and mean spherical approximation solutions of the pair distribution function or perturbation theory predictions of the suspension osmotic pressure and location of the phase boundaries (Fig. 4).<sup>[17,19,20]</sup> These models agree well with experimental observations when the particle surface charge is taken as the adjustable parameter.

**Fig. 4** Osmotic pressure as a function of volume fraction for suspensions of charged 35-nm (diameter) latex particles. The open circles represent the liquid phase (or the disordered state), whereas the solid phase of the suspension is shown in closed circles. The solid line is the prediction of perturbation theory and the dashed line is that of the cell model. The latex particles are highly charged and undergo a fluid/crystal transition at a low volume fraction of 0.14. *Source:* From Ref.<sup>[17]</sup>.

Good agreement is found for osmotic pressure through the disorder/order phase transition using these models.<sup>[18–21]</sup>

In very low ionic strength media, the ions that have dissociated from the particles provide a significant addition to screening of the electrostatic repulsions. Consequently, over extremely wide ranges of volume fractions, suspensions can sit on the edge of order/disorder transitions. Each time the particle concentration is increased, the resulting addition of counterions decreases the range of the interparticle repulsion such that the effective volume fraction lies below 0.495 and the ordered phase remains unstable relative to the liquid phase.<sup>[22,23]</sup>

Encouraged by the accuracy of the effective hard sphere models in capturing the location of the phase boundary, attempts have been made to describe the kinetics of crystallization in charged sphere systems. A one-to-one mapping is complicated by different interpretations of how the diffusivity of the particle changes with the strength of repulsion. Recent experiments, simulations, and modeling efforts reveal the weaknesses of this approach. The location of the maximum in the nucleation rate, which occurs at a  $\phi$  of 0.56 in hard spheres, depends sensitively on the strength and range of repulsions and is often not observed experimentally. In addition, depending on the strength and range of repulsions, drastically different nucleation rates are predicted at similar supersaturations, suggesting that a simple mapping of particle charge and Debye parameter into an effective particle size does not capture the subtleties of the kinetics of phase changes in systems with soft repulsions.<sup>[24,25]</sup>

## WEAKLY ATTRACTIVE SUSPENSIONS

Investigations of the phase behavior of weakly attractive suspensions have seen relatively less work due primarily to a lack of model experimental systems, and/or methods independently characterizing the strength and range of the attractive forces. In the classical colloids literature, the goal has long been to control the state of aggregation that results when van der Waals attractions overwhelm repulsive forces. Van der Waals attractive potentials have contact values of  $\sim AR/12\delta$ , where  $A \sim 1-10kT$  is the material-dependent Hamaker coefficient,  $R$  is the sphere radius,  $kT$  is the product of Boltzmann's constant and the absolute temperature, and  $\delta$  is the distance of closest separation. Values for  $\delta$  will depend on the material used and the morphology of the particles. However, several studies have suggested that  $\delta \sim 0.65$  nm represents a minimum for liquid and molecularly smooth surfaces.<sup>[26]</sup> The study of the phase behavior of attractive colloidal systems has been

limited by the large magnitude of this contact force when  $R$  is larger than  $\sim 50$  nm. Up to a few years ago, most studies of attractive colloidal systems were based on understanding the rates of irreversible aggregation and the morphologies of the resulting aggregates.

Progress in controlling the magnitude of the attractive forces has been made by driving  $A$  to very small values by matching the index of refraction of the particle to that of the solvent, but even here, the number of model systems remains very small. More recently, there has been the realization that when  $R$  is small, the van der Waals attractions are small and the strength of attraction can be modulated in the range of a few  $kT$ .<sup>[6]</sup> Under these conditions, aggregation is reversible and suspensions can undergo phase transitions. This opens the door for connecting discussions of the thermodynamics of solutions and solute/solvent interactions with the language of suspensions, not surprisingly demonstrating the smooth transition in physical behavior as particle size grows from the molecular to the colloidal.

The two best studied systems of attractive colloidal suspensions are based on suppressing van der Waals attractions by index matching the particles while further suppressing attractions by coating the particles with short hydrocarbon chains that act as steric stabilizers. Silica particles coated with octadecyl hydrocarbon chains or trimethoxysilane materials, and polymethylmethacrylate particles stabilized by a layer of polyhydroxyesteric acid suspended in a number of solvents have been used as model hard sphere systems. Attractions are generated in one of three ways. The first two involve changing the state of the coating/solvent interactions by altering the composition of the continuous phase, or by changing suspension temperature. Both methods drive the unfavorable stabilizing hair/solvent interactions, resulting in attractive interactions.

The third method of altering the strength of attraction involves addition of a nonadsorbing polymer. In a solution containing a nonadsorbing polymer, when two colloidal particles approach each other, the polymer is excluded from the gap between the particles. This exclusion leads to an imbalance in osmotic pressure of the polymer solution between the gap and in bulk solution. The imbalance drives the particles together and the resulting attraction is called "depletion" attraction. The strength of attraction is proportional to the polymer concentration, and the range of attraction is determined by the size ratio of polymer to colloid.<sup>[27,28]</sup> Depletion systems have the added advantage of providing a means of independently controlling both the strength and the range of attraction. The disadvantage of using depletion interactions as models of weakly attractive colloidal

suspensions is that the suspension becomes a three-component system and the application of standard pseudo-one-component interaction potentials fails to describe the suspension thermodynamic behavior. Nevertheless, a great deal has been learned through experimental and modeling efforts focusing on depletion systems.

A third system for studying the phase behavior of weakly attractive suspensions involves native nanoparticles. As mentioned above, for these systems, van der Waals attractions are sufficiently small that suspensions become thermodynamically stable without steric coatings or index matching. The strength of the attraction can be modulated through changes in temperature, pH, ionic strength, or concentration of the nonadsorbing polymer.

For all of these systems, one of the keys to understanding phase behavior lies in developing methods to characterize the strength and range of the attractive interaction. One of the advantages of the depletion system is that analytical models are available for characterizing the strength of attraction in the limit of dilute particles. As the particle volume fraction increases, these models fail quantitatively and, in some cases, qualitatively.<sup>[7]</sup> However, the effects of the control variables (i.e., the concentration and molecular weight of the polymer) are captured in these models. Unfortunately, for the development of model systems, there are no a priori methods of knowing how changes in control parameters alter the strength or range of attraction in the octadecyl silica system as solvent composition or temperature is altered, or in nanoparticle suspensions with changes in continuous phase composition. However, it is the sensitivity of the interactions to the chemistry of the particles and solvent that offers the richness of the observed behavior and technological applications of many colloidal systems. As a result, there is growing attention being placed on developing methods for characterizing the effects of continuous

phase composition on the strength of attraction of nanoparticles.

Attractive systems are expected to show disorder/order as well as gas/liquid phase transitions. In the colloidal field, the first models to capture this were those on depletion systems as described by Gast, Hall, and Russel,<sup>[28]</sup> where they demonstrated that when the range of the attraction was on the order of  $0.3R$  or larger, a phase diagram similar to that expected for molecules would be observed. This phase diagram in a space where the inverse of the dimensionless strength of attraction is plotted as a function of particle concentration has a critical point and a triple point expected for systems showing liquid/liquid and liquid/solid phases. As the range of the attraction is reduced, the critical point drops below the triple point and there are only two stable phases predicted: fluids and crystals. Despite having a finite size potential and an attractive potential, thermodynamically stable gas/liquid transition is lost. The critical point lies below the fluid/solid phase boundary. The spinodal for this fluid/fluid phase boundary can be probed when the system is quenched rapidly, at which point the system spontaneously decomposes into a dilute and a concentrated colloidal suspension. A common interaction potential used to describe attractions is the Yukawa potential. The interaction energy  $u(r)$  for Yukawa systems is given by:

$$u(r) = \left\{ \begin{array}{ll} \infty & r < 2R \\ -\frac{\varepsilon}{kT} \frac{e^{(R/\lambda)(1-r/2R)}}{r/2R} & r \geq 2R \end{array} \right\}$$

where  $\lambda/R$  is the range of attraction and  $\varepsilon/kT$  is the strength of attraction. The phase diagram of Yukawa fluids is given in Fig. 5<sup>[29]</sup> for different values of  $\lambda/R$  and, as mentioned above, the critical point begins to drop below the fluid/solid phase boundary for  $\lambda/R = 0.29$ .

**Fig. 5** Phase diagram calculations of the Yukawa potential using the perturbation theory for different ranges of attraction  $\lambda/R$ . When  $\lambda/R < 0.29$  (small ranges of attraction), the critical point begins to move below the fluid/solid phase boundary. The phase diagram of  $\lambda/R = 0.23$  is what is typically seen in a number of protein solutions and in solutions of inorganic nanoparticles. Source: From Ref.<sup>[29]</sup>.

Understanding of the influence of the extent of the attractive well on phase behavior was advanced by understanding the phase behavior of fullerenes ( $C_{60}$ ),<sup>[4]</sup> where detailed calculations showed that no liquid phase would be stable, and protein suspensions, where the existence of a metastable fluid/fluid phase transition was revealed.<sup>[30,31]</sup>

In the limit of very-short-range attractions between particles, the simplest model for the interparticle interaction is the adhesive hard sphere (AHS) potential.<sup>[1]</sup> The AHS potential is a two-parameter potential with  $\Gamma_{\text{AHS}}$  characterizing the strength of interactions and  $R$  the particle radius. Extensive simulations and density functional theory calculations have identified the phase boundary associated with the liquid/liquid transition, percolation, and liquid/solid transition. However, the AHS system contains certain limitations, and predictions of the phase boundary for all values of  $\Gamma_{\text{AHS}}$  are not possible.<sup>[32]</sup> However, as the range of attraction is decreased, the AHS, square well, and Yukawa interactions begin to converge if normalized by a common measure of the strength of attraction.<sup>[6]</sup> The general phase diagram resembles that of a very-short-ranged square well fluid or Yukawa fluid, with the liquid/liquid phase transition lying below the liquid/solid phase transition. Experimentally, this is seen in a number of protein solutions and in solutions of inorganic nanoparticles.

The utility of the square well interaction models in the limit of very narrow wells (i.e., approaching the AHS potential) for describing the thermodynamics of nanoparticle suspensions (proteins and inorganic silicotungstic acid) and in locating crystallization conditions has been repeatedly demonstrated.<sup>[6,23]</sup> Because of the inherent complexity in characterizing all the interaction forces (electrostatic, van der Waals, depletion, solvation and structural forces, hydrogen bonding, and salt bridges) between two nanoparticles in suspension, indirect measures of the overall interactions must be used. The experimental variables suggested for characterizing the interactions have been the inverse osmotic compressibility  $(d\Pi/d\rho)_{\text{sat}}$  at the solubility point, the second virial coefficient ( $B_2$ ), the relative solution viscosity ( $\eta/\eta_c$ ), and the solubility  $\phi_{\text{sat}}$ . Various techniques have been developed for extracting these parameters for model-free representations of phase behavior that become important for testing different interaction potentials. These studies demonstrated the universal nature of the solubility curve when the measured second virial coefficient ( $B_2/16\pi R^3/3$ ) characterizing pair interactions was plotted against the solubility  $\phi_{\text{sat}}$  (Fig. 6).<sup>[23]</sup> Agreement between theory and experiment is excellent. These results suggest that the crystallization boundaries of nanoparticle suspensions are relatively insensitive to the details of the interaction potential and that if two

**Fig. 6** Measured second virial coefficients of STA (solid squares) in different background salt concentrations compared with data on a number of proteins (lysozyme; Bovine Pancreatic Trypsin Inhibitor (BPTI) open circles) in different buffer solutions. The second virial coefficients are non-dimensionalized with the hard sphere value and plotted against the solubility (volume fraction  $\phi_{\text{sat}}$ ) of the respective species. The solid lines are calculations of the attractive Yukawa potential with two different ranges of attractions  $\lambda/R$  of 0.14 and 0.28. The values of 0.14 and 0.28 indicate that attractions between the particles are short-ranged. The experimental data for silicotungstic acid (STA) (at high salt concentrations) and proteins collapse within the narrow range of attractions, which are only a fraction of the particle diameter. The collapse also indicates that proteins and STA are thermodynamically similar; if two suspensions have the same  $B_2$ , then they have the same solubility. This plot also provides an opportunity to extract interaction potential parameters for a given experimental system in a model-independent manner. *Source:* From Ref.<sup>[23]</sup>

suspensions have the same  $B_2/(16\pi R^3/3)$ , then they will have the same solubility. These results have applications in the location of solution conditions giving rise to protein crystals.

Rates of nanoparticle crystallization have been the subject of controversy. In the first place, these crystals often nucleate slowly (Fig. 7).<sup>[33]</sup> Without this being the case, it would not be possible to probe the existence of the metastable liquid/liquid spinodal. Numerous studies have applied classical nucleation theory to extract solid/liquid surface tensions that are in broad agreement with experiments. Kulkarni and Zukoski<sup>[34]</sup> demonstrated that these surface tensions were in good agreement with predictions based on pair interaction models that are capable of predicting the location of the solubility boundary. The influence of the location of metastable liquid/liquid spinodal relative to the solubility curve on the rate of nucleation has been explored. Simulations and analytical models indicate

**Fig. 7** Lysozyme solution in 0.6 M sodium phosphate buffer, pH 7.0, at an initial concentration of 100 mg/mL at 10°C. The solution starts fluidlike (A) and gels over a period of 1 week (B). Crystallites appear to nucleate within the gel (C), which grow (D) and finally form large ordered crystals (E), in equilibrium with a fluid of low protein concentration. A detailed study of the solubility and crystal nucleation kinetics revealed that these phenomena are largely controlled by the strength of attraction and that if two proteins have the same  $B_2$ , then they have the same kinetics of nucleation. Source: From Ref.<sup>[33]</sup>.

that the enhanced compressibility of the suspension near the critical point will greatly enhance the rate of crystal nucleation.<sup>[35,36]</sup> Thus modeling efforts suggest that high-quality crystals can be grown near the critical point of the phase boundary. However, experimental verifications of these observations are difficult because of the high concentrations of proteins at the critical point ( $\sim 400$  mg/mL). There have been a number of experimental studies in measuring the nucleation rates of proteins under a variety of conditions.<sup>[37–39]</sup> Kinetic models of nucleation consistently overpredict experimental estimates. Dixit and Zukoski<sup>[36]</sup> attribute this to the use of simple centrosymmetric potentials in describing the kinetics of nucleation. More sophisticated patchy interactions that better approximate protein interactions with resulting modifications in the nucleation mechanism might provide an answer.

Connections between absolute rates of crystal nucleation and theoretical predictions have led to some controversies. Although many studies confirm that classical nucleation theory captures the supersaturation dependence on the nucleation rate, the absolute rate is very poorly described by these models. As with molecular systems, measuring the rate of nucleation and linking what can be measured to what is predicted by extant models remain at the heart of

this controversy. A significant conclusion is that we have a poor understanding of what it is that controls the rates of crystal formation in supersaturated nanoparticle suspensions.<sup>[37–39]</sup>

As mentioned earlier, control over the strength and range of attractions can be achieved by the addition of non-adsorbing polymers to colloidal suspensions. The important variables in these systems are the polymer concentration ( $c_p$ ), which determines the strength of attraction, and the size ratio of polymer to colloid ( $R_g/R$ ), which determines the range of attraction. Recent experiments performed on silica<sup>[7,8]</sup> and polymethylmethacrylate model systems<sup>[27,40]</sup> characterize phase behavior as a function of particle volume fraction,  $R_g/R$  and  $c_p$ . In addition, osmotic compressibility and microstructures have been measured for the octadecylsilica suspensions suspended in decalin in the presence of polystyrene over a wide range of molecular weights.<sup>[8,9]</sup> A variety of phases are observed depending on the value of  $R_g/R$  and polymer concentration (Fig. 8).<sup>[8]</sup> Even though standard theories could predict the  $R_g/R$  value of 0.3 below which crystallization occurred, the predictions of solution miscibility with

**Fig. 8** Phase diagram of 100-nm (diameter) octadecanol-coated silica particles (inset figure) suspended in decalin in the presence of nonadsorbing polystyrene. The molecular weight of polystyrene is varied to achieve eight different size ratios of polymer to colloid ( $R_g/R$ ) and the phase diagram determined for each  $R_g/R$ . Open symbols represent gel boundaries for  $R_g/R = 0.025$  (circles), 0.061 (squares), and 0.09 (diamonds). Filled symbols represent binodals for fluid–solid [ $R_g/R = 0.243$  (circles)] and fluid–fluid [ $R_g/R = 0.525$  (squares), 0.802 (diamonds), 1.10 (triangles), and 1.74 (reverse triangles)] phase separation. The solid lines (phase boundaries) are drawn to guide the eye. The colloidal silica suspensions are stable below the solid line. As more polymer is added and as one crosses the phase boundary, phase separation/gelation occurs depending on  $R_g/R$ . Source: From Ref.<sup>[8]</sup>.

$R_g/R$  at fixed colloid volume fraction are in direct contradiction to what is observed experimentally. Experimentally, solution miscibility improves as  $R_g/R$  increases at fixed  $\phi$ , whereas standard theories predict the opposite trend. Comparisons with recently developed Polymer Reference Interaction Site Model (PRISM)<sup>[41,42]</sup> led to qualitative agreements with experimental data. PRISM is a three-component model (particles, polymer, and solvent) that treats the polymers as flexible chains of monomer units that have both conformational and translational entropy, which needs to be taken into account in describing the thermodynamics of colloid–polymer mixtures. The theory takes into account particle–particle, polymer–polymer, and polymer–particle interactions and qualitatively captures the right trends in phase behavior.

In addition to crystallization and liquid–liquid phase separation, suspensions experiencing very-short-range attractions are observed to gel when  $R_g/R < 0.1$ .<sup>[7,8]</sup> Gelation is a phenomenon in which particles aggregate, forming a space-spanning structure that has a finite elastic modulus and yield stress. As mentioned before, gelation is a kinetic phenomenon and hence cannot be described by standard thermodynamic models. A dynamic model, which captures the arrest of particles with increasing polymer concentration and hence predicts the gelation boundary, is needed. The recently developed mode coupling theory (MCT), combined with PRISM (for colloid polymer mixtures), is capable of predicting gel boundaries.<sup>[43,44]</sup> MCT views the gel as particles trapped by a network of bonds that hinders the particle motion, resulting in a nonergodic state. Thus gelation (according to MCT) is caused by formation of long-lived cages. Gelation occurs at the point where the long-range self-diffusivity drops to zero. MCT is capable of predicting density autocorrelation functions as are measured by dynamic light scattering and has been applied to hard sphere systems where it captures many of the details of the colloidal hard sphere glass transition. It has also been applied to attractive suspensions where the gel line and dependence on  $R_g/R$  have been explored and the theory qualitatively captures the observed trends, particularly for  $\phi$  above 0.2.

MCT is also successful in predicting another interesting phenomenon observed when increasing amounts of polymer are added to glassy hard sphere suspensions (i.e.,  $\phi > 0.58$ ). The experimental observation is that, on addition of polymer (or when turning on a weak attraction), particles, on average, move closer together, but the coherence of the first shell of particles is disrupted. The result is that particles that are trapped by their nearest neighbors in the glassy state are now free to diffuse and the glass melts. However, on adding more polymer, the coherence of the first shell of particles is reestablished, the ability of particles to

diffuse freely is diminished, and, with a sufficiently large polymer concentration, the suspensions gel. MCT is able to explain the observed phenomena based on the “cage” effect.<sup>[44]</sup> Thus, by introducing attractions in the system, one can go from glasses to liquids to gels. Recent studies on the dynamics of these systems demonstrate that the internal dynamics of gels is different from those of glasses. In particular, in glasses, the root mean square (RMS) displacement scales on the particle diameter, whereas in the gels, the RMS displacement of the particles scales on the localization length that is determined by the extent of the interparticle attraction and the particle volume fraction.

Of particular interest is the suggestion that suspensions of particles experiencing extents of attraction less than about  $0.1R$  will not display thermodynamically stable phase transitions. Instead, with increasing volume fraction or with increasing strength of attraction, these suspensions gel or form irreversible aggregates. Thus the fractal flocs formed in irreversible aggregation (such as when salt is added to dilute latex suspensions) may result from short-range attractions rather than from strong attractions. This phenomenon can be circumvented in some cases. For example, if uniform suspensions are made up below the gel line in depletion systems and the particles are allowed to settle, crystals will form even when  $R_g/R < 0.1$ . This observation indicates that understanding of the dynamics of attractive colloidal suspensions remains a fruitful area of research.

## CONCLUSION

Suspensions of nanoparticles display a wide range of phase behavior—glasses, gels, crystals, and even separation into two liquid phases. The key variables that control the phase behavior are the range and strength of particle interactions. These variables can, in turn, be tuned in a number of different ways: by adding salt and polymer, by changing temperature, etc. Progress has been made in understanding the physics behind the phase separation process by working with well-characterized suspensions where the particles are spherical and interact with centrosymmetric potentials. This work has provided a basis for understanding the effects of particle anisotropy of interactions on phase behavior and the kinetics of the assembly process. As we look into the future, the challenges lie in extending the concepts and tools developed on simple systems to systems that are more complex, including anisotropic (rods and biological systems such as DNA) particles, and to mixtures of different kinds of particles (e.g., rods and spheres). Questions that must be answered include how interactions in such complex systems can be tuned to make them assemble into

useful structures. For example, most studies of order/disorder phase transitions have focused on systems that produce cubic crystals. However, proteins are known to crystallize into a wealth of space groups. Is it possible to engineer the space group into which particles assemble by designing particle shape or surface chemistry? Similar questions can be asked about gels: Is it possible to alter the nature of the particle interactions to create gels with the desired volume fraction and flow properties by engineering particle size and shape? Answering these questions requires advances in descriptions of phase behavior and kinetics of phase transitions as well as new synthetic approaches that result in particles of controlled surface chemistry. As an indication of the opportunities that are developing, we conclude this section by giving below a few examples involving systems with more complex interactions that lead to interesting phase behavior.

Tohver et al.<sup>[45,46]</sup> recently described a new mechanism for stabilizing colloidal particles. They noticed that when small amounts of charged nanoparticles were added to a gelled colloidal microsphere suspension (gelation occurs because of the attractive van der Waals forces), the gel melts and the suspension flows. However, increasing the amount of the nanoparticles flocculates the suspension. The initial stabilization mechanism is attributed to the segregation of the nanospheres on the surface of the microsphere colloidal particles because of their highly repulsive coulombic interactions in solution. This haloing effect results in a dense cloud of nanoparticles around each large particle such that when two large particles approach, they feel repulsive osmotic forces similar to that developed by overlapping double layers. This reduces the long-range van der Waals interactions between the colloidal spheres, thereby stabilizing the suspension. Increasing the amount of the nanospheres increases depletion attractions between spheres, thereby flocculating them at higher concentrations.

Polyelectrolytes (DNA, F-actin, and viruses) are complex molecules (in size and shape) that have a charge distribution on their surface, which is quite different from the uniform charge distribution on spheres that we dealt with in “Weakly Attractive Suspensions.” In solution, charged polyelectrolytes repel each other (DNA in water) in the presence of monovalent ions, which is what is expected because like charges always repel. However, in the presence of multivalent ions, like charge attractions have been observed in a number of polyelectrolyte systems. Butler et al.<sup>[47]</sup> studied polyelectrolyte condensation using anionic rodlike M13 virus and a series of “tunable” divalent cations with the aim of understanding the role of ion multivalence and geometry in the phase change process. Using the experimental system, they were able to construct a multivalent ion–polyelectrolyte phase

diagram and developed an experimentally motivated criterion for like-charge attraction based on the ion valence, ion size, and the Gouy–Chapman length. The phase diagram defines regions between disordered rods and regions where the rods have condensed into an aligned structure. This phase behavior is of interest because it demonstrates the ability of multivalent ions to produce a lowest free-energy state for electrostatically repulsive rods and provides insights into novel methods for organizing anisotropic particles.

Adams et al.<sup>[48]</sup> describe a rich phase diagram for mixtures of colloidal rods (filamentous bacteriophage fd virus) and spheres (polystyrene latex, polyethylene oxide, and polyethylene glycol). The phases they observed include: bulk demixing into rod-rich and rod-poor phases, and microphase separation into a variety of morphologies. One microphase consists of layers of rods alternating with layers of spheres; in another microphase, the spheres reversibly assemble into columns, which in turn pack into a crystalline array. Using the concepts of depletion attractions, they were able to predict the majority of the experimentally observed phases. The spheres and rods were modeled as hard objects, and the work done on the phase behavior of just pure hard spheres and hard rods aided in the development of a theory for the mixtures. However, the simple theory is unable to predict the existence of the columnar phase—the description of which remains a theoretical challenge.

The above cases were chosen to exemplify opportunities that exist for manipulating the states of aggregation of colloidal suspensions. Clearly, by working with strengths of attraction and repulsion on the order of a few times the average thermal energy of the system and by manipulating the degree of anisotropy of particle interactions, a wide range of structures can be built. This field will continue to require attention as the assembly of nanostructures continues to be of scientific and technological significance.

## INTRODUCTION

A variety of nanoparticles (NPs) have been synthesized using the cage protein apoferritin and *Listeria* ferritin. Metal oxide NPs (Co, Ni, and Cr) and semiconductor NPs (CdSe and ZnSe) were described to be made by using apoferritin with a 7 nm diameter inner cavity. The synthesized NPs show small-size dispersion, which is ideal for use as a nanoelectronic device component. There are many kinds of protein cages suitable as biotemplates, and researchers have been searching for new biotemplates with an inner cavity. Larger or smaller cage-shaped proteins have been used as biotemplates and the mechanism of biomineralization has been studied. Recent works concerning the synthesis of NPs using supramolecular protein cages are reviewed. The applications of NPs made using biotemplates are also introduced.

## BACKGROUND

Nanotechnology includes a very wide range of research fields, ranging from biology to semiconductor engineering. This emerging technology has the potential to answer many difficult, so far unsolved problems by means of nanometric approaches. There are many materials being used in nanotechnology, but it is not an exaggeration to say that NPs are the fundamental component of nanotechnology. Various NPs are used or expected to be used in many applications such as magnetic recording materials, catalytic materials, fluorescent markers, drug delivery systems, and quantum electronics. Especially, conductive or semiconductor NPs are anticipated to be good quantum electronics device components. They are also used to make the nanostructures using bottom-up technology.

There are a number of methods for making NPs and they are classified into three categories: physical methods, chemical methods, and biological methods. Physical methods include grinding, laser abrasion, and ion injection. Chemical methods include the sol-gel method and the tri-*n*-octylphosphine oxide (TOPO) method. Biological methods include using proteins and biomineralization using a nanometric inner cavity

or outer surface of biosupramolecules for synthesizing NPs. There are advantages and disadvantages in each of the three methods, and researchers synthesize NPs using the method that most closely matches their needs.

Miniaturization of electronic device components to nanoscale dimensions is one of the most intensively studied research areas in nanotechnology. It is clear that the conventional fine-process technology based on photolithography cannot produce nanometer-size structures. To overcome this challenging problem, Yamashita et al. proposed a method utilizing the NPs or nanowires (NWs) synthesized using a biotemplate. The biotemplate technique is one of the most suitable methods to synthesize uniform NPs and NWs, when the inner cavity of a protein shell is used as a spatially restricted synthesis chamber. Because electron energy levels are strongly dependent on the NP or NW size, the homogeneity in size is ideal for an electronics device component. This is also true for photoluminescence. Biological methods offering uniform particle sizes are, therefore, well suited for synthesizing NPs for nanoelectronic devices.

NPs synthesis using the cavities of biotemplate molecules is currently a hot research area. Researchers are synthesizing a variety of uniform, high-quality NPs using several kinds of cage-shaped proteins such as CCMV, *Listeria* ferritin, DPS, HSP, and ferritin. Yamashita group mainly uses the cage-shaped protein, ferritin, to synthesize metal and semiconductor NPs and is elucidating the biomineralization mechanism of NPs in the cavity. In this entry, the recent proceedings and the latest research results of NP synthesis using a biotemplate are described.

## SYNTHESIS OF METAL COMPLEXES AND METAL OXIDE MATERIAL NPs IN THE APOFERRITIN PROTEIN

Ferritin is a major cellular iron-storage protein. Ferritin protein exists widely in many biological species and plays an important role in the homeostasis of ferrous

**Fig. 1** Schematic drawing of the cage-shaped protein—apoferritin without core and ferritin with core.

ion levels in the body. The ferrihydrite cores in ferritin can be removed fairly easily by dialysis against a solution containing a reducing agent.<sup>[1]</sup> Ferritin without a ferrihydrite core is called apoferritin. Fig. 1 shows schematic drawing of the apoferritin molecule. The outer and inner diameters are approximately 12 and 7 nm, respectively. There are narrow channels along the threefold axis connecting the cavity and outside, through which iron ions pass into the cavity. The native apoferritin consists of 24 polypeptide subunits, and there are two types of subunits, the light-chain subunit (L-subunit) and the heavy-chain subunit (H-subunit). H-subunit has a ferroxidase center that oxidizes ferrous iron to ferric iron. L-subunits play an important role in the self-assembly of ferritin molecules into a two-dimensional (2-D) crystal at the air–water interface via a salt-bridge interaction.

There are many previous works describing how metal complexes and inorganic materials are sequestered in the native apoferritin cavity.<sup>[2–12]</sup> Okuda et al.<sup>[7]</sup> also fabricated nickel hydroxide NPs in the horse spleen apoferritin (HsAFr) cavity by incubating ammonium nickel sulfate solution with HsAFr. The Ni core was imaged by transmission electron microscopy (TEM) after staining with 1% aurothioglucose. Aurothioglucose is too big to go through the channels and cannot stain the cavity, which makes it possible to investigate core formation. The optimized conditions for nickel core formation were 0.3 mg/ml HsAFr and 5 mM ammonium nickel sulfate in water containing dissolved carbon dioxide. The pH was maintained at pH 8.6 using two buffer solutions of 4-(2-hydroxyethyl) piperazine-1-ethanesulfonic acid) and 3-(Cyclohexylamino)-2-hydroxy-1-propanesulfonic acid (HEPES-CAPSO) with 20 mM ammonia. Ammonium ions were supplied to suppress bulk precipitation. Interestingly, the nickel oxide core did not form in a degassed reaction solution. It was also shown that the absence of carbonate ions leads to no nickel hydroxide core formation. The existence of carbonate ions is indispensable for nickel hydroxide core formation. The core formation ratio (CFR) of nickel hydroxide in the apoferritin cavity is nearly 100% (Fig. 2). The CFR was calculated using TEM images, dividing the

**Fig. 2** Typical TEM images of cobalt, nickel, and chromium NPs synthesized in the HsAFr cavity. NPs were observed by TEM with 1% aurothioglucose staining. The TEM image negatively stained shows many dots surrounded by ferritin protein shells. As aurothioglucose is too big to penetrate through narrow channels, the dots are attributed to individual metal cores.

number of ferritins with core by the total number of ferritin molecules. The synthesized nickel complexes NPs were characterized by energy dispersive X-ray spectrometry (EDS) and two EDS peaks specific to nickel (7.5 keV and 0.9 keV) were observed. Judging from the synthesis conditions and EDS measurements, it was concluded that the core is nickel hydroxide.

Okuda et al.<sup>[7]</sup> also synthesized chromium NPs in the HsAFr cavity. Chromium cores formed in about 80% of apoferritin cavities (Fig. 2). The formation of chromium cores needed carbonated ions or carbon dioxide bubbling in the reaction solution, as is the case for nickel hydroxide NP synthesis. The role of carbonate ions in the chemistry of the core formation reaction remains unknown, but they may coordinate nickel and chromium ions and stabilize them in the bulk solution or accelerate the hydroxylation in the apoferritin cavity compared to the bulk solution outside.

The above experiments used native ferritin molecules. Native apoferritin is a heteroassembly of L-subunit and H-subunits. The stoichiometry of L- and H-subunits varies from molecule to molecule, which is undesirable from an application point of view. Therefore, Takeda et al. produced recombinant apoferritin and investigated the difference between native ferritin and homogeneous recombinant ferritin,<sup>[13]</sup> and Iwahori produced several kinds of recombinant ferritins. In this entry, two important recombinant ferritins will be introduced.

1. Fer-0 recombinant ferritin: all L-subunits.
2. Fer-8 recombinant ferritin: all L-subunits lacking the first eight amino acids.

Nickel core formation by Fer-8 was studied. 0.3 mg/ml recombinant apoferritin Fer-8 was incubated in the

reaction solution with 5 mM ammonia nickel sulfate, 150 mM HEPES, CAPSO, and 20 mM ammonia water around pH 8.7 for 24 hr at room temperature. After the core formation process, the solution was centrifuged at low speed to discard precipitates and the supernatant was observed by TEM. TEM image revealed that nearly 100% of Fer-8 formed nickel cores. A similar result was obtained with HsAFr. Nickel hydroxide cores can be formed in the native and recombinant ferritin and the nickel hydroxide core formation needs carbonate ions.

Douglas and Stark<sup>[6]</sup> synthesized cobalt oxide NPs in the HsAFr cavity and *Listeria* ferritin by oxidizing Co(II) with H<sub>2</sub>O<sub>2</sub> while the reaction solution was dynamically titrated at pH 8.5 using NaOH. Tsukamoto et al. also successfully formed a metal complex core using cobalt oxide (Co<sub>3</sub>O<sub>4</sub>) in HsAFr and Fer-8.<sup>[12]</sup> In this case, a one-pot synthesis method was employed. The one-pot synthesis using buffer solution is more suitable for mass production, because the pH control using a buffer agent is very simple. The effect of the buffer reagents on the stability of cobalt ions and cobalt complex ions, which affects the cobalt core biomineralization, was studied. A thorough survey of the optimum conditions for the one-pot Co<sub>3</sub>O<sub>4</sub> core synthesis revealed that the optimum conditions consist of mixing 3 mM Co(II) ion with 0.5 mg/ml apoferritin in 100 mM HEPES pH 8.3 buffer solution followed by the oxidation of Co (II) ion by the addition of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) at 50°C. Under these conditions, Co<sub>3</sub>O<sub>4</sub> cores were formed in over 90% of apoferritin cavities. The synthesized core analysis by X-ray photoemission spectroscopy (XPS) and electron energy-loss spectroscopy proved that they contained cobalt atoms, and the X-ray powder diffraction (XRD) structure analysis confirmed the core structure as Co<sub>3</sub>O<sub>4</sub>, which was consistent with the results obtained from lattice images of the cores by high-resolution TEM observations.

### SYNTHESIS OF SEMICONDUCTOR NPs IN THE APOFERRITIN CAVITY

Reports of inorganic NP synthesis in the apoferritin cavity have so far mostly been of metal complexes. It is of great interest to explore the possibility of synthesizing compound semiconductor NPs in the apoferritin cavity. Because the electron energy levels of the semiconductor NPs depend on their size and shape, semiconductor NPs can be a quantum dot or photofluorescence marker and are very attractive for nanoelectronics. However, the introduction of oppositely charged ions is very difficult and there are only a few reports of II–VI compound semiconductor NP synthesis. Kim and Mann<sup>[14]</sup> reported small cadmium

**Fig. 3** TEM images of CdSe NPs synthesized in the HsAFr cavity. The images are stained by 1% aurothioglucose. (A) Cores are surrounded by white rings, which are negatively stained protein shells. The arrowhead (a) shows the apoferritin with CdSe core and the arrowhead (b) shows the apoferritin without CdSe core. (B) TEM image of synthesized CdSe-ferritin molecule without stain. Homogenous dots from CdSe NPs were observed.

sulfide (CdS) core formation in the apoferritin cavity,<sup>[14]</sup> and Yamashita, and Hara reported synthesis of homogenous cadmium selenide (CdSe)<sup>[15]</sup> and Iwahori reported that of zinc selenide (ZnSe)<sup>[16]</sup> semiconductor NPs.

For the synthesis of CdSe NPs in the apoferritin cavity (Fig. 3), Yamashita et al. developed a new chemical reaction system. In aqueous solution, which is the fundamental solution for the biotemplate NPs synthesis, the chemical reaction between Cd<sup>2+</sup> and Se<sup>2-</sup> is very fast and induces CdSe aggregation very quickly. Therefore, Yamashita et al. designed a slow chemical reaction system where Cd<sup>2+</sup> is stabilized by excess ammonia and forms positively charged tetra-aminocadmium ions (Cd(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup>). Se<sup>2-</sup> ions are supplied by selenourea. Selenourea is comparatively unstable in aqueous solution and slowly degrades to release Se<sup>2-</sup>. This slow chemical reaction of tetra-aminocadmium ions and selenium ions leads to suppression of the bulk precipitation in the reaction solution. CdSe nuclei are produced very slowly in the bulk solution, but in the apoferritin cavity, where the Cd<sup>2+</sup> ions are concentrated by the electrostatic potential made by the inner negative amino acid residues, nuclei are formed quickly. Once the nuclei are made, the CdSe surface works in a self-catalytic way so that homogenous CdSe semiconductor NPs are synthesized in the apoferritin cavity. The consumption of Cd<sup>2+</sup> and Se<sup>2-</sup> by the crystal growth in the cavity further lowers the possibility of a nucleus appearing in the bulk solution. Therefore, this slow chemical reaction system can produce fully developed CdSe semiconductor NPs selectively in the apoferritin cavity.

**Fig. 4** High-resolution TEM image of CdSe NPs in the apoferritin cavity. (A) A single crystal of CdSe. The diameter of CdSe NPs is 7 nm. (B) Diameter distribution of synthesized CdSe NPs.

XPS data of the synthesized CdSe-ferritin revealed that the cores are composed of Cd and Se. After heat treatment at 500°C to remove the protein shell, a set of fairly sharp XRD peaks was observed and the core structure was determined to be a cubic phase (zinc blend) CdSe with a little hexagonal phase (wurtzite). The average diameter of the obtained CdSe cores using TEM images was 7 nm, which is the same as that of the apoferritin cavity. The dispersion of diameters was small, and the standard deviation of the diameter was less than 10% of the average diameter (Fig. 4).

Following the CdSe NP synthesis, Iwahori et al. reported the successful synthesis of homogenous ZnSe NPs in the apoferritin cavity. ZnSe is also a promising material for n-type semiconductors. ZnSe NPs could be used as a quantum label for biological use, because its fluorescent light does not quench easily. The slow chemical reaction synthesis process was slightly modified for ZnSe NPs, and the optimum reaction conditions for ZnSe NPs was determined.<sup>[16]</sup> The CFR for ZnSe NPs reached more than 90% using the determined optimal conditions. The characterization of the synthesized ZnSe NPs in the apoferritin cavity by XRD and EDS revealed that they were a collection of cubic ZnSe polycrystals (Fig. 5).

To study the mechanism of ZnSe NP synthesis in the apoferritin cavity, Iwahori et al.<sup>[16]</sup> constructed three recombinant apoferritins, which differ in the electric charge of the threefold channel and the inner surface of apoferritin cavity.

1. Fer-8—the recombinant apoferritins that are composed of only L-subunit and lack the first eight amino acid residues from N-terminal.
2. 8A—the recombinant apoferritin derived from Fer-8 in which the Asp-131 and Glu-134 amino acids at the threefold channel were replaced by neutral alanine amino acid residues.

**Fig. 5** TEM image of ZnSe NPs and the EDS analysis of ZnSe synthesized in the apoferritin cavity. The images were stained by 1% aurothioglucose. (A) Cores are surrounded by white rings, which are negatively stained protein shells. (B) An EDS spectra of synthesized ZnSe NPs. The C and Ti peaks are ascribable to the TEM grid.

3. 8AK—the recombinant apoferritin derived from 8A, which has the Glu-58, Glu-61, and Glu-64 replaced by positively charged lysines.

ZnSe NPs were synthesized in the cavities using these three purified recombinant apoferritins. ZnSe CFR of three recombinant apoferritins depended on the amino acid residues of the threefold channel and inner cavity.<sup>[16]</sup> Three factors are found to be important to ZnSe NP synthesis in the apoferritin cavity.

1. Zn ion transformation through the threefold channel, which selectively introduces Zn ion into the apoferritin cavity.
2. Zn ion accumulation in the apoferritin cavity by the internal positive potential made by glutamic acid residues.
3. ZnSe nuclei formation at a nucleation site inside the cavity.

These results are potentially useful for the synthesis of a variety of compound semiconductor NPs in the apoferritin cavity.

## FABRICATION OF BIOTEMPLATE NPs IN CAGE-SHAPED PROTEINS

NP synthesis using the biotemplate, apoferritin, has been described above. Other kinds of biosupramolecules have also been used as biotemplates to synthesize NPs. Such biotemplates include mammalian protein cages, small protein cages from bacteria, and viral protein cages. Choosing the protein cages from nature, the researcher can fabricate a variety of NPs of different size and materials.

Viral protein cages have a wide variety of shapes and sizes and, hence, are good templates to produce various sizes of NPs. The adenovirus has a diameter of close to 100 nm, and the cowpea mosaic virus (CPMV) has an inner cavity with a diameter of 30 nm. Cowpea chlorotic mottle virus (CCMV) has an inner cavity with a diameter of 28 nm, and the average diameter of the brome mosaic virus (BMV) particle is 26 nm and the inner cavity is only 8 nm.<sup>[17]</sup>

CCMV undergoes a reversible pH-dependent swelling that results in a 10% increase in virus size. This transition is the result of an expansion at the pseudo threefold axis of the virus particle, which causes the formation of 60 separate openings (each 0.2 nm in diameter) in the protein shell. Douglas and Young<sup>[18]</sup> utilized this character and synthesized paratungstate and decavanadate in the CCMV using the pH-dependent reversible gating system. The synthesized NPs showed a diffraction pattern consistent with the ammonium salt of paradodecatungstate ion,  $(\text{NH}_4)_{10}\text{H}_2\text{W}_{12}\text{O}_{42}\cdot 4\text{H}_2\text{O}$ . A similar approach was used to constrain the mineralization of a vanadate species in the cavity of CCMV. This synthesis also results in the formation of monodisperse vanadate NPs with essentially the same size distribution as that seen for the paratungstate. These crystals showed XRD consistent with a mixture of  $\text{Na}_6\text{V}_{10}\text{O}_{28}\cdot 18\text{H}_2\text{O}$  and  $(\text{NH}_4)_6\text{V}_{10}\text{O}_{28}\cdot 18\text{H}_2\text{O}$ .

Considering the smaller cages, which are more attractive from nanoelectronic point of view, there is *Listeria* ferritin (LisFr). This ferritin-like protein from the bacteria *Listeria innocua* has been shown to form a twelve-subunit cage structure making as 4 nm diameter interior cavity (Fig. 6).<sup>[19,20]</sup> This small cage structure

has the capacity to hold 500 Fe atoms as a ferric oxyhydroxide.<sup>[21,22]</sup> Allen et al.<sup>[23]</sup> have cloned the LisFr into an *E. coli* expression system and purified recombinant apoL-FLP (raLisFr), which does not have Fe atoms in the cavity. They investigated the Fe mineralization in raLisFr under non-physiological conditions. In the reaction solution at 65°C and pH 6.5, raLisFr mineralizes Fe NP in the cavity. The analysis revealed that the cores are ferromagnetic  $\gamma\text{-Fe}_2\text{O}_3$ .<sup>[23]</sup> Douglas and coworkers have also been able to form cobalt NPs in raLisFr. They synthesized two types of cobalt NPs,  $\text{Co}(\text{O})\text{OH}$  at 23°C and  $\text{Co}_3\text{O}_4$  at 65°C. Both cobalt NPs were 5 nm in diameter, which is the same as the cavity size of raLisFr.<sup>[24]</sup>

An old technique was renewed by Belcher et al., when the phage display method was used to select peptides with specific affinity against the semiconductor surface, GaAs.<sup>[25]</sup> Now, as a result of researchers' efforts, many such target-specific peptides are available. Kramer et al. recently reported that silver NPs (Ag-NPs) were synthesized in the apoferritin cavity. They used genetically engineered human L-subunit ferritin (HLCF) with a silver-binding peptide, AG4. AG4 is a dodecapeptide (Asn-Pro-Ser-Ser-Lue-Phe-Arg-Tyr-Leu-Pro-Ser-Asp) selected by a phage peptide display library. This dodecapeptide was shown to be able to reduce the silver ions to metallic silver at neutral pH and synthesize Ag NPs.<sup>[26-28]</sup> They constructed chimera protein, AG4 peptide sequence fused to the C-terminal of L-chain ferritin sequences, and this chimera protein makes a 24-mer cage-shaped protein with the AG4 peptide displayed on the inner cavity surface. When the LCF-AG4 protein cages were incubated in the presence of 0.4 mM  $\text{AgNO}_3$ , the Ag NPs with an average diameter of 5 nm was synthesized in the cavity of LCF-AG4. Recently, many kinds of metal target-specific peptides have been isolated by the phage display method. If the most suitable metal-binding peptide for the purpose was selected and the fusion-protein cage was made, the NP suitable for various applications could be synthesized.

	Ferritin	<i>Listeria</i> ferritin
Diameter	12 nm	9 nm
Diameter of cavity	7 nm	4 nm
Molecular weight	450 kDa	240 kDa
No. of subunits	24	12

**Fig. 6** Schematic drawing of HsAfr (A) and apoferritin from *Listeria innocua* (B). The spherical hollow shell of ferritin is composed of 24 polypeptide subunits. The *Listeria* ferritin is composed of 12 polypeptide subunits. The inner and outer diameters of the protein shell are about 7 nm and 12 nm for ferritin and about 4 nm and 9 nm for *Listeria* ferritin.

## APPLICATION OF BIOTEMPLATE NPs

Yamashita group used ferritin to make a 2-D array of nanodots for a floating nanodot gate memory (FNGM). FNGM has a similar structure to metal-oxide semiconductor field-effect transistor (MOSFET), but has a nanodot array embedded in the silicon dioxide layer just above the channel. Electrons are stored in the nanodot array, usually one electron per dot, and shut off the channel current by electrostatic potential. The storage of electrons is controlled by the gate electrode. For this FNGM, a well-ordered array having nanodots of the same size (less than 10 nm) is

**Fig. 7** TEM image of the 2-D array of apoferritin stained by uranyl acetate on the TEM grid coated with carbon. The TEM grid was treated with ion coater to make a hydrophilic layer before use. The black dots represent the apoferritin cores stained with uranyl acetate. The surrounding white parts represent the apoferritin protein shells. A well-ordered 2-D array is clearly visible.

necessary. It is very difficult for conventional semiconductor technology to fulfill this target. Yamashita et al. employed ferritin molecules to overcome this problem.

The first step is to make a ferritin monolayer with a high density. Yoshimura<sup>[29]</sup> demonstrated that in the presence of 2% glucose, a well-ordered 2-D array of ferritin molecules could be made beneath a denatured polypeptide film at the air–water interface (Fig. 7). Furuno, Sasabe, and Ulmer can make this 2-D array of ferritin molecules on the artificial polypeptide, poly-1-benzyl-L-histidine (PBLH), membrane.<sup>[30]</sup> A ferritin molecule has a divalent cation-binding site at the two-fold axis surface, which promotes 2-D crystallization. The ferritin 2-D crystal has a density near to  $10^{12}$  dots/cm<sup>2</sup>. Furuno, Sasabe, and Ulmer further transferred the ferritin-nanodot array onto a hydrophobic Si substrate. Negatively stained TEM images showed almost perfect hexagonally close-packed arrays. High-resolution SEM visualized the iron oxide cores held within the protein shells. A clear hexagonally packed array of distinct white dots is observed. Because the ferritin should be placed at the designed area, some method for placing the ferritin monolayer on the target area is necessary. Yoshii et al. modified the silicon substrate with aminosilane. Aminosilane is positively charged and ferritin is negatively charged at neutral pH. Therefore, the aminosilane layer attracts ferritin, and ferritin adheres to the modified aminosilane. This method can also produce a ferritin monolayer with high density, around  $10^{12}$  dots/cm<sup>2</sup>.<sup>[31]</sup>

The second step is to eliminate the protein moiety from the protein array. For use in electronic devices,

the protein shell must be removed from the ferritin array. It was anticipated that heat treatment would eliminate the protein shell of the ferritin molecule. A 500°C heat treatment for 1 hr under nitrogen gas was experimentally proven to eliminate the protein shell from the ferritin molecule. Yamashita et al. confirmed the removal of the protein shell from the ferritin molecule by atomic force microscopy (AFM) observation in contact mode, Fourier transform IR spectroscopy (FTIR), and weight-loss measurement.<sup>[32,33]</sup> Detailed experiments confirmed that the ferritin protein shells were eliminated by the heat treatment at around 450°C for 1 hr under nitrogen. Recently, Yoshii et al. demonstrated that the proteins could be eliminated completely by 500°C heat treatment in a rapid thermal annealing (RTA) furnace for 10 min under oxygen. XPS measurement showed that the spectrum peak from nitrogen atom completely disappeared after RTA heat treatment. In this case, ferritin was adsorbed on the aminosilane layer, and the RTA treatment eliminated the aminosilane layer too.<sup>[31]</sup> Hikono et al. also demonstrated that UV/ozone treatment for 45 min at 115°C eliminates the protein moiety of the ferritin array.<sup>[33]</sup> The obtained nanodot array has a density of about  $10^{12}$  dots/cm<sup>2</sup>,<sup>[32]</sup> which is dense enough to be used for a floating nanodots gate.

The third step is embedding the nanodots in the silicon dioxide layer. Before embedding, the iron oxide nanodots have to be reduced. This was carried out using the ammonia plasma treatment. Now, Hikono et al. are currently studying electron storage by this nanodots array. We can fabricate a 2-D array of iron NPs on the Si substrate by bionanoprocess. This array of nanodots with homogenous size has a high density ( $10^{12}$  NPs/cm<sup>3</sup>), which is difficult to be achieved by conventional methods. The fabrication of the key component of the FNGM is just one example (Fig. 8). The method of making key components based on biomineralization, self-assembly, and elimination of the

**Fig. 8** Schematic drawing of the floating gate memory (A) and a cross section TEM image of a nanodevice (B).

Fig. 9 Some applications of the “bionanoprocess.”

cage protein can be extended to many other applications. Fig. 9 shows some examples of Yamashita group's other targets.

## CONCLUSIONS

Researchers can make many types of NPs including metal oxide and semiconductor NPs in the cage-shaped protein, apoferritin. The synthesized NPs have some advantages compared to chemically synthesized NPs. The semiconductor-ferritin could be used as a photochemical reagent for sensing, a drug delivery system, a biomarker, a photo device, and so on. The number of the kinds of NPs that can be formed using the bio-temple method is increasing and we can expect to see useful products addressing specific problems soon. The proposal by Yamashita, Hayashi and Hara to make electronic components using the heterocomplex consisting of the inner NP and outer protein shell provides a unique solution for nanofabrication.

There are many kinds of biosupramolecules usable as biotemplates for the biomineralization of inorganic materials. These molecules could be employed to produce many kinds of heterocomplexes consisting of an inner inorganic material portion and an outer protein sheath of various shapes and sizes. These complexes can be used as self-assembling nanoblocks for fabricating nanostructures. By closely studying nature, we can open up a new biological pathway for nanofabrication using protein supramolecules.

## ACKNOWLEDGMENTS

We thank Mr. H. Furusho of Nara Institute Science and Technology for the high-resolution TEM observation and Dr. M. Okuda, Matsushita Electric Industrial Co., Ltd., for the valuable TEM images. We also thank Dr. M. Muraoka of CREST, Japan Science and Technology Agency, for the valuable discussions and Ms. R. Tsukamoto for the TEM image of cobalt oxide NPs.

## INTRODUCTION

During the past decade or so, considerable interest has grown in the potential commercial and technological exploitation of nanoscale materials in analytical chemistry.<sup>[1]</sup> A particular focus of this interest has been the utilization of specific size-dependent electronic, optical, or magnetic properties. Nanoparticles are crystalline clusters (metallic, semiconducting, or insulating) composed of a few hundred to a few thousand atoms and are, characteristically, of nanometer dimension. One consequence of this size is that many of their properties are dominated by their surface rather than by the bulk volume<sup>[2]</sup> and, indeed, this fact alone can make these structures very amenable to chemical or environmental influence, or “tuning.” Their nanometer diameter is also the same order of magnitude as the de Broglie wavelength of electrons/holes at room temperature and this, then, can lead to a quantization of electronic/hole energy levels, a phenomenon that has led to the term “quantum dots” (QD). The energy-level spacings are related to particle size.<sup>[3]</sup> Although the term “nanoparticles” has been coined only at a time when advances in microscopy have allowed us to resolve them as such, nanoparticles have been in use for many years; for example, Faraday carried out pioneering work with gold nanoparticles, and some of the intense colors evident in stained glass arise from the presence of nanometer-sized oxide clusters.

Gold nanoparticles received substantial attention during the past decade or so. The potential technical importance of monolayer-protected metal nanoparticles in developing nanoscale optoelectronic devices, (bio)chemical sensors, corrosion-resistant materials, and new catalysts has made them one of the primary targets of highly intensive, nanoparticle-based research activity. To date, for example, both single electron and nonlinear optical devices have been constructed from these materials.<sup>[4–6]</sup> In addition to utilizing the optical and electronic properties inherent in metallic structures, the magnetic characteristics of suitable particles have also been of some interest, particularly in

consideration of separation technologies. For example, nanoparticles of iron oxide ( $\text{Fe}_3\text{O}_4$ ) can be suitably modified with a biological moiety of interest, e.g., a cell and their “superparamagnetic” properties used in magnetic field modulated manipulations/separation.<sup>[7]</sup> The possible use of magnetic nanoparticles as contrast agents in magnetic resonance imaging has also been cited.<sup>[8]</sup> Through suitable surface chemical modification, it should be possible to generate magnetic nanoparticles with a propensity to concentrate in particular tissue (or cellular) regions allowing, e.g., enhanced image contrast generation between diseased or cancerous cells and healthy cells. To date, these have both been shown to be more effective than conventional magnetic resonance imaging (MRI) agents (such as gadolinium complexes) and capable of allowing in vivo cellular tracking.<sup>[9]</sup>

This report will aim to outline the general properties of metallic and semiconducting nanoparticles, their modification and possible application in high-sensitivity, selective ion sensing. There is no universally adopted definition as to what constitutes a nanoparticle, but we will be concerned here with the properties and utilization of particles <100 nm in diameter. Although more progress has been made in the functionalization of metallic (notably gold and silver) particles, the properties and potential utilization of semiconducting particles will also be discussed.

## METALLIC NANOPARTICLES

Although metal colloids have been known since the mid-18th century, only during the past decade or so has it been possible to controllably generate homogeneous samples and to subsequently scrutinize them at levels of resolution comparable to particle size.<sup>[10,11]</sup> Although much of the seminal (and applied) work in this field has been carried out with gold, nanometer-sized metal particles of silver,<sup>[12]</sup> platinum,<sup>[13]</sup> iridium, and palladium<sup>[14]</sup> have also been prepared. Although recent work has recognized that nanoparticle shape (in addition to size) greatly influences physical and

chemical properties,<sup>[15,16]</sup> this topic will not be discussed here.

## Synthesis and Characterization

Metal nanoparticles can be formed through laser vaporization of metallic rods. However, this method is not generally amenable to either scaling up or subsequent chemical modification strategies. Interestingly, with particles prepared under such conditions, certain “magic numbers” of constituent atoms are evident,<sup>[17]</sup> an observation consistent with nonbulk, “atomistic” character. Perhaps the most practical and flexible means of nanoparticle generation is by chemically reductive routes in solution. As “bare” metallic nanoparticles are typically unstable in solution controlled surface functionalization (either during or after synthesis—see below) has been key. Aqueous phase citrate reduction of HAuCl<sub>4</sub> has been, perhaps, the major workhorse in this area; subsequently, surface-bound citrate moieties can be readily displaced by thiolated organics in the formation of monolayer-protected metallic clusters (MPCs). A breakthrough in this field was the demonstration by Brust and coworkers<sup>[11]</sup> of a solvent-based, high-concentration, monodisperse synthesis through a surfactant catalyst-based phase transfer of chloroaurate ions (typically with subsequent reduction by a borohydride). Most conveniently, chloroaurate reduction is carried out in the presence of alkanethiols,<sup>[11]</sup> and, to a large extent, it is possible to control nanoparticle size through the relative ratios of tetrachloroaurate and thiol. In essence, these capped nanoparticles behave like large organic molecules, in that they can be separated from solution in powdered form, redissolved in solvent, and recrystallized as required. The surface functionalization afforded by these preparative methods stabilizes the particles to aggregation and further allows their properties to be influenced by the structure of the monolayer-forming molecules. In addition, this functionalization can be utilized in mediating surface-confinement (e.g., self-assembly of the nanoparticle itself onto an underlying solid support). Analogous chemistry can be used in the formation of other particles—chloroplatinate reduction yields, for example, platinum nanoparticles.

## Properties

Metal nanoparticles have extraordinary size-dependent optical properties, not present in the bulk metal. Specifically, nanoparticles of silver, gold, and copper show distinct and well-defined plasmon absorption in the visible spectrum, an absorption characterized by

an extremely large molar adsorption coefficient. These unique optical, electrical, and surface chemical characteristics are controllable through both particle size and aggregation,<sup>[18,19]</sup> and can also be “tuned” to a degree by the nature of the surface functionalization.<sup>[20–22]</sup> Interestingly, the effect that the size-dependent electrical characteristics of nanoparticles can have on the properties of surface-confined molecules has recently been resolved in a <sup>13</sup>C NMR study.<sup>[23]</sup>

Although diffraction analyses have shown that nanoparticles adopt the same crystal structure as the bulk metal, this appears to be less the norm as the particle size falls. For example, gold nanoparticles can adopt an icosahedral structure quite different to the bulk face-centered cubic arrangement. The valence and conduction band density of states (DOS) of these particles undergo significant variance with size; specifically, the initially continuous DOS is progressively replaced by discrete energy levels, the spacing of which increases with decreasing particle size (Fig. 1). As this spacing exceeds thermal energy, a “band gap” effectively opens up in the metal. At smaller sizes still, discrete, energetically separated, quanta are resolvable. These size effects are observable in both metallic and semiconducting particles, although, in the latter, “quantum dot” behavior can be observed at comparatively large (tens of nanometers) particle size.

From the perspective of developing derived electro-analytical devices, the redox properties of nanoparticles have been of some interest. The redox behavior of MPCs has been probed both diffusively in solution<sup>[24,25]</sup> and in surface-confined mono- or multilayer films.<sup>[26–30]</sup> Again, as soon as nanoparticles fall below a finite size (<1 nm), available electronic states become quantized and, electrochemically, this has the effect of the particle behaving, in essence, as a multivalent redox species.<sup>[31]</sup> The specific electrostatic charging of the metallic core of monolayer protected nanoparticles has also been referred to as quantized double layer charging.<sup>[20]</sup> The ability of these films to mediate current flow is of obvious application to the development of sensors.

**Fig. 1** Schematic layout showing the progression from metallic band structure to quantized electronic structure as nanoparticle dimensions fall.

## Postsynthesis Nanoparticle Functionalization

Although it is commonly advantageous to modify nanoparticles as they are created, the covalent attachment of molecules to the surface of a nanoparticle is, generally, a dynamic process in which the surface-confined molecules are in dynamic equilibrium with those in the surrounding solution. Because of this, it is possible to displace surface bound molecules with those for which surface-confinement is more thermodynamically favorable—for example, it is possible to displace short chain alkane thiols with those of longer chain.<sup>[32]</sup> The use of terminally functionalized alkanethiols facilitates the controlled introduction of surface chemistry into generated nanoparticles—they can be rendered anionic, cationic, hydrophobic and/or suitable for coupling to other molecules or surfaces.

## Biomodification

Although the electron scattering propensity of metallic nanoparticles makes them useful biotagging markers,<sup>[33,34]</sup> the association of nanoparticles with biomolecules further brings with it the possibility of using them in highly sensitive optical or electrical bioassays. To date, methods have been developed where protein, antibodies, and oligonucleotides can be robustly anchored to particles. Nanoparticles heavily functionalized with oligonucleotides have been used as probes in a variety of DNA detection methods and as elemental building blocks in materials synthesis schemes based upon the sequence-specific hybridization properties of DNA.<sup>[35–37]</sup> Typically, the direct adsorption of protein or enzyme onto bare metallic surfaces is accompanied by gross change in protein fold (denaturation) and loss of biological activity. Interestingly, several recent studies have indicated biostability at colloidal metal surfaces.<sup>[38]</sup>

## SEMICONDUCTING NANOPARTICLES

Much excitement has recently surrounded the potential optical utilization of spherical semiconducting nanocrystals (typically 15–120 Å in diameter),<sup>[39,40]</sup> such as those composed of cadmium sulfide,<sup>[40]</sup> cadmium selenide, or gallium arsenide.<sup>[41]</sup> As with metallic nanoparticles, the dimensions lead to very interesting optical and electronic properties arising from the confinement of excitons (electron/hole pairs) within the particle, and their subsequent quantized behavior. These properties have led to novel research activity associated with the development of quantum computers, laser diodes, and solar cell technology. The semiconducting band gap associated with these particles is tunable through diameter control at the point of synthesis—the smaller the particle, the greater the energy level spacing

between quantized levels; in the case of fluorescence, the absorption and emission peaks shift to longer wavelengths with increasing particle size.<sup>[36]</sup>—2.5 nm CdSe particles, for example, fluoresce in the green, while 7-nm equivalents fluoresce in the red.<sup>[36]</sup> The potential use of these structures as fluorescent labels has been a core focus during the past 2–3 years; the advantages they hold over more traditional organic fluorophore labels are marked. The fact that equally sized quantum dots made of different materials give rise to different emission/absorption frequencies means that quantum dots are tunable fluorophores. They have wider excitation and narrower emission spectra than conventional organic dye molecules; the former is desirable because several probes with different emission peaks can be excited with a single source, decreasing the number of equipment that might be needed to perform imaging (in fact, QDs can be excited efficiently at any wavelength shorter than that of their emission peak<sup>[36]</sup>). A narrow emission spectra reduces spectral cross-talk between different detection channels; in other words, fluorophores of differing emission peaks appear clearer and more distinct from each other. Additionally, these dots also suffer considerably less from the problems of photobleaching inherent in organic dyes and have an associated higher quantum yield (thus they appear “brighter”).<sup>[42]</sup> These quantum yields can be further increased by surrounding the dot with an epitaxially grown layer of larger band gap semiconducting material. For example, cadmium selenide dots can be capped with zinc sulfide. These so-called, “core-shell nanocrystals” have associated quantum yields that can be as high as 80%.<sup>[43]</sup>

## Synthesis

Semiconducting dots are typically synthesized in organic solvent at high temperature from metallic salt and insulator precursors (e.g., a cadmium salt with powdered selenium) in the presence of a stabilizing surface-active agent. As a direct result of this method of forming (stabilized and solubilized) quantum dots, freshly made particles are generated with a surface coating, commonly trioctyl phosphine oxide (TOPO). As with metallic nanoparticles, it appears that the electrical properties of particles are strongly affected by geometry as well as size.<sup>[44]</sup> Likewise, as properties are size-dependent, it is clearly advantageous to ensure that size distributions are as narrow as possible in any sample.

## Functionalization

Commonly, quantum dots (and nanoparticles in general) are functionalized by utilizing capping molecules with thiol groups. These capping molecules attach to

the surface of the quantum dot by binding at the sulfur atom. This is simple to achieve experimentally: normal procedure involves adding the cap to a colloidal dispersion of quantum dots in an organic solvent and then heating.<sup>[45]</sup> Monodentate binding leads to stable isolable products, but bidentate binding has also been used<sup>[46]</sup> and, theoretically, gives a more stable cap/surface interaction. To utilize the fluorescent characteristics of these structures in biological media they must, of course, be made water-soluble, and capping with a hydrophilic thiol is one means of achieving this (Fig. 2). A more involved (but ultimately more stable) method of aqueous solubilization is achievable through surface silanization.<sup>[42]</sup> As well as allowing solubility refinements, these surface functionalization methodologies can, subsequently, also be used in either coupling of the quantum dots to other molecules (biomolecules, for example) or their surface assembly.<sup>[47]</sup>

### THE SURFACE-ASSEMBLY OF NANOPARTICLES

To make use of the intrinsic physiochemical properties of these particles in the development of novel

electronic and/or optical devices, methods must be established whereby controlled (many of the potentially useful properties are strongly perturbed on aggregation) assembly on solid surfaces can be achieved.<sup>[48,49]</sup> In recent years, a variety of methods have been reported whereby mono (two-dimensional) and multilayers (three-dimensional) of both metallic<sup>[31,50,51]</sup> and semiconducting<sup>[52–54]</sup> particles have been generated (with various degrees of control and homogeneity) and characterized. The “new physics” associated with these surfaces has opened up tremendous opportunities for both fundamental research and new applications.<sup>[32,55–58]</sup> Although many groups have utilized physical methods of depositing particles, covalent,<sup>[59,60]</sup> or ionic<sup>[61,62]</sup> assembly offers more control<sup>[63–69]</sup> (Fig. 3). The assembly of nanoparticle films can also be electrochemically modulated in cases where the particles are initially decorated with redox-active moieties.<sup>[70]</sup> A number of biomolecule-mediated nanoparticle assembly strategies have also been proposed for both metallic and semiconducting particles.<sup>[37,45,71]</sup>

Because the most useful quantum dot surfaces are those generated from closely packed (although not physically in contact) colloids, considerable efforts

**Fig. 2** Functional self-assembly on the surface of semiconducting quantum dots can be used to render them both water soluble and amenable to subsequent (bio)chemical functionalization.

**Fig. 3** Schematic representation of a covalent surface assembly protocol for the immobilization of monolayer-capped gold nanoparticles on a functionalized gold electrode surface.

have been expended in attempts to control this, something which is easiest to achieve if particle–surface interactions are maximized (ideally at the expense of particle–particle interactions).<sup>[72]</sup> In a typical, well-packed 10-nm nanoparticle adlayer, there are  $1 \times 10^{10}$ – $1 \times 10^{11}$  colloids/cm<sup>2</sup>, depending on edge-to-edge distance. These assembled adlayers are conveniently analyzed at angstrom levels of resolution, by electron microscopy or scanning probe microscopy.

The immobilization of colloidal nanoparticles onto optically transparent electrode surfaces [such as indium tin oxide (ITO)], on which optoelectrochemical analyses can be performed, has also been demonstrated.<sup>[73]</sup> Electrochemical studies have resolved electron transfer rate constants between nanoparticles and underlying electrode surfaces of the order of  $100 \text{ sec}^{-1}$ <sup>[74]</sup> and, predictably, this shows significant dependence on the alkanethiol modification of the particles.<sup>[75]</sup> Uosaki et al.<sup>[62]</sup> demonstrated that, in addition to the strong electronic coupling between

surface-confined nanoparticles and their underlying support, fast electron transfer is possible from redox-active moieties attached to gold particles and the underlying electrode. Even in multilayer films, (thermally activated hopping) electron transfer is effectively “channeled” to/from the underlying support via intervening particles. The sensitivity of these electrochemical characteristics to environment is of direct relevance to the generation of derived sensing systems.

### ION SENSING AT NANOPARTICLE SURFACES

The development of molecular receptors designed to selectively recognize and sense charged or neutral guest species of biological and environmental importance is a highly topical research field. The “reporting” of recognition may be through “physical change,” such as an interfacial mass change associated with bonding (detectable through piezoelectric devices). One may

imagine that the “interaction” (binding) and “signaling” regions of a sensor are distinct, and that the monitored signal—be it optical, electrochemical, or otherwise in nature—is reliably and reproducibly perturbed by specific interactions occurring at the neighboring binding site. With electrochemical sensors, perturbation of a voltammetrically monitored electron transfer process, achieved by localization of a redox-active group (e.g., ferrocene) in the vicinity of the receptor, may be achieved by one or a combination of through-space and through-bond interactions. Optical sensing can be achieved through perturbation of an optical signal, typically by equivalent mechanisms. We will focus here on optical and electrochemical transduction where specific molecular association is accompanied by a change in the monitored optical or electrochemical signals derived from the sensor. Such changes can facilitate qualitative or quantitative analyte determination.

Supramolecular chemistry may be defined as the investigation of molecular systems in which the components are reversibly associated by noncovalent intermolecular interaction. From a sensing perspective, such systems may be loosely described as comprising of a “host” sensor and a “guest” analyte species, the latter being neutral, cationic, or anionic. The binding intermolecular forces include electrostatics (ion–ion, ion–dipole, and dipole–dipole), hydrogen bonding,  $\pi$ – $\pi$  stacking interactions, dispersion and induction forces (van der Waals), and hydrophobic or solvophobic effects. Individually, these interactions are relatively weak, but in combination they lead to thermodynamically stable complexes, the formation of which can be utilized in the generation of ion sensors.

### Cation Sensing

The binding of a cation at a receptor site can be achieved through electrostatic ion–ion or ion–dipole interactions. In general, it is advantageous to utilize polydentate receptor sites that, for well-known thermodynamic reasons (chelate and macrocyclic effects), exhibit increased cation binding affinity. Oxygen-containing crown ethers were the first macrocyclic ligands synthesized which bound alkali metal cations with high selectivity (tunable through structure/geometry). Cryptand and spherand receptor molecules are more highly organized and can accordingly associate very strongly with specific s-block cationic analytes. Through the incorporation of redox-active moieties into these receptors, sensory systems electrochemically responsive to, e.g., lithium,<sup>[76]</sup> sodium,<sup>[77]</sup> and potassium,<sup>[78]</sup> as well as larger cations (some of considerable environmental concern), such as rubidium and cesium,<sup>[79]</sup> has also been achieved.

### Anion Sensing

The physiological and environmental importance of inorganic anions has fuelled a considerable amount of interest in anion recognition and sensing.<sup>[80]</sup> For example, nitrates and phosphates are present in low concentrations in wastewater, but high levels are a contributing factor to eutrophication and, accordingly, are of environmental significance. Although substantial progress has been made in the development of specific, sensitive, cation receptors, similar work with anions has been hindered by their characteristic small charge density (relative to isoelectronic cations) and, subsequently, general low binding affinity. The additional effects of competitive solvation mean that aqueous-phase anion recognition remains a considerable challenge. The design and construction of receptors that can selectively recognize and sense anionic guest species via a macroscopic physical response is thus a current area of chemical sensor technology receiving considerable attention.<sup>[81]</sup> Anions are excellent electron pair donors, so they will strongly interact with suitable electron pair acceptors, the simplest of these being an electropositive hydrogen atom capable of forming a hydrogen bond. The directionality of hydrogen bonds introduces the possibility of designing receptors with specific shapes, capable of differentiating between anionic guests of different geometry. Again, by combining a binding site with redox-active moiety, electroanalytical methods can be applied to anion sensing. In recent work, the redox-active ferrocene moiety was used in the electrochemical sensing of anions, both in organic and aqueous media.<sup>[81,82]</sup> Transduction of anion binding is achieved by through-space and through-bond stabilization of the higher ( $\text{Fe}^{\text{III}}$  in the case of ferrocenium) oxidation state and, in voltammetric experiments, this is observable through a cathodic shift in the ferrocene/ferrocenium electrochemical half-wave potential. Acyclic, macrocyclic, and calixarene amide-functionalized ferrocene derivatives have all been subsequently shown to undergo substantial cathodic perturbations of the respective metallocene redox couple in the presence of a variety of anions of biological and environmental importance. These molecular sensors are capable of detecting  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{H}_2\text{PO}_4^-$ ,  $\text{ReO}_4^-$ , and  $\text{CH}_3\text{CO}_2^-$  (down to low micromolar levels) with, in some cases, the strength of binding correlating with basicity of the anionic guest.

### Surface-Confined Chemical Sensors

Self-assembled monolayers (SAMs) can be formed from the exposure of a pristine metallic surface to suitably functionalized molecules, which subsequently form ordered, two-dimensional crystalline arrays; the

degree of ordering being dependent on molecular structure and size, substrate morphology, coverage, temperature, and solvent. By combining molecular-scale recognition with such assembly, it is possible to develop a powerful means of generating interfaces capable of analyte detection under a variety of conditions. The “surface tethering” of receptors yields a number of specific additional advantages; efficiency, in terms of quantity of material required, is high; the sensor can be portable, robust, and capable of being used in a variety of environments. In addition to this, and as discussed below, the preorganization of molecular receptors at a surface enhances the thermodynamic driving force associated with receptor/analyte binding and, therefore, both binding affinity and detection limits.<sup>[83]</sup>

Recent work has shown that the introduction of a surface-anchoring thiol moiety into a redox-active anion sensor allows the generation of robust sensing molecular arrays capable of analyte detection in a variety of polar and nonpolar environments. Specifically, by incorporating hydrogen bond donor amide groups and directly linking these functionalities to a redox-active ferrocene unit, hydrogen-bond mediated anion recognition is accompanied by a significant perturbation in the electrochemical characteristics of the monolayer. Strikingly, the anion binding affinities associated with such SAMs are, in some cases, orders-of-magnitude greater than those associated with the same receptors free in solution. This “surface amplification,” which can lead to the development of highly effective sensors, is attributable to two

things: 1) The “macrocyclic effect” is the entropy- and enthalpy-driven increased thermodynamic stability of a complex formed between an ion (usually cationic) and a multidentate macrocyclic ligand in comparison to the equivalent complex formed with open chain (noncyclic) ligands. By “preorganizing” the host pseudo macrocycle on a surface, and thereby restricting its vibrational and rotational degrees of freedom, the entropic driving force accompanying complex formation is further increased. 2) The comparatively low dielectric constant of the SAM receptor binding site is also likely to significantly enhance anion binding efficacy. The ability to tune both geometry and binding affinity of the host molecular receptor allows one to achieve highly selective sensing. For example, the SAMs shown in Fig. 4 are able to sense dihydrogen phosphate in the presence of more than a 10,000-fold molar excess of halide in solvent. Functional surfaces of this type are able to detect low levels of perrhenate anion (a model for pertechnetate, an environmentally important radioactive waste product of the nuclear and radiopharmaceutical industries) in *aqueous* solution. By increasing both receptor binding affinity and electroanalytical detection sensitivity, it should be possible to extend this aqueous sensing to more basic anions.

### Nanoparticle Sensors

The optical and/or electrical/electrochemical properties of metallic or semiconducting nanoparticles and

**Fig. 4** Schematic representation of a self-assembling, hydrogen-bonding ferrocene amide capable of electroanalytical anion sensing. With the specific receptors shown, hydrogen phosphate anion recognition cathodic shifts in the ferrocene half-wave potential are  $>290$  mV in magnitude—greater, to our knowledge, than anything reported to date. *Source:* From Ref.<sup>[81]</sup>.

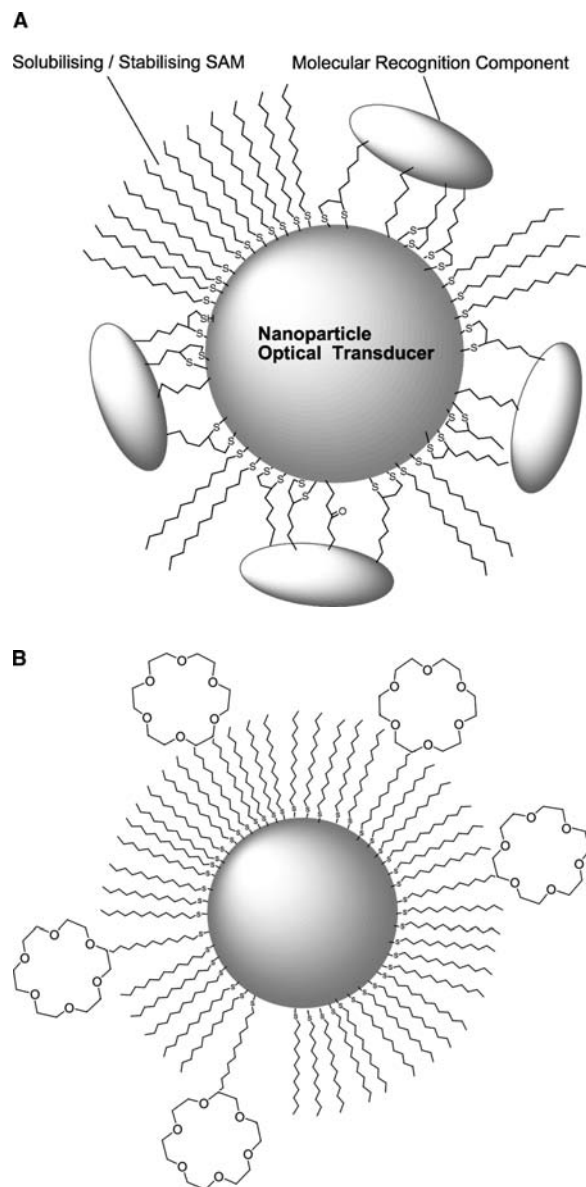

their arrays can be applied to molecular sensing in a variety of ways. One can envisage the role of the nanoparticles being one or combinations of the following:

1. Acting as structural template to preorganize the binding site/receptors—in this case, transduction is not from the particle itself.
2. Utilizing the nanoparticle optical properties (plasmon absorption or fluorescence) in transduction—the optical properties of gold nanoparticles (both in solution and surface-confined), for example, are highly sensitive to both the dielectric properties of the intermediate environment and aggregation.
3. Making use of nanoparticle conductance in either the electrochemical sensing of molecular binding at mono- or multilayer films, or in recognition-mediated change in film conductance.

Perhaps the least technically challenging, but nonetheless demonstrably powerful, use of nanoparticles in sensing lies with colorimetric assays. Additionally, nanoparticle arrays have considerable potential in vapor-phase analyte detection, Raman, and optical or electrochemical recognition.

### Colorimetric sensing

As mentioned earlier, gold nanoparticles exhibit characteristic plasmon absorptions that typically give their solutions a pink coloration. The sensitivity of this visible absorption (note: stable nanoparticle suspensions do not appreciably scatter visible light) to aggregation can be utilized in the nanoparticle equivalent of the latex agglutination test,<sup>[84]</sup> in which analyte-mediated color change is readily detectable through the use of standard UV–visible spectroscopy. Perhaps the best example of this has been recently demonstrated by Mirkin and coworkers in high-sensitivity colorimetric detection of DNA.<sup>[85]</sup> In this work, gold nanoparticles were surface-functionalized with thiolated single-stranded DNA. In the presence of *femtomolar* levels of the complementary DNA, subsequent hybridization-mediated agglutination leads to a visible red-to-purple color change. Colorimetric immunoassays have also been developed based on either antibody or antigen nanoparticle functionalization.<sup>[86]</sup> Related colorimetric titrations have recently been extended to the generation of ion-sensing systems. Specifically, by self-assembly of appropriately functionalized receptors on nanoparticles, cation- or anion-mediated linking or aggregation can be spectroscopically monitored (Fig. 5). In using self-assembling thiolated crown ethers, Lin et al.<sup>[87]</sup> were able to

**Fig. 5** A) Diagrammatic representation of a nanoparticle appropriately functionalized such that its properties are stable, it is soluble in an appropriate environment, and labeled with a molecular receptor/chemical or biochemical recognition agent. The latter may be a coordination site, oligonucleotide or antibody, for example. B) Place exchange of solubilizing alkyl thiols with a thiolated crown ether produces nanoparticle species that are sensitive to cations; 18-crown-6 and 15-crown-5 ether modified nanoparticles are sensitive to low levels of potassium. Thiolated carboxylic acid modified colloids are sensitive to the presence of heavy metal cations. *Source:* From Refs.<sup>[87]</sup> and<sup>[88]</sup>.

construct colorimetric assays, based on standard, proximity-linked, coupling of plasmons, for potassium, with detection limits down to low micromolar level. Similarly, cadmium-, mercury-, and lead-responsive assays have been developed.<sup>[88]</sup>

## Vapor phase sensing

The initially Ohmic, thermally activated, conductance properties of MPC films are sensitively dependent on the separation of, and intervening medium between, the particles. The “intercalation” of organic vapor into such films leads to a detectable decrease in the conductance. Although this phenomenon appears to be highly dependent on the structural aspects of the nanoparticle film, it may be applicable to the generation of highly robust sensors.<sup>[89]</sup> To date, several research groups have demonstrated fast, reversible, and highly sensitive (<5 ppm in some cases) responses to a variety of solvent vapors.<sup>[90]</sup> Although the mechanisms of vapor sensitivity are poorly understood, the phenomenon has been qualitatively considered in terms of both film swelling and dielectric change.<sup>[91,92]</sup>

## SERS—Raman sensing at surfaces

The Raman scattering attainable from an adsorbate on a rough metal surface is greatly enhanced over the attainable rate on flat substrates. This enhancement, observable on “active metals,” is greatest when the surface roughness is of the order of tens of nanometers and, although not fully understood, is associated with the ability of such surfaces to enhance/focus electromagnetic radiation. Although it is nearly 20 years since the discovery of surface-enhanced Raman scattering of molecules adsorbed at suitable roughened metallic interfaces,<sup>[93,94]</sup> where up to  $10^6$ -fold enhancements over the adsorbate natural Raman scattering can be observed, the generation of suitable roughened surfaces by etching or deposition methods suffers from reproducibility issues. Through the surface-confinement of nanoparticles, homogeneous surfaces of precisely appropriate roughness can be reproducibly fabricated. Furthermore, the plasmon characteristics of colloids appear to further magnify signal enhancement.<sup>[48]</sup> The use of colloidal gold or silver nanoparticles in enhancing the spectroscopic data attainable from interfaces has been demonstrated,<sup>[95,96]</sup> where million-fold enhancements leading, in some cases, to attomolar sensitivity, have been observed.<sup>[97]</sup>

## Electroanalytical sensing

Through the functionalization of colloidal gold nanoparticles with self-assembling amidoferrocenes, Astruc et al.<sup>[98,99]</sup> were able to demonstrate the establishment of an effective redox probe for dihydrogen phosphate and hydrogen sulfate in an organic solvent medium. This work makes use of the diffusive nature of solubilized nanoparticles, the facile access of anions to the hydrogen-bonding receptor site, and the reliable

electrochemical communication with redox-active units confined to the particle surface. Although additional preorganizational effects were noted in these studies, they pave the way to others in which the controlled assembly of redox-active molecular or ionic receptors on nanoparticles (free in solution or assembled in arrays on a surface) may lead to highly effective electroanalytical devices.

## Plasmon and optical sensing

Plasmon resonance sensors are ubiquitous in the study of interfacial (bio)molecular interactions and function by detecting changes in local refractive index with high sensitivity.<sup>[100]</sup> The collective oscillation of electrons responsible for the characteristic plasmon absorption of metallic nanoparticles is highly sensitive to changes in local (surface) refractive index.<sup>[101,102]</sup> In view of the associated local enhancement of electromagnetic field, one may propose that such a surface can act as an “antenna” for interfacial processes such as molecular recognition. By utilizing the environmental sensitivity of appropriately functionalized nanoparticles, one might envisage the development of related SPR sensors of nanometer (“molecular level”) dimension. Because we have observed that it is possible to modify nanoparticles surfaces with SAMs, the terminal functionality of which is flexible, it is possible to generate stable colloids which are sensitive to/reactive to different species<sup>[103]</sup> (Fig. 5). In pursuit of this and related optical goals, several groups have recently generated nanoparticles functionalized with molecular recognition moieties.<sup>[20,82,99,104]</sup>

As a specific example, and with the aim of producing optical and redox-active nanoparticle anion sensors, the synthesis of a new amide–disulfide functionalized zinc metalloporphyrin has been reported.<sup>[82]</sup> This compound can be self-assembled on to gold nanoparticles to produce a novel anion-selective optical sensing system (Fig. 6). In this work, the nanoparticle itself is utilized as a diffusive “template” on which the receptor is “preorganized.” The zinc Lewis acid and hydrogen bond-mediated recognition of halide, nitrate, or dihydrogen phosphate by the zinc metalloporphyrin center is associated with a perturbation of the porphyrin optical spectrum. What makes this particularly striking is the ability of the nanoparticle to generate a solution-phase, but preorganized, receptor of high analyte binding affinity. As discussed in the previous section, the combined enthalpic and entropic factors associated with the monolayer-based, receptor site and its surrounding low dielectric are such that binding constants are enhanced by more than 2 orders of magnitude in comparison to the nonparticle-confined receptor (Table 1). Significantly, this enhanced binding affinity is such that anion recognition in a

**Fig. 6** Schematic of an anion-sensing zinc porphyrin nanoparticle. The tetrapodal porphyrin is anchored to the nanoparticle surface through disulfide moieties. Note, for reasons of clarity, that the relative sizes of nanoparticle and porphyrin are false. *Source:* From Ref.<sup>[82]</sup>.

mixed aqueous/solvent system, a challenging situation because of the competitive solvation of the anion, is possible. By further tailoring the receptor site chemical and geometric properties, it should be possible to

generate yet more powerful sensing systems. Because functionalized SAMs can be similarly generated on semiconducting nanoparticles, sensing systems based on, e.g., a recognition-based perturbation of fluorescence may be feasible.

**Table 1** Association constant ( $\log K$ ) data for anion binding by Zn porphyrin receptor both assembled on the surface of a nanoparticle and free in solution

Anion	Particle free Zn porphyrin	Particle bound Zn porphyrin
$\text{Cl}^-$	>6	>6
$\text{Br}^-$	4.12	4.97
$\text{I}^-$	3.21	4.00
$\text{NO}_3^-$	2.41	3.22
$\text{H}_2\text{PO}_4^-$	>6	>6

## CONCLUSION

The potential impact of nanoscale science and technology on our lives is considerable. In recent years, much progress has been made in both generating and analyzing nanoscale material. To exploit some of the striking properties observed in matters of such dimensions, methods must be developed where homogeneous samples of material can be produced in useful quantities and incorporated into functional devices. In this article, we have attempted to summarize recent progress made in characterizing and utilizing the size-dependent properties of nanoparticles and quantum dots. Specifically, we have outlined and demonstrated

methods by which the environmental sensitivities inherent in these structures can be used in sensing technologies. Although interest in generating smaller analytical devices for been around for some time, only in recent years has it been possible to make use of the specific functional properties that are apparent at the nanometer scale. The ability to selectively and sensitively detect ions is of considerable environmental, clinical, and chemical importance. Through designed functionalization of nanoparticles with receptor moieties, it is possible to construct derived optical or electroanalytical assays. We have specifically introduced methodologies whereby nanoparticle-based ion assays can be developed. Through further refinement of nanoparticle functionalization, manipulation, and interrogation, the creation of a vast number of novel and highly responsive sensory devices seems feasible.

## INTRODUCTION

Advanced materials composed of inorganic nanoparticles are currently one of the most dynamic areas of scientific research. These particles represent significant fundamental and commercial interest with a wide range of applications including the next generation of optics, electronics, catalysts, and sensors. In the past 20 years, with the increasing developments in nanotechnology, nanoelectronics, and nanobioelectronics, functional building blocks with which to construct microstructures and devices are under intensive investigation. Increasing attention has been paid to metal or semiconductor nanoparticles, which have also been called nanocrystals, nanoclusters, quantum dots, and Q particles.

Nanoparticles are in the size range of 1–100 nm, which lies between single atoms or molecules and bulk materials, and their chemical and physical properties differ markedly from those of the bulk solids. The reasons for these properties can be attributed to high surface area and quantum size effect, which is caused by the reduced size in three dimensions. One typical example is that the melting temperature of nanoparticles strongly depends on the particle size and is substantially lower than the bulk melting temperature. The melting point of 2.5-nm Au nanoparticles is ~40% lower than that of bulk gold. Similar behavior has been observed for CdS nanoparticles. At the same time, with the decrease in the number of atoms in the particles, their electronic properties also start to change. This is the so-called quantum size effect, which can be observed as a blue shift in the optical band gap or exciton energy. When the size of particles is reduced to nanometer scale, the number of atoms at the surfaces or grain boundaries of the crystalline regions is comparable to the number of those that are in the crystalline lattice itself. Physical and chemical properties, which are usually determined by the molecular structure of the bulk lattice, become increasingly dominated by the defect structure of the surface. During the preparation of nanoparticles, engineering of the size and surface structure is of both theoretical and practical

importance, because it leads to mechanical, chemical, electrical, optical, magnetic, electro-optical, and magneto-optical properties that are substantially different from those observed for the corresponding bulk materials. Chemists, biologists, and materials scientists have studied and reviewed the preparation and characterization of metal and semiconductor nanoparticles in detail, focusing on their physical and chemical properties.<sup>[1–24]</sup>

Nanoparticles can be synthesized from a variety of materials with controllable sizes, shapes, and structures, but because of their high specific surface area and low surface energy, nanoparticles are not stable in ambient circumstances, and they must be incorporated in certain kinds of materials. Materials such as reverse micelles and surfactant vesicles,<sup>[25]</sup> glass,<sup>[26,27]</sup> zeolites,<sup>[28,29]</sup> and polymers<sup>[30–34]</sup> have been used as the substrate to prepare composite materials containing nanoparticles. During the preparation of such materials, the substrate not only can prevent the nanoparticles from aggregation, but also can accurately control their size and surface structure. In addition, in applications for optical, electrical, and magnetic devices, nanoparticles are mostly used in the form of thin films. Currently, such films can be made by spin coating,<sup>[35–37]</sup> spraying,<sup>[38,39]</sup> chemical deposition,<sup>[40–42]</sup> electrical deposition,<sup>[43–46]</sup> Langmuir–Blodgett (LB) technique,<sup>[47–51]</sup> and layer-by-layer self-assembly (LBL) method.<sup>[51–57]</sup>

In this entry, we will focus on the preparation of nanoparticles in polymer matrices and the assembly of nanoparticles at interfaces.

## PREPARATION OF NANOPARTICLES IN POLYMER MATRICES

Polymers have been considered one of the most important matrix materials for the preparation and application of nanoparticles because of their mechanical, optical, electrical, and thermal properties.<sup>[30–34]</sup> In polymer networks, movements of nanometer-sized particles are restricted by the polymer chains, so aggregation is avoided and the nanoparticles are stabilized

**Fig. 1** Scheme for the assembly of metal sulfide nanoparticles in polymer networks. *Source:* From Ref.<sup>[64]</sup>.

by the polymer networks. The size and size distribution of the particles can also be controlled by the concentration and density of metal ions. In order to prepare nanoparticles in polymer networks, the metal ions should be previously dispersed in the polymer networks. There have been two methods for the incorporation of metal ions into polymer networks.

The first method involves the introduction of metal ions into polymer networks by a metal-ion-containing monomer. PbS nanoparticles with an average size of 4.0 nm have been prepared in polymer networks by H<sub>2</sub>S treatment of a copolymer of styrene and lead methylacrylate.<sup>[58,59]</sup> The concentration of the metal ions could be controlled by altering the relative proportion of the two monomers. Infrared (IR) measurements and the variations of the molecular weight of the copolymer before and after reacting with H<sub>2</sub>S implied that there exist Pb–OOC bonds on the surface of the nanoparticles. PbS nanoparticles act as cross-linking agents, and the interaction of the polymer with the nanoparticles gives a surface chemical modification of the PbS nanoparticles, which strongly affects the optical properties of the nanoparticles.

The second method involves the introduction of metal ions into polymer networks by ion-exchange adsorption.<sup>[60–65]</sup> As shown in Fig. 1,<sup>[64]</sup> cross-linked polymer networks were formed by polymerization of styrene with a cross-linking agent. Then the polymerizate was sulfonated by sulfuric acid, and the product could be immersed in an aqueous solution that contained metal salts to adsorb metal ions into the polymer networks by exchange with H<sup>+</sup> of –SO<sub>3</sub>H. By varying the duration of the ion exchange and the concentration of the metal salt solution, we can control the concentration of the metal ions. The metal-ion-containing polymer networks could be dissolved in

an organic solvent and then treated with H<sub>2</sub>S gas, after which the solution turns yellow but without precipitation, which shows the formation of CdS nanoparticles. The resulting nanoparticles had a narrow particle size distribution. By this method, CdS, Cu-doped ZnS, and Cu<sub>2</sub>S/CdS/ZnS nanoparticles could also be prepared. All these results indicated that the polymer networks could effectively prevent the particles from growing and aggregating.

Metal or semiconductor nanoparticles may also be prepared in situ in the microdomain space formed in block copolymers.<sup>[66–71]</sup> Block copolymers exhibit phase separation, which may help isolate the nanoparticles as they form. When a copolymer is used as the matrix for nanoparticles, the particle size is controlled by the composition of the copolymer and the concentration of metal ions. Nafion film, which is a type of ionic polymer and can adsorb metal ions by ion exchange, has also been used to prepare nanoparticles.<sup>[72–75]</sup> Similarly, the size of the nanoparticles can be controlled by the initial metal ion concentration and subsequent thermal annealing treatment.

## THIN FILMS OF NANOPARTICLES

### Nanoparticles in LB Films

Transferring a well-packed monolayer from aqueous solution surfaces to solid substrates was demonstrated about 60 years ago by the Langmuir–Blodgett (LB) technique. Surfactant structures have also been used for direct assembly of metallic, semiconducting, and magnetic nanoparticles. This organization can be accomplished by adsorbing particles electrostatically to charged surfactant headgroups or by in situ

generation of particles beneath monolayers at the air–water interface.<sup>[47–51,76–83]</sup> Surfactant monolayers with attached nanoparticles can be transferred to solid supports using standard LB techniques.

Monolayers of surfactants have proven to be versatile as templates for the in situ growth of thin nanoparticle films. These monolayers are formed from a range of naturally occurring and synthetic surfactants or from a mixture of suitable surfactants, and their two-dimensional phase behavior and structure are well understood. Fendler and Meldrum have described the formation of sulfide semiconductor nanoparticulate films under a Langmuir monolayer of surfactants as follows:<sup>[51]</sup> After the spreading of surfactant monolayer on the air–water interface of the metal ion solution with an atmosphere of H<sub>2</sub>S, metal sulfide bonds formed at a large number of sites at the monolayer–aqueous interface. Well-separated nanoparticles of metal sulfide then formed and coalesced into interconnected arrays of semiconductor nanoparticles and a porous semiconductor particulate film composed of particles 20–40 Å thick and 30–80 Å in diameter. Once the first layer of semiconductor nanoparticulate film formed, subsequent layers were deposited up to a plateau thickness beyond which the film cannot grow. The presence of a monolayer with an appropriate surface charge is essential to the formation of the sulfide semiconductor nanoparticulate film. In the absence of a monolayer, infusion of H<sub>2</sub>S over an aqueous metal ion solution resulted in the formation of large, irregular, and polydispersed metal sulfide particles, which precipitated in the bulk solution before settling to the bottom of the trough. Furthermore, the nanoparticulate film could not form under positively charged monolayers.

Thin films of nanoparticles can also be fabricated by spreading surfactant-stabilized nanoparticles on aqueous solutions and then transferring them to solid substrates by the LB technique. The technique can be regarded as analogous to monolayer formation from simple surfactants. Nanoparticulate films were formed at the air–water interface by dispersing surfactant-stabilized nanoparticles on an aqueous subphase, which was contained in a Langmuir trough. There are many intrinsic benefits to this method. The nanoparticles are prepared before the incorporation into the films, allowing one to control their dimensions, physical properties, and the particle size and distribution. Gao et al. have reported the fabrication of Fe<sub>2</sub>O<sub>3</sub>/polymer composite film using the LB method.<sup>[77]</sup> Methacrylic acid was used as the surfactant to prepare Fe<sub>2</sub>O<sub>3</sub> nanoparticles by the microemulsion method in a system of water–toluene. After a cross-linking agent together with an initiator were added into the organosol and reacted under ultrasonic stirring, an organic–inorganic composite microgel was obtained. This composite

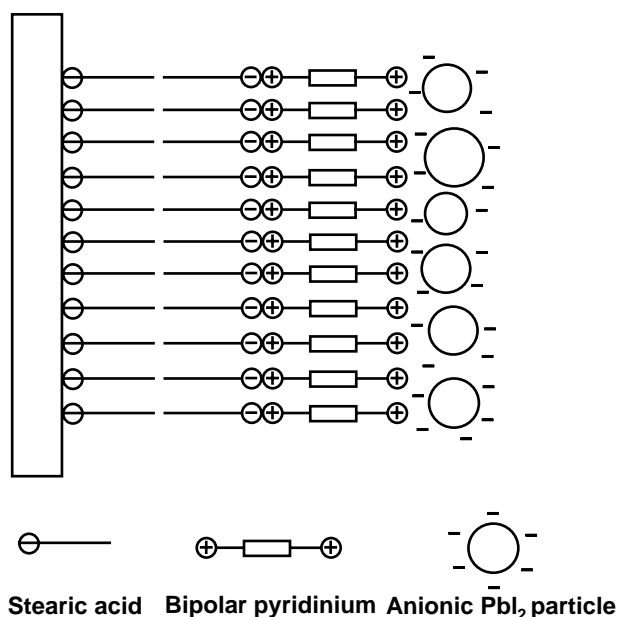

microgel showed good amphiphilic properties and could be transferred onto solid substrates from a pure water interface using the LB technique. Infrared and UV–visible (UV–vis) spectra of the film showed the presence of some residual vinyl groups, which means that the microgel could be further polymerized. Polymerization of surfactant in the composite films improved the stability of the LB film.

### Assembly of Nanoparticle Monolayers

Solution-based approaches to surface assembly of metal and semiconductor nanoparticles typically involve electrostatic or covalent binding of the particle to a surface-bound molecular or polymeric thin film.<sup>[84–90]</sup> Self-assembly of metal nanoparticle monolayers on polymer-coated substrates yields macroscopic surfaces that are highly active for surface-enhanced Raman scattering (SERS).<sup>[85–87]</sup> Nanoparticles are bound to the substrate through multiple bonds between the colloidal metal and functional groups on the polymer such as cyanide (CN), amine (NH<sub>2</sub>), and thiol (SH). Self-assembly of nanoparticles onto the oppositely charged substrate surface is governed by a delicate balance of the adsorption and desorption equilibria. The efficient adsorption of one monolayer of nanoparticles onto the oppositely charged substrate surface is the objective of the immersion step. Preventing the desorption of the nanoparticles during the rinsing process is of equal importance. The optimization of the self-assembly in terms of maximizing the adsorption of nanoparticles from their dispersions and minimizing their desorption upon rinsing requires the correct selection of stabilizers and the careful control of the kinetics of the processes.

The deposition process may also be performed on a substrate modified by an LB film, which may give a charged surface. As we have reported,<sup>[91]</sup> one monolayer of PbI<sub>2</sub> nanoparticles can be adsorbed on a substrate modified by LB films through electrostatic interactions. First, we transferred two layers of Y-type LB film of stearic acid onto some hydrophilic substrates, which allowed one layer of bipolar pyridinium to be adsorbed onto the carboxylic surface of the LB film. Finally, we deposited one layer of anionic PbI<sub>2</sub> after the bipolar pyridinium. The structure of the self-assembled monolayer film is shown in Fig. 2. Substrates such as Si, CaF<sub>2</sub>, quartz, glass, Ag, and Au are widely used for LB processes, so LB film-covered slides can provide a wide range of substrates for a self-assembled monolayer of nanoparticles. In order to observe the PbI<sub>2</sub> nanoparticles monolayer in the self-assembled film with transmission electron microscopy (TEM), a copper grid covered with a very thin layer of formvar was used as the LB film substrate. A TEM

**Fig. 2** Scheme for one monolayer of  $\text{PbI}_2$  nanoparticles in the stearic acid–bipolar pyridinium– $\text{PbI}_2$  four layer structure. Source: From Ref.<sup>[91]</sup>.

photograph of the self-assembly film shows that all the  $\text{PbI}_2$  nanoparticles are round and closely packed, but without any large aggregates. As a comparison, one droplet of the  $\text{PbI}_2$  solution was dropped onto the grid and blown dry with  $\text{N}_2$ . TEM measurements showed that the small particles had aggregated into large ones during the evaporation in the sample preparation. This contrast proves that the bipolar pyridinium film interacts with the nanoparticles strongly and can effectively keep the small particles from aggregating.

Covalent attachment strategies often take advantage of the reactivity of the outer shell atoms in the nanoparticles. Many metallic and semiconductor nanoparticles (Au, Ag, CdS, CdSe) have a high affinity for amine and/or thiol moieties.<sup>[54]</sup> For example, Colvin et al. have covalently attached CdS nanoparticles to Au and Al substrates using bifunctional cross-linkers.<sup>[84]</sup> Natan and coworkers have assembled Au and Ag nanoparticles on  $-\text{NH}_2$  and  $-\text{SH}$  terminated organosilane polymers on silica substrates.<sup>[85,87]</sup> The kinetics of this surface-assembly reaction have been investigated in some detail, affording control over the number of particles on the surface.

Alternatively, close-packed monolayers of alkanethiol-stabilized nanoparticles have been formed by solvent evaporation.<sup>[17,18]</sup> Self-assembled arrays involve self-organization of size-selected nanoparticles encapsulated in protective, compact organic coatings into monolayers, thin films, and superlattices. A key step in this process is the fabrication of size- and shape-controlled nanoparticle superlattices that can grow large

enough for technological applications. In this case, the length of the organic ligand defines the distance between particles. This distance has a pronounced effect on the electronic properties of the resulting structure. Particles that can be self-assembled are usually smaller than 10 nm in size, and it is in this size range that many exciting and unusual physical properties are enhanced.

### Layer-by-Layer Assembly of Nanoparticles

The LBL method developed by G. Decher is one of the most promising new methods of thin film deposition, and it is often used for oppositely charged polymers.<sup>[92–94]</sup> Recently, it has also been successfully applied to thin films of nanoparticles and other inorganic materials,<sup>[51–57]</sup> such as Au,<sup>[95–97]</sup> Ag,<sup>[98–101]</sup> CdS,<sup>[102]</sup> PbS,<sup>[103]</sup>  $\text{Fe}_3\text{O}_4$ ,<sup>[104–106]</sup> CdSe,<sup>[107–109]</sup> HgTe,<sup>[110]</sup>  $\text{TiO}_2$ ,<sup>[111]</sup>  $\text{SiO}_2$ ,<sup>[112–114]</sup> and others.<sup>[115–119]</sup> Its simplicity and universality combined with the resulting high quality of coatings and uniform distribution of nanoparticles open broad perspectives for this technique both in research and in industry. Compared with other techniques for the fabrication of thin films of nanoparticles, the LBL method has two main advantages: 1) simplicity (the relative ease of preparation and versatility have contributed to the rapid development of this method), 2) universality (tolerance of the substrate shapes and materials and the dual, organic–inorganic nature of the coating).

The LBL assembly of nanoparticles can be described as the sequential adsorption of monolayers of nanoparticles on positively charged layers of a polyelectrolyte. Interestingly, purely inorganic LBL films were described more than 30 years ago.<sup>[120]</sup> The deposition of the films can be performed in a cyclic manner, which is made possible by the overcompensation of surface charge, which often takes place when polyelectrolytes and other high molecular weight species are adsorbed onto a solid–liquid interface. The construction of an LBL film of nanoparticles requires four simple steps.<sup>[52]</sup> 1) prime a cleaned substrate by absorbing a layer of surfactant or polyelectrolyte onto its surface; 2) immerse the primed substrate in a dilute aqueous solution of a cationic or anionic polyelectrolyte for the optimized length of time for adsorption of a monolayer; 3) rinse and dry the substrate; 4) immerse the polyelectrolyte monolayer covered substrate in a dilute dispersion of oppositely charged semiconductor nanoparticles, also for the optimized length of time for adsorption of a monolayer of nanoparticles. These four operations complete the self-assembly of one polyelectrolyte–nanoparticle bilayer, and by repeating them, multilayered self-assembly films of polyelectrolyte and nanoparticles can be fabricated. The electrostatic attraction between semiconductor colloids

and a layer of polyelectrolytes ensures the facile adsorption. At the same time, the electrostatic repulsion between similarly charged species in solution limits the thickness of the newly formed thin layer of nanoparticles.

Our group has reported several kinds of LBL films of nanoparticles,<sup>[121–131]</sup> among which we have also fabricated a CdS nanoparticle/cationic polyelectrolyte multilayer film based on electrostatic interactions.<sup>[122]</sup> An aqueous solution of CdS nanoparticles was prepared by the addition of mercaptoacetic acid as a stabilizer agent. Infrared measurements imply that mercaptoacetic acid was chemically modified on the surface of CdS nanoparticles through thiol groups, with carboxylic acid groups pointing to the solvent, and the carboxylic acid group was in a state of  $\text{COO}^-$ , which made it possible to use the surface-modified CdS nanoparticles as the negatively charged species in the LBL assembly process. A quartz substrate covered with aminopropylsilane was prepared by treating with the vapor of 3-aminopropyltriethoxysilane and then reacted with HCl solution to become positively charged. Then, using the LBL method, negatively charged nanoparticles and positively charged polyelectrolyte could be alternatively deposited on the substrate. The structure of the LBL film is shown in Fig. 3. UV-vis absorption spectroscopy was used to monitor the LBL assembly process, and the similarity of the absorption spectra of the alternating films to that of the CdS nanoparticles in the visible region implies that the CdS nanoparticles were successfully assembled in the alternating film. In the UV-vis spectra (Fig. 4) of multilayer films with different numbers of layers, a linear increase of the absorbance of CdS

**Fig. 3** Scheme for the assembly of CdS nanoparticles in LBL films. *Source:* From Ref.<sup>[122]</sup>.

**Fig. 4** UV-vis absorption spectra of the LBL films of CdS nanoparticles and a cationic polyelectrolyte with different numbers of layers. Inset: absorbance vs. number of layers at 340, 400, and 461 nm. *Source:* From Ref.<sup>[122]</sup>.

nanoparticles could be observed, which indicates that the oppositely charged species were deposited equivalently in different steps during the LBL process. The deposition process was also monitored by quartz crystal microbalance (QCM), which can detect the adsorption of the charged species in the LBL films. The QCM results of the LBL film in different steps also show a uniform deposition process.

The driving force of the LBL process of nanoparticles could be not only electrostatic interactions, but also coordinative interactions<sup>[132,133]</sup> or hydrogen bonds.<sup>[134,135]</sup> As is well known, there exist typical coordinate complexations between pyridine and some transition metals. Based on coordinative bonds, CdS nanoparticles with general Cd-rich surfaces could be assembled in LBL films by alternating deposition with poly(4-vinylpyridine) (PVP). The construction of CdS/PVP multilayer film is shown in Fig. 5. The substrate was modified first to create a surface covered with pyridine groups. The resulting substrate was then dipped into a colloidal CdS solution to adsorb one layer of CdS nanoparticles. After being washed, the substrate was transferred to the PVP solution to absorb one PVP layer. The CdS/PVP multilayer films were prepared by repeating the above steps. UV-vis spectra were used to monitor the self-assembly process, confirming a stepwise and uniform assembly process. The driving force for the CdS/PVP multilayer film was identified by IR spectroscopy. By comparing IR spectra of pure PVP and the multilayer film (Fig. 6), a new peak at  $1610\text{ cm}^{-1}$  appeared in the spectrum of the multilayer film. Since the coordinate complexation between pyridine groups and metal ions usually exhibits this band because of the formation of coordination bonds, we considered that CdS nanoparticles were assembled into the multilayer film based on the

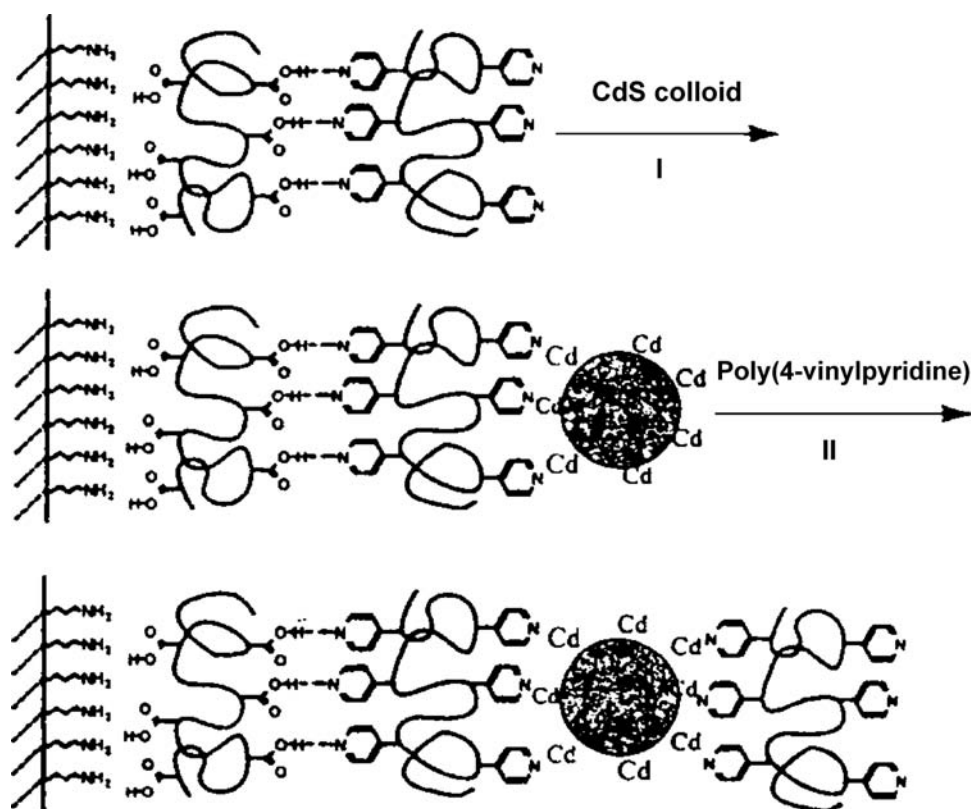

Fig. 5 Scheme for the build-up of alternating films of PVP/CdS nanoparticles based on coordinative bonds. *Source:* From Ref.<sup>[134]</sup>.

formation of coordinative bonds between the surface Cd atoms of CdS nanoparticles and the pyridine groups of PVP. We also found that CdS nanoparticles that have S-rich surfaces could not be assembled with PVP, which ensures the driving force to be coordinative bonds.

It has recently been reported that nanoparticles could also be formed in situ in LBL films of polyelectrolytes.<sup>[136–139]</sup> Silver nanoparticles were prepared in situ within poly(acrylic acid) (PAA) and poly(allylamine hydrochloride) (PAH) multilayer films. Carboxylic acid groups in the PAH/PAA-based multilayers bind silver cations by ion exchange with the acid protons. Subsequent reduction forms metallic nanoparticles. Because PAA has a pH-dependent degree of ionization, the multilayer film can be fabricated with different concentrations of free acid groups that are available to bind silver cations depending on the multilayer assembly pH. The nanoparticle size and silver concentration can be controllably increased by reducing the assembly pH of PAH/PAA-based multilayers. Furthermore, because the metal-binding carboxylic acid groups are reprotonated upon nanoparticle formation, the synthesis methodology can be repeatedly cycled to incorporate more silver cations, which increases the size and concentration of silver nanoparticles.

Recently, the LBL process has been applied to the surface modification of colloidal microspheres, which represent attractive building blocks from which to create ordered and complex materials. Möhwald and co-workers have demonstrated the LBL assembly of polyelectrolytes on the surface of colloidal latex spheres.<sup>[140,141]</sup> The main advantage of this LBL process is that the film thickness on the colloidal spheres could be fine-tuned by altering the number of layers deposited and the solution conditions from which the polymers are adsorbed. More recently, nanoparticles of SiO<sub>2</sub>, Ag, and Au have also been assembled on the surface of colloidal microspheres.<sup>[24,142–148]</sup> Assembly of nanoparticles on the surface of colloidal microspheres resulted in the formation of nanoparticle-coated microspheres. By removing the colloidal microspheres template through calcination or dissolution, hollow spheres of metal or silica were formed, which may find applications in catalysis, sensing, optics, and separations.

## CONCLUSION

With the development of nanoscience and nanotechnology, nanosized building blocks as nanoparticles will attract more and more attention. In both bulk and film

**Fig. 6** Infrared spectra of (A) pure PVP and (B) PVP/CdS multilayers. Source: From Ref.<sup>[134]</sup>.

structures, nanoparticles can be stabilized and assembled. We have introduced the incorporation of polymers as the substrates for nanoparticles and the assembly of nanoparticles in thin film structures such as LB films, self-assembled monolayers, and LBL multilayers, which have proved to have potential applications in optics, electronics, magnetism, catalysis, and sensors. Research will now focus on controlling the size, shape, and surface structure of nanoparticles, as well as fabricating new nanostructured materials and looking for new applications. The assembly of nanoparticles on microscale substrates such as patterned surfaces or microspheres, and the physical and chemical properties of single nanoparticles continue to invite our scrutiny.

## Abstract

This entry considers mechanosynthesis of nanophase powders, i.e., the production of nanophase compounds by mechanochemical action starting from elemental powders. The paper focuses on the operating principles of the most common devices employed for the process, along with some kinematic aspects, some specific mechanical considerations, thermodynamic and kinetic issues, atomistic of mechanically induced phase transformations, and a detailed example in kinetics. The entry ends with current applications and industrial trends of mechanosynthesized powders.

## INTRODUCTION

Among the different processes that are able to produce nanocrystalline powders in bulk quantities, mechanosynthesis, i.e., the synthesis of nanograined powders by means of mechanical activation, is one of the most interesting from an industrial point of view. Mechanosynthesis of nanophase powders is one of the less sophisticated technologies—and in such a sense also the most inexpensive—to produce nanophase powders; in fact it exploits devices and processes that have many aspects in common with mixing, fine grinding, and comminution of materials. However, it does have interest for applications, as in principle this is a very low-cost process and its potential for industrial applications is very significant. This entry describes the basis of the process, some possible applications and perspectives of mechanosynthesized nanophase powders and some simple ideas that are able to depict part of the process, with a specific mind to the mechanosynthesis of nanocrystalline materials starting from elemental powder precursors. Mechanosynthesis belongs to the family of process technologies known as mechanical alloying, which are basically using the same or very similar apparatuses, i.e. milling or size reduction devices, which could be generally described as ball mills. A recent thorough analysis by Suranarayana<sup>[1]</sup> of the processes related to mechanical alloying defines mechanosynthesis as a mechanochemical synthesis, attributing most of the research work in this field of mechanical alloying to McCormick,<sup>[2]</sup> Takacs,<sup>[3]</sup> and Matteazzi,<sup>[4]</sup> it is also necessary to quote the fundamental and pioneering work of Butyagin<sup>[5]</sup> and Boldyrev<sup>[6]</sup> and some important developments by Calka.<sup>[7]</sup> Although, owing to many different process parameters and conditions, a complete modelling of the mechanical alloying process and mechanosynthesis

of nanophase materials would be an aim very difficult to reach, it is useful to identify the *operating principle of the most common devices* employed for the process, along with some *kinematic aspects, some specific mechanical considerations, and thermodynamic and kinetic* issues of the process as well. Finally, current production of mechanosynthesized powders and perspectives will be briefly discussed.

## THE MECHANOSYNTHESIS PROCESS

The concept of the mechanosynthesis process is very simple: to seal in a vial some—usually powdered—materials along with grinding media, which are usually balls, and to reduce the size of the materials by mechanical action, providing in the same time an intimate mixing of the different materials introduced, so close that diffusion and chemical reactivity are greatly enhanced. For clarity, one could consider a mixture of elemental powders—for simplicity, we could limit to powders of element *A* and element *B*—introduced in a cylindrical container, the jar of a vibrating mill, with repeated and prolonged impacts imposed by mechanical energy imparted to grinding media (Fig. 1).

Depending on the nature of the reactants, different intermixing mechanisms are possible; generally speaking, the ductile phase tends to incorporate—if such a phase is present—a more brittle phase, with a tendency to form particles that are microscopically (to a scale of  $\mu\text{m}$ ) folded.

With prolonged milling, the crystal size of both reactants decreases in an exponential way, following a decreasing trend with the processing time  $t$  of the type:<sup>[8,9]</sup>

$$d = d_f + (d_i - d_f)e^{-c_1 t} \quad (1)$$

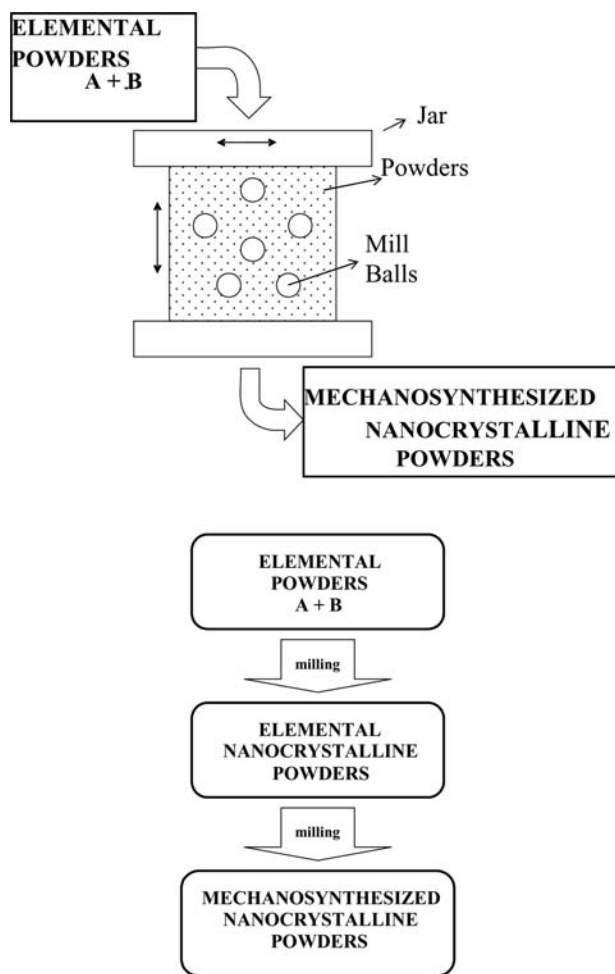

Fig. 1 Mechanochemical synthesis schematic process and steps.

where  $d$  should be considered representative of the crystal size, being  $d_i$  the initial,  $d_f$  the steady state crystal size and  $c_1$  an empirical constant depending on the process parameter. Other possible trends of the crystal size evolution with milling time are discussed in the next paragraph, especially if exothermic effects of the reaction  $A + B \rightarrow A_xB_y$  are to be taken into account.

The gradual transformation of the milled powders from a rather coarse to a nanocrystalline grain size could be simply depicted as a formal reaction:

Fecht<sup>[10]</sup> has been considering mechanical milling—i.e. the reduction of metal powders of elements and intermetallic compounds to nanocrystalline powders by grinding—and he has proposed empirical estimates for the enthalpy stored. These estimates could be a base for an evaluation of the mechanochemical energy transfer imparted to the powders. In mechanochemical processing, as time is increasing, along with the energy imparted to the materials, new phases/compounds

tend to appear. It has been generally recognized, by different authors, that the generic reaction path linking the time evolution of the reactants with time is sigmoidal.<sup>[8–10]</sup> We shall come back to this point dealing with the process kinetics. Here, we could depict the second step of the reaction as:

This is an oversimplification, as the mechanochemical synthesis process occurs continuously. However, it may be useful to evaluate, for instance, energetic aspects.

## KINEMATIC AND MECHANICAL ASPECTS

Milling devices are of different nature: vibrating mills, planetary mills, attritor mills, and tumbling mills—with efficiencies in the process that are decreasing from vibrating to tumbling—have been employed successfully. The different devices employed for research purposes are described in Koch;<sup>[11]</sup> there has been a tendency of different research groups<sup>[5,12,13]</sup> to develop ad hoc mills for the synthesis by milling of nanophase materials. Figure 2 describes a mill developed in the University of Udine, which has been scaled-up to be industrially employed.

The most important physical parameters involved are well described in a series of papers by Cocco and Delogu,<sup>[8,9,14]</sup> in an attempt to propose a quantitative understanding of the mechanical alloying processes. These authors have underlined the importance of relating basic and phenomenological aspects, suggesting that the framework of solid-state chemistry and chemical kinetics should be the most fruitful to interpret results and develop new trends. For the sake of simplicity, considering a mill with just one ball, and adopting the terminology of Butyagin,<sup>[5]</sup> one of the pioneers in the field of mechanochemistry, they propose: where  $m_b$  and  $m_p$  are the mass of the ball and of the powder. With such a situation, it could be interesting to adopt the quantitative techniques used in engineering the deformation processes, as it has been proposed earlier by Maurice and Courtney.<sup>[15]</sup> In any case, with the aid of simple kinetic trends, the milling time should be related to the energy dose, not only for device scale up but also for process control. This could help, for instance, to control exothermic mechanochemical reactions where combustion appears, imparting the completion of a mechanochemical synthesis of nanocrystalline materials.

A possible new design for a jar for laboratory milling is the one presented above (Fig. 3), together with its constructional details. The purpose of the experimental jar is to use a diathermic oil to monitor heat release during processing. The jar has been produced with integral

**Fig. 2** Experimental vibrating mill for the synthesis of nanophase materials in significant quantities. *Source:* From Ref.<sup>[12]</sup>.

internal channels by means of selective laser sintering<sup>[16]</sup> and it is available for experimentation on SPEX 8000 mills; typical dimensions of the main cylinder are 75 mm in height, 60 mm in outside diameter.

## THERMODYNAMICS

Mechanochemistry is a technique involving far from equilibrium processing; so, in principle, thermodynamics arguments should not be of help; however, it is possible to conceive the most simple reaction in the mechanochemistry of nanocrystalline materials—the one involving elemental powders *A* and *B*—as a two-step process: the first could be thought as a reduction of the crystal domains, the second as the formation of a nanophase compound or alloy. Fecht's extrapolation may be employed for the first step, Miedema model for the second step, assuming that the enthalpy of alloy formation is the same also in the nanocrystalline status.<sup>[10]</sup>

This approach is able to give order of magnitude correct results, as could be checked comparing these semi-empirical calculations<sup>[10]</sup> to the actual heat release.<sup>[17]</sup>

Fecht proposed an empirical regression with an analysis by means of DSC (differential scanning calorimetry) data on nanocrystalline metals and intermetallic compounds obtained by 24 hr ball milling by SPEX milling. Scanning up to 870 K with 20 K/min, he got the results listed in Table 3.

These data allow to estimate the excess enthalpy stored:

$$\Delta H/\Delta H_f = 8.5 \cdot 10^{-5} T_m \quad (2)$$

where  $\Delta H_f$  is the enthalpy of melting.

## KINETICS

For what concerns kinetic evolution, the situation is very complex. We have different and contrasting phenomena. Dealing with the mechanochemistry of nanophase materials, we are interested to obtain a crystal size of the order of tens of nanometers, which is usually considered an effective value for applications. The crystal size evolution with time could be depicted with equations of the type (1) reported here. More in detail, a phenomenological modeling approach to size refinement of metal crystallites under mechanical processing could be described as the following. In the framework of what we have previously described, the processing of powder in ball mills is characterized by three fundamental features. First, the transfer of energy to powders takes place at impact events involving both powders and milling tools. Second, only small powder amounts are trapped between milling tool surfaces at impact. Third, the granular flow inside the reactor allows an efficient redistribution and homogenization of powders after each impact.<sup>[18]</sup> Having all powder particles roughly the same, probability of being involved in collisions, mechanical processing can be regarded as a discrete process with statistical character.

A statistical description of the progressive decrease of the domains of coherent diffraction as a function of the number of collisions in a given sequence can be hardly based on the total number of powder particles. In fact, this is continuously modified during the course of mechanical treatment as a consequence of fracturing and coalescence processes.<sup>[1]</sup> A suitable quantity to consider is instead the volume of powder trapped at collision. Depending on the size of milling tools, their relative impact velocity and the total amount of powder inside the reactor,<sup>[19,20]</sup> it keeps approximately constant during the whole time of mechanical treatment.

**Fig. 3** (A) Prototype vial for the Spex 8000 Mill, along with a section view of internal channels. (B) Prototype vial for the Spex 8000 Mill: constructional details for the direct metal selective laser sintering processing.

A statistical modeling of ball milling must necessarily address a few fundamental questions concerning the relationships between processing parameters and rate of crystallite size decrease. How large is the powder amount involved at impact in deformation processes severe enough to result in a crystallite size decrease? How many impacts are necessary to attain a given average crystallite size? Being the powder amount trapped at collisions, only a small fraction of the total powder charge inside the reactor, which is the relationship between the total number of impacts and the number of collisions undergone by a given fraction of powder?

Approximate answers to such questions can be found by developing a simple phenomenological model referred to the case of mechanical processing carried out by employing a single milling ball. Under the assumption that the volume  $v_{\text{imp}}$  and the average density  $\rho$  of powders trapped at collision keep constant during the processing, the mass  $m_{\text{imp}} = v_{\text{imp}} \rho$  of powder involved on the average in individual collisions is also constant. The rate of crystallite size decreases is proportional to the volume fraction  $x_{\text{imp}} = v_{\text{imp}}/v_p$  of powder worked at impact,  $v_p$  being the total volume of powder inside the reactor. However, it is generally believed that the fraction of trapped powder must

**Table 1** Butyagin terminology for an elementary mechanochemical process: ball milling with one ball, after Cocco<sup>[14]</sup>

Physical quantity	Expression	Units
Impact energy	$E = \frac{1}{2} m_b v_{imp}^2$	J
Impact frequency	$N$	hit/s
Milling intensity	$I = NE = \frac{1}{2} Nm_b v_{imp}^2$	W

experience critical loading conditions (CLCs) to undergo microstructural refinement. Correspondingly, the crystallite size will decrease only in the fraction of powder that would have been subjected to a mechanical stress  $\sigma$  higher than a given threshold value  $\sigma_0$ . The volume fraction  $k$  of powder experiencing CLCs at impact is then expected to be smaller than  $x_{imp}$ . Under the assumption that the powder charge keeps perfectly homogeneous after each impact, all the volume fractions  $k$  in which it can be ideally subdivided have the same probability of being involved in a collision. These assumptions allow an analytical description of the kinetics of mechanically induced processes on a statistical basis.

Let  $\chi_0$  be the volume fraction of powder never subjected to CLCs. Of course,  $\chi_0$  is equal to 1 as far as no impact occurs. At the first collision, a volume fraction  $\chi_1(1) = k$  of powder has undergone for the first time CLCs. The fraction of powder charge never subjected to CLCs is then equal to  $\chi_0(1) = 1 - k$ . After the second impact, the fraction of powder never subjected to CLCs becomes equal to  $\chi_0(2) = (1 - k)^2$ . The fractions of powder subjected to CLCs one and two

times are instead, respectively,  $\chi_1(2) = 2k(1 - k)$  and  $\chi_2(2) = k^2$ . The fraction of powder  $\chi_0(n)$  that never experienced CLCs can only decrease as the number  $n$  of collisions increases according to the following equation:

$$\chi_0(n + 1) = \chi_0(n) - k\chi_0(n). \quad (3)$$

The amount of powder subjected to CLCs for  $i$  times after  $n$  impacts depends instead on two contributions. The first one is quantified by the fraction  $k\chi_i(n)$ , which at the  $n^{\text{th}}$  collision is subjected to CLCs for the  $(i + 1)$ -th time and becomes part of the fraction  $\chi_{i+1}(n)$ . The second contribution is due to the fraction  $k\chi_{i-1}(n)$ , which, experiencing CLCs for the  $i^{\text{th}}$  time at the  $n^{\text{th}}$  collision, becomes part of the fraction  $\chi_i(n)$ . It then follows that

$$\chi_i(n + 1) = \chi_i(n) - k\chi_i(n) + k\chi_{i-1}(n). \quad (4)$$

The experimental evidence that a large number  $n$  of collisions is generally required to observe a significant decrease of the average crystallite size  $L$  suggests that the fraction  $k$  of powder subjected to CLCs at impact is small.<sup>[1,20]</sup> Under such circumstances, Eqs. (3) and (4) can be written in continuous form. Correspondingly,

$$d\chi_0(n) = -k\chi_0(n)dn \quad (5)$$

and

$$d\chi_i(n) = -k\chi_i(n)dn + k\chi_{i-1}(n)dn. \quad (6)$$

Equations (5) and (6) can be readily solved, the solutions being, respectively,

$$\chi_0(n) = e^{-kn}, \tag{7}$$

and<sup>[21]</sup>

$$\chi_i(n) = \frac{(kn)^i}{i!} e^{-kn}. \tag{8}$$

Being the total amount of powder inside the vial constant,  $\sum_{i=0}^{\infty} \chi_i(n) = 1$ .

The set of mathematical functions defined by Eqs. (7) and (8) can be used to roughly describe the kinetics of crystallite size refinement process under the assumption that the powder subjected to CLCs for  $i$  times has a characteristic average crystallite size  $L_i$ . The crystallite size  $L$  averaged over the whole powder charge inside the reactor is then equal to

$$L = \sum_{i=0}^n \chi_i(n) L_i = \left[ L_0 + knL_1 + \frac{(kn)^2}{2} L_2 + \dots \right] e^{-kn}. \tag{9}$$

It can be seen that  $k$  represents the apparent rate constant of the process. The crystallite size decrease is expected to be progressive and then  $L_0 > L_1 > L_2 > \dots > L_i > \dots$ . The connection between successive  $L_0, L_1, L_2, \dots, L_i, \dots$  values is, however, completely lacking, experimental evidences indicating only that a final asymptotic value  $L_f$  is attained. Yet, the relationship between the  $L_0, L_1, L_2, \dots, L_i, \dots, L_f$  values represents one of the outstanding questions regarding the process of crystallite size decrease. What is the  $L_i$  value attained by powder fraction  $\chi_i(n)$  subjected  $i$  times to CLCs? How many times CLCs must be undergone by a given volume fraction of powder to attain the final asymptotic  $L_f$  value of crystallite size?

According to Eq. (9), the gradual decrease of the average crystallite size  $L$  can be completely characterized only when all the  $L_0, L_1, L_2, \dots, L_i, \dots, L_f$  values are estimated. Although possible in principle, such result is not obtainable by currently available experimental methods. The comparison between experimental data and theoretical curves can, however, still provide useful insight provided that some possible relationships between the  $L_0, L_1, L_2, \dots, L_i, \dots, L_f$  values are considered. In the simplest case, the final asymptotic  $L_f$  value is attained already after the first critical loading event. Under such circumstances,  $L_0 \neq L_1 = L_2 = \dots = L_i = \dots = L_f$  and Eq. (9)

can be re-written as

$$L = L_0 e^{-kn} + L_f (1 - e^{-kn}). \tag{10}$$

When the final asymptotic  $L_f$  value is attained after two critical loading events  $L_0 \neq L_1 \neq L_2 = \dots = L_i = \dots = L_f$ . Correspondingly,

$$L = L_0 e^{-kn} + L_1 kn e^{-kn} + L_f [1 - (1 + kn)e^{-kn}]. \tag{11}$$

Along the same line, when the final asymptotic  $L_f$  value is attained after three critical loading events  $L_0 \neq L_1 \neq L_2 \neq L_3 = \dots = L_i = \dots = L_f$  and

$$L = L_0 e^{-kn} + L_1 kn e^{-kn} + \frac{(kn)^2}{2} e^{-kn} + L_f \left[ 1 - \left( 1 + kn + \frac{(kn)^2}{2} \right) e^{-kn} \right]. \tag{12}$$

Equations (10)–(12) and analogous ones obtainable under different assumptions can be adjusted to express the Neperian logarithm of the ratio between  $(L - L_f)$  and  $(L_0 - L_f)$ . Accordingly, in the first case considered

$$\ln \frac{(L - L_f)}{(L_0 - L_f)} = -kn, \tag{13}$$

in the second case

$$\ln \frac{(L - L_f)}{(L_0 - L_f)} = -kn + \ln \left[ 1 + \frac{(L_1 - L_f)}{(L_0 - L_f)} kn \right] \tag{14}$$

and in the third one

$$\ln \frac{(L - L_f)}{(L_0 - L_f)} = -kn + \ln \left[ 1 + \frac{(L_1 - L_f)}{(L_0 - L_f)} kn + \frac{(L_2 - L_f)}{(L_0 - L_f)} \frac{(kn)^2}{2} \right]. \tag{15}$$

A detailed characterization of experimental curves of crystallite size decrease as a function of the number  $n$  of collisions and a proper fitting procedure can thus provide indications on the crystallite size  $L_0, L_1, L_2, \dots, L_i, \dots$  values as well as on the apparent rate constant  $k$ .

The feasibility of such a comparison between experimental data and theoretical curves is shown for Cu powders with nominal purity level of 99.99%. The reader interested in details is kindly addressed to original papers.<sup>[22,23]</sup> Powder processing was carried out in a commercial Spex/Mixer Mill mod. 8000 equipped with a variable speed electrical motor controlled by a

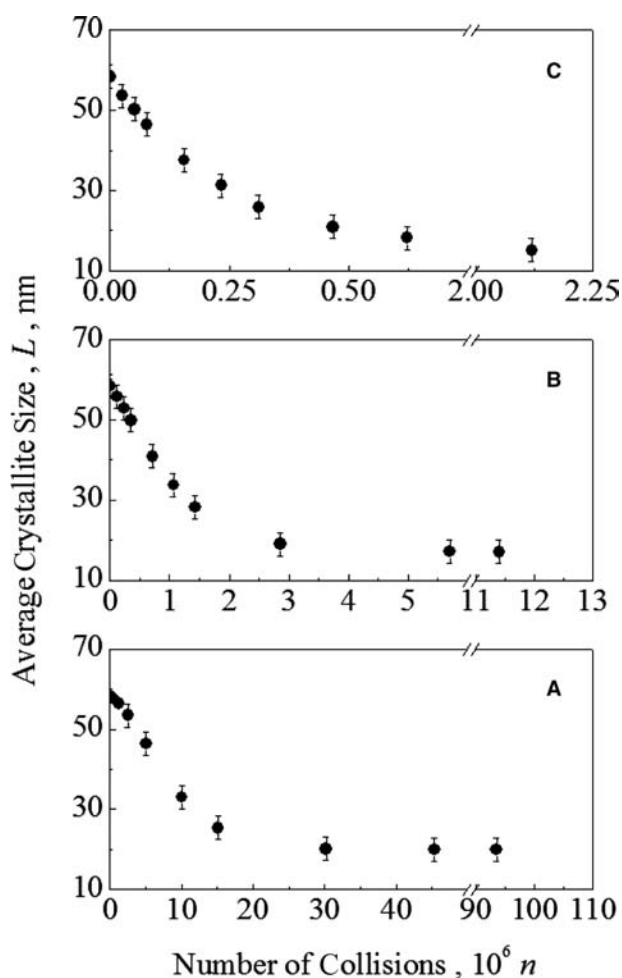

frequency inverter.<sup>[22,23]</sup> The mill was operated at about 25, 28, and 43 Hz. Amounts of powder equal to 8 g were treated under Ar atmosphere in a stainless steel vial with a single ball at impact energies roughly equal to 0.03, 0.10, and 0.25 J. The lowest impact energy at the lowest mill frequency was obtained by using a SiN ball with diameter and mass of about 14 mm and 4.5 g, respectively. In all the other cases, a stainless steel ball with the same diameter but a mass of 12 g was used. Undesired effects due to different powder amounts trapped at impacts are thus avoided.

The decrease in the average crystallite size was quantified by X-ray diffraction (XRD) analyses on powders sampled at given milling times. A Rigaku Diffractometer D/Max equipped with a Cu-K $\alpha$  radiation tube and a graphite monochromator in the diffracted beam was used. Crystalline peak profiles were analyzed with the Rietveld method.<sup>[22,23]</sup> The average size  $L$  of coherent diffraction domains and the strain content  $\varepsilon$  were estimated according to the Williamson–Hall method.<sup>[22,23]</sup>

Experimental data obtained at the aforementioned impact energies are quoted in Figs. 4A–C as a function of the number  $n$  of collisions. It can be seen that the average crystallite size  $L$  undergoes a monotonic decrease at rates increasing with the impact energy  $E$ . The initial crystallite size  $L_0$  is the same for all the curves, but different final values  $L_f$  are found. In particular,  $L_f$  decreases as  $E$  increases.

Although trends in Fig. 4A–C have apparently the same shape, significant differences become evident when the Neperian logarithm of  $(L - L_f)/(L_0 - L_f)$  is quoted as a function of the number  $n$  of collisions as in Fig. 5A–C. Data in Fig. 5A are best-fitted by Eq. (15), apparent rate constant  $k$  and crystallite sizes  $L_1$  and  $L_2$  being the fitting parameters. The initial and final  $L_0$  and  $L_f$  values are indeed known. Three critical loading events are then necessary at an impact energy of 0.03 J to decrease the crystallite size roughly from 58 to 20 nm. Data reported in Fig. 5B and obtained at the intermediate impact energy of about 0.10 J are best-fitted by Eq. (14). In this case, the fitting parameters are  $k$  and  $L_1$ . The kinetic model suggests, therefore, that two critical loading events are necessary to decrease the crystallite size roughly from 58 to 17 nm at about 0.10 J. Finally, the linear plot in Fig. 5C obtained at about 0.25 J is best-fitted by Eq. (13), where  $k$  is the only fitting parameter. Accordingly, a single critical loading event is sufficient for the crystallite size to decrease from about 58 to 15 nm.

The different  $L_i$  values worked out by best-fitting procedures are reported in Fig. 6 as a function of the number  $i$  of critical loading events. Such data provide a first rough insight into the kinetics of crystallite size decrease under mechanical processing by relating the

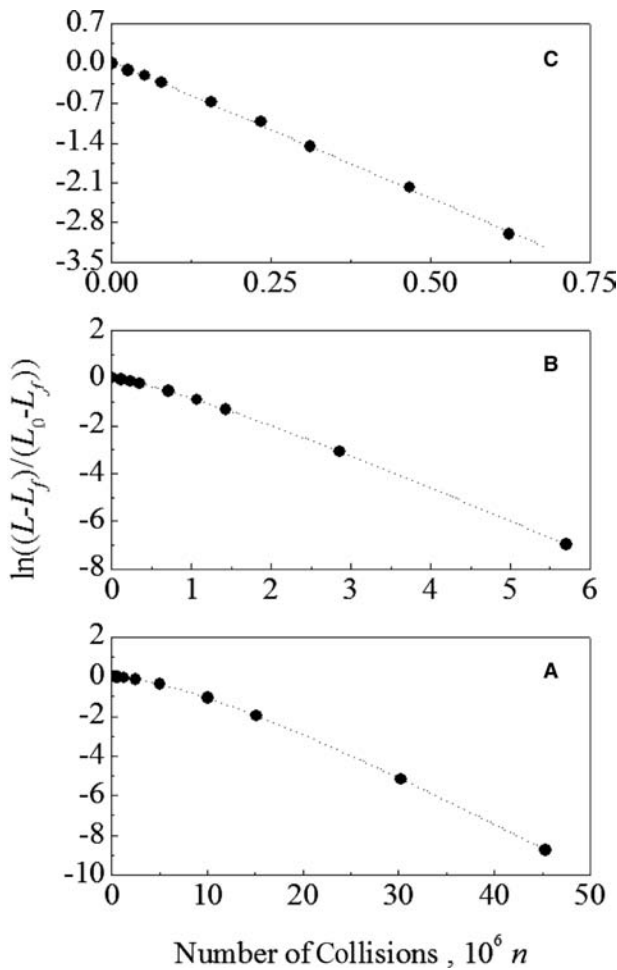

**Fig. 4** The average crystallite size  $L$  as a function of the number  $n$  of collisions for experimental trials performed at  $E$  values equal to (A) 0.03, (B) 0.10, and (C) 0.25 J. Error bars are included. The bars of the first points in (A) have been eliminated for the sake of clarity.

average impact energy  $E$  to the number of critical loading events necessary to decrease the crystallite size of a given powder volume from the initial to the final value. It appears that at high impact energy, the high mechanical stress attained induces a sudden drop of crystallite size from the initial value to the lowest one possible under such loading conditions. The crystallite size decrease becomes, however, as more gradual as impact energy and impact loading becomes lower.

If thermal effects are present, i.e. if the enthalpy of reaction  $A + B$  is high enough to increase temperature, we should introduce a term:

$$\frac{\partial}{\partial t} d(t, T) = f(t) + g(t) e^{-\frac{E}{RT}} \quad (16)$$

where  $E$  is an activation energy,  $R$  is the gas constant, and  $T$  the absolute temperature. This leads to an

**Fig. 5** The Neperian logarithm of the ratio  $(L - L_f)/(L_0 - L_f)$  as a function of the number  $n$  of collisions for experimental trials performed at  $E$  values equal to (A) 0.03, (B) 0.10, and (C) 0.25 J. Best-fitted curves are also shown.

integrated form of the type:

$$d(t) = \int_0^t f(u) + g(u) e^{-\frac{u}{\tau}} du + d_0 \quad (17)$$

where  $d_0$  is the initial grain size. Even though this is a hypothesis that neglects chemistry and assumes the existence of just one chemical species or compound, this equation is too general to be exploited on a practical ground; however, it does take into account the mechanism of grain reduction due to milling action in the term  $f(t)$  and the grain growth in the second term. If the reaction  $A + B$  is exothermic enough, adiabatic temperature  $T$ , for the sake of simplicity, may be evaluated considering a simple first principle calculation. In the case the temperature is low enough, the integral equation will coincide with Eq. (1). Avvakumov<sup>[24]</sup> has proposed a kinetic equation for

**Fig. 6** The crystallite size  $L_i$  of powders subjected to CLCs for  $i$  times. Impact energies are indicated.

mechanochemical synthesis, Cocco, Delogu<sup>[8,9,14]</sup> and others have validated it in some applications of mechanical alloying. One should consider the elements  $A$  and  $B$  that react to form the compound  $A_nB$  at the initial ratio of the  $A$  on  $B$  reactant in the reaction:

By considering  $\alpha$  as the degree of reaction, atoms reacted on the initial atoms,  $n$  as the stoichiometric number,  $m$  as the initial atomic ratio of  $A$  atoms on  $B$  atoms and  $\varepsilon$  as  $n/m$  ratio, a generalized Avvakumov equation is proposed here:

$$\frac{\partial}{\partial t} \alpha(t) = (1 - \alpha(t))(1 - \varepsilon \alpha(t))f(t) \quad (18)$$

With the initial condition  $\alpha(t = 0) = 0$ , it is possible to integrate then the equation to:

$$\alpha(t) = \frac{e^{\left(-\int_0^t f(u) du + \int_0^t f(u) du \varepsilon\right)} - 1}{-1 + \varepsilon e^{\left(-\int_0^t f(u) du + \int_0^t f(u) du \varepsilon\right)}} \quad (19)$$

which is still a complicate expression. More insight could be given if the elemental powders are introduced in the vial with an initial ratio  $m$  of  $A$  on  $B$  species equal to the stoichiometric ratio of the formed compound  $A_nB$ ,  $n$ . In such a case  $\varepsilon = n/m = 1$  and the

equation simplifies to:

$$\frac{\partial}{\partial t} \alpha(t) = (1 - \alpha(t))^2 f(t) \quad (20)$$

which may be integrated as:

$$\alpha(t) = \frac{\int_0^t f(u) du}{\int_0^t f(u) du + 1} \quad (21)$$

Now it is possible to make the position

$$F = \int_0^t f(u) du \quad (22)$$

and formally calculate  $\alpha$  as a function of  $F$ .

$$\alpha = \frac{F}{F + 1} \quad (23A)$$

It is possible to invert such a relationship to estimate the unknown function  $f(t)$  on the basis of experimental evolution.

$$F = \frac{\alpha}{1 - \alpha} \quad (23B)$$

Coming back to the general solution, one could consider equation (19) as a function of  $F$  as:

$$\alpha_\varepsilon = \frac{e^{(F(\varepsilon-1))} - 1}{\varepsilon e^{(F(\varepsilon-1))} - 1} \quad (24)$$

In general, the two  $F$  functions will be different; however, it is quite likely that the  $f(t)$  function does not depend strongly on composition, as it physically takes into account the mechanical response at a microstructural level of the mixture to the repeated impacts of the balls. This is equivalent to assume that the crystal size evolution does not change too much with slight variations of composition. It is then possible, by algebraic substitution, to link the more simple kinetics, described by Eq. (19) at initial stoichiometric ratio, to the general described by Eq. (18) in such a way:

$$\alpha_\varepsilon = \frac{e^{\left(\frac{\alpha(\varepsilon-1)}{1-\alpha}\right)} - 1}{\varepsilon e^{\left(\frac{\alpha(\varepsilon-1)}{1-\alpha}\right)} - 1} \quad (25)$$

where  $\alpha$  may be computed using the values of the mixture at initial stoichiometric composition.

## ATOMISTIC MECHANISM OF MECHANICALLY INDUCED PHASE TRANSFORMATIONS

The nature of atomistic processes underlying physical and chemical transformations induced by mechanical processing is a long-standing problem. Far from being satisfactorily solved, it is the focus of a lively debate constantly stimulated by the development of conceptual frameworks alternative to the defect-enhanced thermal diffusion scenarios initially proposed.<sup>[25–30]</sup> These latter represent a generalization of the mechanisms based on thermal diffusion developed to rationalize solid state amorphization reactions in binary diffusion couples.<sup>[25]</sup> The analogy between layered arrangements used in diffusion couples and lamellar microstructures observed during the initial stages of mechanical treatment suggested that their underlying mechanisms could be similar.<sup>[25–30]</sup> Phase transformations taking place under mechanical processing conditions were thus interpreted in terms of diffusion processes with a rate enhanced by structural defects accumulated in the solid.<sup>[25–30]</sup> The hypothesis that mechanochemical transformations proceed via thermal diffusion implies, however, severe limitations to its applicability and suffers eventually of an incapability to explain fine thermodynamic and kinetic features. Most difficulties originate from the evidence that chemical processes governed by diffusion must be governed by a suitable driving force. Accordingly, mechanically induced phase transformations could take place only in chemical systems characterized by a negative enthalpy of mixing.<sup>[25–30]</sup> In spite of this, solid state reactions are also observed in the case of immiscible systems with positive enthalpy of mixing and of pure intermetallic phases.<sup>[1]</sup> However, the obtainment of crystalline solid solutions and disordered solids implies in principle a raise of free energy and then the generation of a thermodynamic driving force opposed to mixing and disordering.

The evident shortcomings mentioned here are to a large extent avoided by different approaches laying emphasis on the capability of mechanical forces to induce atomic-scale mixing phenomena independent of thermal contributions.<sup>[31–48]</sup> Theoretically predicted or numerically inferred atomic-scale mechanisms are based on interface roughening<sup>[32]</sup> and shear-induced disordering processes.<sup>[34]</sup> Within these conceptual frameworks, thermal diffusion is not rejected or excluded in principle, but the key role is played by atomic displacements resulting from the action of shear stresses.<sup>[31–38]</sup> The fundamental motivations underlying aforementioned mechanistic hypotheses originate from the evidence that severe mechanical loads produce a series of local shear events on the microscopic scale,<sup>[1]</sup> with consequent localization of considerable amounts of energy in relatively small regions of solid phase.<sup>[31–48]</sup>

The shear induced rearrangements of atomic species results in turn in the generation of complex aggregates of atoms with defective coordination.<sup>[43,45–48]</sup> During the time period of mechanical loading, such rearrangements mediate mass transport and chemical mixing.<sup>[43,45–48]</sup> Once the load is removed, shear events are interrupted and transient defective structures relax and to a large extent disappear as a consequence of thermal equilibration.<sup>[46–48]</sup> These evidences suggest therefore a strong coupling between thermally and mechanically induced mechanisms of mass transport, establishing a connection between the conventional thermal diffusion scenarios and more recent approaches. As a result, mechanochemical phase transformations can be thought to originate from the competition of so-called ballistic displacements and thermal effects.<sup>[31–48]</sup>

Despite the considerable efforts operated, the intimate mechanisms governing mechanically induced processes are, however, still a matter of debate and the role of localized mechanical stresses as well as of related excited states need suitable clarification. In light of the complicated nature of mechanochemical transformations, governed by intertwined hierarchies of atomistic events, numerical simulations are expected to play an increasingly important role in the definition of detailed mechanistic scenarios. A clear example of the potential of such methods when applied to shear induced transformations is given by their capability of satisfactorily addressing the questions related to the dissolution of nanometer-sized precipitates into crystalline matrices in binary immiscible systems.<sup>[45]</sup> Numerical findings clearly showed that shear induced mass transport is connected in this case with the motion of dislocations generated during plastic deformation.<sup>[45]</sup> A mechanistic regime resembling the one observed in turbulent flow mixing was accordingly observed.<sup>[45]</sup> Another striking feature of shear induced processes becomes evident when interface mixing is studied.<sup>[34,46,47]</sup> Molecular dynamics calculations have indeed shown that the mutual dissolution of chemical species at plane interfaces, illustrated in Fig. 7 for the case of an amorphizing Ni–Zr system,<sup>[46,47]</sup> produces a power-law dependence of the intermixed layer thickness analogous to that characteristic of thermal diffusion.<sup>[34,46,47]</sup> Correspondingly, the square of layer thickness increases linearly with time, even though the atomic-scale mechanism governing mixing is completely different from the vacancy-mediated one underlying thermal activation. Similar results are found in studies concerning the impact of rough surfaces.<sup>[48]</sup>

It follows that the simple time dependence of the number of atoms intermixed is not able to univocally define the transformation mechanism and that numerical investigations, though limited by the availability of suitable computational resources, represent the most

**Fig. 7** The effects of shear on a smooth Ni–Zr interface. Shearing is carried out by moving the upper Ni semi-crystal (light gray atoms) to the right and the bottom Zr semi-crystal (dark gray atoms) to the left. Configurations refer to the times quoted. The whole system consisted of 18,000 Ni atoms arranged in a stacking sequence of 20 (111) face-centered cubic *cF4* planes and 18750 Zr atoms arranged in a stacking sequence of 30 (100) hexagonal close-packed *hP2* planes. Simulation details can be found elsewhere. *Source:* From Refs.<sup>[46,47]</sup>.

promising method to shed light on the details of mechanochemical transformations.

### AN EXAMPLE IN THE MECHANOSYNTHESIS OF Fe<sub>3</sub>C

Kinetic quantitative studies are not very common in mechanochemistry of nanophase materials. A set of experiments was performed several years ago, and results were published in Ref.<sup>[49]</sup>. In such a system,<sup>[50,51]</sup> experimental results suggest that fracturing of graphite crystal progresses by steps: fracturing along the hexagonal plane and subsequent fracturing of the hexagonal networks. Most of the experiments were performed at a fixed initial stoichiometric composition, 3 Fe 1 C; this composition corresponds to that of cementite Fe<sub>3</sub>C.

**Fig. 8** Mechano-synthesis of nanocrystalline iron carbides: plot of equation (23B) suggests a possible parabolic trend of  $F(t)$  function; squares are experimental data.

In such conditions, in the modified Avvakumov equation (18) reported earlier,  $\varepsilon = 1$  holds, and it is possible to consider the simpler equation (19) and its solution (20). Using a Spex 8000 vibrating laboratory mill, with 6 g of powder charge and a ball to powder weight ratio 10 to 1, it was possible to identify by appropriate microstructural analysis—Mossbauer spectroscopy and X-ray diffraction—several phases, Fe, C, a low carbon martensite like alloy and three main types of carbides. If we simplify the kinetic trend considering  $\text{Fe}_3\text{C}$ , cementite, as the unique carbide present, and we neglect the martensite-like alloy, we have to take into account just three chemical species: Fe, C, and  $\text{Fe}_3\text{C}$ . In such a way, the real kinetic evolution is simplified; experimental results are reported for iron in Table 3.

The  $F(t)$  function presented above is as in Fig. 8.

The  $R^2$  value for a quadratic fit is high indeed and a good correlation is found linking  $(\alpha/(1-\alpha))$  to  $F(t)$ . The almost parabolic trend of  $F(t)$  means that the derivative of the  $F(T)$  function,  $f(t)$ , could be linear. It is possible that an approach decoupling the two main contributions to reaction rates in mechano-synthesis would be found in the future, linking  $f(t)$  to the crystal size evolution. Considering such a hypothesis, Eq. (20) could become:

$$\frac{\partial}{\partial t} \alpha(t) = \frac{c(1 - \alpha(t))^2}{d} \quad (26)$$

which one may solve as:

$$\alpha(t) = \frac{\int_0^t \frac{1}{d(u)} du}{\int_0^t \frac{1}{d(u)} du + \frac{1}{c}} \quad (27)$$

The crystal size evolution  $d(t)$  may be evaluated by means of X-ray diffraction line broadening;

experimental results for this specific system are presented in Table 4.

One might check that the crystal size evolution could be assumed as a simple reciprocal function of time. In this case  $1/d_{\text{Fe}} = 0.0259t + 0.0111$  and  $1/d_{\text{C}} = 0.0682t + 0.0189$ , where  $d_{\text{Fe}}$  and  $d_{\text{C}}$  are the iron and carbon crystal size. The reciprocal of the grain size  $d$  could be assumed as<sup>[10]</sup>  $1/d = 1/d_{\text{Fe}} + 1/d_{\text{C}}$  and in this case, by summing  $1/d_{\text{Fe}}$  and  $1/d_{\text{C}}$  contribution, as  $1/d = 0.0941t + 0.03$ . Substituting this expression in Eq. (26) and integrating as in Eq. (27), one could obtain:

$$\alpha(t) = \frac{ct(941.t + 600.)}{941.ct^2 + 600.ct + 20000.} \quad (28)$$

where  $c$  should be evaluated by data fitting. With the choice  $c = 0.81$ , the data fitting is excellent, apart from the first three or four points of the kinetics; this could be due to an erroneous attribution of the

**Table 4** Iron and carbon crystal size evolution in the mechano-synthesis of nanophase iron carbides with a laboratory SPEX 8000 mill

Milling time (h)	Fe crystal size (nm)	C crystal size (nm)
0.25	38	24.6
0.5	32.5	20.4
0.75	34.2	15.7

3	13.4	
3.5	8.8	
5	9.3	

hyperfine field distribution in the Mossbauer spectra at early milling times.

The agreement with the  $F(t)$  function is also excellent, as reported in Fig. 9.

## INDUSTRIAL TRENDS AND RESULTS

At the moment of writing this entry, there are two companies that are exploiting successfully the mechanochemical synthesis of nanocrystalline powders: Advanced Powder Technology Pty Ltd<sup>[52]</sup> of Perth, Western Australia, and M.B.N., Italy.<sup>[53]</sup> Both companies have strong connections with the university field and could be considered as spin-offs of the research group of Matteazzi<sup>[5]</sup> and McCormick.<sup>[2]</sup> Matteazzi has pioneered the works in the mechanochemical synthesis of nanophase powders and, along with Le Caer, he was the first to employ the terminology “mechanochemical synthesis” in obtaining nanocrystalline carbides and silicides<sup>[54]</sup> and aluminides.<sup>[55]</sup> These compounds, and especially carbides, have remarkable industrial applications in the field of cutting tool materials. Matteazzi chose the  $Fe-C$  system as a model for the mechanochemical synthesis of nanocrystalline carbides for the availability of a powerful tool in microstructural analysis, Mossbauer spectroscopy,<sup>[56]</sup> which is applicable to Fe-containing systems. Subsequently, he studied alumina-based nanocomposites<sup>[57]</sup> and the solid state reduction of oxides such as the transformation of haematite to nanocrystalline wustite.<sup>[58]</sup> Further works

**Fig. 9** Experimental results (in squares) in mechanochemical synthesis of iron carbide compared with values calculated according to real crystal size evolution [(Eq. 28)].

include the first reported applications of mechanochemical synthesized materials to catalysis<sup>[59,60]</sup> and the development of a vibrating mill<sup>[12,13]</sup> scaling up the possibilities of mechanochemical synthesis of the SPEX 8000 mill. Latest developments include the study of grain growth and of consolidation by means of CIP (cold isostatic pressing) and HIP (hot isostatic pressing).<sup>[61]</sup> The Italian company M.B.N.<sup>[53]</sup> has now developed and scaled-up, with an industrial production capacity of 200 t/years of materials, several of the earlier work by Matteazzi. The company is now focusing on the Mechanomade<sup>®</sup>, which is basically a mechanochemical synthesis technique, and on consolidation technologies such as forging and extrusion with the processes of Mechanoforge<sup>®</sup> and Mechano XT<sup>®</sup>. These techniques have led, for instance, to the production of an  $Al_2O_3$  doped copper alloy (99% Cu, 1%  $Al_2O_3$ ), which has outstanding mechanical properties (Yield strength 800 MPa, Ultimate Tensile Strength 900 MPa).

McCormick has obtained the most interesting results in the field of mechanochemical synthesis of nanocrystalline materials. With different coauthors and collaborators, along the years, he has started studying the Mechanical Alloying process, considering further some constructional details of vibrating mills. He has recently exploited some results in the field of displacement mechanochemical reactions, which are interesting for the industrial field to patent a specific process—now property of an industrial spin-off of the University of Western Australia, Advanced Powder Technology Pty Ltd<sup>[52]</sup>—that has been called mechanochemical processing MCP<sup>®</sup>. Mechanochemical processing consists of solid-state displacement mechanochemical reactions caused by collisions between particles and balls inside mills. At the end of the reactions nanocrystalline powders (grain size  $\sim 10$  nm) within a soluble salt matrix are obtained. Thermal treatments, at low or intermediate temperatures, are typically performed depending on the specific nanocrystalline powders to be obtained. The final step is washing the salt matrix with appropriate solvents, allowing to get separated nanoparticles.

The use of a diluent phase may be necessary to:

1. Avoid combustion reactions during milling
2. Reduce the volume fraction of nanoparticles (in this way it is possible to avoid nanoparticles being agglomerated).
3. Control the particle size distribution.

Comparing it with the more simple mechanochemical reaction, which has been presented in previous paragraphs, it is harder to model the physicochemical process. McCormick has obtained main results by using single ( $A + BC \rightarrow AB + C$ ) or double ( $AB + CD \rightarrow AD + BC$ ) displacement reactions.

For instance, in the production of ultrafine Co and Ni particles<sup>[62]</sup> with a narrow particle size distribution of 10–20 nm, the reactions:

were obtained by SPEX 8000 processing with a ball-to-powder ratio 3 : 1 and with typical processing times of the order of 24 hr. Here and in other previous works, a remarkable effect of the diluent phase NaCl was observed on the influence of the mean particle size, being of the order of nanometers in case 25–50% wt diluent, and increasing it to the micron range when not present.

Further examples include the synthesis of metal sulfide nanoparticles<sup>[63]</sup> reaction of the type:  $\text{ZnCl}_2 + \text{CaS} \rightarrow \text{ZnS} + \text{CaCl}_2$ , with a mean particle size, observed by TEM, of 12 nm.

The synthesis of metal-oxide nanoparticles was described in Ref.<sup>[64]</sup>. A representative reaction is:

Finally, one should also consider the activities of the Institute of Solid State Chemistry and Mechanochemistry of Novosibirsk, RUS,<sup>[65]</sup> which have a research experience in the field of mechanochemistry dating back to 1970s. Several applications, which span from the metal industry to the field of medicine and cosmetics, are now directed to the mechanochemical synthesis of ceramic powders such as, for instance, nanocrystalline  $\text{Al}_2\text{O}_3$ .<sup>[66]</sup>

## CONCLUSIONS

This entry has presented some aspects of mechanochemical synthesis of nanophase powders, with an elementary modeling of the process<sup>[67]</sup> and a general perspective on the results in the field. Mechanochemistry is one of the most appealing technologies for the synthesis of nanophase materials and, at an industrial and commercial level, it is already exploited for sintered products,<sup>[53]</sup> abrasive processing,<sup>[52]</sup> catalysis,<sup>[52,53]</sup> medical,<sup>[53]</sup> cosmetic,<sup>[53,65]</sup> and even cleaning applications. Among different mechanochemical processes, MCP® process—which combines mechanochemical synthesis with appropriate thermal post-treatments—appears the most interesting for its capability to obtain nanocrystalline powders of the order of 10–20 nm of many different materials.

Possible research activities, related to applications in the field, would most likely include the study of the influence of diluents in mechanochemical reactions and techniques for engineering, controlling, and sizing particles, which have dimensions two order of magnitude less than the finest powders used in metal powder technologies.

More details of the technologies of nanostructured material synthesis by mechanical attrition, in which mechanochemistry should be inserted, are described in the entry by Koch<sup>[68]</sup> in this Encyclopedia; the reader is referred there not only for a more thorough description of these technologies, but also to appreciate shortcomings of this methodology, mainly represented by powder contamination during milling, which have not been discussed here.

## ACKNOWLEDGMENTS

The authors thank Dr. Nicola Zampa for technical help in CAD drawings; Fabio Miani appreciates fruitful discussion and communication with Prof. Carl Koch.

# Nanoporosity Evolution on Dealloying

Jonah Erlebacher

Department of Materials Science and Engineering, Johns Hopkins University,  
Baltimore, Maryland, U.S.A.

## INTRODUCTION

Nanoporous metals (NPMs) are materials formed during selective chemical or electrochemical dissolution of one or more components out of a homogenous alloy. This process is known as *dealloying* or *selective dissolution*. Dealloying transforms initially dense alloys into materials with a uniform, open porosity, with ligament widths and spacings tunable between just a few nanometers to many hundreds of nanometers, and usually employing only the simplest electrochemical processing. This entry reviews the physical characteristics of NPMs, the experimental variables that can be fruitfully varied in their fabrication, and the theoretical models that attempt to explain nanoporosity evolution during dealloying.

Historically, selective dissolution has been primarily studied in those technologically important systems for which the formation of nanoporosity is undesirable. For instance, Zn can be selectively dissolved from brass (Cu/Zn alloys) and can lead to stress corrosion cracking.<sup>[1]</sup> The dealloying of strength-hardening S-phase precipitates in the important aviation alloy Al-2024 can lead to pitting corrosion and, ultimately, materials failure;<sup>[2]</sup> even stainless steels may be dealloyed of iron if the chromium content is too small.<sup>[3]</sup> Within the context of corrosion, dealloying is obviously problematical, and a significant amount of effort has been made in its avoidance.

## NANOPOROUS METALS FORMED BY DEALLOYING

However, for some systems, dealloying yields nanoporous materials with remarkable properties. For example, the dealloying of silver from silver/gold alloys<sup>[4–6]</sup> or copper from copper/gold alloys<sup>[7]</sup> results in the formation of nanoporous gold (NPG). This material has highly positive characteristics: 1) a uniform open porosity; 2) a very high surface area (greater than 5 m<sup>2</sup>/g);<sup>[8]</sup> 3) a conductive bicontinuous network with characteristic length tunable between 5 and 1000 nm;<sup>[9]</sup> and 4) a biocompatible surface to which can be attached all sorts of functionalized biomolecules

via thiol endgroup chemistry. In this light, NPG is an attractive catalyst support material, with vast applicability in sensor designs of all kinds. Furthermore, NPG can be formed in a variety of useful forms, including bulk, thin film, and, recently, nanowires.<sup>[8]</sup> For these reasons, NPG represents the prototypical example of an NPM, but is only one example of a number of different alloys that can be rendered nanoporous by dealloying. An incomplete list of alloys that have been dealloyed includes (Ag, Cu)/Au,<sup>[4–6]</sup> (Ag, Ni, Cu)/Pd,<sup>[10,11]</sup> Al/(Cu, Ni),<sup>[12]</sup> and Mn/Cu,<sup>[13]</sup> where the first element(s) in the couple is the element(s) selectively dissolved, leaving behind the second element(s) porous.

Fig. 1 shows a plan view scanning electron microscopy (SEM) micrograph of a thin film with nominal composition Ag<sub>65</sub>Au<sub>35</sub> (at.%) dealloyed in nitric acid under free corrosion (i.e., simply immersed in concentrated nitric acid). Silver is readily soluble in nitric acid, whereas gold is not. After approximately 5 min in nitric acid, the entire film has been dealloyed of silver, and the result is that the initially dense film has been transformed into a nanoporous film with ligaments approximately 20 nm in diameter and with spacing also of approximately 20 nm. Silver and gold are completely miscible across the entire composition range and thus the alloy has not phase-separated prior to dealloying. This is the key point underlying the physics of nanoporosity evolution during dealloying—the nanoporous structure observed is simply not an “excavated” one. Rather, porosity forms dynamically during selective dissolution via mass transport of the gold atoms from their original lattice sites to sites along the nanoporous backbone. Such a conclusion is borne out by a number of experimental observations involving X-ray and neutron diffraction that fail to probe any preexisting structure prior to dealloying.<sup>[14]</sup> The anodic dissolution of silver from silver/gold alloys has yielded pores as small as 5 nm.<sup>[6]</sup> Such a diffusion of the noble alloy components from their “bulk” lattice positions to the porous skeleton *during* dissolution is a characteristic feature of all systems that can be dealloyed.

For the purposes of this entry, we restrict the definition of NPMs to include only those materials created by selective dissolution at room temperature. Open,

**Fig. 1** Plan view SEM micrograph ( $\times 200,000$ ) of a nanoporous gold film with nominal predealloying composition  $\text{Ag}_{65}\text{Au}_{35}$  (at.%), dealloyed in nitric acid under free corrosion.

porous metals have been made by other methods, including electrochemical plating through colloidal or liquid crystal templates,<sup>[15,16]</sup> reduction of metal oxides,<sup>[17,18]</sup> etc. A related class of NPMs formed by selective dissolution that has found wide applicability for the catalysis of hydrogenation is the Raney<sup>®</sup> catalyst.<sup>a</sup> These materials are made by a selective dissolution of Al from Al (at.%)–rich Al/Ni or Al/Cu alloys in hot NaOH solution.<sup>[12]</sup> The morphology of Raney catalysts typically is nanoporous Ni or Cu with pore diameters  $< 5$  nm; however, the alloy usually falls apart during dissolution, with the ultimate result that the Raney catalysts are also typically nanoparticulate. We speculate that the reasons for this disintegration may be because of the complex phase diagram of Al/Ni and the presence of intermetallics with widely different lattice parameters, or, it may be because of a lack of mobility of the remaining Ni atoms under conditions of selective dissolution.

### Physical Characteristics of Alloys That May Be Dealloyed

A significant collection of evidence has led to the identification of a number of general physical characteristics required of the alloys that may lead to nanoporosity on dealloying. The four most important characteristics are:

- a. *The difference in dissolution potentials  $\Delta E$  of the alloy components or soluble complexes of*

*the alloy components must be sufficiently large.* If so, a potential can be applied across an electrochemical cell at a magnitude where the less noble alloy components dissolve into electrolytes, but the more noble components do not. A difference in the dissolution potentials of the alloy components of several hundred millivolts is usually adequate as a general benchmark.

- b. *The composition of the alloy must be neither too rich nor too poor in the more noble species.* As discussed below, if the alloy is too rich in the noble species, no dealloying will occur. Conversely, if there is too little noble species, porosity evolution cannot be maintained and one is usually left with a mass of distinct nanoparticles collected in the bottom of a beaker.
- c. *Surface diffusion of the more noble species must be sufficiently fast in electrolytes.* Given that the more noble element species must move from their original lattice sites and agglomerate into the backbone of the nanoporous sponge, at the very least, they must move fast enough. As discussed below, a benchmark of  $10^{-14} \text{ cm}^2 \text{ sec}^{-1}$  seems reasonable as a minimal diffusivity for which one may observe dealloying.
- d. *The alloy must be sufficiently homogenous and ideally stress-free.* Good uniform porosity is not observed even in such lattice-matched alloys as Ag/Au when residual stresses or inhomogeneities exist. Such factors manifest themselves in insidious ways: in vapor-deposited thin films, there are often residual stresses because of mechanical interactions between the film and the substrate, which can lead to cracking at grain boundaries during dealloying; in bulk materials, there can be segregation of one component to the grain boundary during annealing cycles, and this, too, can lead to cracking at grain boundaries.

### Physics of Nanoporosity Evolution during Dealloying: The Fundamental Problem

The central issue that any model for nanoporosity evolution during dealloying must address is the fact that the atoms of the more noble species in the alloy must physically move from the lattice sites they occupied in the unattacked alloy and reposition themselves in the backbone of a highly porous skeleton during selective dissolution. The fundamental problem associated with this movement is that the driving force for such rearrangement is counterintuitive. Usually,

<sup>a</sup>Raney<sup>®</sup> is a registered trademark of W. R. Grace and Co.

the driving force for atomic diffusion follows a concentration gradient, or follows a direction so as to lower overall surface area; but in nanoporosity evolution, this does not occur. Given the fact of movement of the noble alloy component, it might be thought that, optimally, the noble atoms might arrange themselves on the surface to form a dense monolayer, protecting the bulk of the alloy from further dissolution (a process called *passivation*). Because typical alloy compositions are a few tens of percent noble elements, passivation should occur only after a few tens of monolayers have been dissolved. For sufficiently low applied potential, this in fact does occur, but for applied potentials over a critical potential  $E_c$ , it does not. Despite some kind of atomic mobility, the noble atoms move in such a way as both to agglomerate (moving against a concentration gradient as they diffuse from the base of pits, where there exists a surface with locally bulk alloy composition to the noble element-rich walls of the porous skeleton) and also to increase dramatically the surface area of the material as it becomes nanoporous.

An early suggestion to account for the observed enrichment of noble atoms in the porous skeleton is based on the observation that as porosity evolves, the near-surface region becomes depleted of the less noble species. This will create a concentration gradient perpendicular to the average alloy/electrolyte interface position, driving bulk diffusion of the less noble species to the surface where they can be dissolved away.<sup>[19]</sup> However, early on, it was recognized that volume diffusion in the unattacked alloy is quite slow, with diffusion coefficients extrapolated to room temperature typically significantly less than  $10^{-30} \text{ cm}^2 \text{ sec}^{-1}$ .<sup>[20]</sup> A “back-of-the-envelope” calculation shows that this diffusion rate is too small, and yields an estimate of the required magnitude: Typical velocities of the interface between the porous region and the unattacked bulk alloy are on the order of one monolayer per sec (we have measured this rate for  $\text{Ag}_{65}\text{Au}_{35}$  alloys), with corresponding characteristic widths of 5–10 nm. If surface diffusion is operative, noble atoms on the surface must agglomerate by diffusing a distance on the order of 1 nm (less than half of a pore diameter) in about 1 sec, suggesting the required benchmark surface diffusion coefficient to be minimally on the order of  $10^{-14} \text{ cm}^2 \text{ sec}^{-1}$ .

Until recently, it also could have been argued that surface diffusion was also too slow. At the time the bulk diffusion mechanism was proposed, only a few measurements of the surface self-diffusion coefficient for many of the materials in porosity-evolving alloys had been measured, and only in vacuum. Even now, there are few such measurements, and such non-electrolyte measurements typically yield diffusion coefficients (extrapolated to room temperature) orders

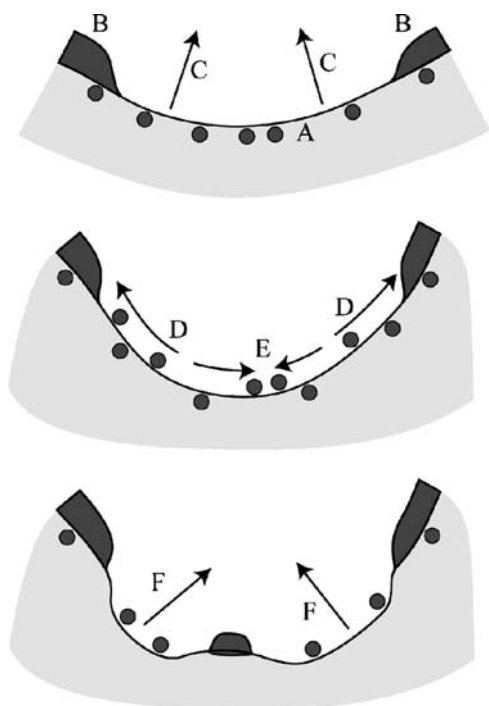

of magnitude slower than the benchmark;<sup>b</sup> for this reason, a consideration of bulk diffusion necessarily required invoking the formation of faster-moving esoteric pointlike defects such as divacancies in order for mass transport to be consistent with the observed etch rates.<sup>[19]</sup>

Thus it is quite remarkable that the surface diffusivity of fcc metal adatoms was discovered to be, in fact, many orders of magnitude faster in electrolytes than in air or vacuum, typically greatly exceeding the proposed threshold value. The first indication of such behavior was seen during in situ electrochemical scanning tunneling microscopy (STM) of alloy dissolution in which islanding of the noble species was observed at room temperature.<sup>[22,23]</sup> A global measurement of surface diffusion on Au and Pt surfaces shows a strong dependence of diffusivity on applied potential, and both are much faster in electrolytes than in any other environment for which a measurement of surface diffusivity has been made (for details, see below). Bulk diffusion likely plays little, if any, role except perhaps in dealloying of very low melting temperature alloys such as In/Sn.<sup>[24]</sup>

### Model of Nanoporosity Evolution during Dealloying

Of course, just because noble species *can* move out of growing pits does not mean they will necessarily do so. The reason they do is schematically illustrated in Fig. 2, and has to do with the particular way in which pits penetrate into the bulk alloy, coupling the kinetics of etching with the thermodynamics of the alloy/electrolyte interface.<sup>[4]</sup> Consider one of the pits at the interface between nanoporous material and unattacked alloy; the sidewalls of the pit are connected to the already-formed porosity, so they have nominally pure noble species composition whereas the base of the pit is comprised of pure alloy. To propagate the pit further, a less noble atom is first pulled out of the base of the pit, leaving behind a vacancy coordinated primarily with less noble atoms (as required of percolation; see below). The etch front spreads laterally, then pulls out all less noble atoms in the base of the pit within the next monolayer of dissolution. The noble atoms that are left behind could stay in place as adatoms,

<sup>b</sup>Relevant extrapolation relies on large area mass transfer diffusion measurements, and not the diffusivities of particular species observed atomistically using scanning probe or field ion microscopy (for typical surface diffusion coefficients, see Ref.<sup>[21]</sup> and references therein). The surface mass transfer self-diffusion coefficients of Pt, Au, and Cu in vacuum, extrapolated to room temperature, are  $4.6 \times 10^{-22}$ ,  $2.7 \times 10^{-19}$ , and  $1.2 \times 10^{-14} \text{ cm}^2 \text{ sec}^{-1}$ , respectively.

**Fig. 2** Schematic illustrating how porosity evolves during selective dissolution. 1) In the base of a pit, the alloy surface (A) is exposed between regions of accumulated noble component (B) at the base of any already-formed nanoporous skeleton. Atoms of the less noble alloy component in the exposed alloy surface are dissolved into the electrolyte (C). 2) As the interface dissolves, the surface area increases, and noble adatoms are released onto the surface. These adatoms condense onto already-agglomerated noble atom clusters (D), or nucleate new clusters (E) when noble atom ligaments (B) are too far away. 3) The less noble element in the exposed alloy surface dissolves into the electrolyte (F), and the cycle of increasing pore area and noble element agglomeration repeats.

populating the base of the pit and slowing down further dissolution, but the thermodynamics of the alloy/electrolyte interface (see below) predicts that such a condition would place the surface far out of equilibrium, thus the adatoms will tend to agglomerate and coarsen. The nearest places to agglomerate are the sidewalls of the pit, where the pit connects to the noble element-rich porous skeleton, so it is to there that they diffuse. This diffusion either occurs after the lateral etch front that penetrated a monolayer into the bulk has consumed all the less noble atoms in that monolayer (in which case the noble species really are left as adatoms), or the noble atoms are swept along with the lateral etch front as it etches out of the pit. Which particular mechanism is chosen likely depends on the applied potential (i.e., the etch rate), but in either case, the noble atoms have swept themselves out of the base

of the pit, which continues to penetrate further into the bulk of the alloy.

This scenario, our current “working model” of alloy dissolution, predicts that the length scale of porosity is set very early in the dissolution process, basically within the first monolayer of dissolution, for this is the only point in time at which the noble atoms agglomerate into two-dimensional islands without the presence of preexisting pore walls. The particular island spacing chosen  $\lambda$  will depend on the etch rate, the density of nucleated islands, and also on how long the islands have to coarsen before the next layer of alloy is attacked. Whatever spacing the system chooses,  $\lambda$  becomes characteristic of the dealloyed microstructure. If the diameter of a pit is equal to or less than  $\lambda$ , then noble atoms will always have time to get to the pore sidewalls. If the diameter of a pit is greater than  $\lambda$ , the noble atoms will nucleate a new passivating cluster and the pit will bifurcate.

It is important to realize that as a pit grows into the bulk, its time-averaged radius of curvature always increases. In a continuum picture, we may say that the local velocity of the pit is always normal to its surface. Atomistically, the pit radius increases because of the undercutting of its sidewalls. This is perhaps best seen by a consideration of the early stages of porosity evolution. Let a (111) facet of the bulk fcc alloy be exposed to electrolyte. Initially, the less noble component is etched out of the topmost monolayer, and the noble elements agglomerate into clusters with spacing  $\lambda$ , as discussed above. When the second monolayer gets attacked, the bases of the noble atom islands get fed with more noble atoms, forming noble element-rich mounds. As the alloy gets etched further, the bases of these mounds are fed by noble atoms released from the alloy in between them. But the circumferences of the mounds are growing at the same time that the area of fresh alloy surface is diminishing. This means that the bases of the mounds are becoming noble element-poor, thus susceptible to undercutting. These coupled processes lead to a model in which a pit radius of curvature effectively increases as it penetrates into the bulk. Eventually, these pore radii become greater than  $\lambda/2$ , a new cluster nucleates, the pit bifurcates, and the process continues ad infinitum.

The particular value of  $\lambda$  that a system will choose to take depends on a wide variety of parameters including: 1) etch rate (which depends on the choice of electrolytes, applied potentials, and the concentration of less noble constituents predissolved in the electrolyte); 2) surface diffusivity (which depends on the choice of materials, but also the variation in diffusivity with applied potential); and 3) the thermodynamics and composition of the alloy itself (what phases exist).

## CLASSICAL CHARACTERIZATION OF DEALLOYING

### The Parting Limit

Empirically, it is observed that if the noble alloy constituent is of sufficiently high concentration in the alloy, no selective dissolution can occur. This composition is referred to as the *parting limit*, a reference from the gold purification industry, which, for a long time, has used selective dissolution to “part” silver from gold. The parting limit varies widely for the alloys known to exhibit nanoporosity evolution, but typically sits between 20 and 60 at.%.<sup>[25]</sup>

The origin of the parting limit is likely because of a combination of geometrical percolation and surface diffusion, as suggested by Sieradzki, Corderman, and Shukla<sup>[26]</sup> and demonstrated through atomistic simulation. Geometrical percolation of the less noble component becomes the baseline criterion for dissolution. If the less noble atoms are not sufficiently percolating through the structure, there is no chance for dissolution to proceed past atoms near the surface. For example, in the fcc lattice, the geometrical site percolation threshold is 0.198.<sup>[27]</sup> Thus in principle, no dissolution should occur for compositions richer than approximately 80% in the noble component. This criterion does not work well for the silver/gold alloys. To account for the difference, copious surface diffusion of gold may be invoked; for sufficiently high gold fraction (over about 50 at.%), the silver atoms are connected by only single-digit wide chains, which are quickly plugged up by gold atoms diffusing into terrace defects left by silver atoms, blocking further dissolution and functionally suppressing the parting limit for the system compared with geometrical site percolation.

### The Critical Potential

When the potential applied to a dealloy system is sufficiently positive, copious dissolution of the less noble element occurs. In fact, dissolution rates can be quite high (hundreds of milliamperes per square centimeter), and it is in this regime that porosity evolution occurs. If the voltage is sufficiently small, a current decay is observed and the surface enriches in the more noble component, passivating it from further dissolution. By “sufficiently large” is meant a qualitative measure—a voltage higher than the dissolution overpotential for the pure less noble component, but still lower than the potential required for dissolution of the more noble component. Similarly, a “sufficiently small” voltage is still larger than the dissolution overpotential for the pure less noble component, but less than the sufficiently large voltage leading to porosity evolution.

The cutoff potential  $E_c$  between the potential regime leading to passivation and the regime leading to nanoporosity evolution is called the *critical potential*.<sup>[25]</sup> Although central to nanoporosity evolution, the critical potential is the least understood of the basic phenomena associated with dealloying. Usually, the critical potential is introduced in the context of a potential sweep, a measure of the anodic dissolution of current vs. applied potential as the potential is ramped more positively at a fixed rate. A generalized polarization curve obtained this way is illustrated in Fig. 3. At low potentials, the dissolution current is usually small but constant; on reaching the critical potential, the dissolution current rises exponentially. The critical potential depends quite sensitively on alloy composition. For the range of compositions for which Au/Ag alloys exhibit dealloying behavior (up to 50 at.% Au), the critical potential spans a 500-mV range.<sup>[28]</sup>

The critical potential is essentially empirical. An arbitrary current threshold is established (e.g., 1 mA/cm<sup>2</sup>), and the critical potential for a particular alloy composition is identified when, during a potential sweep, the dissolution current rises above this threshold.<sup>[28]</sup> Microscopically, it seems that the critical potential is the dividing potential between a potential regime in which surface diffusion driven by capillarity (surface energy reduction) wins over roughening and leads to passivation, and a potential regime in which capillarity is too slow to prevent porosity evolution.

Seen in the context of the working model (see above), the microscopical evolution of the surface during a potential sweep is as follows: The small current associated with passivation is associated with the removal of the less noble species from the first few monolayers of materials. The noble species remaining has plenty of time to agglomerate into islands, and even coarsen. Within this time, the surface remains

**Fig. 3** Typical shape of anodic polarization curves for systems exhibiting dealloying. At low potentials, the alloy remains flat and partially passivated with the noble alloy components. Above the critical potential, nanoporosity may evolve.

basically flat. Scanning tunneling microscopy observations of flat surfaces populated with islands have been seen in a number of systems, including Ag/Au and Cu/Au alloys.<sup>[22,29,30]</sup> By the time that the potential has risen to  $E_c$ , a significant fraction of the surface may be covered with the more noble species, and this will inhibit the onset of copious pitting. This suggests that the empirically measured critical potential as defined via a current threshold may be significantly higher than a “fundamental” critical potential truly separating passivation from porosity evolution. At the very least, the critical potential should be sweep rate-dependent, decreasing with increasing sweep rate, and, in fact, this observation has been recently made.<sup>[28]</sup>

## DETAILS OF MICROSCOPICAL PHYSICAL PROCESSES INVOLVED IN DEALLOYING

### Multiscale Description of Dealloying

Fig. 4 illustrates all of the various processes occurring simultaneously during the selective dissolution of an alloy and the formation of a nanoporous material. The range of scales associated with the various microscopical processes is large. An incomplete list includes: 1) solution-phase transport of cations through the nanochannels into the bulk of the electrolyte and the development of solution side concentration gradients (scale: microns); 2) the range of mechanical interaction between the nanoporous overlayer and the unattacked material (scale: millimeters); and 3) length scales associated with the agglomeration of the more noble element into clusters (scale: nanometers). In this section, we examine how various intrinsic aspects of dealloying may affect nanoporosity evolution.

**Fig. 4** Typical physical processes occurring on different length scales during dealloying. (A) Transport and concentration gradients in electrolytes (micrometers to centimeters); (B) mechanical interaction between the unetched bulk alloy and the growing nanoporous overlayer (nanometers to millimeters); (C) surface diffusion at the alloy/electrolyte interface (nm); (D) transport of dissolved cations through nanochannels (nanometers laterally, millimeters in extent); and (E) chemical dissolution kinetics (nanometers).

### Solution-Phase Transport during Dealloying

It has long been recognized that the rate-limiting step during porosity evolution cannot be the solution side transport of the cations from alloys. A diffusion-limited condition in the electrolyte would result in a condition akin to that of electropolishing,<sup>[31]</sup> and the interface would only stabilize, regardless of any effect of selective dissolution. This can be seen through a perturbation analysis, the fundamental notion of which is that a protuberance on the alloy/electrolyte interface will etch faster than a pit because the tip of the protuberance is slightly closer to the edge of the diffusion barrier layer. Thus the only effect a diffusion-limited condition may have on porosity evolution is to slow etching from pits (at the bottom of which exists exposed alloy), and this will tend to stabilize the evolving structure.<sup>[32]</sup>

### Mechanical Properties of Nanoporous Overlayers

Although not central to the issue of what materials may be selectively etched to form nanoporosity, it is still quite important to keep in mind that as a porous region forms, there is a reasonably sharp boundary between the porous overlayer and the unattacked alloy. If the porous overlayer and the bulk alloy have different mechanical properties, or if a significant stress in the overlayer develops (as may be the case if the lattice parameter of the overlayer is different from the bulk alloy), then this gradient in stress and mechanical properties may lead to cracking and other undesirable materials failure. Such issues have been of central importance in the field of *stress corrosion cracking*.<sup>[1]</sup>

### Surface Diffusion

Measurement of the surface diffusion coefficient of the noble atom species at the alloy/electrolyte interface is central to a detailed understanding of how nanoporosity evolves during selective dissolution. This quantity is, in general, very difficult to measure, but enough data have been gathered to show conclusively a generally large enhancement of the surface diffusion rate for a few of the metals typically involved in dealloying (Au and Pt) over their diffusivities in air or vacuum (typically four to five orders of magnitude faster).

Good measurements of surface diffusivity can be made by observations of the morphological evolution of initially rough surfaces. The method is based on the classical theory of morphological relaxation developed by Mullins<sup>[33]</sup> and Herring,<sup>[34]</sup> the essence of which is that, in the absence of other factors, a non-flat surface will evolve toward planarity to reduce

its overall surface energy at a rate related to the diffusivity of the species involved in surface mass transport. Such measurements give an average measure of surface diffusion coefficients typically averaged over a range of orientations, and may be performed in a variety of environments, including air, vacuum, or electrolytes under potential control.

Therefore the measurement method uses an initially rough surface, and tracks its surface area with time. Surface area may be measured by a variety of methods including integrated charge passed when forming a monolayer of hydride or oxide,<sup>[16]</sup> or tracking of the time evolution of the charge of the double layer.<sup>[35]</sup> Measurements of surface diffusivity made using these methods have been made for Au and Pt: For Au, at potentials near critical potentials (approximately 400 mV vs. SCE for  $\text{Ag}_{80}\text{Au}_{20}$ ), surface diffusivity is on the order of  $10^{-14} \text{ cm}^2 \text{ sec}^{-1}$  in  $\text{H}_2\text{SO}_4$ , reaching the abovesuggested benchmark required for dealloying, and rises further with increasing potential.<sup>[36]</sup> In contrast, platinum does not have surface diffusivity more than the order of  $10^{-18} \text{ cm}^2 \text{ sec}^{-1}$  at moderate applied potentials in a variety of electrolytes.<sup>[37,38]</sup> Although significantly faster than its value in vacuum,<sup>[21]</sup> the surface self-diffusion rate of Pt seems to be too slow to allow porosity evolution to occur by the mechanism of the working model. In fact, this observation may explain why Pt alloys, although satisfying the homogeneity and nobility requirements for dealloyable materials, have, to date, not yielded an alloy that can be rendered nanoporous by selective dissolution.

### Postdealloying morphological evolution

The suggestion that surface diffusion is rapid for fcc metals in electrolytes is confirmed by postdealloying morphological evolution experiments in which a fully dealloyed material with a nanoporous microstructure remains immersed in electrolytes for extended periods. With copious surface diffusion, the surface area is expected to diminish with time because mass transport is driven by surface energy reduction. If the geometry of the material remains self-similar (i.e., stays porous but with larger and larger ligaments), then the characteristic length scale of the porosity  $l$  should grow as  $l \sim t^{1/4}$ .

Neutron scattering experiments have confirmed that this scaling behavior indeed is observed for NPG remaining immersed in nitric acid, and diffusion studies in other electrolytes suggest that a variety of electrolytes may be used.<sup>[14]</sup> Fig. 5 shows a plan view SEM of the real-space time evolution of a fully dealloyed and nanoporous thin film (originally 32 at.% Au) immersed in nitric acid at room temperature. The length scale of the porosity ranges from 10 nm at the smallest, as-formed end of the time scale, to nearly 50 nm after immersion in nitric acid for a day at room temperature. The time scale for coarsening is generally much greater than the time scale for porosity evolution in the first place (in Fig. 5, the film was fully porous after 12 min). This suggests an advantageous feature for nanomanufacturing—it should be possible to make whatever size porosity is desired, quench the

**Fig. 5** Coarsening of dealloyed structures by continued immersion in electrolytes at room temperature. Illustrated are plan view SEM micrographs of a film of  $\text{Ag}_{65}\text{Au}_{35}$  (at.%) immersed in nitric acid for various intervals. The film is completely dealloyed of silver by 12 min, and continues to coarsen at room temperature because of enhanced gold surface self-diffusion in the electrolyte.

system in air or water (quench in the sense of putting into an environment where the kinetics of surface diffusion turns off), and then coarsen the material to the desired porous length scale simply by a timed immersion in the proper electrolyte. A similar coarsening behavior is also observed for thermal cycling, but here it is generally required to anneal at elevated temperatures.<sup>[9]</sup>

### Thermodynamics and Adatom Kinetics of the Alloy/Electrolyte Interface

To get a sense of the equilibrium concentration of noble component adatoms on the surface of the alloy, a regular solution model may be used for the alloy/electrolyte interface.<sup>[4]</sup> The components of the solution are not the constituents of the alloy; rather, the components of the solution are adatoms (and really only adatoms of the noble alloy constituent), and “nothing” (more realistically, lattice positions occupied by adsorbed anions). Such a model gives the interface free energy  $f$  as a function of adatom surface fraction  $c$ , depending on an ideal entropy of mixing, and an enthalpy of mixing, depending only on bond energies and the average coordination of each species. For reasonable values of the bond energies, the model yields a minimum in  $f$  vs.  $c$  at approximately  $c_{\text{eq}} \sim 10^{-8}$  per site. This number represents the fraction of adatoms of the noble element one might find at the alloy/electrolyte interface where the alloy is not dissolved away and is extremely low. Therefore, when the acid attacks the alloy and quickly removes the less noble atoms from the base of the pit, the noble adatoms left behind are in a highly non-equilibrium state. This provides the driving force for transport out of the pits.

The kinetics of the surface diffusion of noble adatoms cannot be adequately described by simple Fickian diffusion because the concentration gradient of noble atoms rises, moving out of the pit; this is to be expected because of the highly non-equilibrium state of the adatoms on the surface. A model that adequately describes noble atom diffusion must incorporate at least two phenomena: 1) if the noble atom concentration is supersaturated, noble atoms should tend to agglomerate, diffusing against a concentration gradient as they form clusters; and 2) if the local noble concentration is nearly dense, no diffusion should occur. It has been shown that the Cahn–Hilliard diffusion equation incorporating concentration-dependent mobility demonstrates these characteristics, and a continuum model for the evolution of the alloy/electrolyte interface based on this model reproduces many of the characteristics of nanoporosity evolution.<sup>[4]</sup>

### CONCLUSION

Nanoporosity formed from the selective dissolution of alloys containing functionally more and less noble elements is a general method to form high surface area materials out of monolithic dense starting structures. For this reason, this class of materials holds particular promise for development into technologically important nanostructured materials. Thin films of starting alloy materials may be deposited and subsequently dealloyed. Thus nanoporous materials should be easily integrated into conventional microelectronics or microfluidics. Their high surface area may be functionalized with different chemisorbed or electrodeposited materials, making them useful in sensor applications or other applications where high conductivity nanoporous materials are desired. Furthermore, the characteristics of nanoporous materials may be straightforwardly tuned using a minimal set of parameters—in particular, length scales of porosity are smaller when dealloyed at higher applied potential, and larger length scale porosity may be made simply by postdealloying heat treatment or immersion into the proper electrolyte.

Within a greater nanotechnological context, the utility of very high room temperature surface diffusivities in electrochemical environments has yet to be fully exploited. Nanostructures placed in particular electrochemical environments may be susceptible to morphological decay over very short time periods, which may be advantageous to smoothen out undesirable roughness. In addition, the electrochemical environment may be simply adjusted in a variety of different ways, from the applied potential to the dissolution/deposition rate. The competition between roughening effects because of selective dissolution, noble atom agglomeration, and the smoothening effects of capillarity will certainly yield many kinds of interesting non-equilibrium pattern formation phenomena of which nanoporosity evolution is just one example.

## INTRODUCTION

Porous aluminum oxide has stimulated considerable interest as a nanostructural template, primarily because of the self-organized formation of extremely well-aligned cylindrical pores.<sup>[1–13]</sup> One of the fascinating aspects is the tunability of the interpore distance and pore diameter by simple variation of the anodization parameters<sup>[1,2,4,6,9,11,13]</sup> such as voltage and electrolyte solution composition. Apart from the application of aluminum oxide films as filtration membranes,<sup>[14]</sup> they are frequently used to fabricate nanowires with large aspect ratios.<sup>[13,15–20]</sup> Many different materials, such as metals, both magnetic<sup>[21–29]</sup> and nonmagnetic,<sup>[30–36]</sup> semiconductors,<sup>[37–44]</sup> nanotubes,<sup>[45–48]</sup> and even heterostructures,<sup>[49]</sup> have been grown in the porous membranes using primarily electrodeposition. Furthermore, porous aluminum oxide membranes have also been used as humidity sensors,<sup>[50,51]</sup> or as cathodes for organic light-emitting diodes.<sup>[52]</sup>

To control and optimize the formation of the aluminum oxide structure as well as the deposition of material within this porous matrix, in situ characterization techniques will certainly be required. Optical reflection techniques provide a nondestructive method to in situ monitor processes such as the anodization and the growth of nanowires. A major advantage of these techniques is their full compatibility with electrochemical or vacuum environments. Several spectroscopic ellipsometry studies of porous aluminum oxide structures, obtained under different anodization conditions, have been published.<sup>[53–56]</sup> These investigations were performed on aluminum oxide films, formed by anodizing bulk aluminum samples. Different optical models have been proposed, which take into account

the porosity of the film itself, but also include the barrier layer structure between the oxide matrix and the bulk substrate. In these models, the number of parameters is often large due to a proper description of the barrier layer. Determination of the properties of the anodized film in terms of actual physical quantities is not straight forward.

To avoid the aforementioned problems related to the barrier layer, and also to enable an accurate determination of the film thickness, a thin-film sample geometry is employed. The aluminum layer has a well-defined thickness, which can be determined by ex situ techniques, such as electron microscopy. Moreover, full anodization of the aluminum layer allows a smaller number of model parameters, as no bulk aluminum remains and the aforementioned barrier layer is practically absent. In this work, we show that scanning electron microscopy (SEM) enables accurate ex situ characterization of the film thickness and the pore structure after anodization. Ellipsometry spectra are analyzed using an optical model, which takes into account the anisotropy of the porous structure arising from the randomly distributed, aligned pores within the oxide. Based on the original work by Bruggeman<sup>[57]</sup> and Wien,<sup>[58]</sup> expressions are given for the parallel and perpendicular components of the dielectric functions, in terms of the cylinder fraction and a nanoporosity of the aluminum oxide matrix. The resulting fit parameters are quantitatively compared with the sample structure determined from electron microscopy images. Furthermore, chemical etching in phosphoric acid solutions enables controlled widening of the pores, and therewith provides a means to test the accuracy of our model. Moreover, we show that ellipsometric experiments on samples etched under different

conditions allow identification of the etch process in terms of the order of the etch reaction and the corresponding rate constant.

## ANODIZATION OF ALUMINUM THIN-FILM SAMPLES

Thin-film aluminum samples are grown by conventional sputtering on a silicon wafer (Philips Research Laboratories, Eindhoven). Prior to aluminum sputtering, a 75-nm platinum layer is deposited on a 10-nm titanium adhesion layer. The aluminum layer grown on top of this structure is approximately 1- $\mu\text{m}$  thick. Scanning electron microscopy (SEM) indicates that the actual thickness amounts to  $920 \pm 5$  nm, while the titanium and platinum layers have a combined thickness of  $85 \pm 5$  nm. Wafers are cut into  $14 \times 14$  mm samples to enable mounting in the anodization cell, which is schematically illustrated in Fig. 1. After mounting of the sample using an O-ring, a circular area with a diameter of 7.5 mm is exposed to the electrolyte.

Porous aluminum oxide is obtained by anodization of the aluminum film in a two-electrode configuration at a constant voltage of 15 V in 15 vol.%  $\text{H}_2\text{SO}_4$  at room temperature with continuous stirring. The

**Fig. 1** Schematic representation of the anodization cell used in the experiments. Also shown is the time evolution of the anodization current during the anodic oxidation at 15 V in 15 vol.%  $\text{H}_2\text{SO}_4$  aqueous solution.

procedure is identical to that described by Van der Zande et al.<sup>[31]</sup> A typical anodization transient is shown in Fig. 1. An initial current peak is observed as a result of double-layer charging, followed by a current plateau corresponding to a constant anodization of the aluminum. After approximately 70 sec, the current rapidly increases, indicating that the pore fronts have reached the platinum substrate. For longer times, oxidation of water gives rise to oxygen gas evolution, which leads to bubble formation.

## STRUCTURAL CHARACTERIZATION OF THE NANOPOROUS STRUCTURE

To enable accurate quantitative modeling of our optical results, the structural properties of the aluminum films before and after anodization have been characterized. Scanning electron microscopy provides information on the film thickness, pore distribution, and the pore diameter, while X-ray diffraction is used to characterize the crystallographic structure of the films in the pristine and as-anodized state.

### Scanning Electron Microscopy

Scanning electron microscope measurements are performed with a LEO Gemini 1550 FEG-SEM, equipped with a field emission gun plus Thermo Noran Vantage EDX system and Thermo Noran MAXray parallel beam spectrometer. The electron acceleration voltage can be set between 200 V and 30 kV; owing to this low voltage, deposition of a thin metal (gold) film is not required. This lateral resolution is approximately 2 nm.

A typical top-view SEM image of the as-anodized samples is shown in Fig. 2A. An approximately random distribution of pores in the aluminum oxide film is observed after anodic oxidation. Despite the apparent absence of azimuthal order, there is a preferred lateral distance separating adjacent pores. To quantify this, we used Scion Image software (Beta 4.0.2, Scion Corporation) to calculate the radial distribution function by radial integration of the autocorrelation image such as that shown in Fig. 2B; the result is shown in Fig. 2C. A single peak is observed at a distance of 33.5 nm, corresponding to the average interpore distance. The absence of peaks at larger distances indicates that there is no long-range organization of the pores in the film. Close examination of the autocorrelation image in Fig. 2B indicates that there is some azimuthal order in a sixfold symmetry. The pore density, as determined from the top-view images, amounts to  $950 \mu\text{m}^{-2}$ . With the interpore distance as determined above from the radial distribution function, we calculate that the pore density for a perfect hexagonal

**Fig. 2** (A) Top-view SEM image of as-anodized porous aluminum oxide. The image size is  $1\ \mu\text{m} \times 1\ \mu\text{m}$ . (B) The autocorrelation image calculated from the SEM image, from which the radial distribution function in (C) is obtained by radial integration. In (D), the average inter-pore distances obtained from the radial distribution functions for our samples are compared to literature values.

arrangement amounts to  $1029\ \mu\text{m}^{-2}$ . Because of a certain degree of azimuthal disorder exhibited by the ring structure in the insert in Fig. 2B, the actual density obtained by counting the pores is slightly lower. In Fig. 2D, the average inter-pore distances, determined for our samples anodized at 15 and 20 V, are compared to results in literature,<sup>[6]</sup> spanning a much larger range of anodization potentials. Clearly visible is the linear relation between the inter-pore distance and the applied voltage.

Cross-section SEM images are identical to what has been described in the literature, and clearly show the parallel alignment of the pores, with the same average inter-pore distance as determined from the top-view

images. The pores initiate at the surface and extend all the way down to the platinum layer. For the as-anodized aluminum oxide, the average pore diameter of 11.5 nm is the same throughout the film thickness. The thickness of the aluminum film prior to anodization, as determined from SEM images, amounts to approximately 920 nm. Upon anodization, the film considerably expands to approximately 1400 nm. The expansion by 50% is anomalously large. When we neglect the porosity and only consider the film thickness and the densities of aluminum and aluminum oxide, a maximum thickness increase of 30% is to be expected. The aforementioned 50% expansion can only be explained by taking into account the 10% mesoporosity due to the cylindrical pores [as determined from images such as those in Fig. 2A] and an additional 33% nanoporosity of the aluminum oxide matrix, which will be discussed later. The latter porosity arises from defects and nanosized voids resulting from the considerable deformation upon anodization and the corresponding material transport away from the substrate. More quantitatively, the charge involved in the anodization procedure (obtained by integration of the curve in Fig. 1) can be related to the aluminum density. From this, we conclude that practically all aluminum atoms are oxidized to trivalent  $\text{Al}^{3+}$ .

## X-Ray Diffraction

High-angle X-ray scattering measurements are performed using a single-crystal diffractometer (CAD4, Enraf Nonius) employing a rotating anode Cu-K $\alpha$  source ( $\lambda_{\text{CuK}\alpha} = 1.542\ \text{\AA}$ ). The instrumental broadening for this system is estimated to be  $0.2^\circ$ . Scans are performed in the  $\theta$ - $2\theta$  configuration.

The X-ray diffraction experiments show that the platinum and aluminum layers before anodization are polycrystalline. A part of the X-ray spectra for samples before and after anodization are shown in Fig. 3. The high-intensity Si 004 peak corresponding to the substrate is observed at  $69.2^\circ$ . We designate the first peak at  $2\theta = 33.3^\circ$  as the interface Si 002 peak as the corresponding volume peak is “forbidden”; the intensity ratio of the Si 004 and Si 002 peaks is indeed more than  $10^4$ . The two peaks for the sample prior to anodization in Fig. 3 at  $2\theta = 38.6^\circ$  and  $2\theta = 40.0^\circ$  correspond to Al 111 and Pt 111, respectively. Very small, but still discernable, are the Al 002 and Pt 002 contributions. The diffraction peak positions are in perfect agreement with the lattice constants  $a = 4.05\ \text{\AA}$  and  $a = 3.92\ \text{\AA}$  for fcc aluminum and platinum, respectively.

After anodization, the Pt 111 peak is still present, but the Al 111 peak is no longer observed. From the height of the Al 111 peak prior to anodization and

**Fig. 3** X-ray diffraction spectrum before and after anodization of the aluminum film. The diffraction peak positions for silicon, aluminum, and platinum are indicated.

the noise level in spectrum, we estimate that more than 95% of the aluminum has been transformed into aluminum oxide. This is in good agreement with the conclusion in the previous section based on the quantitative analysis of the anodization experiment. Also, in contrast to the original sample, the X-ray spectrum of the anodized sample in Fig. 3 exhibits broad background intensity. We attribute this background signal to the amorphous aluminum oxide formed upon anodization. The amorphous nature of the aluminum oxide is also supported by the absence of any peaks related to crystalline alumina.

### OPTICAL CHARACTERIZATION BY SPECTROSCOPIC ELLIPSOMETRY

The optical properties of our samples prior to anodization and after formation of porous aluminum oxide are characterized using spectroscopic ellipsometry. Also, the effect of pore widening by chemical etching is investigated. In ellipsometry, the change of the polarization state of linearly polarized light is measured upon reflection at the surface. The complex reflection coefficient  $\rho$  is defined as

$$\rho = \frac{r^p}{r^s} = \tan(\Psi)e^{i\Delta} \quad (1)$$

where  $r^p$  and  $r^s$  are the reflection coefficients for the parallel and perpendicular polarizations, respectively. For a single interface,  $r^p$  and  $r^s$  represent the Fresnel

reflection coefficients. Historically, the quantity  $\rho$  is expressed in the two angles,  $\Psi$  and  $\Delta$ . Although the actual ellipsometry measurement is relatively simple, the analysis of the results is often complicated. An accurate model is required for the system under consideration, which enables simulation or fitting of the results.

The optical response of a multilayered structure with known dielectric functions can be calculated using the Abeles matrix algorithm. Details of the original method are described by Azzam and Bashara.<sup>[59]</sup> Two types of matrices are used. One describes the transition from medium  $m$  to medium  $m + 1$

$$\mathbf{I}_{m,m+1} = \frac{1}{t_{m,m+1}} \begin{pmatrix} 1 & r_{m,m+1} \\ r_{m,m+1} & 1 \end{pmatrix} \quad (2)$$

where  $r_{m,m+1}$  and  $t_{m,m+1}$  are the Fresnel reflection and transmission coefficients, respectively. Another matrix describes the light passage through the medium and involves the phase factors

$$\mathbf{L}_{m,m+1} = \begin{pmatrix} e^{-i\Delta_m} & 1 \\ 1 & e^{i\Delta_m} \end{pmatrix} \quad (3)$$

where  $\Delta_m = (2\pi/\lambda) d_m n_m \cos(\theta_m)$  with  $\lambda$  being the wavelength of the light in vacuum (in nm),  $d_m$  the thickness of layer  $m$  (in nm),  $\theta_m$  the angle of the light, and  $n_m$  the refractive index of medium  $m$ . The angles in the various media are related through Snell's law:

$$n_m \sin(\theta_m) = n_{m+1} \sin(\theta_{m+1}) \quad (4)$$

For our system consisting of an anodic aluminum oxide layer ( $m = 2$ ), a platinum layer ( $m = 3$ ), and a titanium layer ( $m = 4$ ) on a silicon substrate ( $m = 5$ ), in contact with the ambient (air;  $m = 1$ ), a matrix product is defined

$$\mathbf{A} = \mathbf{I}_{1,2} \mathbf{L}_{2,3} \mathbf{I}_{3,4} \mathbf{L}_{4,5} \quad (5)$$

and the overall reflection coefficient is calculated from  $r = \mathbf{A}_{21}/\mathbf{A}_{11}$ . For both the parallel and perpendicular polarizations, the reflection coefficients  $r^p$  and  $r^s$  can be obtained by inserting the appropriate Fresnel coefficients in Eq. (2) and the ellipsometric quantity in Eq. (1) can be calculated.

In the case of a film with uniaxial anisotropy, i.e., with an out-of-plane dielectric function  $\epsilon_{ex}$  (the extraordinary direction) different from the dielectric function  $\epsilon_{or}$  parallel to the substrate surface (the ordinary direction), the same matrix formalism can be used.<sup>[59]</sup> For our films, in which the cylindrical pores give rise to such uniaxial anisotropy, this is schematically represented in Fig. 4. Obviously, the optical response for the  $s$ -polarization remains unchanged and is completely

**Fig. 4** Schematic representation of the geometry and structural anisotropy of an anodized thin-film aluminum sample, indicating the ordinary and extraordinary directions referred to in the text.

described by the ordinary dielectric function  $\epsilon_{or}$ . For the  $p$ -polarization, a modified propagation angle is calculated by inserting the extraordinary refractive index  $n_{ex} = (\epsilon_{ex})^{1/2}$  into Eq. (4). For the rest of the calculation, only the ordinary dielectric function  $\epsilon_{or}$  of the anisotropic medium has to be taken into account.

### Anisotropic Model for Porous Anodic Aluminum Oxide

As is evident from the previous section, the samples have a clear structural anisotropy. However, several studies on the optical characterization of anodic aluminum oxide templates on bulk aluminum substrates did not take this into consideration.<sup>[53–55]</sup> Results obtained on films, formed on bulk aluminum by anodization in sulfuric acid, indicated that there was no apparent optical anisotropy. Because of the small dimension of the pores, conventional effective medium approximations yielded adequate results. Ellipsometry measurements on our samples, which consist of a fully oxidized aluminum thin film with a well-determined thickness, indicate that optical anisotropy needs to be taken into account. Especially upon widening of the pores by chemical etching, the anisotropy becomes more pronounced as the pore sizes substantially increase. To obtain adequate, unambiguous fit results, we incorporated the optical anisotropy in a model that contains a minimum number of three parameters: 1) a film thickness; 2) a mesoporosity, related to the cylindrical void fraction; and 3) a nanoporosity of the aluminum oxide matrix.

As described in a previous section in relation to the thickness increase of the film during anodization, the aluminum oxide matrix is highly amorphous and presumably consists of a highly porous, noncrystalline

structure containing voids with sizes in the low-nanometer range. In the work by Palibroda, Farcas, and Lupsan<sup>[60]</sup> the structure of the oxide was reported to be gel-like, containing a large number of “bubbles,” formed during the anodization procedure. The effective dielectric function of the nanoporous aluminum oxide, with porosity  $f_p$ , is modeled using the conventional effective medium approximation established by Bruggeman<sup>[57]</sup>

$$0 = (1 - f_p) \frac{\epsilon_{Al_2O_3} - \epsilon_p}{\epsilon_{Al_2O_3} + 2\epsilon_p} + f_p \frac{\epsilon_a - \epsilon_p}{\epsilon_a + 2\epsilon_p} \quad (6)$$

where  $\epsilon_a$  and  $\epsilon_{Al_2O_3}$  represent the dielectric functions of the ambient (air in all cases presented here;  $\epsilon_a = 1$ ) and that of the aluminum oxide structure (we use the value of crystalline  $Al_2O_3$ ), respectively.

The system with uniaxial anisotropy, formed by the almost perfectly aligned cylindrical pores in the oxide matrix, is described by two different dielectric functions  $\epsilon_{ex}$  and  $\epsilon_{or}$  (Fig. 4). The extraordinary component describes the optical response of the film for electric field vectors parallel to the long axis of the cylindrical pores. Owing to the relatively small difference in dielectric constants of the oxide and the ambient, screening effects can be neglected. Therefore we can interpret the system of parallel pores as a set of parallel plates, and use the corresponding Wiener bound<sup>[58]</sup> to describe the dielectric function  $\epsilon_{ex}$

$$\epsilon_{ex} = (1 - f_{cyl})\epsilon_p + f_{cyl}\epsilon_a \quad (7)$$

where  $f_{cyl}$  represents the overall pore volume fraction.

For the ordinary component, we consider a cross section through the film parallel to the interface. The effective dielectric function  $\epsilon_{or}$  of this two-dimensional system of randomly distributed circles (with  $\epsilon_a$ ) in the oxide matrix (with  $\epsilon_p$ ) is modeled using an adaptation from the original work of Bruggeman,<sup>[57]</sup> which will be briefly outlined. Bruggeman provides expressions for the dielectric function  $\epsilon'$  of small spherical inclusions of fraction  $\delta'$ , with dielectric function  $\epsilon_i$ , in a host matrix with  $\epsilon_h$ , for both the two- and three-dimensional cases. These equations, referred to as the Rayleigh formulas, can be summarized in a generalized expression

$$\frac{\epsilon' - \epsilon_h}{\epsilon' + (n-1)\epsilon_h} = \delta' \frac{\epsilon_i - \epsilon_h}{\epsilon_i + (n-1)\epsilon_h} \quad (8)$$

with  $n = 2, 3$  as the system dimension. Rewriting yields an expression for the effective dielectric function

$$\epsilon' = \epsilon_h \frac{1 + \delta'(n-1) \frac{\epsilon_i - \epsilon_h}{\epsilon_i + (n-1)\epsilon_h}}{1 - \delta' \frac{\epsilon_i - \epsilon_h}{\epsilon_i + (n-1)\epsilon_h}} \quad (9)$$

As  $\delta'$  is small, we may neglect higher-order terms to obtain

$$\epsilon' \approx \epsilon_h \left( 1 + \delta' n \frac{\epsilon_i - \epsilon_h}{\epsilon_i + (n-1)\epsilon_h} \right) \quad (10)$$

The above is only valid for infinitely small inclusions. Bruggeman extended this to an arbitrary concentration  $f$  of one medium dispersed in the host material. Consider a first inclusion  $\delta'$  of medium with  $\epsilon_i$  in the host with  $\epsilon_h$ ; this will result in a dielectric function  $\epsilon'$  of this quasi-homogeneous medium, as given by Eq. (10). A second inclusion  $\delta''$  will give rise to an effective dielectric function

$$\epsilon'' \approx \epsilon' \left( 1 + \delta'' n \frac{\epsilon_i - \epsilon'}{\epsilon_i + (n-1)\epsilon'} \right) \quad (11)$$

where  $\epsilon'$  is the dielectric function of the quasi-homogeneous material before adding  $\delta''$ . In general, to obtain an increase  $d\delta_1$  of material with dielectric function  $\epsilon_i$ , in case of an already present fraction  $\delta_1$ , an amount  $\delta' = d\delta_1 / (1 - \delta_1)$  needs to be added. This can be explained as follows: A fraction  $\delta_1$  of the amount  $\delta'$  is distributed in the already-present quantity  $\delta_1$ , while only a fraction  $1 - \delta_1$  of  $\delta'$  leads to an increase of  $\delta_1$ . From Eq. (11), we find

$$\frac{d\epsilon}{n\epsilon} = \frac{d\delta_1}{1 - \delta_1} \frac{\epsilon_i - \epsilon}{\epsilon_i + (n-1)\epsilon} \quad (12)$$

which can be rewritten to yield

$$\left( \frac{1}{\epsilon_i - \epsilon} + \frac{1}{n\epsilon} \right) d\epsilon = \frac{d\delta_1}{1 - \delta_1} \quad (13)$$

The right-hand side is integrated from  $\delta_1 = 0$  to  $\delta_1 = f$ , while on the left we integrate from  $\epsilon = \epsilon_h$  (initially at  $\delta_1 = 0$ , there are no inclusions) to  $\epsilon = \epsilon_{or}$  (the final effective dielectric function of a fraction  $f$  of the medium with dielectric function  $\epsilon_i$  in the host matrix with  $\epsilon_h$ ):

$$\int_{\epsilon_h}^{\epsilon_{or}} \left( \frac{1}{\epsilon_i - \epsilon} + \frac{1}{n\epsilon} \right) d\epsilon = \int_0^f \frac{d\delta_1}{1 - \delta_1} \quad (14)$$

We obtain

$$1 - f = \frac{\epsilon_i - \epsilon_{or}}{\epsilon_i - \epsilon_h} \sqrt{\frac{\epsilon_h}{\epsilon_{or}}} \quad (15)$$

which, for our two-dimensional system ( $n = 2$ ) with

$\epsilon_i = \epsilon_a$  and  $\epsilon_h = \epsilon_p$ , yields

$$1 - f = \frac{\epsilon_a - \epsilon_{or}}{\epsilon_a - \epsilon_p} \sqrt{\frac{\epsilon_p}{\epsilon_{or}}} \quad (16)$$

### Ellipsometry Spectra of As-Anodized Porous Aluminum Oxide Films

For optical characterization, we use a rotating polarizer spectroscopic ellipsometer equipped with a Xe lamp and a scanning monochromator. Measurements are performed in the visible and near-UV region of the spectrum at wavelengths between 300 and 800 nm at a fixed angle of incidence. The angle of incidence can be set between 45° and 70°.

In Fig. 5, a typical ellipsometry spectrum is shown for an anodized film. As already described in the previous sections, anodic oxidation leads to a highly porous oxide structure of approximately 1400-nm thickness, which is essentially transparent for visible light. This explains the oscillations observed in both  $\cos(\Delta)$  and  $\tan(\Psi)$  in Fig. 5, which arise from interference of light reflected at the platinum/aluminum oxide interface and at the aluminum oxide/air interface.

**Fig. 5** Ellipsometry spectrum for an as-anodized porous aluminum oxide film. The open circles represent experimental data obtained at an incident angle of 60°. The solid lines result from the fitting procedure as described in the text.

The solid lines in Fig. 5 represent the result of a fitting procedure using the Abeles matrix algorithm and the optical model described in preceding sections, using bulk dielectric functions taken from literature. The aforementioned three parameters are varied, leading to a thickness of 1400 nm, a cylinder fraction  $f_{\text{cyl}} = 9.9\%$ , and a nanoporosity  $f_p = 28\%$ . The numerical fit errors in all cases amount to approximately 3%, 3%, and 10%, for the thickness, the cylinder fraction, and the nanoporosity, respectively. These results are in good, quantitative agreement with what we concluded from analysis of the SEM images on identical samples.

To verify the accuracy of our model, we also performed measurements at different incident angles. Although the absolute values of both  $\cos(\Delta)$  and  $\tan(\Psi)$  are different, oscillations similar to those in Fig. 5 are observed. Comparison of the experimental results at different angles to calculations of the optical response using the parameters obtained from the fitting procedure as described in relation to Fig. 5 yields perfect correlation between the calculation and the measurements, supporting the validity of our model.

Despite the convincing results presented above, one might argue that, even after prolonged drying under ambient conditions, some aqueous solution may still be present in the porous structure. Especially for nanoporous oxide materials, it has been reported that water, incorporated during the preparation, is still present within the nanovoids.<sup>[61]</sup> This would have a pronounced influence on the analysis of the optical response in terms of (Eqs. (6), (7) and (16)). To obtain an indication if there is any water present in as-anodized samples after drying in air, we performed ellipsometry measurements on such a sample before and after heating to approximately 200°C under moderate vacuum conditions. All optical spectra, both before and after heating in vacuum, were identical, indicating the absence of water within the porous structure of the as-anodized samples. This indicates that either there is indeed no water present within the nanoporous matrix, or that the water is contained in such small volumes that capillary forces prevent evaporation of the aqueous solvent even at elevated temperature. However, the latter explanation may be dismissed. As we will show in the next section, chemical etching does not affect the nanoporous structure, presumably because of the fact that aqueous solution is not able to penetrate into the (sub)nanometer-sized voids.

### Tunable Pore Sizes by Chemical Etching

Chemical etching in aqueous phosphoric acid solutions leads to controlled, homogeneous widening of the pores along their entire length. Apparently, diffusion

**Fig. 6** (A) Scanning electron microscope and (B) atomic force microscope images of a porous aluminum oxide sample after chemical etching for 10 min in a 2 vol.%  $\text{H}_3\text{PO}_4$  aqueous solution. Scan size in the AFM image is  $1 \mu\text{m} \times 1 \mu\text{m}$ .

of the etchant or etch products is not rate limiting. The average pore diameter in Fig. 6A after immersion of the as-anodized sample in 2 vol.%  $\text{H}_3\text{PO}_4$  solution for 10 min increases from 11.5 nm to approximately 22 nm. Upon prolonged etching and/or using a higher concentration of phosphoric acid, the pores become wider. Furthermore, the enlargement of the pores now also enables the study of these membranes using atomic force microscopy (AFM) as shown in Fig. 6B. Atomic force microscopy measurements are performed using a PicoScan (Molecular Imaging) operated in a.c. mode, using silicon cantilevers (Nanosensors). The pore size of as-anodized samples is too small compared to the tip radius; the tip cannot reach into the pores to obtain a good image. After sufficient pore widening, the pores can be imaged, but they appear markedly smaller than their actual size.

We studied the effect of chemical etching using spectroscopic ellipsometry, with a twofold objective: 1) The use of a noninvasive technique allows a fast characterization of the time evolution of the porous system; and 2) the controlled etching of the pores allows us to verify the validity and assess the accuracy of our optical model as it has been described in the previous section.

In Fig. 7, the ellipsometry spectrum of a sample after chemical etching for 10 min in 3 vol.%  $\text{H}_3\text{PO}_4$  is shown. Comparison with the results in Fig. 5 indicates that the number of oscillations has decreased. This can

**Fig. 7** Ellipsometry spectrum for a porous aluminum oxide film after chemical etching for 10 min in 3 vol.% H<sub>3</sub>PO<sub>4</sub> aqueous solution. The open circles represent experimental data obtained at an incident angle of 60°. The solid lines result from the fitting procedure as described in the text.

be qualitatively understood by the fact that, owing to the higher cylinder fraction, the refractive index and thus the optical thickness is reduced, which gives rise to a change of the interference. Also, with decreasing wavelength, the amplitude of the oscillations in both  $\cos(\Delta)$  and  $\tan(\Psi)$  decreases. This is direct evidence for the contribution of anisotropy to the optical response. In the absence of anisotropy, the amplitude of the oscillations will be identical over the entire energy range, as long as the substrate (platinum in our case) has a slowly varying dielectric function. The solid lines in Fig. 7 are obtained by fitting the results to our optical model, as described in the previous sections. Clearly, the calculated lines are in perfect agreement with the measured data, therewith supporting our model. The fit results indicate a thickness of 1395 nm, a cylinder void fraction  $f_{cyl} = 46\%$ , and a nanoporosity  $f_p = 34\%$ . When we compare these results with that obtained for the as-anodized sample, chemical etching leads to a significant increase of the cylinder fraction. It may be expected that chemical etching leads to a decrease of the film thickness, but the change is within the error of the fitting procedure. The same holds for the negligible increase of the nanoporosity during chemical etching.

The cylinder fraction is related to the average pore radius  $r$  through

$$f_{cyl} = \rho_{cyl} \pi r^2 \tag{17}$$

where  $\rho_{cyl}$  is the pore density as determined from SEM images, such as those in Figs. 2 and 6. Comparison of the radii determined from SEM images to those obtained from analysis of ellipsometry spectra show that there is good agreement over the entire range of cylinder fractions. This provides valuable evidence for our anisotropic optical model.

The etch rate, and therewith the pore widening process, depends on the concentration of the phosphoric acid solution. This is shown by the solid symbols in Fig. 8, in which the cylinder fraction is plotted as a function of etch time for different etchant concentrations. With an increasing amount of H<sub>3</sub>PO<sub>4</sub> in solution, the etch rate, and thus the rate with which the pores are widened, rises.

A simple model is used to analyze the results in Fig. 8. If we assume a linear etch rate  $\nu(c) = dr/dt$ , which only depends on the acid concentration  $c$ , the linear increase of the pore radius  $r$  with time  $t$  is given by

$$r = r_0 + \nu t \tag{18}$$

where  $r_0 = 5.75$  nm is the initial pore radius after anodization prior to chemical etching. The time dependence of the cylinder fraction is obtained by taking

**Fig. 8** Three-dimensional representation of the cylinder fraction  $f_{cyl}$  obtained from ellipsometry measurements, as a function of etching time in different H<sub>3</sub>PO<sub>4</sub> solutions. The solid lines represent fit results as described in the text.

the derivative of Eq. (17)

$$\frac{df_{\text{cyl}}}{dt} = \frac{df_{\text{cyl}}}{dr} \frac{dr}{dt} = \rho_{\text{cyl}} 2\pi r \nu \quad (19)$$

where  $dr/dt = \nu$ . After substitution of the time dependence of the pore radius, the above expression is integrated to yield

$$f_{\text{cyl}} = f_0 + \pi \rho_{\text{cyl}} (2r_0 \nu t + \nu^2 t^2) \quad (20)$$

where  $f_0 = \rho_{\text{cyl}} \pi r^2$  is the initial cylinder fraction before chemical etching. With the linear etch rate  $\nu(c)$  being the only parameter, we fitted the data in Fig. 8. The etch rate  $\nu(c)$  as a function of the  $\text{H}_3\text{PO}_4$  concentration  $c$  is described by  $\nu(c) = kc^n$ , with the order  $n = 2/3$  and a rate constant  $k = 1.7 \times 10^{13} \text{ m}^3 \text{ s}^{-1} \text{ mol}^{-2/3}$ .

Finally, analysis of ellipsometry spectra using the aforementioned model also yields values for the nanoporosity  $f_p$ . Although there appears to be a relatively small increase of  $f_p$  in the initial stages of the etch procedure, it is much less pronounced than the increase of the cylinder fraction  $f_{\text{cyl}}$ . In fact, the variation of  $f_p$  is almost within the numerical fitting errors. Furthermore, there is no discernible difference for high and low  $\text{H}_3\text{PO}_4$  concentrations. Apparently, owing to their very small size, the voids within the nanoporous structure are not accessible to the solvent that inhibits chemical etching in these (sub)nanometer voids. This is not unlikely, as the considerable deformations during the anodic oxide formation give rise to a large number of defects, such as dislocations and vacancies.<sup>[60,62,63]</sup> Obviously, these small “voids” in the amorphous oxide matrix are not accessible to the relatively large water molecules. The average nanoporosity amounts to approximately 36%. This is in good agreement with the value we indirectly deduced on the basis of the film thickness increase upon anodization of the aluminum, as determined from SEM images.

## CONCLUSION

We have presented a detailed characterization study of porous aluminum oxide formed through anodization of thin-film aluminum samples with a well-defined geometry. Prior to anodization, the thickness of the aluminum film was determined using scanning electron microscopy. X-ray diffraction experiments yield powder-like spectra, indicating that the aluminum layer is polycrystalline.

Electron microscopy clearly shows the formation of randomly distributed, but almost perfectly aligned, cylindrical pores with their long axis perpendicular to the film/substrate interface. Additionally, comparison

of X-ray diffraction spectra obtained before and after anodization show a nearly complete transformation of aluminum to aluminum oxide.

Ellipsometry spectra, obtained after anodization, were analyzed in terms of a newly developed model, which contains only three physically relevant parameters: the film thickness, the cylindrical pore fraction, and a nanoporosity of the remaining aluminum oxide matrix. The model accurately reproduces the experimentally observed features, and the absolute values of the fitting parameters are in perfect agreement with that observed in electron microscopy images.

Chemical etching of the porous structure in diluted phosphoric acid solution gives rise to a homogeneous widening of the pores over their entire length. This provides us with an ideal system to verify the accuracy of our optical model. The increase of the cylinder fraction with increasing etching time and etchant concentration, as determined from ellipsometry spectra, is again in perfect agreement with electron microscopy images. In contrast to the cylinder fraction, the nanoporosity of the aluminum oxide remains unchanged, presumably because of the inaccessibility of the small defect-like voids in the amorphous oxide to the etch solution.

## ACKNOWLEDGMENTS

Philips Research (Eindhoven) is gratefully acknowledged for supplying the samples. This work is part of the research program of the Stichting voor Fundamenteel Onderzoek der Materie (FOM), financially supported by the Nederlandse Organisatie voor Wetenschappelijk Onderzoek (NWO) and Philips Research.

## INTRODUCTION

In this entry, the cryomilling process and its products are covered, including the formation of nanostructured powders and their thermal stability. The microstructural changes that occur during consolidation and secondary processing are also considered. Finally, the mechanical properties of the bulk product will be discussed. The discussion focuses on metals, with particular attention paid to aluminum alloys, and their potential as high-strength structural materials.

## BACKGROUND

Cryomilling is a mechanical attrition technique in which powders are milled in a slurry with milling balls and a cryogenic liquid, originally developed to produce dispersion strengthened metal powders.<sup>[1–3]</sup> Because cryomilling relies on severe plastic deformation, the formation of nanostructures within the powder particles can be compared to other ball milling methods, as well as to microstructural refinement of bulk materials attained via equal channel angular pressing (ECAP), friction stir processing, and cold working. As a powder metallurgy technique, it requires a consolidation step, and changes in microstructure and properties during consolidation can be compared with those for consolidated or compacted nanoparticles and traditional ball-milled powders.

The possible advantages to using a cryogenic liquid, usually nitrogen, rather than carrying out the milling at room temperature, are that the low temperature suppresses the annihilation of dislocations, a larger dislocation density is possible, and the development of the nanostructure is obtained in a shorter time.<sup>[3]</sup> The extent to which these advantages are realized in practice differs between material systems and have not been explored to the fullest. For softer metals, like

aluminum, the particular advantage of the cryogenic temperature is that it prevents substantial agglomeration of the powder during milling. For reactive metals, it can reduce the amount of contamination, oxygen in titanium, for example.

## STRUCTURAL EVOLUTION DURING CRYOMILLING

The processing parameters for cryomilling are very similar to ball milling, i.e., the time of milling, the ball-to-powder mass ratio, the size of the mill, and the milling media (material and ball diameter) can significantly influence the end product. Modified ball-milling attritors are used, connected to a liquid nitrogen feed, with an inserted thermocouple to ensure that the liquid nitrogen in the milling chamber is kept at a constant level. Typical parameters for cryomilling are a ball-to-powder mass ratio of 36:1, 6 mm diameter chrome steel balls, an attritor rotation speed of 180 rpm, and a milling time of 8 hr. A small amount (~0.25 wt%) of stearic acid is added to the slurry to prevent powder agglomeration. The powder used for cryomilling usually has a preferred size of about 50  $\mu\text{m}$ , which is not changed significantly after milling has been completed. As of now, there has been little investigation of the effect of cryomilling parameters on the structure and properties of the final, consolidated material.

## Formation of Nanocrystalline Structure

A basic empirical description of the development of nanostructures during mechanical milling, which cryomilling is likely to follow, has been presented by Fecht.<sup>[4]</sup> This comprises a three-stage process of grain refinement, starting with the localization of deformation into shear bands with high dislocation density,

which is followed by annihilation and recombination of dislocations, forming nanometer-scale subgrains. This subgrain structure extends throughout the sample during continued milling. The final stage is the transformation of the subgrain boundary structure to randomly oriented high-angle grain boundaries.<sup>[4]</sup>

The minimum grain size achievable by ball milling,  $d_{\min}$ , has been related to several physical properties for elemental metals. In the case of melting temperature ( $T_m$ ), there is an inverse relation for  $d_{\min}$  for lower melting point fcc metals. For hcp, bcc, and higher melting point fcc metals (above that of Pd at 1555°C),  $d_{\min}$  is constant with respect to  $T_m$ , where the value of  $d_{\min}$  is ranked fcc < bcc < hcp.<sup>[5,6]</sup> However, if  $d_{\min}$  is normalized by the magnitude of the respective Burgers vector,  $b$ , metals of all three crystal systems, including some alloys, can be represented by an equation of the form

$$\frac{d_{\min}}{b} = A \exp[-cT_m] \quad (1)$$

where  $A$  and  $c$  are constants.<sup>[7]</sup> For fcc metals, an inverse relationship has also been found between  $d_{\min}$  and bulk modulus, and a direct relationship between  $d_{\min}$  and the minimum equilibrium distance between two unstressed edge dislocations.<sup>[6]</sup> More recently, Mohamed was able to support Fecht's empirical model with a demonstration of the relationship between  $d_{\min}$  and the activation energy for recovery, which in turn can be related to melting temperature and bulk modulus.<sup>[7]</sup> One consequence of these correlations, especially pertinent to a discussion of cryomilling, is the prediction that milling at lower temperatures will not reduce  $d_{\min}$  appreciably in metals with lower self-diffusion activation energies, such as Al.

Another factor to consider in the grain refinement process is microstructural inhomogeneity. The empirical model cited previously describes deformation localized

into shear bands that ultimately comprise the entire sample.<sup>[4]</sup> It would not be surprising, therefore, to find microstructural features that manifest different relative degrees of deformation, and not simple log-normal distributions of randomly oriented equiaxed grains.

For cryomilled Al–7.5Mg, two distinctive components of the microstructure were observed after cryomilling for 8 hr: A random distribution of equiaxed grains between 10 and 30 nm in diameter and, less frequently, elongated grains measuring 100–200 nm long by 30 nm wide as shown in Fig. 1.<sup>[2,8]</sup> A similar microstructure was observed in cryomilled commercial purity Al.<sup>[9]</sup> Transmission electron microscopy (TEM) investigation of cryomilled Al–7.5Mg–0.3Sc revealed that the mean width of the elongated regions in cryomilled powder was essentially equal to the average grain size of equiaxed grains.<sup>[10]</sup> These elongated grains were compared to the lamellar structures that arise during cold rolling of wrought Al to high strains, with continued deformation taking place within the individual lamellae, producing subgrains that are roughly equiaxed.<sup>[9,11,12]</sup> This microstructure is thus consistent with the empirical model, but the appearance of high-angle grain boundaries separating elongated regions is not necessarily anticipated.<sup>[4]</sup> The implication for the cryomilled Al–Mg, though not stated, is that these microstructures are evidence of insufficient milling time. Elongated grains of similar dimensions were also reported as a transient feature in cryomilled Inconel 625, present in samples milled for 4 and 6 hr, but not in powder milled for 8 hr.<sup>[13]</sup>

A high dislocation density and microtwins have been observed in cryomilled Al alloys, as shown in Fig. 2, where high-resolution electron microscopy (HREM) investigation revealed a density of dislocations of  $1.3 \times 10^{17} \text{ m}^{-2}$  in the elongated grains described above.<sup>[2]</sup> In comparison, for cold rolled Al–Mg alloys

**Fig. 1** Transmission electron microscopy images showing the two different microstructures present in as-cryomilled Al–7.5Mg powder: (A) elongated grains and (B) equiaxed grains. *Source:* From Ref.<sup>[2]</sup>.

**Fig. 2** High-resolution electron microscopy images showing the microstructure of cryomilled Al-7.5Mg. (A) Typical elongated grain. (B) An enlarged Fourier-filtered image of the area marked with a black square in (A) imaged using (000) and a {111} pair. Dislocations are indicated with a “T”. (C) Equiaxed grains where grain A contains a five-fold twin, marked with smaller arrows, and grain B contains microtwins and stacking faults. There is a 5° small-angle grain boundary between grains A and C marked with two larger arrows. *Source:* From Ref.<sup>[2]</sup>.

the dislocation density was  $5 \times 10^{15} \text{ m}^{-2}$  at a strain of 3.5. Many of the cryomilled dislocations existed as dipoles, which are often present in heavily deformed metals. Within the equiaxed grains, few dislocations were seen. However, twins were frequently observed in grains with dimensions less than 10 nm, as shown in Fig. 2(C). It is worthwhile to note that the occurrence of twins is not common in Al and its alloys. In addition, the HREM investigations also found some nonequilibrium grain boundaries in the as-milled powder.

A significant aspect of the cryomilled microstructure to consider is the presence of nanoscale dispersoids. While  $\text{Al}_2\text{O}_3$  or carbide particles may be present in Al-bearing alloys, as in mechanically alloyed materials, the additional formation of AlN is the result of milling in the liquid nitrogen environment. Examples of

**Fig. 3** High-resolution electron microscopy images of AlN dispersoids in extruded cryomilled Al-10Ti-2Cu: (A) higher magnification image of a single dispersoid and (B) multiple dispersoids adjacent to a grain boundary. *Source:* From Ref.<sup>[14]</sup>.

dispersoids with a length of approximately 10 nm in extruded cryomilled Al-10Ti-2Cu are shown in Fig. 3.<sup>[14]</sup> There have been some differences reported in the size and nature of the nitrogen-containing dispersoids: While a cryomilled Al- $\text{Al}_2\text{O}_3$  composite contained platelets about 10 nm and separated by 80 nm, in NiAl the dispersoids ranged in size from 5 to 100 nm, and were distributed inhomogeneously after consolidation.<sup>[1,15-17]</sup> However, it must be mentioned

that reported values for the dispersoid particle spacing come from materials consolidated and processed by different means, using widely varying temperatures, so they likely do not represent the as-milled distribution for each of the systems.

### Thermal Stability of Cryomilled Powders

Nanocrystalline materials for structural application produced via cryomilling or mechanical milling require the consolidation of the powders, which has often been evaluated a priori by isothermal annealing experiments to assess the thermal stability of the microstructure. It must be noted that these studies do not include grain growth that could arise due to the application of both temperature and stress, for example, as experienced during hot isostatic pressing.

On the basis of the available data for cryomilled alloys presented graphically in Fig. 4, cryomilled Al, or alloys containing Al, would appear to be more thermally stable than Ni or Fe. Fe-2.6Al, for example, exhibits much greater thermal stability than Fe without Al.<sup>[18-23]</sup> Although the incorporation of the oxide layer on the premilled Al powders probably adds resistance to grain growth, as has been described for milled Al, the presence of nitride dispersoids in the structure is likely to be of paramount importance in stabilizing the grain size. AlN has a higher stability compared to Fe and Ni nitrides. Ni<sub>3</sub>N, for example, decomposes above 500°C.<sup>[19,24]</sup> The importance of N-containing dispersoids was emphasized when NiAl was cryomilled in liquid Ar, so that no AlN or Al(ON) could form, and the grain growth of this material during isothermal annealing led to grain sizes roughly an order of magnitude larger than when the NiAl was milled in liquid nitrogen.<sup>[25]</sup>

Inconel 625 departs from the usual behavior of increasing grain size above 700°C, as shown in Fig. 4,

since annealing at 900°C actually led to a smaller grain size. This was attributed to the precipitation of two niobium-bearing phases, Ni<sub>3</sub>Nb and NbC, and their stabilizing effect.<sup>[23]</sup>

Investigation of both mechanically milled Fe and cryomilled Al has indicated two different values of activation energy for grain growth, depending on the annealing time and temperature.<sup>[22,26]</sup> In both cases, lower temperature data gave a better fit to the parabolic grain growth relationship given by

$$D^{1/n} - D_0^{1/n} = kt \quad (2)$$

where  $D_0$  and  $D$  are the grain size initially and at time  $t$ , respectively, and  $k$  is an Arrhenius-type rate constant that includes the activation energy for grain growth. The denominator of the exponent,  $n$ , would be 0.5 in the ideal case where the only driving force on the grain boundary results from its curvature. Deviations from this value, which are the norm, are attributed to pinning of the grain boundaries.<sup>[27]</sup> The higher temperature data were fitted to a model that accounts for pinning forces on a migrating grain boundary. Both Fe and Al relied on Burke's equation:

$$\frac{D_0 - D}{D_m - D} + \ln\left(\frac{D_m - D_0}{D_m - D}\right) = kt \quad (3)$$

where  $D_m$  refers to the maximum grain size that would arise purely from the pinning force.

### CONSOLIDATION OF CRYOMILLED POWDERS

Typically, prior to consolidation, the cryomilled powder is transferred to Al cans fitted with hollow stems and valves for hot vacuum degassing, to remove

Fig. 4 Graph showing the variation of grain size with isothermal annealing temperature of various cryomilled powders.

gaseous impurities such as H, the presence of which would severely embrittle the material. The temperatures and times used for degassing can significantly increase the grain size of the powder above that for the as-milled condition. For Al, annealing data suggests grain growth at the degassing temperature from about 25 to about 65 nm, based on x-ray diffraction and TEM measurements.<sup>[18]</sup> Once the degassing cycle is completed, the can is then sealed at the stem to preserve the vacuum.

### Hot Isostatic Pressing

Beginning with the earliest work, the most common primary consolidation route has been hot isostatic pressing (HIPping). In this case, cryomilled Al was HIPped at approximately  $0.84T_m$ , but the as-HIPped microstructure was not described with nearly the same detail as the as-milled powders.<sup>[1]</sup>

Like the milling process itself, where the evolution of particle size and morphology is paralleled by grain size refinement, the HIP consolidation process also takes place at two length scales. Modeling of the HIP process typically focuses on the densification of the powders, and not the transformations taking place within the powders.<sup>[28]</sup> The densification has been described as a three-step process, beginning with loose packing of powder in the can, elimination of connected porosity due to the growth of necks at contact points between adjacent particles, and reduction of the size of individual pores.<sup>[29]</sup> The growth of necks and filling in of pores at each stage is accomplished by a combination of plastic deformation of the powder particles, power-law creep, and mass diffusion to the remaining free surfaces.

The consequence of the HIP densification is that the material filling the pores is different from that originating directly from the cryomilled powder. This is clearly seen in Fig. 5, which shows the microstructure of cryomilled Al 5083 that had been HIPped at a temperature of  $300^\circ\text{C}$  ( $0.67T_m$ ) and a pressure of 172 MPa.<sup>[30]</sup> In Fig 5(A), an optical micrograph of the as-HIPped material shows contrast between the lighter-colored material surrounding the milled particles and the particles themselves. Additionally, Fig. 5(B) presents a TEM image of a shared particle boundary which illustrates the difference in grain size between the particles, for which the grain size averages less than 100 nm, and the surrounding interparticle regions, for which the grain sizes range between 1 and  $3\mu\text{m}$ .<sup>[30]</sup> Based on the optical image in Fig. 5(A), these coarse-grained regions represent about 10–20% of the sample. Not only are the interparticle regions coarser grained, they are probably free of the dispersoids that give the cryomilled material high thermal stability. It is therefore

**Fig. 5** Micrographs of as-HIPped Al 5083: (A) optical showing cryomilled material surrounded by lighter interparticle material arising from densification and (B) TEM showing the coarser grained interparticle region between the fine grained material originating from the cryomilled powder. *Source:* From Ref.<sup>[30]</sup>.

likely that the interparticle regions will increase in relative grain size upon further thermo-mechanical processing. A higher HIP temperature has been correlated with a larger number of relatively coarse grains (300–1000 nm) and a lower strength.<sup>[31]</sup>

### Extrusion

Powder metallurgy products must be fabricated in such a way as to break up prior particle boundaries, homogenize the material, and close remaining pores to eliminate possible stress concentration points that can serve to initiate cracks or lead to failure by interface debonding. As illustrated in Fig. 5, HIPping does not necessarily homogenize the material completely,

and it may not be entirely sufficient to remove residual porosity, necessitating additional processing. The favored method until now has been extrusion. The first reported cryomilling of Al (with  $\text{Al}_2\text{O}_3$ ) used a combination of HIP and extrusion, while an initial effort to cryomill NiAl with 0.5 wt%  $\text{Y}_2\text{O}_3$  used HIPping or extrusion of canned powders at three different reduction ratios.<sup>[16,17]</sup>

During extrusion, it has been found for cryomilled Al 5083 that the average grain size increases by 130–250%.<sup>[32]</sup> However, in general, there has not been a lot of reported research on the comparison of extruded microstructures with that obtained directly from HIPping. The increase in grain size during extrusion depends on the relative effect of the dispersoids and the solute atoms, which in turn would depend on their distribution throughout the grains. If a network of dispersoids exists at the grain boundaries, the grain boundaries must break free, or the dispersoids themselves might migrate during extrusion. Alternatively, if the dispersoids are generally found in the grain centers, the presence of Mg at the grain boundaries of cryomilled Al 5083 could be important. However, high Mg mobility in Al at the extrusion temperatures used (150–250°C) would allow grain boundaries to migrate and lead to grain growth. In this case, the final extruded grain size would reflect the distribution of the dispersoids.

Ongoing research activities regarding the processing of cryomilled powders include alternative primary consolidation methods, such as cold isostatic pressing (CIPping) and secondary processing, including different types of extrusion, forging, hot pressing, and rolling.

## MECHANICAL PROPERTIES OF CRYOMILLED MATERIALS

Consolidated cryomilled materials have exhibited much increased strength over conventionally processed material, usually at the expense of ductility. For the Al alloy 5083, the yield strength ( $\sigma_y$ ) and ultimate tensile stress (UTS) of cryomilled material has been measured to be around 450 and 500 MPa, compared to 120 and 275 MPa for relatively coarse (grain size  $\sim 200 \mu\text{m}$ ) 5083. The cryomilled Al 5083 also had greater strength than ECAP material, which had a UTS of  $\sim 350$  MPa. However, whereas the ECAP Al 5083 had a similar strain at fracture to the conventional material, the elongation of the cryomilled Al 5083 was about half.<sup>[33]</sup> Cryomilled Al–7.5Mg was also found to have a  $\sigma_y$  and a UTS about 30% above those of the strongest commercially available form of Al 5083, but in this case there was no apparent decrease in ductility.<sup>[34]</sup> This was attributed to the presence of ductile, crack blunting micrometer-size grains that had developed in the HIPped and extruded structure. It is possible that the

large grains may have developed out of the HIP structure discussed previously.

Cryomilled Al–Mg–Sc alloy and Al–Mg alloys were consolidated and processed to have a grain size of about 200 and 300 nm, respectively. The Al–Mg–Sc alloy exhibited a  $\sigma_y$  of 630 MPa, a UTS of 730 MPa, and an elongation-to-failure of approximately 2.7%.<sup>[35]</sup> The material consolidated from cryomilled Al–Mg powder also had a high strength, having a  $\sigma_y$  and UTS of 642 and 847 MPa, respectively, and it failed in the strain-hardening region, with a similar low ductility of 1.4%.<sup>[36]</sup> Inspection of the stress–strain curves revealed a brief strain-hardening region after yielding and a low strain-hardening region. In addition, localized shear (Lüders) bands and macroscopic necking have been observed in cryomilled Al–Mg alloys.<sup>[37]</sup>

The fundamental reason for the increased strength of cryomilled structural alloys, in comparison to those processed conventionally, is probably the increase in  $\sigma_y$  due to a reduction in the mean grain size ( $d$ ) based on the Hall–Petch relationship:

$$\sigma_y = \sigma_0 + k_y d^{-1/2} \quad (4)$$

where  $\sigma_0$  is the lattice friction stress, and  $k_y$  is the Hall–Petch slope. Two cryomilled systems for which grain size variation has been achieved by changing the HIP temperature are commercial purity Al and Al 5083. The average grain sizes for cryomilled extrusions were in the range 100–200 nm for the Al and 150–300 nm for the Al 5083, and their Hall–Petch plots are shown in Fig. 6.<sup>[30,31]</sup> The calculated  $k_y$  values were 0.09 and 0.28  $\text{MPa} \sqrt{\text{m}}$  for the cryomilled Al and Al 5083, respectively.

It has been found that extruded cryomilled Al alloys have a yield stress roughly 15% higher than mechanically alloyed Al at a similar fraction of dispersoid particles.<sup>[24]</sup> Establishing the precise reason for the difference is complicated by the presence of AlN and a smaller grain size for the cryomilled alloys. Both strengthening contributions are considered additive, but the grain size distribution and uneven particle spacing may well complicate the extent to which separate contributions can be determined.<sup>[38]</sup> Two other sources of strengthening may also need to be taken into account: that due to differences in the concentration and the distribution of solute atoms and dislocations.

Stress–strain curves for two extrusions of cryomilled commercial purity Al with average grain sizes of 116 and 179 nm are shown in Fig. 7.<sup>[39]</sup> The larger grain size, obtained by using a higher HIP temperature, resulted in an increase in the ductility at the expense of a drop in the strength. The curves in Fig. 7 show only the extent of uniform plastic deformation. After

**Fig. 6** Hall-Petch plots relating yield stress to the mean grain size for extrusions of cryomilled Al and Al 5083. *Source:* From Refs.<sup>[30,31]</sup>.

**Fig. 7** Room temperature stress-strain curves (strain rate of  $10^{-3} \text{ sec}^{-1}$ ) for extrusions of cryomilled Al HIPped at different temperatures. The data are displayed to the extent of uniform plastic strain. *Source:* From Ref.<sup>[39]</sup>.

the onset of necking, reductions in area were more than 20% and 50%, respectively, hinting that greater elongations can be achieved if flow localization can be prevented.<sup>[31]</sup>

Alloys with a bimodal grain size distribution have been investigated as a means to enhance ductility through the blending of cryomilled powder with a fraction of unmilled powder of the same chemical composition.<sup>[36]</sup> The nanostructured regions of bimodal Al-7.5Mg alloy had grain sizes of 100–300 nm. In the consolidated material, there were also larger grained bands, originating from the unmilled powder, which had a grain size of  $\sim 1 \mu\text{m}$ . There was a trend of decreasing strength and increasing elongation with an increasing fraction of micrometer-grain material, as shown in Fig. 8. A good combination of strength and ductility was obtained in the cryomilled Al-7.5Mg with 30% added unmilled powder.<sup>[36]</sup>

**Fig. 8** Room temperature stress-strain curves for extrusions of cryomilled Al-7.5%Mg containing from 0% to 30% unmilled coarse grained (CG) powder. *Source:* From Ref.<sup>[36]</sup>.

## CONCLUSIONS

The properties of cryomilled materials indicate both their promise and areas where additional work is necessary. In the powder form, the cryomilled materials exhibit grain sizes that are comparable to the minimum grain sizes achieved in mechanical milling. The thermal stability of cryomilled Fe is similar to that of mechanically milled Fe, but can be increased dramatically by the addition of Al. In the case of cryomilled Al-bearing alloys, their relative thermal stability exceeds that of Fe and Ni, probably due to the presence of Al nitrides that form during milling. Once consolidated, cryomilled materials typically possess considerable strength compared to both conventional and fine-grained materials processed by other methods.

The consolidation history has a significant effect on the mechanical properties of nanostructured materials. The microstructures of the consolidated materials are fairly complex, and a full understanding of the mechanical behavior remains tentative. Despite the complexity of the microstructure, existing data on cryomilled Al indicate that the Hall–Petch relationship describes the mechanical properties to a reasonable degree. This in turn suggests that dislocation interactions at grain boundaries are responsible for the plastic deformation, and not alternative mechanisms such as grain boundary sliding. The observation that coarse grains within the fine-grained matrix improve ductility has prompted an effort to increase fracture toughness by blending relatively coarse-grained unmilled powder with the cryomilled powder prior to consolidation and secondary processing.

# Nanostructured Catalysts

Ravichandra S. Mulukutla

Nanoscale Materials, Inc., Manhattan, Kansas, U.S.A.

## INTRODUCTION

Practicing green chemistry has become more important over the last decade, reflecting the design, development, and implementation of chemical products and processes to reduce or eliminate the use and generation of substances hazardous to human health and the environment. Some of the principles of green chemistry<sup>[1]</sup> are as follows: 1) It is better to prevent waste than to treat or clean up waste after it has been created. 2) Synthetic methods should be designed to maximize the incorporation of all materials used in the process into the final product. 3) The use of auxiliary substances, solvents, separation agents, and others should be avoided; when used these substances should be innocuous. 4) Employ catalysts or catalytic reagents as selective as possible and that are superior to stoichiometric reagents. Hence, the application of catalysts in chemical reactions and more so the impact of nanostructured catalysts is the scope of this article; a few examples will be discussed pertaining to the topic. A catalyst is considered to be active in any given chemical process if it shows high conversion, is selective to the desired products, is stable for a prolonged period of time, and has good mechanical strength. Out of all the concerns, conversion and selectivity dictate the fate of the catalyst in a larger way as it can significantly change the economics of the process. High conversion can be achieved in general if the catalyst species is not sintered during the reaction and selectivity is achieved from the specific crystal structure of the catalytic active metal or the metal oxide precursor. Hence, controlling the catalyst species at molecular level is possible if catalysts were fabricated at nanometer scale. From the definition, particles of between 1 and 10 nm in size have definite crystal structure at nanometer level, and hence the application of nanostructured materials as catalysts can drastically change the conversion and selectivity in the chemical processes. This article describes in detail how nanostructured catalysts affect the catalytic process in comparison to bulk catalysts. More examples can be found in the book chapter written by Klabunde and Mulukutla.<sup>[2]</sup>

## NANOSTRUCTURED CATALYSTS FOR SELECTIVE PROCESSES

Selectivity in a chemical reaction is defined as the production of one molecule out of many other thermodynamically feasible product molecules. There is an enormous opportunity, for to understand selectivity is very important, and it is less understood than activity.<sup>[3]</sup> On the nanometer scale, bifunctional catalysis has been documented as playing a major role in selectivity. On nanostructured catalysts reactant molecules undergo chemical change to produce intermediates. These reaction intermediates will then diffuse a certain distance to other sites where they undergo further rearrangements to produce the final product, which then desorbs. In this case, selectivity changes markedly with conversion. As can be seen from Fig. 1, nanostructured catalysts can be divided into two classes: the first category is composed of nanoparticles of metals supported on metal oxides or molecular sieves and the second includes high-surface-area nanocrystalline metal oxides themselves as catalysts or catalyst supports. Examples for each category are shown and will be described in detail in the following sections.

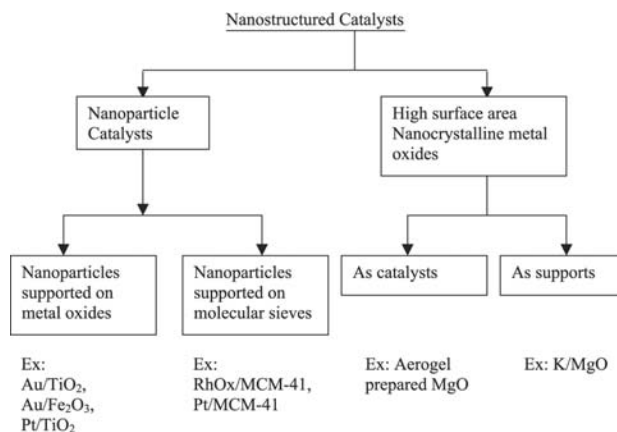

## NANOPARTICLE SUPPORTED CATALYSTS

Nanoparticle catalysts can be designed and synthesized from various methodologies.<sup>[4]</sup> The most attractive and appropriate methods involve nanoparticles of metals or metal oxides supported on inert oxides, molecular sieves, and polymers.

### Gold Nanoparticle Catalysts

Gold nanoparticle catalysts have attracted wide attention because of their wide applications in CO oxidation, epoxidation of propylene, water-gas-shift reaction, hydrogenation of unsaturated hydrocarbons, and liquid phase selective oxidation.<sup>[5]</sup> It is well known that gold is a poor catalyst in the bulk form,

**Fig. 1** Classification of nanostructured catalysts.

whereas gold nanoparticles supported on oxides exhibit high catalytic activity. A schematic representation of gold nanoparticles supported on oxides is shown in Fig. 2A.

Zhong and Maye<sup>[4]</sup> demonstrated a novel approach involving monolayer-encapsulated metal nanoparticles in a core-shell nanostructured assembly as shown in Fig. 2B. The core-shell assembled nanostructure undergoes structural or morphological changes during catalytic activation and reaction within both the individual core-shell structure and the collective network environment. The monolayer encapsulation imparts the nanoparticles with shell reactivity and processibility dictated by functional groups in a three-dimensional framework.

**Fig. 2** Schematic representation of nanoparticle catalysts.<sup>[2]</sup> (A) Oxide-supported nanoparticle catalyst, (B) core-shell nanoparticle catalyst. *Source:* Reprinted with permission from Ref.<sup>[4]</sup>. Wiley-VCH Verlag GmbH.

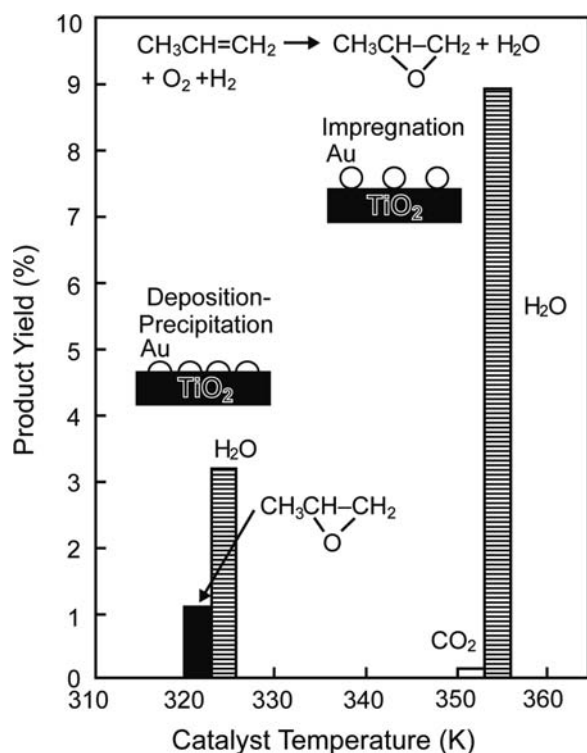

**Fig. 3** Turnover frequencies and bandgaps measured by STM as a function of the diameter of Au islands deposited on TiO<sub>2</sub>. *Source:* Reprinted with permission from Ref.<sup>[5]</sup>. Elsevier Science B.V. © 2001.

Valden et al. reported Au/TiO<sub>2</sub> catalyst<sup>[6]</sup> and demonstrated the change in turnover frequency (TOF) of CO oxidation with the change in the diameter of Au islands. As can be seen from Fig. 3, the CO oxidation reaches a maximum at an Au cluster diameter of 3.5 nm, where Au partially loses its metallic nature. They have suggested that this transition might be correlated to the high catalytic activity.

Hayashi and coworkers<sup>[7]</sup> found that Au supported on TiO<sub>2</sub> could catalyze epoxidation of propylene in the gas phase containing O<sub>2</sub> and H<sub>2</sub>. There are several factors that influence the catalytic activity of the reaction. The most important is the method of preparation, as shown in Fig. 4. The Au/TiO<sub>2</sub> was prepared by either an impregnation method or a deposition precipitation method. The impregnation method did not result in selective oxidation, but instead complete oxidation to H<sub>2</sub>O and CO<sub>2</sub>, whereas the direct precipitation method led to epoxidation with selectivities above 90%. The difference in the structure of the catalysts prepared by the different methods influences the selectivity. The impregnation method produces large, spherical Au particles with sizes of about several tens of nanometers in diameter, whereas the direct precipitation method results in small hemispherical Au particles strongly contacted with TiO<sub>2</sub> support. This is a very interesting example of how structure and size of the nanoparticles affects the selectivity of the reaction.

**Platinum Nanoparticle/MCM-41 Catalysts**

Over the last three decades, there have been considerable efforts to synthesize platinum nanoparticle supported catalysts and attempts to study the selectivity

**Fig. 4** Epoxidation of propylene over Au/TiO<sub>2</sub> prepared by different methods. *Source:* Reprinted with permission from Ref.<sup>[5]</sup>. Elsevier Science B.V. © 2001.

in various organic reactions. A classical example is the work of Junges et al.,<sup>[8]</sup> who prepared Pt nanoparticles on MCM-41 and applied the catalyst for low-temperature carbon monoxide oxidation. In this work, three methods were employed to synthesize Pt-MCM-41: 1) incipient wetness, 2) ion exchange, and 3) in situ methods. The Pt particle sizes obtained with the three preparation methods varied substantially. For the in situ loading the final average particle size was around 4–6 nm, and TEM observation revealed that the 4-nm-sized particles are located in the pore channels of the MCM-41, while the larger particles might be present on the external surface of MCM-41. The samples synthesized by ion exchange method resulted in 10-nm-sized particles. The incipient wetness impregnation resulted in 2-nm-sized Pt particles with total Pt loading up to 2% mass. All three catalysts were evaluated for CO oxidation with air in an open flow reactor at gas hourly space velocity 25,000 hr<sup>-1</sup>. The synthetic methods, which resulted in different sizes of Pt particle, had a strong influence on the catalytic performance. The best performance was observed on the samples prepared by incipient wetness, where 50% conversion was achieved at a temperature of 85°C due to the Pt nanoparticles around 2 nm, which resulted in high conversion. The other two catalysts showed 50% conversion between 110° and 130°C.

The work on Pt nanoparticle catalysts provided ample evidence that nanoparticles of Pt can exhibit high rates for CO conversion.

### RhOx Nanoparticle/MCM-41

Mulukutla et al.<sup>[9–12]</sup> synthesized RhOx nanoparticles in the MCM-41 molecular sieve via a sol-gel method. As shown in Fig. 5, assorted sizes of RhOx nanoparticles were prepared by changing the conditions of the

**Fig. 5** TEM photographs of (A) Rh-MCM-41-A-200; (B) Rh-MCM-41-B-200, and (C) Rh-su-MCM-41-200. *Source:* Reprinted with permission from Ref.<sup>[12]</sup>. Elsevier Science B.V. © 2002.

synthesis. The size and location of the resulting rhodium oxide particles varied with the hydrothermal synthesis conditions as shown in TEM photographs in Fig. 5. The RhOx nanoparticles in Rh-MCM-41-A with Si/Rh = 200 (Fig. 5A) grew to 6- to 8-nm RhOx particles and they seemed to be located in the bulk of MCM-41. The local structure of MCM-41 might have been destroyed because the particle sizes were larger than the MCM-41 pore diameter (3.2 nm). The argument for RhOx on the surface has been ruled out from the comparison with the MCM-41 supported RhOx sample (Fig. 5C) with a similar Rh loading. Furthermore, the RhOx particles in Rh-MCM-41-A (Fig. 5A) were orthorhombic, whereas the RhOx particles supported on the MCM-41 surface were hexagonal, demonstrating the different locations between the two samples.

The Rh-MCM-41-B with Si/Rh = 200 (Fig. 5B) possessed <3-nm-sized RhOx particles, which were smaller than the MCM-41 with pore diameter of 3.4 nm. TEM photograph of Fig. 5B depicts that the RhOx particles are located in the pore channels of MCM-41. Fig 5C is a TEM photograph of the Rh-su-MCM-41 having Si/Rh = 200, where rhodium oxides are observed as aggregates of about 10-nm size, while the MCM-41 pore channels are clearly visible.

RhOx nanoparticles in the MCM-41 with different particle sizes, structures, and locations in the MCM-41 were used as catalysts for NO-CO reactions. The NO reduction with CO was performed in the presence and absence of O<sub>2</sub>. On the Rh-MCM-41-B catalyst, the NO conversion to N<sub>2</sub> and N<sub>2</sub>O in the absence of O<sub>2</sub> began between 275° and 300°C as shown in Fig. 6. The conversion to N<sub>2</sub>O reached a maximum of 30% at 325°C. The selectivity to N<sub>2</sub> increased with

**Fig. 6** The NO conversion to N<sub>2</sub> and N<sub>2</sub>O against reaction temperature on the Rh-MCM-41-B catalyst; (O) N<sub>2</sub>, (□) N<sub>2</sub>O, (—) NO + CO + O<sub>2</sub>, (---) CO + NO. Source: Reprinted with permission from Ref.<sup>[11]</sup> Acta Materialia Inc. Published by Elsevier Science Ltd. © 2001.

temperature and reached 92% at 375°C. Excess oxygen (4%) was added to the stream of NO and CO, which resulted in unexpected promotion of the NO conversion to N<sub>2</sub> and N<sub>2</sub>O as shown in Fig. 6. The reaction in the presence of O<sub>2</sub> proceeded at 250°C, whereas it did not proceed below 275°C in the absence of O<sub>2</sub>. The promotion phenomenon by excess O<sub>2</sub> is of interest and it may be attributed to the nanosized rhodium oxide precursors in the pore channels of MCM-41. The excess O<sub>2</sub> usually poisons the Rh catalysis since O<sub>2</sub> oxidizes CO to CO<sub>2</sub> very rapidly. It was concluded that under the reaction conditions NO conversion was promoted in the NO-CO reaction in the presence of excess O<sub>2</sub> on the Rh-MCM-41-B catalyst.

Fig. 7 depicts the NO conversion to N<sub>2</sub> and N<sub>2</sub>O on the Rh-MCM-41-A catalyst with and without O<sub>2</sub>. At 275°C there was about 75% conversion to N<sub>2</sub> and the rest was N<sub>2</sub>O, and at the higher temperatures the selectivity toward N<sub>2</sub> was 100%. However, the presence of O<sub>2</sub> in the stream dramatically suppressed the conversion of NO, and the NO conversion to N<sub>2</sub> and N<sub>2</sub>O began above 375°C. Thus, the Rh-MCM-41-A catalyst, which had RhOx particles of the size of 6–8 nm exhibited a negative effect of excess O<sub>2</sub> on the NO conversion. These results are entirely different from those observed with the Rh-MCM-41-B catalyst. NO conversion to N<sub>2</sub> and N<sub>2</sub>O in the NO-CO reaction on the RhOx supported on MCM-41 (Rh-su-MCM-41) catalyst exhibited a negative effect by excess O<sub>2</sub>. This feature resembles that observed with the Rh-MCM-41-A catalyst. This observation on the nanostructured RhOx-MCM-41 is emphasized to show that the active sites in different locations and particles sizes play a significant role in the catalytic reaction of NO-CO in presence of O<sub>2</sub>.

**Fig. 7** The NO conversion to N<sub>2</sub> and N<sub>2</sub>O against reaction temperature on the Rh-MCM-41-A catalyst; (O) N<sub>2</sub>, (□) N<sub>2</sub>O, (—) NO + CO + O<sub>2</sub>, (---) CO + NO. ## NANOCRYSTALLINE METAL OXIDE AS CATALYSTS/CATALYST SUPPORTS

Synthesis of high-surface-area nanocrystalline alkaline metal oxides has drawn much attention because of their high surface area and adsorption capacity compared to their commercial analogues. Some examples are MgO, CaO, TiO<sub>2</sub>, and Al<sub>2</sub>O<sub>3</sub>. The extraordinary properties of these nanocrystalline oxides are due to the morphological features of the small crystallites possessing higher populations of reactive surface sites such as edges, corners, and ion vacancies. It has been proposed that some of these nanocrystalline metal oxides, because of their defective sites, might have catalytic properties and that they can be used as catalyst supports because they have high surface area. The following are some examples where nanocrystalline MgO exhibited catalytic properties. In addition, it has been used as support for synthesizing superbase catalysts.

### Aerogel-Prepared MgO

Utamapanya, Klabunde, and Schlup<sup>[13]</sup> prepared nanocrystalline MgO through an aerogel method using supercritical drying and were successful in obtaining high surface areas in the range of 400–500 m<sup>2</sup>/g with crystallite sizes of about 3 nm. The nanocrystalline MgO obtained is referred to as AP-MgO.

### Chlorination of Hydrocarbons with Aerogel-Prepared MgO

Aerogel-prepared MgO, when exposed to Cl<sub>2</sub> gas at atmospheric pressure and room temperature, exothermally formed an extremely reactive AP-MgO-Cl<sub>2</sub> adduct; 15% Cl<sub>2</sub> by weight was adsorbed on the surface.<sup>[14]</sup> The chlorine adduct was able to chlorinate hydrocarbons in a batch reactor. The normal forms of MgO did not react with Cl<sub>2</sub> gas. Richards, Mulukutla, and Mishakov<sup>[15]</sup> performed further investigation on the characterization of the AP-MgO-Cl<sub>2</sub> adduct, conducting pulse reactions and demonstrating the catalytic behavior of AP-MgO in the chlorination of hydrocarbons. The XPS characterization of AP-MgO-Cl<sub>2</sub> indicated that the binding energy for Cl 2p is 198.2 eV and this value corresponds to monochloro compounds similar to NaCl and KCl. Hence, the chlorinated species on the surface of AP-MgO is not MgCl<sub>2</sub>. As shown in Fig. 8A, the chlorination of propane conducted over AP-MgO at temperatures from 0° to 200°C proceeded in normal light. The expected products were 1-chloropropane, 2-chloropropane, and 1,2-dichloropropane. Fig. 8B shows the reaction data conducted without AP-MgO where the reaction

**Fig. 8** Chlorination of propane (A) with AP-MgO catalyst. (B) Blank reaction. *Source:* Reprinted with the permission from Ref.<sup>[13]</sup>. Acta Materialia Inc. Published by Elsevier Science Ltd © 2001.

proceeded with the help of normal light. As noted, the selectivity to 1,2-dichloropropane up to 60% was observed when the reaction was conducted at 200°C with AP-MgO, with simultaneous decrease of the 2-chloropropane. The selectivity was not affected in the case of a blank reaction.

### Dehydrochlorination of 1-Chlorobutane with Aerogel-Prepared MgO

Mishakov et al.<sup>[16]</sup> and Fenelonov et al.<sup>[17]</sup> evaluated nanocrystalline MgO for dehydrochlorination of 1-chlorobutane. Exposure of AP-MgO to 1-chlorobutane at 200–350°C resulted in both stoichiometric and catalytic dehydrochlorination to form isomers of butene and simultaneous topochemical conversion of MgO to MgCl<sub>2</sub>. The resulting MgCl<sub>2</sub> was believed to be an active catalyst for the dehydrochlorination reaction. As shown in Fig. 9, the

**Fig. 9** Kinetics of chlorobutane conversion at different temperatures. *Source:* Reprinted with permission from Ref.<sup>[17]</sup>. American Chemical Society © 2001.

conversion of chlorobutane at different temperatures over time established the formation of active  $\text{MgCl}_2$  from AP-MgO. The formation of such an active catalyst species on the surface of nanocrystalline MgO was possible only with AP-MgO. Hence, this work is a striking example of how a high-surface-area catalytic species such as  $\text{MgCl}_2$  can be formed from a nanocrystalline MgO.

### Potassium/Aerogel-Prepared MgO

The high surface area of AP-MgO in the range of  $350\text{--}500\text{ m}^2/\text{g}$  can be used as a support. Sun and Klabunde<sup>[18]</sup> prepared potassium metal-doped nanocrystalline MgO, which exhibited high activity in base-catalyzed isomerization and alkylation. It was established that 10 wt.% of K-doped AP-MgO showed 100% conversion to isomerized products from 2,3-dimethyl-1-butene at room temperature in 30 min. However, the use of commercial analogues and lower-surface-area MgO did not result in such high conversions. The edges/corners on the polyhedral crystallites of high-surface-area MgO are responsible for creating superbasic sites to obtain a highly active isomerization catalysts.

### CONCLUSION

This entry demonstrates that nanostructured catalysts can be designed by several methods. The prominent ways are synthesizing metal nanoparticles supported on metal oxides and sol-gel method of generating

metal/metal oxide nanoparticles in MCM-41 molecular sieves. Nanocrystalline metal oxides with high surface area, which were prepared from aerogel methods, can be used as catalysts or catalyst supports. The examples show that nanostructured catalysts have a significant influence on the conversion and selectivity of the chemical reactions. Control and understanding of particle size and structure of the catalytic active species is the most important factor in achieving the difference between the catalytic property of nanostructured catalysts vs. bulk catalysts.

# Nanostructured Catalysts: Design and Synthesis

Hua Chun Zeng

Department of Chemical and Environmental Engineering,  
National University of Singapore, Singapore, Singapore

## INTRODUCTION

Natural and manmade catalytic materials are among the oldest “nanostructured materials” known long before the era of nanoscience and nanotechnology. The classic heterogeneous catalysts consist of active nanoscale metal component(s) and solid carriers,<sup>[1]</sup> namely, “inert” oxide supports such as alumina, silicates, or magnesium oxide, to increase the reaction surface area and metal utilization. Conventional processing techniques for fabrication of supported catalysts contain one or more of the following steps: impregnation, precipitation, coating, rewashing, ion-exchange, pulverization, dyeing, and calcination, etc.<sup>[2]</sup> Nanoscale metal clusters or particles can be thus formed on the oxide carriers after these processes. It is now well known that the particle size, local composition, and structure (shape) of nanoscale catalysts determine the ultimate catalytic activity and selectivity. For example, it has been demonstrated that the activity of TiO<sub>2</sub>-supported gold particles is very sensitive to their size (2 to 3 nm) in the CO oxidation reaction with oxygen at ambient conditions.<sup>[3]</sup> It is also well known that the structure and composition of nanocatalysts may change under the reaction conditions, and thus their performance could be time-dependent. Nonetheless, prevailing catalyst preparation still remains largely as a technological art rather than a science, although surface science has significantly deepened our general understanding of heterogeneous catalysis using single-crystal model catalysts.<sup>[4]</sup>

Over the past 15 to 20 years, we have witnessed exciting advances in the design and synthesis of low-dimensional nanostructured materials, ranging from fullerenes, carbon nanotubes, supramolecular assemblies, mesoporous structures, to various organic-inorganic hybrid materials. Taking advantage of the rapid development in nanoscience and nanotechnology, a wide range of synthetic techniques are now in place. For example, nanostructured materials can be prepared with constrained or unconstrained synthetic methods, in which inorganic or organic templates (e.g., porous oxides, organic ligands, well-oriented crystal planes, and supramolecule-directing agents) are commonly employed. With these newer approaches

and knowledge, a huge variety of nanostructured catalytic materials have been designed and synthesized, which will be the main review topic of the present entry. With the emphasis on catalytic prospect, the objective of this entry thus aims at introducing various design and synthesis strategies for this new class of materials. Future challenges and research directions in this area will also be addressed.

## DESIGN AND SYNTHESIS OF NANOSTRUCTURED CATALYTIC MATERIALS

Because of the advances in nanostructured catalytic materials and assembling methodologies, we may have to reexamine the roles of each component in the traditional heterogeneous catalysts and redevelop the technology. In fact, a practical solid catalyst is normally not a simple chemical compound, but a highly organized multicomponent materials system (e.g., active components and carrier). In this regard, a modern view of solid catalysts is different from the traditional one. An organized assembly of catalytic materials can be considered as a “catalyst device”,<sup>[5]</sup> and the ways of chemical and structural organizations in the device will give profound impacts on its ultimate performance. In the foreseeable future, a transformation from the traditional catalyst preparation to a more sophisticated “assembly” technology is anticipated in view of the rapid progress of this field. As the first steps toward this end, nonetheless, various nanocomponents with desired chemical and structural properties and organization programmability must be fabricated and investigated for the constitution of a nanocatalyst “toolbox.” In the following sections, we will look into the current trends of research in this important area.

### Architectures of Porous Materials

Many significant progresses in porous materials have been made over the past two decades, which extends the commonly known zeolites (chemical formula  $M_{x/n}^{n+}[(AlO_2)_x(SiO_2)_y]^{x-} \cdot zH_2O$ , where  $M^{n+}$  represents

a metal cation; pore diameter <1 nm) from microporous regime (pore diameter <2 nm) to mesopores (2–10 nm),<sup>[6]</sup> large mesopores (>10 nm), and macropores (>50 nm). In particular, crystalline VPI-5 with uniform pores larger than 1.0 nm had been synthesized for the first time in 1988, as illustrated in Fig. 1.<sup>[7]</sup> Subsequently, periodic mesoporous solids were discovered by Mobil researchers in 1992.<sup>[8]</sup> These ordered porous materials with large pore openings had significantly enhanced our ability in utilizing intrapore chemical reactivity and space confinement for catalytic reactions, sorption processes, ion exchange, as well as materials synthesis, including architectures for growth and organization of functional nanomaterials. For example, hexagonal MCM-41 and cubic MCM-48 (Mobil codes) can be prepared with cationic surfactants under basic conditions. These mesoporous silicates together with various modifications (i.e., with metal cations via ion exchange, complexation, and direct “planting”)<sup>[9]</sup> allow us to tailor chemical and thermal properties to meet different working environments. For instance, isomorphous substitution and post-synthesis incorporation of active metal species are the two major methods for metal introduction to mesoporous silica.<sup>[10]</sup> Furthermore, surface functionalization with organic groups will change the chemical properties of the surfaces, forming hybrid inorganic–organic

mesoporous silicates. In the latter cases, the mesopores of the prepared solids can be viewed as nanoscopic reactors, separators, or host templates for chemical processes and nanostructured materials fabrication.

Various methods have been developed to introduce organic surface groups onto the mesoporous hosts, on the basis of chemical reactions between the hydroxyl-covered surfaces and reactive silane coupling agents. For example, covalent grafting, coating, and co-condensation reactions are common methods to tailor surface properties these days.<sup>[11]</sup> In grafting processes, surface modification with organic ligands and functional groups is normally carried out by silylation that takes place on free and geminal silanol groups [i.e.,  $\equiv\text{Si}-\text{OH}$  and  $=\text{Si}(\text{OH})_2$ ] under dry conditions. On the other hand, coating provides a means to introduce organics onto hydrated pore surfaces where a monolayer of water is present to form organosilanes. Compared to the above two methods, the co-condensation process is a more direct method. The surface organic functional groups can be anchored together with the formation of mesoporous silicates under so-called “one pot” synthetic conditions.<sup>[12]</sup> These organic–inorganic hybrids possess a number of advantages for catalytic applications that organic polymers and amorphous/nonporous silica counterparts do not have.<sup>[11]</sup> In many cases, space confinement and

**Fig. 1** (A) Pore characteristics in some representative aluminophosphates  $\text{AlPO}_4\text{-11}$ ,  $\text{AlPO}_4\text{-5}$ , and VPI-5. (B) Measured pore sizes by argon adsorption techniques, noting that the VPI-5 shows a pore diameter greater than 1.0 nm. *Source:* From Ref.<sup>[7]</sup>.

stabilization of the catalyst in the mesoporous solid can be attributed to the observed enhancement of catalytic activity. These materials have demonstrated utility as catalysts in acid/base catalysis, oxidations, reductions, enantioselective catalysis, stereospecific polymerizations, and fine chemicals synthesis.<sup>[11]</sup> Rich inclusion chemistry of this class of materials with guest species in the internal space had been reviewed recently.<sup>[9]</sup>

Over the past decade, increasing research activities have been shown in the fabrication of hierarchical porous structures that possess ordered pores ranging from micro- to macroscale. There have been a number of techniques developed.<sup>[7]</sup> For example, microporous colloidal particles have been used for shape-, film-casting to prepare a range of hierarchical porous structures. On the other hand, bulk dissolution and restructuring of preexisting oxides have been used to fabricate shaped hierarchical structures of zeolite. Furthermore, structures with mesoporosity can be prepared by using surfactants as structuring directing agents.<sup>[7]</sup> In addition to these approaches, new film formation methods allow us to fabricate various zeolite and molecular sieve layers and membranes. In recent years, pore sizes of ordered mesoporous oxides have been extended up to 10 nm with the use of block copolymers, and from 100 nm to 1  $\mu\text{m}$  with Latex spheres as templating structures.<sup>[13,14]</sup> For example, non-ionic polyethylene oxide surfactants were used to prepare wormhole-like, MSU-type SBA-n and CMI-1 mesoporous materials. With decaoxyethylene-cetyl-ether or polyoxyethylene(6)tridecyl-ether surfactants, hierarchical macroporous metal oxides had been synthesized without using polymeric sphere template.<sup>[13]</sup> It is believed that the macro-mesostructured metal oxides were formed through an intermediate phase of supermicelles (the length in the micrometer range and the diameter in the submicrometer range) and mesostructured nanoparticles of metal oxides. The removal of the organic components resulted in the formation of hierarchical mesoporous-macroporous structures.<sup>[13]</sup> The approach had been successfully applied to  $\text{ZrO}_2$ ,  $\text{Nb}_2\text{O}_5$ ,  $\text{Ta}_2\text{O}_5$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{CeO}_2$  oxide systems, and the networks of the pores can be preserved at elevated temperatures to meet catalytic applications. Very recently, hierarchical and self-similar growth of self-assembled mesophase crystals in micrometer size had been investigated with the assistance of glass substrate. Ordered octahedral crystal building units can be assembled into various high-ordered stack structures via edge-sharing. It is found that the large structures are formed through stepwise nucleation from the edges of the previous crystals.<sup>[15]</sup>

In addition to the general interest in the synthesis and design of micro-, meso-, and macroporous materials, there are interests in the preparation of single-site molecular receptors in silica matrix for specific

adsorption and catalysis applications. Using molecular imprinting techniques, both microporosity and chemical functionality have been achieved for this new class of organic-inorganic hybrid materials. Typically, bulk-imprinted silica with hydrophilic framework can be prepared via copolymerization of the imprint organosilane(s) with a silica source (normally, silicon alkoxides such as tetraethyl orthosilicate, TEOS), followed by a mild thermal treatment.<sup>[16]</sup> Fig. 2 shows a flowchart of this type of synthesis, where organic functional groups (such as amines) can be immobilized into the silica matrix possessing high specific surface area. The imprinted silicas can act as shape-selective base catalysts,<sup>[17]</sup> and the hydrophilic framework prepared in this way offers an interesting potential to stabilize polar reactive intermediates and transition states at the active sites.<sup>[16]</sup>

Finally, it should be mentioned that the mesoporous materials can be used as traditional high-surface-area catalytic supports for active metal loading. On the other hand, nanostructured metallic catalysts encapsulated can nucleate the expansion of the mesopore channels. For example, prefabricated gold and platinum nanoparticles had been investigated to tune the pore size of the mesoporous silica (SBA-15) that are grown around them (e.g., in the range of 9.2 to 11.6 nm).<sup>[18]</sup>

Other important applications of the porous materials include template synthesis of nanostructured catalytic materials used as either individual (freestanding) catalysts or basic building blocks for self-assembly, as will be discussed in subsequent sections.

## Designs of Layered Organic-Inorganic Nanohybrids

In recent years, layered organic-inorganic materials have attracted increasing research attention not only because of the fundamental interest in general supramolecular chemistry, but also because of their potential usage as precursors for catalytic nanomaterials processing. There are two basic types of clay materials: cationic and anionic clays. The cationic clays, which have been investigated extensively over the past decades, were conventional catalysts used in oil cracking before the replacement of zeolites in 1964.<sup>[19]</sup> They have been used in many industrial chemical processes such as isomerization, liquid refining, and Friedel-Crafts alkylation, including some emerging environmental technologies (such as cation exchange and waste carriers).<sup>[19]</sup> In this class of materials, cations are located in the lamellar space (interlayer space) formed by negatively charged alumino-silicate layers. As they are generally prepared starting from the natural minerals, these clays and modified clay catalysts promise widespread industrial applications in the future owing to

**Fig. 2** Process of molecular imprinting in bulk silica. (A) Sol-gel hydrolysis and condensation catalyzed by HCl. (B) Removal of the aromatic core and creation of a cavity with spatially organized aminopropyl groups covalently anchored to the pore surfaces. Source: From Ref.<sup>[17]</sup>.

the low cost. Similar to cationic clays, anionic clays also have alternate lamellar structures, but with an opposite charge arrangement. Anionic clays are mainly synthetic. The preparation is relatively simple and inexpensive; they can be synthesized primarily with coprecipitation, anion exchange, and structure reconstruction methods. Hydrotalcite-like compounds (HTlcs), for example, have been investigated

extensively over the past decade, and they have been widely used as catalysts, flame retardants, molecular sieves, anion adsorbents, ion-exchangers, and medicine stabilizers.<sup>[20]</sup> The sheet-like structure containing cations can be derived from layered Mg(OH)<sub>2</sub> (brucite) structure. When divalent cations are partially substituted by trivalent ones, positive charges will be built-up within the octahedron sheets. For solid charge

neutrality, anions have to be intercalated into the interlayer space, as illustrated in Fig. 3. The HTlcs have a chemical formula of  $[M_{1-x}^{II}M_x^{III}(\text{OH})_2]^{x+}(\text{A}_{x/n}^{n-}) \cdot m\text{H}_2\text{O}$  (where M = metal, A = interlayer anions),<sup>[20]</sup> whose properties can be tuned with variations of cationic brucite-like sheets and anionic interlayer species. For example, organics- and polymer-containing HTlcs should be viewed as supramolecular assemblies or nanocomposites composed of organic parts (anionic) and inorganic molecular sheets (cationic).<sup>[21]</sup> It is important to realize that the intercalative ability in these alternately arranged layers is based on electrostatic interaction, and the inorganic parts are dissolvable in acidic environment while the organic parts are removable by ionic exchange or oxidation at elevated temperatures. Furthermore, layer charge density can be tuned with the content of  $M^{III}$  cations in the synthesis. The basal spacing (the distance between two brucite-like sheets) depends on the size of the intercalants. For instance, large-sized biomolecular anions (up to several nanometers), such as nucleoside monophosphates and deoxyribonucleic acid (DNA), have been intercalated into the interlayer space of  $\text{Mg}_{0.68}\text{Al}_{0.32}(\text{OH})_2(\text{NO}_3)_{0.32} \cdot 1.2\text{H}_2\text{O}$  (a pristine HTlc).<sup>[22]</sup> Because of their synthetic versatility in compositional tailoring, this class of organic-inorganic hybrids has been used as precursor compounds for the synthesis of functionalized metal-oxide nanomaterials and nanocomposites after the thermal removal or conversion of polymeric intercalants.<sup>[23]</sup> The chemical nature of the intercalated anions, such as oxidative or non-oxidative, had been investigated with respect to thermal reactions, in which nanostructured  $\text{Co}_3\text{O}_4$  spinel oxides were formed from  $\text{Co}^{II}\text{Co}^{III}$ -HTlc precursors.<sup>[24]</sup> Nanocrystalline  $\text{Co}_{3-x}\text{Al}_x\text{O}_4$  can also be incorporated into the  $\gamma\text{-Al}_2\text{O}_3$  matrix via the simultaneous formation of catalyst and support from the  $\text{Co}^{II}\text{Co}^{III}$ -HTlc and alumina xerogel.<sup>[25]</sup>

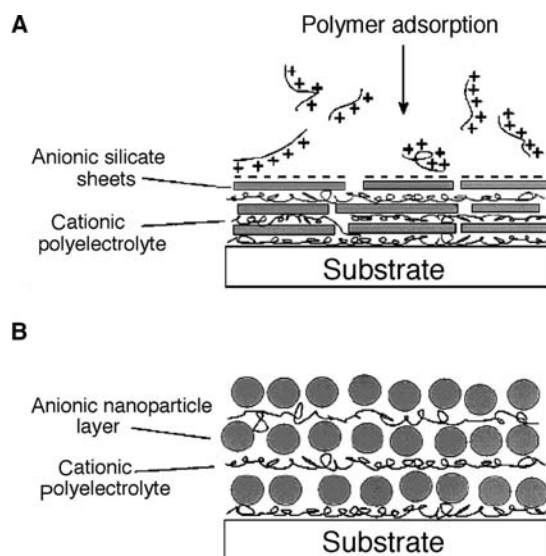

In addition to the above bulk materials preparations, organic-inorganic hybrid materials can also be prepared into thin films to meet new applications. The major synthetic methods employed in this area

**Fig. 3** The hydrotalcite-like anionic-clays have a layered structure similar to that of brucite  $[\text{Mg}(\text{OH})_2]$  but with some positive charges. To maintain the electrical neutrality for the solid, intercalation of anions (e.g., nitrate and carbonate or even DNA) into the interbrucite layers (i.e., interlayer space) occurs, which leads to a hydrotalcite-like structure.

are sol-gel-based techniques, intercalation reactions, layer-by-layer assembly (e.g., Langmuir-Blodgett technique and electrostatic self-assembly), and evaporation techniques, as exemplified in Fig. 4.<sup>[26]</sup> Although the primary objective of these film-fabrication developments is for organic-inorganic electronics, it is believed the hybrid structures prepared can be extended to catalytic applications, including chemical sensors, in the near future.

Very recently, single-crystal bulk organic-inorganic hybrids had been investigated for the fabrication of catalytic nanocomposites and large-scale organization of catalysts under high-temperature environments.<sup>[27,28]</sup> In particular, individual  $\text{MoS}_2$  (used in hydrodesulfurization) layers can be converted from direct sulfidation of single-molecular sheets of  $\text{MoO}_3$  supported with organic “pillars” in the interlamellar layers. As there has been a large variety of metal-oxide-organic hybrids available nowadays, this method provides a new means for the indirect synthesis of lamellar organic-inorganic catalytic hybrid materials consisting of building units of transition metal dichalcogenides.<sup>[27]</sup> To make the catalytic materials usable in high-temperature environments, large-scale organization of metal-oxide nanostructures in a controllable manner at elevated temperatures is highly desirable but particularly challenging, because of the difficulties in controlling the interconnectivity among individual crystallites due to random nucleation and grain growth upon heating. An organized condensation of single-molecular  $\text{MoO}_3$  sheets can be achieved with a controlled removal of the organic intercalants.<sup>[28]</sup> This

**Fig. 4** (A) Electrostatic assembly of anionic inorganic layers and cationic organic layers. (B) A similar assembly of (A) but with negatively charged layers formed from nanoparticles (e.g., CdSe or CdS). *Source:* From Ref.<sup>[26]</sup>.

controlled condensation takes place within the space provided by the pristine organic–inorganic hybrid single-crystals. In this sense, the role of precursor crystal can be viewed as a microscopic “green compact” analogous to the macroscopic one in ceramic processing.<sup>[28]</sup> These new types of catalyst organization may be useful for microreactor systems where fluid stream stability is crucial, because the stacking of nanostructured catalysts can be controlled to reduce flow resistance.

In addition to the above chemical conversion and organization of nanostructured catalytic materials, organic–inorganic hybrids have also been used in the preparation of freestanding nanostructured materials. For example, catalytically important materials such as tungsten oxide nanowires, tungsten disulfide nanotubes, and VO<sub>x</sub>-nanotubes had also been prepared from organic–inorganic hybrid precursors that were preorganized in the forms of lamellar mesostructures.<sup>[29–31]</sup> The final nanostructures are formed either with high-temperature processing or with hydrothermal treatment. These synthesized individual inorganic nanostructures will be the subject of the next section.

### Nanobuilding Blocks and Mesoscale Self-Organizations

The research in low-dimensional catalytic materials has blossomed in many new directions since Iijima’s discovery of carbon nanotubes in 1991.<sup>[32]</sup> For example, syntheses of low-dimensional catalytic nanostructures of MoS<sub>2</sub>, WS<sub>2</sub>, MoO<sub>3</sub>, TiO<sub>2</sub>, V<sub>2</sub>O<sub>5</sub>, ZrO<sub>2</sub>, Co<sub>3</sub>O<sub>4</sub>, ZnO, etc. have been carried out,<sup>[33–41]</sup> together with fabrications of nanostructured catalyst carriers such as MgO, Al<sub>2</sub>O<sub>3</sub>, and SiO<sub>2</sub>.<sup>[42–44]</sup> While many significant breakthroughs have been made for the metal oxides and chalcogenides, the search for new types of nanostructures and self-assemblies continues, aiming at complementary functionalities and performances. Technologically, many known catalytic materials are expected to gain better utilizations, because of their new properties and possible high catalytic activities in the nanometer regime (quantum confinement effect).<sup>[39]</sup> Discrete, freestanding nanostructures can be viewed as basic structural units or construction building blocks; they can be used individually or collectively (after a proper organization/assembly, will be addressed soon) in heterogeneous catalysis and chemical-sensing applications.

Many synthetic strategies have been developed for the fabrication of nanostructures. For example, metal oxide nanoparticles (zero-dimension, 0-D) can be prepared rather routinely via sol–gel methods<sup>[45]</sup> and direct precipitation.<sup>[46]</sup> A great variety of core-shell nanostructures (0-D) have also been prepared via

sol–gel and other coating methods (e.g., layer-by-layer deposition) with the assistance of removable inner-core supports.<sup>[47]</sup> On the other hand, one-dimensional (1-D) nanomaterials can be fabricated with the following techniques. 1) Utilizing intrinsic structural anisotropy: Inorganic materials with low structural symmetries can be prepared into 1-D morphology along certain crystallographic axes.<sup>[37,40]</sup> The unidirectional growths can be further manipulated with the assistance of inorganic salts or ionic/nonionic organic surfactants present in the solution synthesis.<sup>[48]</sup> 2) Template-directed growth: In addition to the soft templates (such as self-assembled molecular structures, e.g., micelles discussed in the previous sections), this method utilizes solid templates for growth depositions or chemical insertions. For example, non-porous single-crystalline NaCl substrate and porous supports such as zeolites, MCM-41, and anodic alumina membranes (with parallel 1-D channels) have been used in the synthesis of 1-D nanostructures,<sup>[49]</sup> including semiconductor metallic barcodes (Fig. 5).<sup>[50]</sup> The resultant nanostructures can be harvested by template-removal. In certain cases, however, the template can become a part of the resulting 1-D nanostructures. These latter cases had recently been demonstrated in the synthesis of 1-D bimorph composites of TiO<sub>2</sub>–SnO<sub>2</sub> and Co<sub>0.05</sub>Ti<sub>0.95</sub>O<sub>2</sub>–SnO<sub>2</sub>,<sup>[51]</sup> and in the preparation of Ag/MoO<sub>3</sub> catalytic nanostructures.<sup>[52]</sup> 3) Surfactant-assisted synthesis: Preferred electrostatic and chemical interactions between organic surfactants and certain crystallographic

**Fig. 5** Synthesis of barcoded 1-D materials with alumina membrane template where 1-D channels are parallel to each other. *Source:* From Ref.<sup>[50]</sup>.

surfaces will restrict the growth along certain directions, resulting in the kinetic control of the growth anisotropy. This method had been investigated extensively for metals (e.g., Au) and semiconductor nano-materials such as CdSe, ZnSe, CdS, and ZnS in recent years.<sup>[53,54]</sup> 4) Oriented attachment: This growth mechanism had recently been investigated for the synthesis of 1-D materials such as ZnO nanorods and  $\beta$ -Co(OH)<sub>2</sub> nanoplatelets, respectively, from smaller building blocks.<sup>[55,56]</sup>

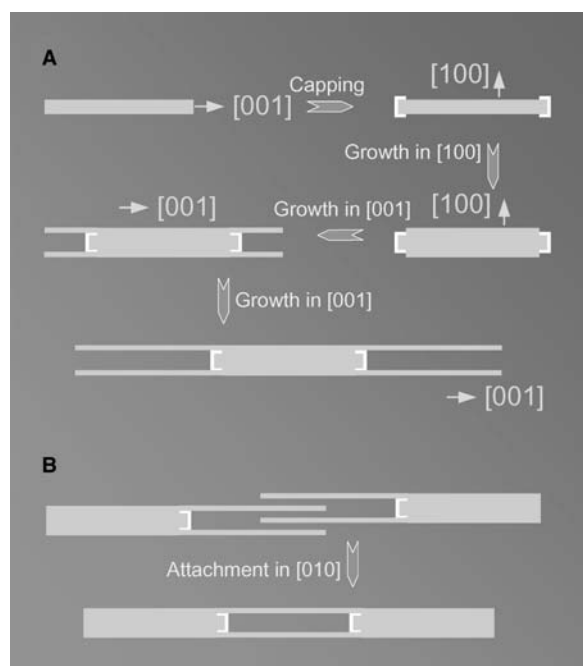

Individual nanostructure units can be used as model catalysts or chemical-sensing devices. For example, a gas sensor for NO<sub>2</sub> detection had been developed with a single nanoribbon of SnO<sub>2</sub>. In the illuminated state (UV light), photo-generated holes recombine with trapped electrons at the SnO<sub>2</sub> surface, desorbing NO<sub>2</sub> and increasing the sensing current.<sup>[57]</sup> The general advantages of nanodevices are small size, fast response, and high sensitivity. If required, 2-D- or even 3-D nanostructures can be further constructed from starting 0-D- or 1-D subunits via mesoscale self-assembly processes. There have been numerous investigations in this area using organic surfactants.<sup>[40,41]</sup> As illustrated in Fig. 6, direct crystallite coupling via oriented attachment process provides another possible means to serve this purpose.<sup>[58]</sup> More examples in this area can be found in the literatures.<sup>[55,59]</sup> Unlike the layered nanostructures (2-D), self-assembled 2-D

nanostructures must possess different properties, because of the presence of discrete low-dimensional subunits and organic capping molecules within the assemblies. The retention or removal of these organizing agents is an important issue in catalytic applications, as the presence of organic components will change the inorganic nature of catalysts (hybridization). Future detailed comparisons for different design strategies are urgently needed.

In addition to the ordered organic–inorganic assemblies, nanoarchitectures of multifunctional catalysts can be further achieved by introducing dispersible organic-capped inorganic nanostructures into 3-D gel matrixes, which will also create the necessary chemical functionality and porosity in addition to the better material utilization. In particular, structurally shaped (or faceted) nanocatalysts may provide predesigned active catalytic sites for the desired chemical reactions, although they may appear to be random in the composite matrixes.

### Interfacial Engineering and Self-Assembly

Our understanding of the catalyst carrier has now gone beyond its supporting role; various levels of participation of carriers in catalytic reactions have been known in atomic and molecular scales.<sup>[60]</sup> As mentioned earlier, the surface functionalities of catalytic materials (in either planar or spherical form) can be further modified with the guide of nanochemistry principles<sup>[61]</sup> and a wide range of surface-engineering processes available.<sup>[47]</sup> In addition to metal single-crystal surfaces that have been investigated extensively over the past three decades, the synergetic effects of catalyst–carrier systems have been investigated with model catalysts, which may be closer to the reality of a heterogeneous catalytic reaction environment. Taking advantage of the electron beam lithography technique, for example, metal nanoparticles have been arrayed on silicon surface at predesignated locations.<sup>[62]</sup> Pt and Ag nanoparticle arrays were prepared at different interparticle distances. By varying the particle size and distances between particles, the structural factors responsible for the selectivity and activity in diverse catalytic reactions had been investigated.<sup>[62]</sup> Other versions of model catalysts on oxidized silicon wafers have also been fabricated by spin-coating technique in recent years.<sup>[63]</sup> These wafer-supported catalytic metal and metal-oxide thin films have been tested under catalytic reaction conditions and investigated with state-of-the-art surface analytical techniques. Various catalyst systems have been studied over the past few years.<sup>[63]</sup> In view of its versatility, this evaluation approach is expected to be suitable for the characterization of various nanostructured

**Fig. 6** (A) Flowchart of synthesis of forklike  $\alpha$ -MoO<sub>3</sub> nanostructures via manipulating growth directions with TiO<sub>2</sub> capping. (B) Oriented attachment between two forklike nanostructures along the [010] direction (perpendicular to the paper). *Source:* From Ref.<sup>[58]</sup>.

catalytic materials that can be prepared into colloidal suspensions for spin-coating.

Apart from electron/ion beam lithography techniques, nanoelectrochemical patterning process and photolithography methods have also been widely used in the fabrication of substrate patterns for the deposition of nanostructured materials. These processes have been conducted in both vapor-phase (e.g., chemical vapor deposition) and liquid phase (e.g., solution growth), producing various patterned 2-D nanostructures on the supports. For example, the hierarchical self-assembly of gold nanoparticles onto an organic bilayer template pattern on silicon had been demonstrated.<sup>[64]</sup> Furthermore, ordered porous structures had been fabricated by self-assembly of zeolite nanocrystals on micropatterned silicate film surfaces.<sup>[65]</sup> Without demanding pretreatments, single-crystal surfaces have recently been proven to be suitable for nanoparticle self-aligned growth. In particular, a hexagonal superlattice of anatase TiO<sub>2</sub> nanospheres has been arranged on  $\alpha$ -MoO<sub>3</sub> (010) surface without any surfactants and surface patterns,<sup>[66]</sup> noting that both TiO<sub>2</sub> and  $\alpha$ -MoO<sub>3</sub> are important catalysts in this material combination. With well-developed surface science techniques, in-depth investigations of supported nanostructured catalysts can be further pursued. Elegant examples in this area have been reported in the literature, as shown in Figs. 7 and 8

**Fig. 7** Scanning tunneling microscopic images of TiO<sub>2</sub>(110)-(1 × 1): (A) clean surface before oxygen exposure, and (B) after oxygen exposure at 650 K. Scanning tunneling microscopic images of Au/TiO<sub>2</sub>(110)-(1 × 1): (C) before CO:O<sub>2</sub> exposure, and (D) after CO:O<sub>2</sub> exposure at 300 K. *Source:* From Ref.<sup>[3]</sup>.

**Fig. 8** A scanning tunneling microscopic image of a MoS<sub>2</sub> nanocluster exposed to atomic hydrogen at 600 K, which resulted in the formation of S vacancies (circled). Models below: side and top views of S vacancies. *Source:* From Ref.<sup>[67]</sup>.

for the investigations on CO oxidation and hydrodesulfurization.<sup>[3,67]</sup> On the (110) surface of TiO<sub>2</sub>, Au particles show high activity at 2–3 nm for CO oxidation. However, Au particles in the Au–TiO<sub>2</sub> composite aerogel retain high activity for the same reaction at a size of 6 nm, because of an increase in the interfacial contact area of the gold with multiple domains of TiO<sub>2</sub> in the aerogel matrix.<sup>[68]</sup> The catalytic bifunctionality of an active composite can thus be explored when the support and catalyst have comparable sizes (within a factor of 2).<sup>[68]</sup>

Similar to vertical arrays of carbon nanotubes, catalytic materials have also been prepared into 2-D arrays, but with an extruding direction perpendicular to the surface. Recently, ZnO nanorods and GaN nanotubes had been prepared with gold nanoparticle catalysts in the vapor phase and with a subsequent thermal treatment to remove inner templates (e.g., in the synthesis of GaN nanotubes, ZnO nanorods were used as templates);<sup>[69]</sup> the diameter of the prepared 1-D nanostructures is proportional to the size of metal catalysts in the synthesis. This method is now widely used in

**Fig. 9** Packing of ball-like anions  $\{[\text{Mo}_2\text{O}_4(\text{CH}_3\text{COO})]_{30} \{(\text{Mo})\text{Mo}_5\text{O}_{21}(\text{H}_2\text{O})_6\}_{12}\}^{42-}$  in the crystal lattice (space filling model viewed along  $[111]$  (top) and perpendicular to  $[111]$  (bottom)). *Source:* From Ref.<sup>[70]</sup>.

the synthesis of 1-D-nanostructures, including the control of periodic chemical component variation along a nanostructure.

### Superpolyhedral Clusters and Their Organizational Forms

Compared with the nanobuilding blocks discussed above, inorganic super fullerene and polyhedral clusters, which have been synthesized in recent years, are

**Fig. 10** Models of the  $[\text{Cd}_{16}\text{In}_{64}\text{S}_{134}]^{44-}$  anionic clusters: (A) a ball-and-stick model, (B) the same view as (A) shown as metal-centered tetrahedra, and (C) crystal packing of the clusters, viewed along the  $c$  axis (the unit cell is framed). The large sphere indicates the central cavity. *Source:* From Ref.<sup>[71]</sup>.

generally much smaller but with more distinct geometrical features. This class of materials is formed from even smaller metal–ligand polyhedra, such as tetrahedrons, octahedrons through edge-, corner-sharing, etc. On the other hand, these super inorganic “molecules” can be further packed into repeated arrangements, giving away larger crystallites. Fig. 9 shows a representative packing of this type of superclusters.<sup>[70]</sup> Instead of oxygen in zeolites, basic units of tetrahedrons can now be extended to sulfur, noting that the ionic radius of  $\text{S}^{2-}$  is much larger than that of  $\text{O}^{2-}$ . For example, metal sulfides can now be prepared into supertetrahedral clusters with a large cavity, as shown in Fig. 10 for  $[\text{Cd}_{16}\text{In}_{64}\text{S}_{134}]^{44-}$  (3.1 nm in edge length).<sup>[71]</sup> A great variety of this type of superpolyhedral clusters and molecules has been prepared nowadays and has been reviewed recently.<sup>[72]</sup> One common feature in these superpolyhedral clusters is their inner cavity. If treated as nanobuilding blocks in their further architectures, the superclusters with inner space will create even more complex structures in addition to their chemical complexity in nanoconfinement regime. Many of these solids show a semiconducting character.<sup>[72]</sup> Apart from the assembly shown in Fig. 9, there have existed a great number of organization schemes of inorganic clusters with organic counterparts.<sup>[45]</sup> These tailor-made organic–inorganic nanocomposites could be potential candidates for future heterogeneous catalysis applications.

### CONCLUSION

We have examined various design and synthesis strategies for the fabrication of nanostructured catalytic materials. Generally speaking, nanostructured “kits-and-parts” as well as their organization methodologies have been available to constitute a nanocatalyst toolbox, i.e., they are ready for direct usage or further assembly. To transform “catalytic materials” to real custom “catalysts”, however, a large research endeavor is needed, and this includes systematic investigations on multicomponent assemblies and resultant chemico-physical properties, including hierarchical pore structures. It is noted that the catalytic

performance of these materials remains largely untested, despite the significant progress in materials research. While traditional methods will still dominate the industrial-scale catalyst processing at the present time, we are beginning to see nanostructured catalytic materials in practical applications of “chemical plant/laboratory-on-a-chip” and chemical-sensing technology where the amount of catalysts required is small, and supported type catalysts may not be needed. For larger-scale industrial chemical processes, for instance, it is believed that the traditional “metal ions impregnation” can be replaced with “nanostructures impregnation,” as the nanobuilding blocks can be prepared into colloidal suspensions for metal loading on general catalyst supports. Furthermore, nanoarchitectures of these building units can be achieved with the well-developed sol–gel technology. Perhaps, simultaneous formation of nanobuilding blocks and supporting oxide matrix should be considered as a next level of architectures, where the catalyst and support could be better integrated in the new-generation catalysts.

# Nanostructured Composites: Carbon-Derived Fibers

Peter M.A. Sherwood

*Department of Chemistry, Kansas State University,  
Manhattan, Kansas, U.S.A.*

## INTRODUCTION

This entry discusses the importance of nanostructure and especially interfacial chemical interactions in the formation of composites where an appropriate matrix material is strengthened by a carbon fiber. Such composites have mechanical and other properties that are especially dependent upon the surface chemistry of the fibers; in other words, the nanostructure of the surface region has a dramatic impact on these properties. The focus of the entry will be upon the types of fiber currently used in composite production, with an emphasis upon the surface chemistry of carbon fibers determined by X-ray photoelectron spectroscopy (XPS) in the core and valence band region.

## CARBON FIBERS

Fibers find a number of important practical applications. Fibers themselves may be woven into a structure that can be one-, two-, or three-dimensional. The surface chemistry of the fibers is important when the fibers are used to generate a fabric, which may require treatment such as dyeing. This entry will focus on carbon fibers. Carbon fibers are light and strong fibers, which consist of largely graphitic character. The microstructure of the fibers can vary considerably depending upon their production, although on a nanoscale dimension the untreated fibers consist largely of graphite. The principal use for these fibers is to employ them to construct a composite which involves a matrix which is often an epoxy resin or plastic.

The remarkable feature of composites composed of a fiber and a matrix is that the surface chemistry of the fiber has a dramatic impact on the mechanical and other properties of the composite. For example, in carbon fiber composites with an epoxy resin matrix the load that can be sustained without fracture for the same fiber and matrix can be increased by a factor of three by changing the surface chemistry of the outer 5 to 10 Å of the carbon fiber surface.

Carbon is known in three principal allotropic forms, graphite, diamond, and fullerenes. Graphite materials have extensive applications associated with their high

thermal and electrical conductivity and their negligible thermal expansion. In addition, they are one of the lightest refractory materials known and possess bio-compatible characteristics.

Perfect graphite has continuous planar hexagonal sheets of carbon atoms with six-member carbon rings with each sheet separated by 3.354 Å from the adjoining sheets. Many less-ordered forms of carbon are known such as pyrolytic carbon where the hexagonal sheets have only short-range order, with intersheet separations that differ from those of perfect graphite.

Carbon fibers were first made in the form of carbon filaments by heating cellulose fibers, an approach used by Thomas Edison.<sup>[1]</sup> Carbon fibers of the type of such value today are high modulus fibers. These fibers were developed independently by Bacon,<sup>[2,3]</sup> Shindo,<sup>[4]</sup> and Watt,<sup>[5]</sup> who all used a process of continual stretching of the precursor material as it was carbonized during heat treatment.

Commercial carbon fibers are derived from two principal sources. The first source is based upon textile fibers, especially polyacrylonitrile. The second source is based upon mesophase pitch. In both cases an initial fiber is heated and stretched leading to decomposition to form carbon in a form which may be more or less graphitic-like. Residual molecules of the precursor may be left; for example, the fiber may contain nitrogen if the precursor was polyacrylonitrile. Carbon fiber manufacturers can vary the stretching and heating conditions to yield a fiber with the desired properties (such as the fiber modulus). A third source of carbon fiber has been less well used and is based upon fibers produced when hydrocarbon gas mixtures pass over a catalyst at high temperatures. These fibers have potential, but there are production difficulties associated with the formation of continuous fiber lengths (referred to as a “tow”) and reproducible fiber diameters. Fibers formed from the two principal sources are generally sold with particular “tow” sizes (such as 3000 fibers and 12,000 fibers) and very substantial lengths.

It has long been recognized that carbon fibers must be surface treated in order that they can be used for composite production. Early attempts to use untreated fibers led to composites with very disappointing

composite properties. Various, commercially confidential, methods were developed for surface treating the fibers. These methods are nearly always made an integral part of the carbon fiber production process, the treatment plant being included in the carbon fiber production line. Most manufacturers sell fibers with surface treatment “tuned” to the matrix application. Thus a particular type of treatment is recommended for epoxy matrices, and a different treatment for phenolic matrices. The particular treatment methods are not reported. In addition to surface treatment, fibers are generally subjected to a thin coating of a polymeric material known as a “size.” This practice is conducted so that the fiber “tows” are easier to handle. In fact, the extent to which fiber surface treatment and sizing impacts the final composite properties is not well understood. The so-called “tuning” of surface treatment to a particular matrix is frequently not based upon a complete understanding of the factors involved. It is the purpose of this entry to address this matter in more detail.

A very full discussion of the synthesis and other important details of carbon fibers can be found elsewhere (e.g., Ref.<sup>[6]</sup>).

### CARBON FIBER SURFACE CHEMISTRY AND TOPOGRAPHY

Carbon fibers can be produced with a range of surface chemistry and topography. Most commercial carbon fibers, with the exception of those specially prepared for high absorption characteristics, have a relatively low surface area. This is deliberate and a feature of the production process, which may lead to grooves on the fibers resulting from the original production process for the fibers, which involves the extrusion of a polymer (such as polyacrylonitrile) or a pitch to produce the fiber.

When a fiber is placed in a matrix material such as a polymer or resin, the initial first step is the wetting of the fiber by the matrix material. This wetting is assisted if there is some chemical or physical interaction between the fiber and the matrix material. The first key step in the process is thus the wetting of the fiber that allows the fiber to come into contact with the matrix, and then the possible chemical interaction between the fiber and the matrix. Interaction between the fiber and the matrix can involve both chemical and physical interaction.

Carbon fibers are surface treated by processes that nearly always lead to the oxidation of the carbon fiber surface. These processes may involve gas-phase oxidants such as ozone, liquid oxidants such as sodium hypochlorite, and electrochemical oxidation in various electrolytes. Plasma oxidation may also be conducted,

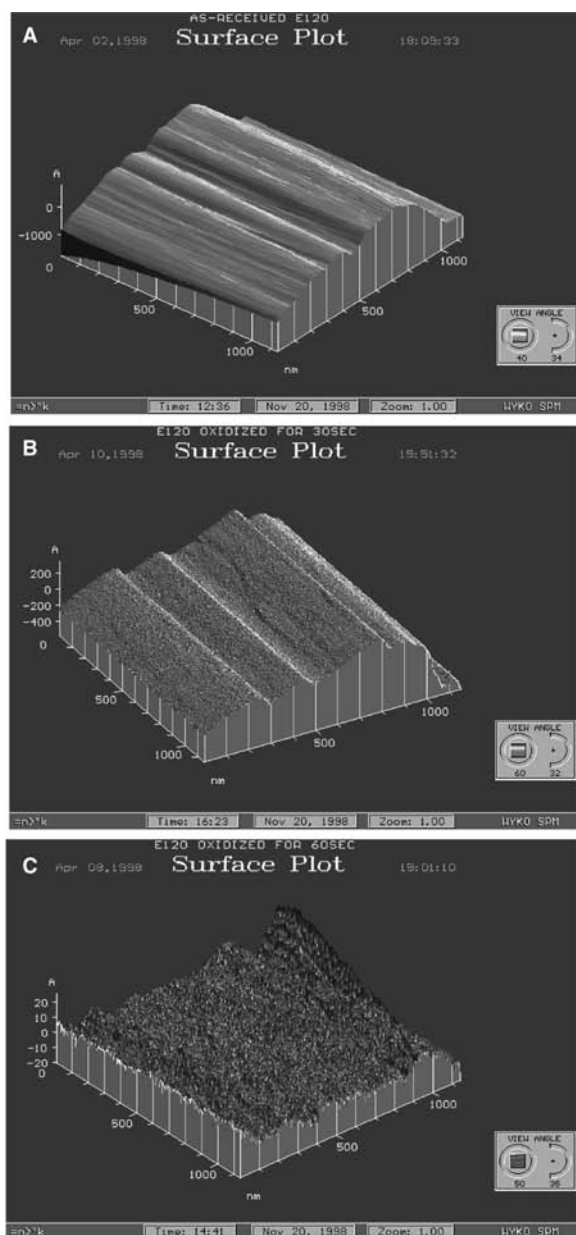

although in practice it presents practical problems as a result of the need to pass the fibers without damage into a very low pressure region with the plasma gas. These surface treatments result in two major changes on the carbon fiber surfaces, namely, a change in the fiber surface chemistry and a change in the fiber surface topography. Unfortunately, it is not possible to separate these two factors in a simple way. This is because the surface treatment methods change both the surface chemistry and topography at the same time. Fig. 1 illustrates this situation for a high-modulus carbon fiber based upon pitch.<sup>[7]</sup> The atomic force microscope (AFM) data for this fiber change substantially as one compares the AFM data (A) for the carbon fiber (which was neither surface treated nor sized by the manufacturer) before treatment with the fiber after treatment. Before treatment the fiber shows a smooth surface with striations, which are associated with the production of the mesophase pitch fibers, used in the production process. When the fiber is subjected to surface treatment resulting from the galvanostatic electrochemical oxidation of the fiber in 1 M nitric acid at 0.5 A for 10 sec, the surface topography clearly changes. Some pitting of the surface can be observed, but the original surface striations from the production process are clearly visible. When the galvanostatic oxidation is conducted for 1 min rather than 10 sec the surface topography changes substantially, with all the original surface striations being lost.

The changes in surface topography produced by the surface treatment are quite clear, and in fact it is clear from the AFM image that the topographical features show differences on a nanoscale dimension.

It is interesting to examine whether there are any changes that arise in the surface chemistry, and not surprisingly one finds that the surface is oxidized by the electrochemical treatment. There are many ways to examine the changes that arise in surface chemistry (for a review, see, for example, Refs.<sup>[8,9]</sup>). One especially powerful method is the use of XPS. This entry will focus on this technique for the following reasons. The technique is normally non-destructive, the information comes from the outer 10–100 Å of the surface, is atomic (i.e., the atomic numbers of the elements in the surface region can be identified), and provides chemical details. It will be shown below that the topographical changes seen in Fig. 1 are also associated with chemical changes, and these chemical changes can be identified by XPS.

### X-RAY PHOTOELECTRON SPECTROSCOPY

X-ray photoelectron spectroscopy [which is sometimes referred to as electron spectroscopy for chemical analysis (ESCA)] is a mature surface analytical probe that is

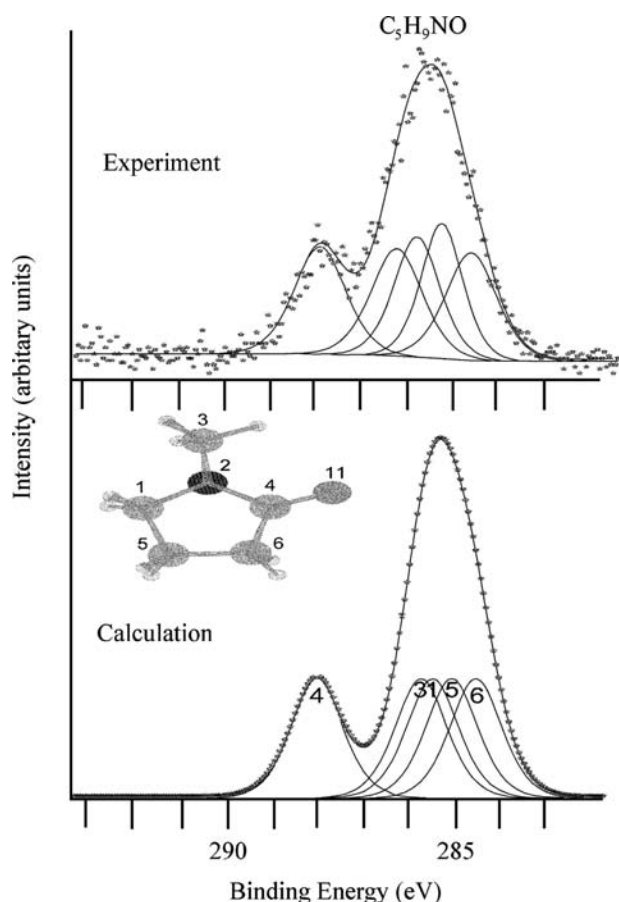

**Fig. 1** Atomic force microscope images of (A) a high-modulus pitch-based carbon fiber that was neither surface treated nor sized, (B) the same carbon fibers after electrochemical oxidation in 1 M nitric acid at 0.5 A for 10 sec, and (C) same as (B) but oxidized for 1 min.

one of a number of ultra-high vacuum surface analysis techniques. The experiment involves placing the sample of interest in an ultra-high vacuum ( $10^{-9}$  to  $10^{-10}$  Torr) and then exposing the surface to soft X-rays. This leads to the emission of photoelectrons from both the core and valence band region. The X-ray light used is normally a soft X-ray, typically Mg  $K\alpha$  (1253.6 eV) or Al  $K\alpha$  (1486.6 eV), the latter source having the advantage that it can be obtained in monochromatic form using a range of commercial X-ray

monochromators. As the energy of the photon is known and the energy of the photoelectron measured, the binding energy that holds the electron into the material is simply obtained by the difference in the photon and photoelectron energy with suitable corrections for sample work function and any charging effects. The core region readily provides information about the type of atom present because core electrons normally come at very distinct binding energies, and an examination of an overall spectrum (i.e., a spectrum collected over a wide energy range, typically 1000 or more electron volts) leads to the easy identification of the elements present. Closer examination of the core region obtained by obtaining photoelectron data over a narrow energy range (typically around 15 eV) allows energy shifts that are characteristic of chemical differences to be identified. It took about 60 years from the first photoelectron spectroscopy experiments before it was realized that core electrons, which take no part in chemical bonding, do in fact give rise to a chemical shift. The reason for this shift is that while the core electrons are strongly attracted to the positively charged atomic nucleus, they are also repelled by the outer valence electrons (the electrons that take part in chemical bonding), leading to a small but readily detectable chemical shift. When the author first started in this field in 1972 it was hoped that chemical shifts might be quite substantial, allowing subtle chemical differences to be determined. It became clear over the past 30 years that these shifts, while very useful, are sometimes small and it is not uncommon for compounds with different chemistry to exhibit similar chemical shifts as a result of a “canceling out” of the principal factors that determine the chemical shift. In fact, the main factors are the charge on the atom from which the photoelectron is ejected, the charge on the surrounding atoms, and the difference in extra atomic relaxation energy between different compounds containing the atom of interest. Atomic charge is a useful but very subjective quantity, because while the nuclear charge (the number of protons in the nucleus) is known exactly, the electronic charge is not clearly defined when it comes to the valence electrons because these electrons are shared between different atoms involved in chemical bonding. Nevertheless, simple models based upon atomic charge have proved very useful for the prediction of core chemical shifts in XPS (see, for example, Ref.<sup>[10]</sup>).

Fig. 2 illustrates the type of information that can be obtained for a simple carbon compound, and how a simple calculation can explain the spectrum. The experimental data are for the compound *N*-methyl-2-pyrrolidinone (NMP), frozen as a solid from the gas phase by forming the solid on a liquid-nitrogen-cooled plate.<sup>[11]</sup> Two peaks can readily be seen in the C1s region, the peak at higher binding

**Fig. 2** X-ray photoelectron spectrum of frozen NMP in the C1s region showing the experimental and calculated spectrum. The calculated spectrum shows the component peak positions obtained from a molecular orbital cluster calculation, with the peak areas obtained by adjusting the number of electrons associated with each atomic orbital type by the orbital's photoelectron cross section.

energy being due to the carbon atom (No. 4) associated with the C=O (where No. 11 is the oxygen atom) group in the molecule. The spectrum can be understood by examination of the calculated spectrum obtained using the relaxation potential model, which suggests that the four remaining carbon atoms form the low binding energy peak around 285 eV. In fact, the observed shift of around 3–3.5 eV from the C–H carbons is typical for the carbon atom of the >C=O group in a wide range of carbon compounds. Fig. 2 indicates that it is expected that the shift between some inequivalent atoms will be small (such as between carbon atoms 1, 3, 5, and 6). The experimental data have been fitted to a number of component peaks. The curve fitting of XPS data is an important approach to the analysis of core XPS data, and the method has proved a valuable method for extracting chemical information in a wide range of systems. Of course, any curve fitting

process is approximate, and there is never a unique answer. The best approach is to use a combination of well-developed fitting procedures, where the understanding of the peak shape and position is good, and combine this approach with a situation where the chemical environment changes and the fitted spectra have to be conducted in a consistent manner.

It is useful at this stage to return to the carbon fiber sample discussed in the previous section. The X-ray photoelectron spectrum observed in this case shows the significant *chemical* changes that accompany the *topographical* changes discussed above. Fig. 3 shows the core and valence band region observed<sup>[7]</sup> for the three samples indicated by (A), (B), and (C) in Fig. 1.

The overall XPS spectrum shows that the surface is practically entirely carbon, which is expected for an untreated and unsized fiber. The detailed O1s region can be seen to be of very low intensity. The detailed C1s region shows some very small amounts of surface functionality that can be seen from the curve fitted features at high binding energy of the principal C1s graphitic peak around 285 eV. In fact, the width and fine details of this peak can be associated with not only residual surface functionality, but also the degree of graphitic character of the carbon fiber.<sup>[12,13]</sup> The 10-sec electrochemical treatment gives the spectra shown in (B). Now a dramatic increase can be seen in the amount of oxygen with respect to carbon. The detailed C1s region now shows an additional peak shifted by about 2 eV from the graphitic peak at

**Fig. 3** X-ray photoelectron spectra of the fibers described in Fig. 1. The overall region identifies the O1s and C1s features which are expanded and curve fitted in the separate C1s and O1s regions.

around 285 eV. In addition, other features can be fitted to the C1s region. The O1s region shows a single intense peak. The 60-sec treatment shown in (C) shows a significant increase in the amount of oxygen, with the detailed C1s region showing the peak at 287 eV now showing the greatest intensity.

These results can be understood in terms of the oxidation of the carbon fiber at the edge sites to form a C/O functionality that lies between a  $>C=O$  and a  $>C-OH$  functionality. This grouping, which will be referred to as the “bridged structure,” can be represented as shown in Fig. 4.

The C–O groups can be seen to have the intermediate functionality described above. The “main peak” is represented by the carbon atoms attached to the oxygen atoms, and this is the peak that corresponds to the feature at 287 eV. The  $\beta$ -carbon peak arises at about 0.7 eV to higher binding energy of the principal graphitic feature around 284.6 eV. It is interesting to note that the principal form of oxidized carbon is the bridged structure of Fig. 4. A number of authors suggest that oxidized carbon forms a stable carboxylic acid surface functionality, but the author finds that while this type of functionality is formed in certain cases it never is very intense, and this type of functionality frequently decomposes with the loss of carbon dioxide. The author has conducted extensive studies of the surface chemistry of these systems, and in nearly all cases the types of functionality described above are found.<sup>[8]</sup>

Core XPS is a very valuable approach to the study of the chemistry of carbon fiber surface, but the approach is not always able to distinguish between different surface functionalities. For example, it is not possible to distinguish between  $>C-OH$  and  $>C-O-C<$  functionality. As noted above the “chemical shifts” obtained with XPS are dependent upon electrostatic effects. The valence band region contains electrons whose energy is determined by the mixing of atomic orbitals to give molecular orbitals that are involved in the chemical bonding of the materials under study. This region gives “shifts” whose position

depends upon the chemical bonding and thus depends upon factors different from those that give rise to the core shifts. The author has found that this region complements the core region and can often distinguish between subtle chemical differences. For example, it is possible to distinguish between  $>C-OH$  and  $>C-O-C<$  functionality. In oxidized carbon systems the C2s and O2s atomic orbitals strongly mix to give molecular orbitals when C/O functionality is present, with shifts that are the reverse to those found in the core region. For example  $>C-OH$  functionality occurs at higher binding energy to  $>C=O$  functionality in the core O1s region, but the reverse is true in the principally O2s valence band region around 25 eV finding energy. Using model calculations it is possible to predict the changes in the valence band region that would arise when different surface functionalities are present. Fig. 5 shows the predicted valence band XPS spectra for a series of oxidized carbon species that are represented by a  $D_{6h}$ -symmetry-substituted coronene structure with different functionalities with the molecular orbitals calculated by multiple scattered wave  $X\alpha$  calculations.<sup>[14,15]</sup> The calculations predict a different separation between the principally O2s region around 25 eV and the principally C2s region around 18 eV. Note how this separation is predicted to be significantly larger for the  $-C-O-C-$  functionality than for the  $-C-OH$  functionality. This has allowed the author to distinguish between these two groups experimentally.<sup>[16]</sup> It should also be noted that the calculations predict that the  $-COOH$  carboxylic acid functionality should give rise to two separated peaks in the valence band region.

### The Effect of Size and Initial Surface Treatment

Most carbon fibers used in practical applications have a surface that is sized and initially surface treated by the manufacturer. The presence of this initial surface treatment and size can have a significant impact on the interaction of the fiber with a matrix. To illustrate

Fig. 4 Representation of the hydrogen-bridged oxide structure (HBS) unit showing the location of the “ $\beta$ ” and “main” carbon atoms.

**Fig. 5** Calculated X-ray photoelectron valence band spectra of model compounds used to represent typical oxidized carbon fiber surfaces. (A) carboxyl, (B) epoxide, (C) carbonyl, (D) bridged, and (E) hydroxide functional groups.

this point consider taking a commercially surface-treated fiber and the same fiber with the commercial surface treatment removed. Let us now apply an oxidative surface treatment to both fibers, which involves potentiostatic treatment in 1 M nitric acid for 20 min.<sup>[17]</sup> The C1s XPS data for both experiments are shown in Fig. 6, where “untreated” refers to the commercially surface-treated fiber with the surface treatment removed.

The fiber with no surface treatment can be seen to exhibit steadily increasing C/O functionality with the “bridged structure” of Fig. 4 appearing as a separate peak at higher binding energy (286.7 eV) than the C1s graphitic peak at 284.6 eV. Note how the corresponding “beta” peak of Fig. 4 is shown with half the intensity as the “bridged structure” at 285.3 eV.

**Fig. 6** X-ray photoelectron spectra of the C1s region of an IM7 commercially surface-treated carbon fiber before and after electrochemical oxidation under potentiostatic conditions in 1 M nitric acid for 20 min. The voltages shown are with respect to the saturated calomel electrode. The “untreated” sample is the IM7 commercially surface-treated sample with the surface treatment removed by heating. Source: From Ref.<sup>[17]</sup>.

At 1.5 and 2.0 V, additional features at 288.1 eV can be seen due to  $>C=O$  surface functionality and 288.8 eV due to  $-CO_2H$  functionality. Note how the curve fitting includes the non-linear background in the fit, and note also how the fit has to be consistent over the whole range of spectra, an illustration of the curve fitting approach discussed above.

In contrast, the spectra for the commercially treated sample show marked differences on electrochemical oxidation from the untreated fiber. The differences are particularly striking at 1.5 and 2.0 V; in fact, the amount of oxidation at 2.0 V seems to be less than that at 3.0 V.

The principal lesson that one can learn from these results is the importance of a well-defined and untreated surface as a precursor for chemical interaction.

The presence of size on a carbon fiber surface might seem to be a simple matter to remove before the fiber was used to form a composite. Solvent extraction

would seem the appropriate approach, but in fact while the size is generally applied in a solvent solution, the removal of the size by solvent is not straightforward. In fact, the surface chemistry is dominated by the size, and solvent extraction does not remove all the size, with significant interaction occurring between the size and the underlying surface treatment. The higher the level of surface treatment the more difficult it is to remove the size.<sup>[7,18]</sup>

## MONITORING THE BURIED FIBER-MATRIX INTERFACE

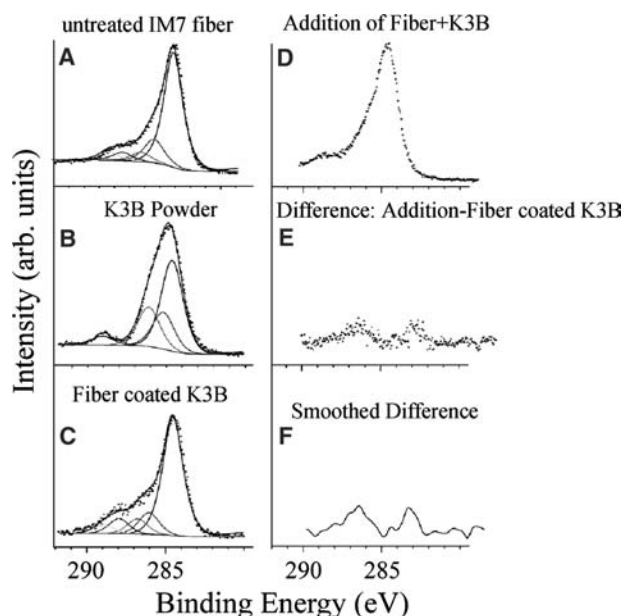

The purpose of surface treatment of carbon fibers is to increase the wetting of the fiber by the matrix and to allow chemical and physical interaction with the matrix material. The interfacial chemistry that occurs between the fiber and the matrix, which has seen to be based on a nanoscale topography on the fiber surface, will be very important in final composite performance.

The author has approached the challenge of examination of this buried interface by developing a technique where photoelectron spectroscopy can be used to probe this interface by placing a very thin layer of the matrix onto the fiber. The matrix layer is so thin that the interfacial region can be probed by XPS. The outer surface region can also be examined and ultraviolet photoelectron spectroscopy (UPS) can be used for this purpose. Fig. 7 illustrates this approach by showing the valence band spectra for a thin film of polyvinyl alcohol placed on an oxide-free orthophosphate coating on metallic aluminum.<sup>[19]</sup> The coating is so thin that the underlying aluminum can be seen, the Al2p region showing two features one because of metallic aluminum and the other because of aluminum orthophosphate, suggesting a film thickness for the phosphate film of about 20 Å. Fig. 7(A) shows the valence band region using X-ray light and UV light. The spectrum in (A) is identical to that in (B), which is for a sample of polyvinyl alcohol when He(II) UV light is used. This confirms that the outer film region is polyvinyl alcohol because the photoelectrons generated by UV light have a much smaller escape depth than those generated by X-ray light. The valence band region in Fig. 7(A) for X-ray light is quite different from that of polyvinyl alcohol shown in Fig. 7(B) and that of aluminum orthophosphate (Fig. 7(A)).<sup>[1]</sup> If the valence band spectrum of polyvinyl alcohol is added to that of the aluminum orthophosphate film, the spectra do not superimpose and this can be demonstrated by using difference spectra.<sup>[19]</sup> Also, an additional peak is seen in the C1s region for the PVA-coated phosphate film.

**Fig. 7** Valence band photoelectron spectra using X-ray and UV radiation. (A) shows the valence band region for a sample of aluminum with an oxide-free phosphate film, coated with a very thin film of polyvinyl alcohol (PVA). In the X-ray photoelectron spectra for (A), “1” is the valence band spectrum for the orthophosphate film on aluminum without any overlying PVA, and “2” the spectrum with the PVA film. (B) shows the valence band region for polyvinyl alcohol. (C) shows the calculated valence band region for polyvinyl alcohol generated from a band structure calculation. *Source:* From Ref.<sup>[19]</sup>.

In a carbon fiber system this buried interface can be probed using this approach. For example, the polyimide matrix material K3B is valuable as a matrix that can withstand higher temperatures than a typical epoxy resin matrix. Unfortunately, it is not easy to obtain a chemical interaction between the carbon fibers and this matrix. It is possible to see chemical interaction when a particular surface oxidation is conducted on the carbon fibers. Fig. 8 shows the C1s core region for an untreated IM7 carbon fiber, for K3B, and for a thin film of K3B on this fiber. The difference spectrum (Fig. 8(E) and 8(F)) between the spectrum with the thin K3B film (thin enough to probe the interface region) and the sum of the carbon fiber and K3B spectrum shows no significant difference. In other words, there has been no chemical interaction at the interface. When the untreated IM7 carbon fibers are electrochemically oxidized under galvanostatic conditions at 0.5 A in 1 M nitric acid for 40 sec, and the process repeated, then the corresponding difference spectrum does indeed show a difference, indicating a chemical

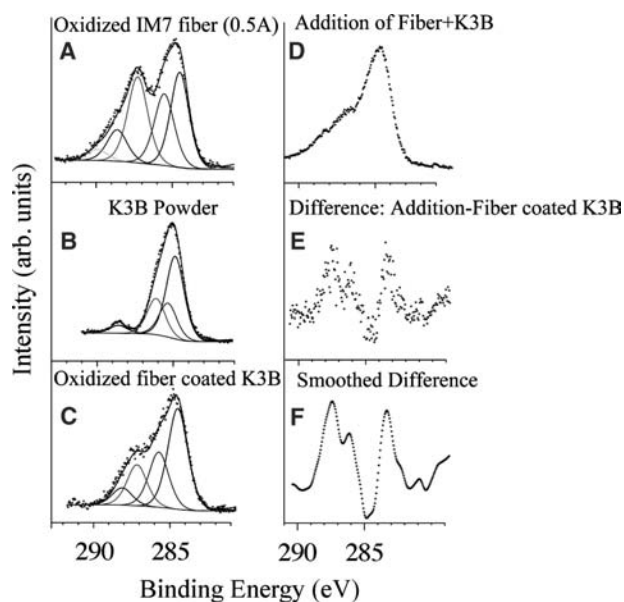

**Fig. 8** X-ray photoelectron spectra of the C1s region for (A) as-received IM7 fibers; (B) K3B powder; (C) fibers in part (A) dip-coated with K3B solution; (D) addition of parts (A) and (B); (E) difference of parts (D) and (C); (F) smoothed version of part (E). The intensity scales for parts (D)–(F) are the same.

reaction between the carbon fiber surface and the K3B (Fig. 9).

When a carbon fiber surface does not chemically react with the matrix material, then a “coupling agent”—another molecule that reacts with both the carbon fiber surface and the matrix—can be used. X-ray photoelectron spectroscopy can be used to monitor the effectiveness of this approach. For example, one can use a titanium alkoxide coupling agent (tetrakis(2-ethylhexyl) titanate, TOT) to couple a surface-treated carbon fiber to a phenolic resin. Fig. 10 shows the way in which the coupling agent acts.

The valence band XPS spectrum can be used to show that the interface between the coupling agent and the fiber and matrix is as suggested. Fig. 11 shows the difference spectrum for the difference between the XPS spectrum of a thin film of a phenolic resin on an E-120 pitch-based carbon fiber electrochemically oxidized in 1 M orthophosphoric acid, and the same situation but with TOT added to the resin. The surface treatment in this case leads to the formation of  $-C-OH$  functionality on the fiber surface. Hence the reaction scheme in Fig. 10. The smoothed difference spectrum in Fig. 11 was obtained using the background-subtracted spectra. It can be seen that the difference spectrum gives good agreement with the spectrum calculated for the  $Ti(OCH_3)_4$  molecule based upon a multiple scattered wave  $X\alpha$  calculation.<sup>[20]</sup> The five features identified in the outer valence band region are in

**Fig. 9** X-ray photoelectron spectra of the C1s region for (A) IM7 fibers galvanostatically oxidized in 1 M nitric acid at 0.5 A for 40 sec; (B) K3B powder; (C) fibers in part (A) dip-coated with K3B solution; (D) addition of parts (A) and (B); (E) difference of parts (D) and (C); (F) smoothed version of part (E). The intensity scales for parts (D)–(F) are the same. *Source:* From Ref.<sup>[11]</sup>.

good agreement with the difference spectrum. The difference spectrum also gives evidence of the presence of oxidized titanium ( $TiO_2$ ). This can be seen when one considers that the calculated spectrum for  $TiO_2$  (based upon a multiple scattered wave  $X\alpha$  calculation on the  $TiO_6^{8-}$  cluster) suggests that the peak identified as “2” in this calculation would fill the valley between peaks 1 and 2 and 3–5 in the calculated spectrum of  $Ti(OCH_3)_4$ . Thus the presence of  $TiO_2$  is consistent with the features observed in the valence band spectrum.

## NANOTUBES AND COMPOSITES

Carbon nanotubes have considerable potential for composite fabrication. In recent years there have been an enormous number of important developments in this area. There are many recent reviews and books on this area (e.g., Ref.<sup>[21]</sup>). The interest in nanotubes as the “ultimate carbon fiber” arises from the very desirable mechanical properties with the potential for a very high Young’s modulus which can be close to that of the in-plane value for perfect graphite, some 10 to 100 times greater than currently available carbon fibers. Single-wall nanotubes have good flexibility unlike carbon fibers, and thus composites with such nanotubes would be unlikely to fracture when exposed

**Fig. 10** Reaction scheme between tetrakis(2-ethylhexyl) titanate (TOT) and an oxidized carbon fiber surface.

to compressive stress along the axis of the fiber, in contrast to carbon fibers reinforced composites.

There has been little success so far in replacing carbon fibers with carbon nanotubes in composite fabrication. The principal problem is the difficulty of getting good interaction between the carbon nanotube and the matrix. This entry has focused strongly on this issue, because it is so important in the development of practical composites. We have seen how this interaction can be studied and achieved in this entry. Further discussion of this issue can be found elsewhere (e.g., Ref.<sup>[21]</sup>). It is likely that the interfacial interaction issues, and other issues associated with the differences between carbon fibers and nanotubes such as the tendency of the latter to aggregate, will limit the use of nanotubes in composite applications.

**Fig. 11** X-ray photoelectron spectra in the valence band region for E-120 pitch-based carbon fibers. The experimental valence band spectra of the fiber which was surface treated by galvanostatic oxidation in 1 M orthophosphoric acid at 0.5 A for 30 sec is shown (indicated as “fiber”), together with the fiber with a very thin coating of a phenol-formaldehyde resin (indicated as “fiber + resin”), and a fiber where the resin coating contains tetrakis(2-ethylhexyl) titanate (TOT) (indicated as “fiber + resin + TOT”). The difference spectra between “fiber + resin + TOT” and “fiber + resin” are shown where a non-linear background was removed from both the spectra and the difference spectra were smoothed. The difference spectra are compared with the calculated valence band spectrum for  $\text{Ti(OCH}_3)_4$  and  $\text{TiO}_2$  calculated by multiple scattered wave  $X\alpha$  calculations.

## CONCLUSION

The surface chemistry associated with the buried interface between a carbon fiber (or carbon nanotube) and the matrix plays a very important role in determining the practical performance of the chosen composite. The surface treatment methods available change both the nanostructure and the chemistry at the interface. Surface science methods, especially XPS, have a very valuable role to play in probing and understanding this interaction.

## INTRODUCTION

Metastable materials with microstructural features, i.e., particles or grain sizes, layer thicknesses, or domain sizes, in the nanometer range (typically less than 100 nm at least in one dimension) have unique features, such as an appreciable fraction of their atoms in defect environments at the grain–interface boundaries, leading to a significant impact on their mechanical, physical, and chemical properties, which significantly differ from those of their conventional coarse-grained counterparts.<sup>[1–5]</sup> Normally, nanostructured materials (NsM) with an average grain size of 5 nm have about 50% of their atoms within the first two nearest-neighbor planes of the grain boundaries, in which distinct atomic displacements from the normal lattice sites occur.<sup>[2,5]</sup> Obviously, this has a strong impact on the properties of the material.

In 1959, Feynman at Caltech, U.S.A., has proposed<sup>[4]</sup> the idea of obtaining an enormously greater range of possible properties of condensed matter by control over the structure in the range of extremely small dimensions (nanometer scale). Later (1982–1985), Gleiter<sup>[1]</sup> was the first to realize a method for the production of such materials with nanometer-sized grains (crystallites). These materials have been categorized by Gleiter<sup>[5,6]</sup> as follows: 1) the dimensions/size of the materials/devices itself are on a nanometer scale,<sup>[6,7]</sup> 2) bulk materials/devices in which a thin surface region has a nanometer-sized microstructure,<sup>[6,8]</sup> or 3) building blocks (grains) of a bulk solid having a nanometer length scale.<sup>[5,6,9]</sup> The technological applications of the above mentioned materials are 1) catalysts and semiconductor devices and 2) surfaces with enhanced corrosion resistance, hardness, wear resistance or protective coatings, and quantum dots. The third category of materials with homogeneous nanometer-sized building blocks is often called “NsM” or nanophase materials, nanocrystalline materials, or supermolecular solids.<sup>[5]</sup> These metastable materials can be synthesized in both metallic<sup>[3,6,10]</sup> and non-metallic/polymeric<sup>[11]</sup> systems. The attempts

on controlled processing, microstructural, mechanical, and specific property characterization to find the applicability of such NsM of either single or multiple phases with layered, rod-shaped, or equiaxed crystallites with/without tailored grain boundary composition or homogeneous dispersion in a second phase matrix are a part of the emerging and rapidly growing field of nanotechnology.<sup>[5]</sup>

## BACKGROUND

It is well known that the mechanical behavior of polycrystalline metals and alloys depends on the grain size,  $d$ . The well-known empirical Hall–Petch relation<sup>[12,13]</sup> relates the yield strength,  $\sigma_y$ , to the average grain size,  $d$ , according to the following equation

$$\sigma_y = \sigma_0 + kd^{-1/2} \quad (1)$$

where  $\sigma_0$  is the friction stress and  $k$  is a constant. This relation yields a linear increase of yield strength with decrease in grain size. However, most measurements<sup>[10,14]</sup> seem to indicate that the strength of polycrystalline metals/alloys drops below the values predicted by extrapolation of Eq. (1) for a grain size of about 8–10 nm. This phenomenon is known as “inverse Hall–Petch relationship.”<sup>[14]</sup> So, it seems that a critical grain size determines the dominant deformation mode, which is governed either by dislocation mechanisms or by grain boundary processes.<sup>[14]</sup> In the lower grain size regime (<10 nm), grain boundary sliding and/or Coble creep apparently constitute the dominant deformation modes.<sup>[14]</sup> However, the determination of the Hall–Petch relationship (strength = hardness/3) is mainly based on hardness measurements. Recent studies<sup>[15–23]</sup> to explore the plastic deformation mechanisms of this class of materials suggest that nanocrystalline materials can also deform by twinning<sup>[15,16]</sup> and rotational movement of grain boundary disclinations triggering grain body

rotation.<sup>[17]</sup> In the former case indentation techniques were used to deform the nanometer-scale grains locally to evaluate the mode of strain accommodation under constrained conditions.<sup>[15,16]</sup> In contrast, it was observed recently that the deformation of bulk consolidated nanocrystalline specimens (grain size <100 nm) proceeds through a shear banding mechanism.<sup>[22,23]</sup> Usually, the strength of bulk nanocrystalline materials is 5–10 times higher than that of the corresponding coarse-grained counterparts.<sup>[24,25]</sup> On the other hand, the ductility of NsM at room temperature has not lived up to the expected level and is often disappointingly low.<sup>[25]</sup> The major limitations of ductility for nanocrystalline materials have been identified<sup>[25]</sup> as: 1) artifacts from processing; 2) force instability; and 3) crack nucleation and propagation instability.

## DEVELOPMENT AND PROCESSING OF NsM AND COMPOSITES

A variety of laboratory-scale processing techniques have been employed in the past decade to synthesize NsM. These can be broadly classified as: 1) rapid solidification;<sup>[26,27]</sup> 2) mechanical alloying and compaction;<sup>[28–31]</sup> 3) severe plastic deformation methods<sup>[32]</sup> including equal channel angular pressing (ECAP)<sup>[33]</sup> and high pressure torsion;<sup>[34]</sup> 4) surface mechanical attrition treatment (SMAT);<sup>[35]</sup> 5) cold working and recrystallization;<sup>[36]</sup> 6) gas-phase condensation of particulates and consolidation;<sup>[1,37,38]</sup> 7) electrodeposition;<sup>[39–41]</sup> 8) controlled annealing treatment;<sup>[42–45]</sup> severe mechanical deformation;<sup>[46,47]</sup> or high pressure torsion<sup>[48]</sup> of as-prepared bulk metallic glasses (BMGs)/amorphous precursors.

Among the above-mentioned techniques, electro- and vapor deposition methods are capable of producing thin films with mean grain sizes, i.e., order of tens of nanometers.<sup>[39–41]</sup> For example, dense single-phase 100- $\mu\text{m}$  thin sheets have been produced in pure (Ni, Co, Cu) and binary alloys (Ni–Fe, Ni–W) with grain sizes of 20–40 nm<sup>[39–41,49,50]</sup> by pulsed electrodeposition techniques. The limitations in these cases are not only the pick-up of impurities like sulfur or carbon, but also hydrogen filled nanobubbles/voids in the material. The other methods are able to produce nano/ultrafine-grained bulk materials. Gas-phase or inert gas condensation methods<sup>[1,37,38]</sup> are mostly used for the production of pure metals, such as Cu, Ni, and Pd, with equiaxed grain sizes in the range of 5–50 nm. The problems associated with this process are limited specimen volume, material yield, and rather high impurity level at the particle boundaries resulting in incomplete densification as well as retaining the nanoscale grain size during consolidation.<sup>[28]</sup> Ball milling or mechanical alloying is one of the efficient

techniques for the production of nanocrystalline materials because of its simplicity and processability to obtain a variety of metastable phases and alloys,<sup>[28–31,51–61]</sup> for example, Ni<sub>60</sub>Nb<sub>40</sub>,<sup>[51]</sup> Fe–Cu,<sup>[54]</sup> Ni<sub>60</sub>Mo<sub>40</sub>, and Ni<sub>85</sub>Mo<sub>15</sub><sup>[55]</sup> solid solutions with largely extended solubility ranges. The production of not only pure nanostructured body centered cubic (bcc), hexagonally close packed (hcp),<sup>[55]</sup> and face centered cubic metals,<sup>[53]</sup> as well as binary Fe–Cu<sup>[54]</sup> and Ni–Mo<sup>[56]</sup> and a variety of other nanostructured alloys,<sup>[57,58]</sup> but also multicomponent alloys<sup>[28,59–61]</sup> has been reported. Specifically, cryomilling in a liquid nitrogen medium has been shown<sup>[30,31]</sup> to produce ultrafine-grained aluminum alloys, and the resulting powder has been consolidated at elevated temperatures to nearly full density with insignificant grain growth. But the principal disadvantages of this processing route include the inability to control the purity of the material, to retain the nanocrystalline grain size, and to obtain full density upon consolidation.<sup>[30,31]</sup> Nanocrystalline metals and alloys with lower impurity contents have been prepared in recent years by severe plastic deformation/SMAT/ECAP including Al alloy–01420, Cu, Ni, Ti, and Ti–6Al–4V, steels, and intermetallic compounds as well as Al–Mg alloys.<sup>[32–38]</sup> In this entry, we will report on structural nanocrystalline/ultrafine-grained Ti-base alloys prepared by metal mold casting. This single-step fabrication procedure is relatively simple and allows easy control of the contamination level.

To improve the ductility of NsM, different composite materials have been developed. These can be broadly categorized according to their microstructures: 1) two phase homogeneous nanostructures (minimum of two constituent phases with nanometer length scale)<sup>[61]</sup> and 2) heterostructures consisting of micro- and nanocrystalline phase mixtures (single/multiple phases with different length scale).<sup>[62–64]</sup> It is quite obvious that the factors governing the strengthening and toughening mechanisms in multiphase composite microstructures include the properties of the reinforcing phases, such as their elastic properties, yield strength, and ductility, as well as the properties of the interface between the different phases in terms of its strength and crystallographic orientation, together with the volume fraction, size, and morphology of the second phase.<sup>[65,66]</sup> The idea behind this composite approach is to avoid catastrophic failure in nanostructured/glassy material by controlling the plastic instability via generation and interaction of multiple shear bands (SBs). In this aspect, Leng and Courtney<sup>[67]</sup> demonstrated the possibility of SB confinement under tension by fabricating laminated composite specimens consisting of a layer of metallic glass bonded between two ductile metal layers. The first category of nanocomposites has been discussed in detail in Ref.<sup>[61]</sup>. The latter category preferably contains a bimodal grain size

distribution, as it was demonstrated for pure Cu,<sup>[62]</sup> or Ti-<sup>[63]</sup> and Zr-<sup>[64,68]</sup> base multicomponent alloys. Ma<sup>[69]</sup> summarized the strategies that were used to improve the ductility of nanocrystalline materials by backing up the grain size (sacrificing some strength owing to a mixture of micro/nanometer-sized grains) for materials prepared by cold working and annealing (for inducing abnormal grain growth) as well as for specimens where a non-uniform grain structure is obtained by introducing a micrometer-sized dendritic phase in a nanocrystalline/ultrafine matrix upon solidification.<sup>[63,64,68]</sup> The basic idea<sup>[70,71]</sup> of preparing such “in situ composite microstructures” was shown to be feasible in improving the ductility of bulk NsM and BMGs,<sup>[64,70–74]</sup> even though a few BMGs show enhanced ductility recently.<sup>[75,76]</sup>

### SYNTHESIS, MICROSTRUCTURE AND MECHANICAL PROPERTIES

The synthesis of the nanostructured composites discussed in this entry is mainly based on arc-melting and/or Cu mold casting. It is well known that BMGs are usually obtained near deep (stable/metastable) eutectics in multicomponent systems.<sup>[77]</sup> However, for the available eutectic reactions in any alloy system, most of them may not be sufficiently deep to allow bulk glass formation at relatively low cooling rates (100–500 K/sec) by casting in metallic molds. In these cases, the nucleation of crystalline phases is expected through eutectic reactions. The cooling rates are very high ( $10^4$ – $10^5$  K/sec) for very thin/smaller diameter samples (100  $\mu\text{m}$ –1 mm).<sup>[78]</sup> Hence, a glassy structure can be formed in this case. On the other hand, the competing eutectic nucleation of crystals cannot be suppressed in larger diameter/thick samples.<sup>[73,78]</sup> However, by obtaining a high degree of undercooling under a range of casting conditions, the growth of these eutectic crystallization products can be restricted to the nanometer scale ( $\sim 100$  nm).<sup>[74,78,79]</sup> Additionally, by adopting multicomponent recipes,<sup>[74,80]</sup> such nanoeutectic structures can be promoted, making them readily accessible upon solidification.<sup>[74,79]</sup>

The microstructure formation of Ti-base nanostructured/glassy alloys can be schematically illustrated with the help of a pseudo-ternary phase diagram (Fig. 1) considering three different groups of constituent elements: 1) Ti (base element); 2) Nb/Ta/Zr/Mo (bcc  $\beta$ -phase isomorphous stabilizers) + Sn; and 3) Cu/Ni/Fe (eutectic matrix formers). The phase fields are plotted on the basis of the microstructural evolution at slow cooling rate of  $10^1$ – $10^2$  K/sec and metastable phase formation on different length scale. There are three (partly) overlapping phase fields that can be distinguished: a glassy region, an eutectic region

Fig. 1 Pseudo-ternary phase formation diagram for the Ti-(Nb, Ta, Zr, Mo, Sn)-(Cu, Ni/Fe) system.

(nanometer length scale), and finally a region where a bcc  $\beta$ -Ti-type solid solution forms, which sometimes coexists with other crystalline phase rather than bcc or nanoeutectic phases (marked as multiphase intermetallics). The overlapping of these regions produces composite microstructures with different length scale.

The glass-forming alloy composition is marked by a circle (G) in Fig. 1. In recent years, bulk glass formation was observed first in  $\text{Ti}_{50}\text{Cu}_{25}\text{Ni}_{20}\text{Sn}_5$ ,<sup>[81]</sup> and subsequently quite a large number of BMGs have been reported, e.g., for Ti-Cu-Ni-Si-B,<sup>[82]</sup> Ti-Cu-Ni-Sn-Be,<sup>[83]</sup> Ti-Cu-Ni-Sn-Be-Zr,<sup>[84]</sup> or Cu-rich Ti-Cu-Ni-Zr<sup>[85]</sup> alloys. These compositions are close to the circle marked as G. However, the glass-forming ability (GFA) of the Ti-base multicomponent alloys<sup>[81–84]</sup> is rather poor in comparison to Zr-base multicomponent alloys,<sup>[86]</sup> and the GFA abruptly decreases for higher Ti + Zr contents in the alloys.<sup>[85]</sup> Moving to the area with higher Ti + Sn content located in the upper left of the glassy region in the phase formation diagram yields nanostructured/glassy composites with submicron-sized hcp Ti particles, e.g., for a  $\text{Ti}_{50}\text{Cu}_{23}\text{Ni}_{20}\text{Sn}_7$  alloy cast to a thickness of 3 mm in diameter.<sup>[73]</sup> A typical microstructure of this type of alloy is presented in Fig. 2. The selected area diffraction pattern clearly confirms the existence of nanocrystalline particles in a glassy matrix. Modification of the glass-forming alloy composition and higher Ti + Nb contents in a  $\text{Ti}_{50}\text{Cu}_{20}\text{Ni}_{20}\text{Nb}_{10}$  alloy<sup>[79]</sup> lead to the formation of a nanoeutectic microstructure in 2–3-mm diameter cast rods.

On the other hand, the formation of micrometer-sized bcc  $\beta$ -Ti phase primary precipitates along with

**Fig. 2** A bright field TEM image of the matrix microstructure of  $\text{Ti}_{50}\text{Cu}_{23}\text{Ni}_{20}\text{Sn}_7$ . The inset shows a selected area electron diffraction (SAED) pattern taken from the matrix confirming the formation of nanocrystalline phase(s). *Source:* From Refs.<sup>[63,73]</sup>

a nanoeutectic microstructure has been observed in a wide range of cooling rates of  $10\text{--}10^3\text{ K/sec}$ .<sup>[80]</sup> The composition of these alloys lies in the “composite” region marked in Fig. 1. Moreover, a broad region of fully bcc beta-Ti phase alloys exists near to the left axis of Ti-(Nb/Ta/Mo/Zr), which can be easily understood when considering the respective binary alloy phase diagrams.<sup>[87]</sup> The composite microstructure formation and their effect on mechanical properties have been investigated by manipulating the compositions in a series of Ti-Cu-X-Sn-M alloy ( $X = \text{Ni, Fe, Cr, Co}$ ;  $M = \text{Nb, Ta, Mo, Zr}$ ).

### Effect of Ta

The variation in the Ti + Ta content of the alloys such as, for example, (T1)  $\text{Ti}_{52.0}\text{Cu}_{19.6}\text{Ni}_{16.8}\text{Sn}_{5.6}\text{Ta}_{6.0}$ , (T2)  $\text{Ti}_{56.0}\text{Cu}_{16.8}\text{Ni}_{14.4}\text{Sn}_{4.8}\text{Ta}_{8.0}$ , (T3)  $\text{Ti}_{60.0}\text{Cu}_{14.0}\text{Ni}_{12.0}\text{Sn}_{4.0}\text{Ta}_{10}$ , (T4)  $\text{Ti}_{64.0}\text{Cu}_{11.2}\text{Ni}_{9.6}\text{Sn}_{3.2}\text{Ta}_{12.0}$ , and (T5)  $\text{Ti}_{58.8}\text{Cu}_{1.1}\text{Ni}_{3.2}\text{Sn}_{5.0}\text{Ta}_{31.9}$  has been investigated systematically.<sup>[88,89]</sup> The compositions are marked in Fig. 1 as T1–T5. It can be seen that these compositions lie near to the glassy region and are shifted toward the left axis of the phase formation diagram. The microstructure of alloy T1 (2-mm $\phi$  rods solidified at  $10^2\text{--}10^3\text{ K/sec}$ ) exhibits mixed amorphous regions and nano/ultrafine-grained matrix. This composition lies in the “nanoeutectic region” in Fig. 1. The presence of a submicron-sized  $\beta$ -Ti phase was revealed from scanning electron microscopy (SEM) and x-ray diffraction (XRD) investigations.<sup>[88]</sup>

With increase of the Ti + Ta content in alloy T3 (3-mm $\phi$  rods) the existence of a micrometer-sized

$\beta$ -Ti phase with dendritic morphology can be observed<sup>[88]</sup> that is homogeneously distributed in a nanostructured matrix, as depicted in Fig. 3A. The XRD pattern [inset to Fig. 3A] clearly shows the presence of strong reflections from the  $\beta$ -Ti phase and broad diffuse peaks from the matrix phase (detailed investigations will be discussed later). The details of the nanostructured matrix revealed by SEM are presented in Fig. 3B, showing the eutectic morphology of the phases. The mechanical properties under uniaxial compression at an initial strain rate of  $10^{-4}/\text{sec}$  of the dendritic phase-reinforced nanostructured eutectic composites of alloys (T1, T2, T3; 2–3 mm $\phi$  as-cast rods) are listed in Table 1. The improvement of the mechanical properties (strength and room temperature plastic deformability) for alloy T3 compared to alloy T1 and other Ti-base bulk glassy alloys<sup>[81]</sup> can be clearly deduced from Table 1. This improvement is because of the presence of the micrometer-sized toughening phase ( $\beta$ -Ti).<sup>[63,88]</sup>

Slowly cooled ( $10\text{--}100\text{ K/sec}$ ) arc-melted ingots of different alloy composition (T2–T5) show a wide variation in the volume fraction of the  $\beta$ -Ti dendrites, whose values are about 20, 35, 65 and 95 vol.%, for alloys T2–T5, respectively.<sup>[88]</sup> A representative microstructure of alloy T3 as observed by SEM and a bright field transmission electron microscopic (TEM) image from the matrix are presented in Figs. 3C and 3D, respectively. The size of the dendritic phase in the arc-melted ingot [Fig. 3C] is larger than that of the 3-mm $\phi$  rods [Fig. 3A] owing to the lower cooling rate of arc-melting. Also the eutectic phases in the matrix are coarser than those in the faster cooled as-cast rods. The eutectic matrix mainly consists of  $\beta$ -Ti- and  $\gamma$ -CuTi-type phases (Fig. 3D) in alloy T3, as reported earlier.<sup>[80]</sup> The arc-melted alloys (T2–T5) with different compositions possess lower yield strength than the as-cast rods (Table 1) because of their coarser microstructural features.

Fig. 4 shows the variation in the mechanical properties of arc-melted ingots owing to different Ti + Ta addition, which ultimately changes the volume fraction of the toughening phase because of the shift of the alloy composition across the composite phase field from right to left, as depicted in Fig. 1. It seems that the yield strength and the plastic deformation for alloys T2–T5 are insensitive to the volume fraction of the dendritic phase. The increase in the elastic modulus for composites T2–T5 is because of the decrease in the volume fraction of the nanostructured matrix phase. Energy dispersive x-ray spectroscopy analyses suggest that there is no significant change in the composition of the dendritic phase, which varies only between 55 and 60 at.% Ti, 2 and 4 at.% Cu, 3 and 4 at.% Ni,  $\sim 5$  at.% Sn, and 26 and 33 at.% Ta.<sup>[88]</sup> However, the near beta alloy (alloy T5, in the single bcc phase field

of Fig. 1) with fully  $\beta$ -Ti microstructure shows a drop in the elastic modulus to 43 GPa (Fig. 4, Table 1) and superplastic-like room temperature compressibility of 62.5% plastic strain without failure.<sup>[88]</sup> The composition of the  $\beta$ -Ti phase was estimated to be  $\text{Ti}_{43.6}\text{Cu}_{0.}\text{Ni}_{1.6}\text{Sn}_{2.0}\text{Ta}_{52.8}$ .<sup>[88]</sup> Probably, a high amount of Ta (~50 at.%) significantly promotes the formation of  $\alpha'$  and  $\alpha''$  martensite in the  $\beta$ -Ti phase.<sup>[90]</sup> This drastically decreases the elastic modulus and increases Poisson's ratio. It has recently been suggested that the deformation mechanism and the pronounced cold workability of near beta Ti(Nb,Ta) alloys are also linked to the formation of deformation twins on a nanometer length scale (Eckert, J.; Das, J.; He, G.; Calin, M.; Kim, K.B. Ti-base bulk nanostructure-dendrite composites: microstructure and deformation. Mater. Sci. Eng. A. Submitted).

**Fig. 4** Effect of composition dependent dendritic volume fraction on Young's modulus (○), plastic strain (●) and yield strength (■).

### Effect of Nb

A large number of alloys with varying Ti + Nb content have been investigated<sup>[91]</sup> by mixing  $Ti_{80}Nb_{20}$  and  $Ti_{40}Cu_{28}Ni_{24}Sn_8$  with different portions to obtain

(N1)  $Ti_{56.0}Cu_{16.8}Ni_{14.4}Sn_{4.8}Nb_{8.0}$ , (N2)  $Ti_{60.0}Cu_{14.0}Ni_{12.0}Sn_{4.0}Nb_{10.0}$ , (N3)  $Ti_{64.0}Cu_{11.2}Ni_{9.6}Sn_{3.2}Nb_{12.0}$ , and (N4)  $Ti_{66.1}Cu_{8.0}Ni_{4.8}Sn_{7.2}Nb_{13.9}$  alloys. The alloys have been prepared by arc-melting and were solidified in the shape of 60 mm × 15 mm × 12 mm bars. The compositions of these alloys are indicated as N1–N4 in the phase formation diagram (Fig. 1) and lie right to left in the diagram according to their chemical composition. The changes in the microstructure with composition are clearly shown in Fig. 5. Alloy N1 contains a relatively fine dendritic phase with distinct epitaxial features, indicating a strong tendency for preferential growth of the dendritic bcc  $\beta$ -Ti phase.<sup>[91]</sup> The volume fraction of the dendrites is evaluated to be about 20 vol.%. It is revealed by TEM that the matrix contains a complex eutectic structure with grain sizes of about 30–200 nm.<sup>[91]</sup> In contrast, alloy N2 (Fig. 5A) contains “lopstick”-like dendrites, which are isolated by the matrix phase. The volume fraction of the dendrites in alloy N2 is about 40 vol.%.<sup>[91]</sup> The matrix exhibits a typical eutectic structure with an interlamellar spacing of about 50–150 nm, as shown in Fig. 5B. The high resolution TEM image from such a fine eutectic structure mainly consists of moiré fringes.<sup>[91]</sup> In case of alloys N3 and N4, both the

**Fig. 5** A BSE image of arc-melted  $Ti_{60.0}Cu_{14.0}Ni_{12.0}Sn_{4.0}Nb_{10}$  showing (A) in situ formed dendrites ( $\beta$ -Ti phase) in a dark matrix; (B) TEM bright field image showing the micrometer-sized dendrites dispersed in a nanoeutectic matrix. BSE images showing an increase in the volume fraction of dendritic phase with increase in Ti + Ta + Sn content in; (C)  $Ti_{64.0}Cu_{11.2}Ni_{9.6}Sn_{3.2}Nb_{12.0}$ ; and (D)  $Ti_{66.0}Cu_{8.0}Ni_{4.8}Sn_{7.2}Nb_{14}$  arc-melted ingots. Source: From Ref.<sup>[91]</sup>.

dendritic phase and the eutectic matrix exhibit a coarser morphology (Figs. 5C and 5D) than that observed for the former alloys N1 and N2. The volume fraction of the  $\beta$ -Ti dendrites is about 60 and 95 vol.% for alloys N3 and N4, respectively.<sup>[91]</sup> Except for alloy N1 (dendrite composition:  $Ti_{55.8}Cu_{1.4}Ni_{1.0}Sn_{20.1}Ta_{21.7}$ ), there is only an insignificant change in the composition of the dendrites for alloys N2–N4, which was estimated to vary from 65 to 67 at.% Ti, 3.5 to 4.5 at.% Cu, 2 to 3 at.% Ni, 5.5 to 9.5 at.% Sn, and 19.5 to 20 at.% Nb.

The mechanical properties of these Ti–Cu–Ni–Sn–Nb alloys have been investigated under compression.<sup>[91]</sup> All four alloys exhibit elastic deformation and pronounced yielding followed by plastic deformation with significant work-hardening. It can be clearly seen from Fig. 6 that there is an increase in the plastic deformability and a decrease in the yield strength with increasing volume fraction of dendrites in the different alloys. The important phenomenon noticed in these alloys is a significant change in the transition behavior from elastic to plastic deformation.<sup>[91]</sup> A higher volume fraction of nano/ultrafine-sized matrix (alloy N1) yields a gradual elastic–plastic transition, whereas alloy N4 with fully coarse  $\beta$ -Ti phase shows a sharp transition. Very similar mechanical properties were also observed when substituting Nb by Mo.<sup>[91]</sup>

### Effect of Sn

The evolution of the microstructure has also been studied for  $Ti_{57-x}Cu_{15}Ni_{14}Sn_{4+x}Nb_{10}$  ( $0 \leq x \leq 10$ ) alloys.<sup>[92]</sup> These alloys (S1:  $x = 0$ , S2:  $x = 5$ , S3:  $x = 10$ ) are located in the pseudo-ternary phase formation diagram (Fig. 1) from the bottom to the top

**Fig. 6** Effect of composition dependent dendritic volume fraction on plastic strain plastic strain (●) and yield strength (■).

with increase in the Sn content. All the alloys were cast as 5-mm diameter cylindrical rods. The microstructures of these alloys reveal that the phase field moves with increasing Sn content from a dendrite + nanoeutectic (hypoeutectic) morphology toward multiphase intermetallics in the hypereutectic region. Fig. 7A shows XRD patterns for alloys S1–S3 with different Sn content. It can be clearly seen that more unknown intermetallics appear with increasing amount of Sn in the alloy composition, which is also confirmed by microstructural observations (Fig. 7D). The existence of the dendritic  $\beta$ -Ti phase together with a nanoeutectic matrix (Fig. 7B) in alloy S1 represents a hypoeutectic microstructure resulting in a yield strength of 1226 MPa with 2.5% plastic strain.<sup>[92]</sup> Increasing the Sn content from 4 to 9 at.% shifts the alloy composition from a hypo- to a hypereutectic microstructure, as depicted in Fig. 7C. This can also be visualized by considering the Ti–Sn(Nb) pseudo-binary phase diagram.<sup>[87]</sup> Alloy S2 has a yield strength of 758 MPa but shows a poor ductility of only about 1%.<sup>[92]</sup> For 14 at.% Sn (S3), the composition of the alloy completely shifts to the intermetallic area, yielding different intermetallics in the as-solidified microstructure (Fig. 7D), as also revealed by XRD (Fig. 7A). S3 exhibits only elastic deformation and fails at only 300 MPa fracture stress.<sup>[92]</sup>

### Effect of Fe, Cr, and Co

To prepare “biocompatible” nanostructure–dendrite composites, He and Hagiwara<sup>[93,94]</sup> substituted Ni in

**Fig. 7** (A) The XRD pattern of as-cast 5 mm $\phi$ ,  $Ti_{57-x}Cu_{15}Ni_{14}Sn_{4+x}Nb_{10}$  ( $x = 0, 5, 10$  at.%) alloys showing the formation of multiphase intermetallics with increase in Sn content. The SEM images of  $Ti_{57-x}Cu_{15}Ni_{14}Sn_{4+x}Nb_{10}$ ; (B)  $x = 0$ ; (C)  $x = 5$ ; and (D)  $x = 10$ . Source: From Ref.<sup>[92]</sup>.

the alloy composition by Fe, Co, and Cr. As Ti-base alloys have been paid a lot of attention in recent years owing to their excellent biocompatibility, low density, excellent corrosion resistance, and good balance of mechanical properties,<sup>[95,96]</sup> this alloy design approach is highly interesting. The Young modulus of the so far available commercial biocompatible Ti-base alloys is very high (110 GPa) compared with that of bone (15–25 GPa).<sup>[97]</sup> This rather high value is detrimental, as a low rigidity of the implants is considered to be effective for promoting bone healing and remodeling.<sup>[96]</sup> Accordingly, it is highly desirable to develop advanced Ti-base alloys, which could imitate the elastic modulus of cortical bone.<sup>[98]</sup>

Along this line the microstructure and mechanical properties of  $\text{Ti}_{60}\text{Cu}_{14}\text{Ni}(\text{Fe},\text{Cr},\text{Co})_{12}\text{Sn}_4\text{Ta}(\text{Nb})_{10}$  alloys<sup>[93,94]</sup> have been investigated. All these alloys were prepared by arc-melting under slow cooling conditions (10–100 K/sec) and reshaped into 60 mm × 15 mm × 12 mm bars. In general there was no change in the microstructural constituents of these alloys observed compared to the earlier discussed nanoeutectic–dendrite composites. Fig. 8A exemplifies the characteristic micrometer-scale bright  $\beta$ -Ti phase in an ultrafine eutectic matrix for  $\text{Ti}_{60}\text{Cu}_{14}\text{Fe}_{12}\text{Sn}_4\text{Nb}_{10}$ .<sup>[93]</sup> The composition of the dendrites was estimated to be  $\text{Ti}_{64.36}\text{Cu}_{9.34}\text{Fe}_{7.61}\text{Sn}_{6.99}\text{Nb}_{11.7}$ ,<sup>[93]</sup> indicating an enrichment with Ti, Nb, and Sn compared to the nominal composition of the alloy. In contrast, the matrix is enriched with Cu and Fe.<sup>[93]</sup> XRD analysis reveals the presence of the bcc  $\beta$ -Ti phase and a hcp  $\alpha$ -Ti phase.<sup>[93]</sup> An increase in the Ti + Sn content without altering the Nb content in the alloy composition was observed to increase the volume fraction of the dendritic phase.<sup>[93]</sup> The compositions of this type of alloys are indicated in Fig. 1 as F1–F5. The increase in the volume fraction of the nanoeutectic structure from <2 to 75 vol.% increases the yield strength from 1050 to 1515 MPa and decreases the plastic strain from 20% to 3.7%.<sup>[93]</sup> Addition of Cr or Co instead of Fe in the alloy gives similar microstructural features as shown in Fig. 8B.

The Co-containing ( $\text{Ti}_{60}\text{Cu}_{14}\text{Co}_{12}\text{Sn}_4\text{Nb}_{10}$ ) (Fig. 8B) and Fe-containing ( $\text{Ti}_{74}\text{Cu}_8\text{Fe}_6\text{Sn}_2\text{Nb}_{10}$ ) alloys exhibit low elastic moduli ( $E$ ) of 67 and 54 GPa, respectively, similar to  $E = 55$  GPa for the well-known Ti–35Nb–7Zr–5Ta (wt.%) alloy.<sup>[95]</sup> However, Ti–35Nb–7Zr–5Ta also has a very low yield strength ( $\sigma_y = 530$  MPa) compared to the novel Ti-base nanostructured composites with biocompatible elements ( $\sigma_y = 1051$  MPa for  $\text{Ti}_{74}\text{Cu}_8\text{Fe}_6\text{Sn}_2\text{Nb}_{10}$ , and  $\sigma_y = 1050$  MPa for  $\text{Ti}_{60}\text{Cu}_{14}\text{Co}_{12}\text{Sn}_4\text{Nb}_{10}$ ).<sup>[94]</sup> This is a significant achievement, as this type of nanostructured composite material<sup>[93,94,99]</sup> combines low modulus and twice higher yield strength compared to conventional Ti-base microcrystalline near beta alloys used so far for biomedical purposes.<sup>[99]</sup>

**Fig. 8** Images [SEM (BSE)] of  $\text{Ti}_{60.0}\text{Cu}_{14.0}\text{X}_{12.0}\text{Sn}_{4.0}\text{Nb}_{10}$  arc-melted ingots (A)  $X = \text{Fe}$  and (B)  $X = \text{Cr}$  showing dendrites in a nano/ultrafine microstructure. *Source:* From Refs.<sup>[93,94]</sup>.

## SOLIDIFICATION MECHANISM

To clarify the solidification mechanism of nanoeutectic matrix–dendritic phase composites,  $\text{Ti}_{60}\text{Cu}_{14}\text{Ni}_{12}\text{Sn}_4\text{Ta}_{10}$  and  $\text{Ti}_{74}\text{Cu}_{14}\text{Ni}_{12}$  alloy were selected for detailed investigations.<sup>[100]</sup> The composition of the latter Ti–Cu–Ni alloy is analogous to the former nanostructure–dendrite  $(\text{Ti} + \text{Sn} + \text{Nb})_{74}\text{Cu}_{14}\text{Ni}_{12}$  alloy composition.<sup>[88]</sup> Both alloys were solidified into 3-mm diameter rods in a Cu mold at a cooling rate of about 250 K/sec.<sup>[74,78]</sup> The as-cast microstructure of the Ti–Cu–Ni–Sn–Ta multicomponent alloy shows similar features<sup>[63]</sup> as described above for the alloys containing a dendritic phase dispersed in a nanoeutectic matrix. The matrix exhibits a two-phase eutectic microstructure with 65–95-nm interlamellar spacing, as shown in Fig. 9A. The eutectic rods are identified as bcc phase (Im3m) with composition  $\text{Ti}_{57.0}\text{Cu}_{7.6}\text{Ni}_{3.1}\text{Sn}_{10.8}\text{Ta}_{21.5}$  corresponding to a  $\beta$ -Ti phase. An indexed nanobeam

**Fig. 9** (A) A TEM bright field image of  $\text{Ti}_{60.0}\text{Cu}_{14.0}\text{Ni}_{12.0}\text{Sn}_{4.0}\text{Ta}_{10}$  (3-mm $\phi$  rod) showing the existence of  $\beta$ -Ti and NiTi phases; (B,C) SAED patterns from the corresponding phases; (D) SEM image of a  $\text{Ti}_{74}\text{Cu}_{14}\text{Ni}_{12}$  alloy showing the eutectoid  $\text{CuTi}_2$  and  $\alpha$ -Ti phases decomposed from the  $\beta$ -Ti phase in a  $\text{CuTi}_2$  matrix formed after peritectic reaction; and (E) An SEM image of  $\text{Ti}_{60.0}\text{Cu}_{14.0}\text{Ni}_{12.0}\text{Sn}_{4.0}\text{Ta}_{10}$  after heat treatment at 1073 K showing formation of the  $\text{CuTi}_2$  equilibrium phase (marked by an arrow). Source: From Ref.<sup>[100]</sup>.

diffraction pattern of this phase is shown in Fig. 9B. The second phase of the nanoeutectic is enriched with Ni and Cu, having a composition of  $\text{Ti}_{49.5}\text{Cu}_{24.5}\text{Ni}_{22.1}\text{Sn}_{1.2}\text{Ta}_{2.7}$ .<sup>[100]</sup> This phase is identified as a NiTi phase (B2) (Fig. 9C) even though it contains a high amount of Cu. Interestingly, the NiTi phase possesses a B19 structure in some regions of the specimen, which is possibly because of the presence of the high amount of Cu in the NiTi phase (>15 at.%), which suppresses the B2  $\rightarrow$  B19 transformation at room temperature.<sup>[100–102]</sup>

The microstructure of the ternary Ti–Cu–Ni alloy reveals dendritic eutectoid colonies consisting of  $\alpha$ -Ti and  $\text{CuTi}_2$  phases in a  $\text{CuTi}_2$  matrix.<sup>[100]</sup> Overall compositional analysis suggests the formation of a primary  $\beta$ -Ti phase, which finally undergoes eutectoid decomposition into the  $\alpha$ -Ti and  $\text{CuTi}_2$  phases.<sup>[100]</sup> There is a peritectic reaction between the primary  $\beta$ -Ti phase and the remaining liquid leading to the formation of the  $\text{CuTi}_2$  matrix,<sup>[100]</sup> which can be understood from the Cu–Ti binary phase diagram.<sup>[87]</sup> Annealing  $\text{Ti}_{60}\text{Cu}_{14}\text{Ni}_{12}\text{Sn}_4\text{Ta}_{10}$  at 1073 K induces the formation of the stable  $\text{CuTi}_2$  phase in the microstructure (Fig. 9E, marked by an arrow).

These investigations clearly suggest that the solidification behavior of  $\text{Ti}_{60}\text{Cu}_{14}\text{Ni}_{12}\text{Sn}_4\text{Ta}_{10}$  can be understood by considering it as a pseudo-ternary (Ti + Sn + Ta)<sub>74</sub> $\text{Cu}_{14}\text{Ni}_{12}$  alloy and by comparing it with an analogous composition in the Ti–Cu–Ni ternary system. After the formation of the  $\beta$ -Ti dendrites in  $\text{Ti}_{60}\text{Cu}_{14}\text{Ni}_{12}\text{Sn}_4\text{Ta}_{10}$ , the  $\text{CuTi}_2$  equilibrium phase is kinetically excluded because of sluggish diffusion in the melt, in the multicomponent recipe, in the higher cooling rate, and in the presence of Nb and Sn, which suppresses the eutectoid decomposition and stabilizes the  $\beta$ -Ti phase.<sup>[88,91,100]</sup> The peritectic formation of  $\text{CuTi}_2$  in the matrix is replaced by a metastable equilibrium between  $\beta$ -Ti and NiTi, which results in eutectic solidification of the remaining liquid even when the alloy is solidified at a low cooling rate of 10–100 K/sec. The metastability of this equilibrium is demonstrated by the recovery of the equilibrium phase ( $\text{CuTi}_2$ ) upon heat treatment of as-cast samples.<sup>[100]</sup>

## DEFORMATION AND FRACTURE MECHANISMS

The fracture surfaces after compression and the slip traces evolved on the specimen surface were widely investigated for Ti–Cu–(Ni,Fe,Co,Cr)–Sn–(Ta,Nb,Mo,Zr) alloys.<sup>[63,88,91,92,103]</sup> Most fractographic observations reveal regions on the fracture surface that are covered by melting features and strong light emission at the moment of fracture.<sup>[104]</sup> Evidence of “liquid droplets” on the fracture surface of dendritic phase-reinforced Ti–Cu–Ni–Sn–X (X = Ta, Nb, Mo) alloys has also been reported.<sup>[104]</sup> It was noticed that these nanostructured composite materials can store a high amount of elastic energy of up to 46 MJ/m<sup>3</sup>.<sup>[104]</sup> This significantly affects their fracture behavior, as conventional Al- and Mg-base alloys, stainless steel, and superalloys<sup>[105–107]</sup> have a resilience of <10 MJ/m<sup>3</sup>. The high stored elastic energy in these nanocomposites is released into a small volume in a narrow SB, leading to a sharp temperature increase within a thin layer during the fast propagation of the shear crack,<sup>[108]</sup> which finally appears as a melting or a vein-like pattern.<sup>[109]</sup>

Even though some of the as-cast alloys crumble into multiple pieces and show a distensile fracture mode of fracture,<sup>[110]</sup> on a macroscopic length scale a correlation between the shear fracture angle and the plastic deformability holds good<sup>[111]</sup> for a series of Ti–Cu–Ni–Sn–Nb nanostructured composites. Table 2 reveals that the macroscopic shear fracture angle ( $\theta_C^E$ ) increases from 46° to 51° in the order of the alloys N1  $\rightarrow$  N4, i.e., with the increase in the volume fraction of dendrites in the alloy (see section “Effect of Nb”). This feature is contradictory to the previous results for BMGs<sup>[112]</sup> and the Mohr–Coulomb criterion,<sup>[113]</sup> which is suitable for monolithic BMGs

**Table 2** Alloy composition, plastic strain,  $\epsilon_p$ , and shear fracture angles,  $\theta_C^F$ , of the investigated alloys

Alloy composition	Plastic strain, $\epsilon_p$ (%)	Final fracture angle, $\theta_C^F$ (°)	Initial SB angle, $\theta_C^O$ (°)	Rotation, $\theta_C^F - \theta_C^O$ (°)

Source: From Refs.<sup>[91,111]</sup>.

and BMG composites.<sup>[109,112,114,115]</sup> The surfaces of all the specimens are full of dense SBs, and they are aligned to both directions ( $\pm\theta_C^F$ ) with the compressive stress axis, i.e., parallel (primary SBs) and perpendicular (secondary SBs) to the final fracture plane. At a low magnification (50 $\times$ ) the SB spacing was measured to be 150  $\mu\text{m}$ .<sup>[116]</sup> For all the alloys, the SBs on the specimen surface display a bended morphology, which is observed from the macro- to the micrometer scale.<sup>[117]</sup>

From these observations it is suggested that the bending or rotation of the SBs is correlated with the high compressive ductility (up to 20–30%) of the four alloys. Therefore, a compressive specimen before and after deformation can be schematically illustrated as in Fig. 10A. Assuming that the original dimension of the specimen is  $a_0 \times a_0 \times l_0$ , the initial shear angle of the SBs is  $\theta_C^O$  and the length of the primary SBs is  $l_{SB}$ . After compression up to a plastic strain,  $\epsilon_p$ , the dimension of the specimen is changed to  $a \times a \times l$ . The angle between the primary shear plane and the stress axis is now  $\theta_C^F$ , owing to a strong rotation. Therefore, if it is assumed that the volume  $V$  of the specimen and the length  $l_{SB}$  of the primary SB remain nearly constant before and after deformation, the following relationships can be proposed<sup>[111]</sup>

$$V = a_0 \times a_0 \times l_0 = a \times a \times l \quad (2)$$

$$l_{SB} = a_0 / \sin(\theta_C^O) = a / \sin(\theta_C^F) \quad (3)$$

For a compressive specimen, the plastic strain  $\epsilon_p$  can be expressed as

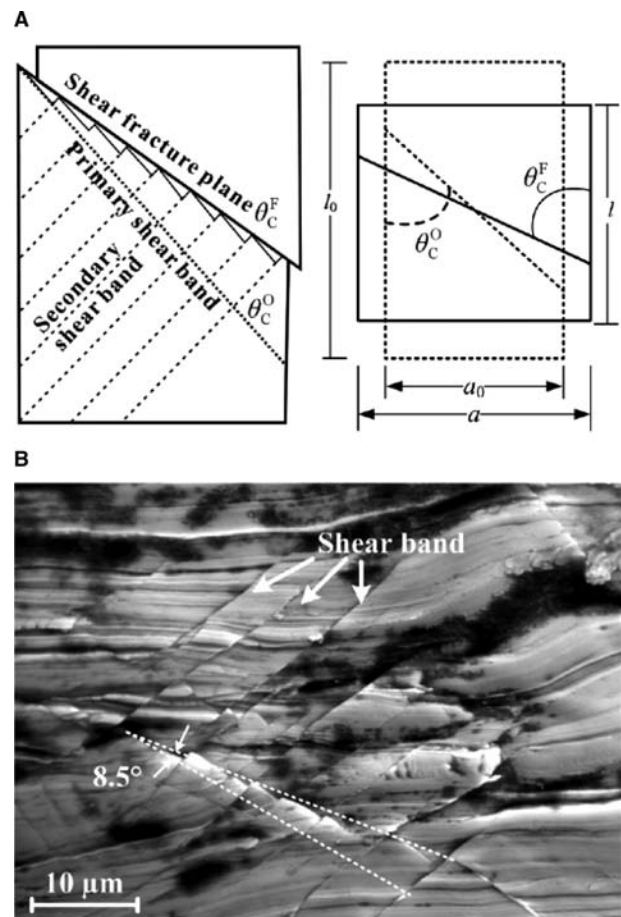

$$\epsilon_p = (l_0 - l) / l_0 \quad (4)$$

From Eqs. (2)–(4), one can get the relationship between  $\theta_C^O$ ,  $\theta_C^F$ , and the plastic strain  $\epsilon_p$  as

$$\sin(\theta_C^O) = \sqrt{1 - \epsilon_p} \sin(\theta_C^F) \quad (5)$$

The initial shear angle  $\theta_C^O$  of the SBs can be calculated from Eq. (5) if the compressive plastic strain  $\epsilon_p$  and the final shear fracture angle  $\theta_C^F$  (Table 2) are known. The initial shear angle  $\theta_C^O$  of the primary SBs with respect to the stress axis is in the range of 40.5–43.5° for the four Ti-base alloys.<sup>[91,111]</sup> Taking the

average value of  $\theta_C^O = 41.8 \pm 0.9^\circ$  and Eq. (5) into account, the possible final fracture angle  $\theta_C^F$  can be calculated. The difference ( $\theta_C^F - \theta_C^O$ ) between the two shear fracture angles before and after fracture, that corresponds to the rotation angle ( $\theta_C^F - \theta_C^O$ ), increases from 2.5° to 10.5° when the compressive plastic strain increases from 8.9% to 30%.<sup>[91,111]</sup>

**Fig. 10** (A) Schematic illustration of the rotation of the primary shear plane because of SB impingement and (B) SEM image (secondary electron contrast) of the intersection and impingement between the two sets of SBs introducing a rotation of 8.5° of the shear plane on a microscopic scale for Ti<sub>66</sub>Cu<sub>8.0</sub>Ni<sub>4.8</sub>Sn<sub>7.2</sub>Ta<sub>14</sub> specimen after 25% plastic deformation. Source: From Refs.<sup>[111,118]</sup>.

**Fig. 11** Microstructural features of the  $Ti_{66}Cu_{8.0}Ni_{4.8}Sn_{7.2}Ta_{14}$  specimen deformed up to ( $\epsilon_p = 8.1\%$ ): (A) formation of slip bands (small arrows) in the dendrites; (B) nucleation and passing of SBs at the dendrite–nanoeutectic matrix interface (dotted arrows); (C) A TEM bright field image of a 25% deformed alloy  $Ti_{66}Cu_{8.0}Ni_{4.8}Sn_{7.2}Ta_{14}$  specimen showing the intersection of SBs in the dendrites and a stepped morphology at the dendrite–matrix interface; and (D) passing of the SBs through the nano-eutectic structure indicating a set of SBs (black arrows) aligned parallel to the interface of eutectic lamellae and restricted propagation (at point 1) of another set of SBs (white arrows) in perpendicular direction, which are further regenerated at point 2. *Source:* From Refs.<sup>[118]</sup>, Eckert, J.; Das, J.; Kim, K.B.; Baier, F.; Löser, W.; Calin, M.; Zhang, Z.F.; Gebert, A. Deformation behavior of a  $Ti_{66}Cu_8Ni_{4.8}Sn_{7.2}Nb_{14}$  nanostructured composite containing ductile dendrites. *J. Alloy. Comp.* Submitted.

To get a clear view on the microscopic length scale, alloy N4 was deformed up to 25% plastic strain.<sup>[116]</sup> A large number of impingement and intersection events of the SBs under primary and secondary direction are observed on the specimen surface, as depicted in Fig. 3A. The SB spacing is on the order of 5–10  $\mu m$  measured at 2000  $\times$  magnification. The intersection of the SBs creates a morphology, which is similar to the surface of a “pineapple.” During plastic deformation of the composite, a set of SBs (primary direction) is activated, and it interacts with the SBs moving to the other direction (secondary direction). Additional deformation enforces the secondary SBs to cut through the primary SBs (Fig. 3D), yielding steps at the intersection points. However, with further deformation shear occurs in both directions (primary and secondary) and creates steps in both primary and secondary SBs to accommodate the applied strain. This finally appears as the structure depicted in

Fig. 10B. The change in the macroscopic fracture angle can be correlated with the impingement of the SBs on the microscopic scale, as illustrated in Fig. 10B by the dotted lines. The initial SB angle rotates by  $8.5^\circ$  after 25% deformation in alloy N4 (Table 2). The activation of two different sets of SBs along two different directions ( $\pm\theta_C^\circ$ ) is quite similar to a dislocation slip mechanism initiated through conjugated slip systems.<sup>[113]</sup>

To reveal the evolution of SBs in nanostructured composites,  $Ti_{66}Cu_8Ni_{4.8}Sn_{7.2}Nb_{14}$  (N4) was deformed up to different amounts of plastic strain (8% and 25%) without failure (Eckert, J.; Das, J.; Kim, K.B.; Baier, F.; Löser, W.; Calin, M.; Zhang, Z.F.; Gebert, A. Deformation behavior of a  $Ti_{66}Cu_8Ni_{4.8}Sn_{7.2}Nb_{14}$  nanostructured composite containing ductile dendrites. *J. Alloy. Comp.* Submitted). A large number of deformation bands were observed on the 8% plastically deformed specimen. The density of these bands is very

high, and their growth is restricted within the dendrites. Because the composite shows a work-hardening behavior, these bands must be “slip bands” that form because of dislocation movement in the dendrites. Typical features of such fine profuse slip bands are presented in Fig. 11A and are marked by small white arrows. The thick black arrows indicate the direction of the applied stress. In most regions the dendrites show “wrinkle”-like features along with a high density of slip bands at the center of the specimen. This indicates that the initiation of the localized deformation is related to both the high-strength nanostructured matrix and the ductile dendrites.<sup>[117]</sup> At this stage it is anticipated that some of the grains in the nanoeutectic matrix may contribute to the strain via dislocation movement. Interestingly, in a region close to the “wrinkled” dendrites, a few SBs are observed to pass through the dendrites, as indicated by a dotted white arrow in Fig. 11A. However, the majority of the area on the specimen surface does not display this feature. These bands are relatively sharper than the slip bands and have different contrast. The overall features suggest that there might be a preferred orientation with the applied stress axis. Because the strain distribution is not completely homogenous in the material,<sup>[116]</sup> these observations validate that the initial deformation originates from dislocation movement and the formation of slip bands inside the dendrites and proceeds through shear banding.<sup>[116]</sup> A magnified image of a set of parallel SBs passing through the interface between the nanoeutectic matrix and the dendrites is shown in Fig. 11B. This observation is very similar to the findings for a  $\text{Ti}_{62}\text{Cu}_{14}\text{Ni}_{12}\text{Sn}_4\text{Nb}_8$  nanocomposite with different volume fraction of dendrites.<sup>[117]</sup> The surface of the 24.5% deformed specimen (alloy N4) shows remarkably different features in comparison to the specimen subjected to only 8% plastic strain. The strongly deformed sample is buckled and barreled. In addition, the formation of highly dense SBs on the specimen surface is observed throughout the sample. A large number of impingement and intersection events<sup>[117]</sup> of the SBs under primary and secondary direction occur on the specimen surface, similar to the one depicted in Fig. 10B. The SB spacing is on the order of 5–10  $\mu\text{m}$ .<sup>[116]</sup>

Further analyses<sup>[118,119]</sup> based on TEM investigations on the nanometer length scale of the 24.5% deformed  $\text{Ti}_{66}\text{Cu}_8\text{Ni}_{4.8}\text{Sn}_{7.2}\text{Nb}_{14}$  specimen revealed a stepped morphology at the interface between the dendrites and the nanoeutectic matrix [Fig. 11C]. The slip transfer from the nanostructured matrix to the dendrites is believed to initiate such a stepped morphology owing to the passing of SBs without generating cracks (Eckert, J.; Das, J.; Kim, K.B.; Baier, F.; Löser, W.; Calin, M.; Zhang, Z.F.; Gebert, A. Deformation behavior of a  $\text{Ti}_{66}\text{Cu}_8\text{Ni}_{4.8}\text{Sn}_{7.2}\text{Nb}_{14}$  nanostructured

composite containing ductile dendrites. *J. Alloy. Comp.* Submitted).<sup>[118]</sup> The SB spacing is only 150–250 nm, as shown in Fig. 11C, although it appears to be 5–10  $\mu\text{m}$  at lower magnification under SEM conditions [Fig. 10B]. A triangle-shape contrast is often observed around the intersection regions between the SBs aligned to two directions inside the dendrites. A high resolution TEM study from the apex of a SB inside a dendrite revealed the existence of amorphous-like and distorted/disordered lattice fringes owing to extensive local lattice distortion in highly strained areas within the dendrites in regions as the one marked by a circle in Fig. 11C.<sup>[119]</sup> On the other hand, passing of SBs (primary and secondary) through the nanoeutectic matrix has also been clearly observed.<sup>[118]</sup> Fig. 11D shows the existence of SBs, which are aligned perpendicular to each other in the nanoeutectic matrix, as marked by the white and black arrows. The passing of the SBs into the matrix becomes easier when propagating under a direction almost parallel with the nanoscale rods (marked by the white arrows).<sup>[116]</sup> On the other hand, the nanoscale eutectic lamellae hinder the propagation of the SBs when they are aligned perpendicularly, as evidenced in Fig. 5B (marked by black arrows). Fig. 11D shows that the SBs (white arrows) are significantly deflected at the interfaces of the eutectic lamellae (at point 1). After a few layers of the eutectic rods the SB regenerates (at point 2) and propagates through the nanoeutectic matrix. This indicates that the nucleation and restricted propagation of SBs are also controlled by the nanometer scale eutectic matrix.

## CONCLUSIONS

A new class of high strength and ductile composites has been developed by tailoring Ti-base BMG-forming alloy compositions by simple in situ processing methods. The nanostructured composites are toughened by choosing the proper composition and by designing the microstructure to a bimodal grain size distribution of micrometer-scale dendrites embedded in a nano/ultrafine eutectic matrix. The evolution of such a metastable nano-heterostructure with different length scale of constituent phases is realized by inexpensive processing for a wide range of cooling rates ( $10^1$ – $10^3$  K/sec). This is a significant achievement to prepare cast nanostructured composites at such a low cooling rate in bulk form (60 mm  $\times$  15 mm  $\times$  12 mm).

The combination of appreciable ductility (up to 61%) and strength (>1800 MPa) together with high elastic strain ( $\epsilon_y \approx 3\%$ ) for these alloys is believed to be promising for several engineering applications such as high-performance springs, microgears, medical devices, sports equipment, wear resistant materials,

etc. Synthesizing such a composite microstructure has paved the way to develop advanced composites by manipulating the microstructures as a function of both composition and casting conditions/cooling rate. Designing new nanostructured alloys with biocompatible elements (Cr, Co, and Fe) that combine both high strength and low elastic modulus (54 GPa) is promising for a wide range of biomedical applications. It is also anticipated that composites having a nanostructured matrix with micrometer-sized ductile dendrites can be widely used to toughen other Ti-, Mg-, La-, Pd-, Fe- and Cu-base NsM.

## INTRODUCTION

Compared to bulk materials, nanoscale materials, with their large surface areas and possible quantum confinement effects, possess distinct electronic, optical, and chemical properties.<sup>[1–3]</sup> Therefore the synthesis of defined nanostructures is of potential interest in various fields including catalysis or microelectronics. In catalysis, for example, interesting applications for metal nanoparticles emerge from an enhanced activity, good selectivity (controllable by surface modifiers), and synergistic effects in bimetallic catalysts.<sup>[4,5]</sup> In electronics, a fundamental concept for miniaturization is the handling of single charges by means of single electron tunneling (SET) in ordered one-, two-, or three-dimensional arrangements of metal or semiconductor clusters.<sup>[6]</sup> Inspired by the unique physical and chemical properties, much effort has been made to tailor defined one-, two-, or three-dimensional nanostructures ranging from ordered nanoparticle arrays to nanowires.<sup>[7,8]</sup>

In biology, nanostructures are familiar objects. Biological components exhibit size dimensions from the nanometer to the micrometer size range together with exceptional molecular recognition capabilities and functionalities for distinct biochemical transformations and translocations. However, many of these biomolecules do not possess the required physical or chemical properties. DNA, for example, has the appropriate recognition capabilities, but poor electric characteristics prevent its direct use in electric circuits.<sup>[9]</sup> On the other hand, inorganic materials such as metals or semiconductors display, for example, the desired electric or optical properties, but their controlled deposition into defined nanostructures is difficult by conventional methods. Recently, the unique features of biological systems have been explored as building blocks for bottom-up assembly or controlled deposition of novel inorganic materials and devices with advanced structures and functionalities.<sup>[10–12]</sup> For example, the specific recognition properties of oligonucleotides<sup>[13,14]</sup> or antibodies<sup>[15]</sup> have been exploited for assembling metal

nanoparticles into well-ordered three-dimensional aggregates. The protein cages of viruses have been used as a template for a controlled deposition and organization of metallic nanoparticles.<sup>[16]</sup> Motivated by future electronic applications, researchers used DNA to control the deposition of metals<sup>[17]</sup> and create conductive nanowires consisting of silver,<sup>[18]</sup> gold,<sup>[19]</sup> palladium,<sup>[20]</sup> platinum,<sup>[21]</sup> and copper.<sup>[22]</sup>

In this entry we address the template-directed deposition of metals on microtubule supports for fabricating metal nanostructures ranging from regular arrays of nanoclusters to continuous nanowires.

## GENERATING NANOSTRUCTURES ON BIOLOGICAL SUPPORTS

Biotemplating strategies take advantage of the characteristic dimensions of biological support, ranging from a few nanometers up to several micrometers. The structure of these biostructures is well defined for a controlled deposition of inorganic materials. Moreover, the surface of these biomolecular components reveals specific patterns of surface functionalities, e.g., amino acid residues or the bases of nucleic acids that are able to bind metal ions or nanoparticles by formation of metal–ligand complexes or electrostatic interaction. In this approach, the biostructure serves as a functionalized scaffold where the metal is generated in situ and shaped into a nanostructure with its morphology dependent on that of the biotemplate.

The basic concept of a surface-controlled, heterogeneous metallization of a biotemplate consists essentially of several steps: First, appropriate metal ions are bound to the biomolecule, creating reactive sites and thus providing activation of defined sites at the biotemplate. Second, the metal ion/biomolecule adducts are treated with a reducing agent establishing metal nuclei attached to the biostructure. In another strategy, nanoparticles that were previously obtained by a homogeneous nucleation process in solution are attached to the surface functionalities of the

biotemplate. Once small metal seeds cover the biotemplate, the metal growth proceeds autocatalytically by consuming the educt feedstock from solution. The final metal coating does not necessarily have to consist of the same metal as the first formed metal nuclei or bound metal seeds, as has been shown by several groups.<sup>[19,23–25]</sup> Within this concept, homogeneous cluster nucleation or heterogeneous background metalization—if the reduction is carried out on a substrate—should be suppressed as much as possible as it leads to unspecific deposition of the metal. Many metal deposition techniques require special reaction conditions influenced by various parameters including applied temperature, educt concentration, the reduction potential of the reducing agent, and, in general, the presence of non-native chemicals. As a consequence, the biomolecular structure used needs to exhibit a sufficient physical and chemical stability toward these non-native conditions for metal deposition.

### STRUCTURAL FEATURES AND PROPERTIES OF MICROTUBULE TEMPLATES

Microtubules, ubiquitously present in eukaryotic cells, are proteinaceous filaments with a diameter of about 25 nm and several micrometers in length.<sup>[26]</sup> As part of the cytoskeleton, microtubules are involved in a variety of cellular functions including maintenance of the cellular shape, segregation of the genetic material during mitosis and meiosis, intracellular transport of organelles as well as cell motility. The repeating unit of these polymeric structures is the  $\alpha\beta$ -tubulin heterodimer, 4–5 nm in diameter and 8 nm in length, and a  $M_w$  of approximately 55,000 each. Microtubules assembled *in vitro* are typically composed of 12 to 14 protofilaments consisting of longitudinally connected heterodimers with a strict  $\alpha\beta$ -alternation. Neighboring heterodimers are tilted by approximately 1 nm with respect to the long axis of the microtubule resulting in a helical array of tubulin subunits. *In vitro*, microtubules can be assembled from tubulin at physiological temperature, pH, and ionic strength in the presence of the cofactors guanosine-5'-triphosphate and magnesium ions. The assembly of microtubules is reversible. At 0°C microtubules depolymerize into the heterodimers, a feature actually exploited to purify microtubule protein from porcine brain by applying several temperature-dependent centrifugation cycles. Even at the assembly–disassembly steady state where the average length of microtubules in solution is constant, microtubules are highly dynamic. They constantly polymerize and depolymerize, both *in vivo* and *in vitro*. Application of such protein assemblies as template or support for inorganic materials, however, requires a certain stability regarding the dynamic

structural properties and the exposure of the biomolecules to non-physiological conditions such as metal ion precursors or elevated temperatures. Therefore we used taxol which suppresses the dynamic instability of microtubules or glutaric dialdehyde which cross-links the tubulin subunits. Treatment with glutaric dialdehyde results in stabilized microtubules remaining intact in the presence of metal ion precursors and up to temperatures of approximately 90°C.

Microtubules are very promising as biotemplates because of their favorable geometric aspect ratio (with a thickness of 25 nm and lengths up to several micrometers) and the variety of potential metal-binding sites at their surface. Moreover, depending on the assembly conditions, tubulin is able to form not only microtubules but also various other polymorphic assemblies with different geometries, among them sheets, ribbons, spirals, or rings.<sup>[27]</sup>

### CONTROL OF METAL NANOSTRUCTURES BY MICROTUBULE SUPPORTS

It is possible to conjugate Au nanoparticles to biological components and, eventually, control their arrangement into one- to three-dimensional structures with interesting physical properties. Conjugation of Au nanoparticles to biological reporter molecules such as antibodies has long been known to be connected with electron-dense tags for biological samples in transmission electron microscopy (TEM).<sup>[28,29]</sup> Mirkin and coworkers prepared three-dimensional Au colloid aggregates revealing, for example, unusual optical<sup>[13,30]</sup> and electric<sup>[31]</sup> properties.

We examined the surface of microtubules as a template to guide the assembly of Au nanoparticles into tube-like superstructures. The Au particles could easily be connected to microtubule supports by simply incubating the Au nanoparticles with the protein assembly. By this method, the microtubule surface was densely decorated by Au nanoparticles. The particles, however, were not arranged in a geometrically regular pattern but were randomly distributed over the whole surface of the biomolecular support. Fig. 1 shows Au particles, ~5 nm in size, arranged along the backbone of a single microtubule. The conjugation of Au particles to protein surfaces may depend upon several phenomena: It is well known that Au atoms bind to proteinaceous surfaces via a covalent bond to S atoms occurring, e.g., in amino acid side chains of methionine or cysteine.<sup>[32]</sup> Cysteine or methionine residues, however, are not located in freely accessible parts of the tubulin molecule on the outside surface of a microtubule. Besides this, at pH 6.8, often used for assembly of microtubules, the surface of a microtubule (isoelectric point: pI 4.2<sup>[33]</sup>) displays a net negative charge which

**Fig. 1** Transmission electron micrograph of Au particles, 5 nm in size, bound to a single microtubule filament by simple mixing of the biostructure with the preformed Au nanoparticles (scale bar, 250 nm). The particles are randomly distributed over the microtubule surface.

should result in the repulsion of the likewise negatively charged Au particles. However, non-specific electrostatic binding could occur at domains positively charged at this pH, e.g., lysine residues which could cause a random distribution of particles over the surface of the biomolecule.<sup>[34]</sup> By another strategy, ~2-nm Au particles attached to microtubule backbones were directly nucleated in situ from  $\text{HAuCl}_4$  in the presence of microtubule templates. As a result, the microtubule surface got densely covered by small, 2.3-nm Au particles. The distribution of particles over the microtubule surface, however, was not completely random, but bore some resemblance to the helical arrangement of the tubulin subunits within the protein assembly (Fig. 2), a feature pronounced in a higher gear for nucleation of palladium on microtubules (see below; Fig. 3).

Metal properties, e.g., catalytic activity and selectivity, and optical and electric properties can be altered by combination with a second metal.<sup>[35]</sup> Bimetallic Au/Pd particles in the size range of 3 to 60 nm have been synthesized by a seed-growth mechanism and stabilized by microtubule supports: In a first step, the Au nanoparticles were linked to the protein surface and, in a second step, these Au seeds were covered with Pd by reduction of  $\text{Na}_2\text{PdCl}_4$  with trisodium citrate at 70°C.<sup>[8]</sup> The formation of the bimetallic Pd/Au

**Fig. 2** Transmission electron micrograph of a single microtubule densely covered by Au nanoparticles, 2.3 nm in size. The particles were directly nucleated in situ with sodium borohydride in the presence of the microtubule template (scale bar, 150 nm).

particles was confirmed by energy dispersive X-ray analysis (EDX). The product of a typical synthesis contained both bimetallic Pd/Au particles and a few Pd particles nucleated directly on the Au-free parts of the protein surface. Examining the catalytic activity by hydrogenation of crotonic acid as a test reaction, we found that the obtained microtubule-supported Au/Pd particles revealed a high catalytic activity under very mild reaction conditions (atmospheric pressure and 25°C) in aqueous reaction medium. Within the size range of the particles investigated (particle diameter, 3.8 to 61.8 nm), an increase in catalytic activity with decreasing particle diameter was observed.

**Fig. 3** Transmission electron micrograph of Pd particles, 3.1 nm in size, nucleated on the surface of a microtubule (scale bar, 20 nm). The particles reflect the arrangement of the helical template. *Source:* From Ref.<sup>[36]</sup>. © 2002, Wiley-VCH.

Microtubules also promote directly the in situ formation of regular nanoparticle arrays with defined patterns when coupled with an appropriate chemical reaction and, as a support, provide some stabilization of the attached particles. Small monometallic Pd nanoparticles were nucleated in situ after incubation with a Pd ion precursor.<sup>[36]</sup> After incubation, the adsorbed metal ions could be subsequently reduced to form ordered arrays of Pd nanoparticles along the backbone of the microtubule reflecting the tubulin pattern in an isomolecular fashion. Depending on the kind of reducing agent used, particles with different sizes were obtained. Reduction with trisodium citrate at 90°C yielded particles having 1.9 nm in diameter. Applying a dimethylamine reduction bath at room temperature allowed the synthesis of slightly larger Pd particles with a mean particle diameter of 3.1 nm. Fig. 3 shows Pd particles on a microtubule obtained by reduction with dimethylamine borane. The particles were mainly attached to the surface of the biotemplate resulting in densely covered microtubule filaments. High-resolution TEM revealed the crystalline character of the particles. Lattice spacings were consistent with a pure metallic palladium phase, which was further confirmed by EDX. Interestingly, the obtained Pd particle arrays resembled closely the helical arrangement of the

tubulin subunits in the protein assembly. The preferential Pd deposition on the biotemplate suggests that in this case specific molecular interactions between functional groups on the protein surface and the Pd in solution were important for the formation of the superlattice arrays. We assume that, firstly, precursor Pd (II) ions were bound to the protein surface, followed by a heterogeneous surface-controlled nucleation process, and, finally, yielding nanosized particles attached to the protein template. The surface of a microtubule consists of defined patterns of amino acid residues providing various active sites for metal ion binding and particle nucleation. The question, however, arises which of these amino acid residues are actually involved in metal ion binding and the process of particle formation. According to the hard acids and bases (HSAB) principle after Parr and Pearson, Pd<sup>II</sup> is a soft metal ion and, thus, is expected to bind to soft donor ligands such as to the N or S atoms in the side chains of tryptophan, histidine, cysteine, and methionine. Some of the amino acids, e.g., lysine and arginine, are protonated at the applied pH, so that they are excluded as donor ligands. Fig. 4A shows a schematic diagram of the  $\alpha\beta$ -tubulin as seen from the outside of a microtubule. It displays the selected amino acids tryptophan, histidine, cysteine, and methionine at the

**Fig. 4** A) Ribbon diagram of  $\alpha\beta$ -tubulin as seen from the outside of a microtubule for selected N and S containing amino acids (cysteine: red; methionine: blue, histidine: green; and tryptophan: orange). B) The solvent accessible surfaces (Connolly surface) for the whole tubulin molecule (gray) and for the selected amino acids remaining freely accessible on the outer surface after assembly into microtubules. The histidine residues ( $\alpha$ : 309, 393, and 406;  $\beta$ : 309) are centrally positioned and easily accessible. These histidine residues should be the preferred sites for Pd<sup>II</sup> binding and particle nucleation. *Source*: From Ref.<sup>[36]</sup>. © 2002, Wiley-VCH.

microtubule outside surface. Tubulin assembly into microtubules involves two types of contacts: head-to-tail binding forming the protofilaments and lateral contacts between the protofilaments. As a consequence, some of the amino acids located in the periphery of the tubulin molecule will be covered after tubulin assembly. Fig. 4B shows the solvent accessible surfaces (Connolly surface) for the remaining amino acids. Some of the shown amino acids are located in channels or only parts of them are exposed to the surface of the molecule. As a result, only four histidine residues are actually centrally positioned on both  $\alpha$ - and  $\beta$ -tubulin at the microtubule's outer surface, and should be freely accessible. We therefore suggest that these histidine residues are potential sites for the binding of Pd ions and Pd particle nucleation. In fact, histidine is a typical metal-binding residue in peptides due to the deprotonated N3 atom in the imidazole ring.<sup>[37–39]</sup> By varying, the experimental conditions it was possible to control the Pd coating of the template. If the reservoir of metal ions present was increased, the Pd clusters on the template grew and were further connected to generate a quasi-continuous coverage of the microtubule surface with palladium aggregates.

The assumption that these metal clusters were heterogeneously grown in situ, after binding of Pd(II) ions selectively at the histidine sites, was supported by theoretical simulations of Ciacchi and coworkers.<sup>[40]</sup> They investigated the heterogeneous nucleation of Pt clusters on DNA and proteins by means of first principles molecular dynamics simulations. They found that Pt dimers formed from a Pt<sup>II</sup> complex, covalently bound to a biopolymer, and a free Pt<sup>II</sup> complex after a single reduction step. The imidazole ring, which is a structural feature of both histidine and the purine bases guanine and adenine, was a key residue at the biopolymer surface to induce the formation of these platinum dimers. The formation of Pt dimers was only possible in the presence of strong donor ligands such as purine DNA bases or histidine amino acids, and appeared to be forbidden in the homogeneous dimer formation reaction leading to a weaker Pt–Pt bond. Because of the delocalized electronic states on the heterocyclic ligands, the biopolymer-bound Pt atoms and dimers accepted reducing electrons more easily than the free complexes or dimers in solution and, moreover, the initially formed Pt–Pt bonds were stabilized. Thus the presence of these ligand systems contributed to enhancing the reaction rate of the heterogeneous cluster nucleation channel. The first-formed Pt nuclei developed then into bigger particles consuming the feedstock of metal complexes in solution and hindering the homogeneous formation of metal particles. As a result, the kinetics of the reduction and deposition process was locally enhanced at the surface of the biopolymer. Thus such a preferential heterogeneous

particle growth on an activated biotemplate permits a certain degree of control over the metallization process.

In addition to Au and Pd, other noble metals such as Rh, Ru, and Ag have been used in material synthesis with this type of microtubule template. Fig. 4 displays small Rh nanoparticles on a microtubule obtained by in situ reduction with NaN<sub>3</sub>. For electroless metal plating with Ni or Co, the surface of the template had to be previously activated with noble metal atoms or clusters. Kirsch and coworkers deposited about 10-nm-thick Ni or Co coats on microtubule templates, which yielded magnetic nanowires with an outer diameter of 50 to 60 nm.<sup>[24,25]</sup> In a first step, the microtubule surface was activated by adsorption of a molecular Pd catalyst. In a second step, Ni or Co was deposited onto the activated microtubules by applying an electroless metallization bath with dimethylamine borane as reducing agent. In their experiments they found clear evidence that nucleation of Ni crystallites started exclusively at the catalytic surface of the Pd catalyst.

## CONCLUSION

The interdisciplinary field emerging between biotechnology and materials science for the production of nanoscale materials is a rapidly growing field. Our results illustrate the potential of protein assemblies as biological components with their unique chemical and topological features for the controlled deposition of metals into well-defined, protein-supported nanostructures. In the interplay, the biological and inorganic components provide structure-directing properties and, furthermore, the biological support stabilizes the resulting nanostructure. Au colloids, for example, have been pursued as building blocks for the formation of wire-like structures through manipulation by microtubule templates. When coupled with an appropriate chemical reaction, microtubules promote the in situ formation of ordered arrays of metal nanoparticles resembling the arrangement of the protein molecules within the assembly. Preferential heterogeneous particle growth on the biotemplate permits control over the metallization process on the nanometer scale. Depending on the reaction conditions, the composites formed range from the isomolecular decoration of every protein molecule with one nanoparticle to the complete coating of the whole protein assembly. Although many examples exist where metallic nanoparticles and materials have successfully been deposited on biomolecules,<sup>[10,11]</sup> there still remains a great demand for new, mild, and selective chemical deposition techniques. One of the major advantages associated with this type of protein assemblies as biological template is that it will enable the future design

of various patterns of nanomaterials, e.g., ring structures exploiting the great diversity in size and shape of biomolecular tools, e.g., the polymorphic tubulin assemblies. A variety of technical obstacles still have to be solved ranging from the currently limited availability of large amounts of the biological building blocks to the improvement of analytical techniques. Because of the very low amount of material used in single nanodevices, the costs of the protein components should normally not limit application. A decrease in production costs will be required, however, for scale-up of both purification techniques and artificial syntheses. Biomolecular structures modified by genetic engineering and combined with an appropriate metal deposition technique will allow producing advanced materials on the nanometer scale with, for example, novel electronic, optical, magnetic, or catalytic properties.

# Nanostructured Materials: Synthesis by Mechanical Attrition

Carl C. Koch

*Department of Materials Science and Engineering, North Carolina State University,  
Raleigh, North Carolina, U.S.A.*

## INTRODUCTION

A wide variety of techniques are being used to synthesize nanostructured materials including inert gas condensation, rapid solidification, electrodeposition, sputtering, crystallization of amorphous phases, and chemical processing.<sup>[1]</sup> Mechanical attrition—ball milling of powders—is a technique that has also been used widely for preparation of nanostructured materials.<sup>[2,3]</sup> The term “mechanical attrition” can be subdivided into “mechanical milling,” which is the milling of single composition powders, often elements, and “mechanical alloying,” which involves milling of dissimilar powders such that material transfer occurs during milling. Unlike many of the methods for synthesis of nanostructured materials, mechanical attrition produces its nanostructures not by cluster assembly, but by the structural decomposition of coarser-grained structures as the result of severe plastic deformation. This has become a popular method to fabricate nanocrystalline materials because of several factors: the simplicity of the process, the relatively inexpensive equipment (on the laboratory scale) needed, and the applicability to essentially all classes of materials. A major advantage of mechanical attrition is the possibility for easily scaling up to tonnage quantities of material for various applications. The disadvantages that are often cited are contamination from the milling media and/or atmosphere, and the need, for many applications, to consolidate the powder product without coarsening the nanocrystalline microstructure.

A number of reviews concerned with the synthesis of nanostructured materials by mechanical attrition have been published in recent years, e.g., those of Koch,<sup>[2,4]</sup> Fecht,<sup>[5]</sup> Suryanarayana and Koch,<sup>[1]</sup> and Fecht.<sup>[3]</sup> This article will serve to update these previous reports. The details of the mechanical attrition processes, equipment used, etc. has been covered in a number of reviews (e.g., Ref.<sup>[4]</sup>), and will not be repeated here. The phenomenology of the development of nanoscale microstructures by mechanical attrition will be reviewed for the various classes of materials including single-phase metals, metallic alloys, brittle materials, and multiphase materials. Several mechanisms proposed for the development of a nanoscale

microstructure will then be described with reference to recent experimental observations. Finally, a brief discussion of the problems associated with mechanical attrition as a processing method will be presented. These are powder contamination and the need to consolidate the powders into bulk form without coarsening the nanoscale microstructure.

## PHENOMENOLOGY—EXPERIMENTAL OBSERVATIONS

### Single-Phase Elements—Mechanical Milling

Mechanical attrition has been found to refine grain size of all solid elements studied to the nanoscale. However, the minimum grain size achieved is dependent on a number of process variables as well as properties of the element. The minimum grain size obtainable by milling has been attributed to a balance between the defect/dislocation structure introduced by the plastic deformation of milling and its recovery by thermal processes.<sup>[6]</sup> It has been found that the minimum grain size induced by milling scales inversely with the melting temperature of the group of fcc structure metals studied.<sup>[6]</sup> These data are plotted in Fig. 1, along with data for other metals and carbon (graphite).<sup>[2]</sup> For these data, only the lower melting point metals show a clear inverse dependence of minimum grain size on melting temperature. The minimum grain size for elements with higher melting temperatures (larger than melting temperature for Ni) exhibits essentially constant values with melting temperature for given crystal structure classes. For these elements, it appears that  $d_{\min}$  is in the order: fcc < bcc < hcp. However, before explanations for the above based on the strain hardening response, twinning, or other fundamental differences in deformation behavior for the various metallic crystal structures can be considered, it should be pointed out that a number of variables can influence the values of the minimum grain size attained by ball milling. First of all, most of the measurements reported in Fig. 1 are based on the analysis of X-ray line broadening measurements. It is now well established that such measurements are subject to difficulty in terms of

**Fig. 1** Minimum nanocrystalline grain size for ball milled elements vs. their melting temperature. *Source:* From Refs.<sup>[2,6–8]</sup>.

absolute quantitative values for grain sizes. Variability among analysis techniques for X-ray line broadening, as well as comparisons between these X-ray line broadening results and those from transmission electron microscopy (TEM) measurements, can be significant. However, most of the data in Fig. 1 are obtained from the Cal Tech group, Professor W. L. Johnson and coworkers,<sup>[6,7]</sup> or from Oleszak and Shingu.<sup>[8]</sup> Both of these groups used the approach of Williamson and Hall<sup>[9]</sup> to estimate the crystallite size and root-mean-square (rms) strain from the X-ray line broadening. Although the mill energies and contamination levels were very different in these studies, remarkable agreement for minimum grain size,  $d$ , is found for Al, Cu, Ni, and Fe. Oleszak and Shingu<sup>[8]</sup> found a lower  $d$  value for W (5.5 nm) than the value (9 nm) obtained by Fecht et al.<sup>[7]</sup> The Cal Tech group used a high-energy shaker mill (Spex 8000), while Oleszak and Shingu used a conventional horizontal low-energy ball mill. The metallic impurity level (Fe) from the shaker mill is much larger ( $\sim 2$  at.% Fe) than that from the conventional ball mill ( $< 0.1\%$  Fe). Conversely, the reported oxygen concentrations were about 4 times higher for powders milled in the conventional mill than for those from the shaker mill. The observation that the minimum nanocrystalline grain sizes for a number of elements milled in a low-energy mill are comparable to those milled in a high-energy mill is contrary to the conclusions previously reported after milling TiNi in a high-energy Spex shaker mill and a lower-energy vibratory mill.<sup>[10]</sup> After about 10 h in the Spex mill, the grain size (determined by both TEM and X-ray line broadening analysis) decreased to about 4–5 nm. At longer milling times, an amorphous structure was observed. Milling for 100 h in the vibratory mill resulted in a grain size of about 15 nm. It was originally assumed that this value represented a saturation to the minimum grain size obtainable in the lower energy mill.

However, in the light of the work of Oleszak and Shingu, it is likely that the  $d_{\min}$  was not obtained at 100 h in the lower-energy mill, and that continued milling may have further reduced the grain size. These results suggest that total strain, rather than milling energy or ball–powder–ball collision frequency, is responsible for determining the minimum nanocrystalline grain size. This is different from ball milling-induced amorphization or disordering, where it appears that the energy and frequency of ball–powder–ball collisions determine the final structures formed in “driven systems.” However, it is consistent with observations of nanocrystallites formed by high strain values using other non-cyclic deformation methods.<sup>[11]</sup> These results suggest that mill energy per se is not critical to the final microstructure, although, naturally, the kinetics of the process are dependent on the energy, and times for attaining the same microstructure can be several orders of magnitude longer in the low-energy mills than in high-energy mills.

Milling temperature has been observed to affect the rate at which the nanocrystalline structure develops. The milling time at which a given grain size was attained in a TiNi intermetallic compound was a function of milling temperature.<sup>[10]</sup> In this case, amorphization occurred at a “critical” grain size of about 4–5 nm, thus the final nanocrystalline grain size at each milling temperature could not be determined. Shen and Koch<sup>[12]</sup> also observed smaller nanocrystalline grain sizes in both Cu and Ni milled at  $-85^{\circ}\text{C}$  compared with samples milled at room temperature. For example, for Cu,  $d = 26 \pm 3$  nm for room temperature milling and  $d = 17 \pm 2$  nm for milling at  $-85^{\circ}\text{C}$ . Evidence for smaller nanocrystalline grain sizes formed by milling at low temperatures have now been observed in a number of materials including the intermetallic compound  $\text{CoZr}$ <sup>[13]</sup> and elemental Zn.<sup>[14]</sup>

### Metallic Alloys—Mechanical Alloying

While the majority of studies of nanocrystalline materials synthesized by ball milling have been on single-composition materials—i.e., either elemental metals, intermetallic compounds, or metal alloys—there have been a number of studies on mechanical alloying of dissimilar powders that result in nanoscale microstructures. First, the alloy effect on nanocrystalline grain size on nanocrystalline alloys will be discussed. These include both alloys made by mechanical alloying of dissimilar powders or milling of alloy powders. It has been suggested that the ultimate grain size achievable by milling is determined by the minimum grain size that can sustain a dislocation pileup within a grain and by the rate of recovery

during milling.<sup>[6]</sup> To estimate the composition dependence of grain size after milling, one may use the formula suggested by Nieh and Wadsworth.<sup>[15]</sup> The minimum distance,  $L$ , between dislocations is given by  $L = 3Gb/\pi(1 - \nu)h$ , where  $G$  is shear modulus,  $b$  is Burgers vector,  $\nu$  is Poisson ratio, and  $h$  is hardness. Indeed, if this is related to the formation of a minimum nanocrystalline grain size, then this nanocrystalline grain size is inversely proportional to hardness, and therefore, in most cases, to composition. In fact, a decreasing nanocrystalline grain size with solute concentration is observed in nanocrystalline alloy systems exhibiting solid solution hardening, such as Cu (Fe), Ti (Cu), Nb (Cu), Cu (Ni), and Cu (Co).<sup>[16]</sup> Also consistent with this is the essentially constant nanocrystalline grain size in Ni (Co), where hardness does not change significantly with composition<sup>[12]</sup> and the increased grain size in nanocrystalline Ni (Cu), Fe (Cu), and Cr (Cu), which exhibit an apparent solid solution softening effect.<sup>[16]</sup> However, the influence of alloying elements on the hardness of the nanocrystalline solid solutions is different from that in conventional polycrystalline solid solutions. The hardness of nanocrystalline solid solutions depends on both solid solution hardening and grain boundary hardening, while the latter makes the major contribution to total hardness. The increase in hardness resulting from the solid solution hardness effect in nanocrystalline alloys is of the same magnitude as that in conventional grain size polycrystalline alloys. However, the addition of alloying elements into the matrix for nanocrystalline alloys may have a strong influence on the grain boundary energy and grain boundary diffusion coefficient and thus on the deformation and recovery mechanisms of the nanocrystalline alloys formed by mechanical attrition. The different deformation and recovery behaviors are responsible for the various grain sizes obtained by milling and thus for the decreased or increased grain boundary hardening effects for the various nanocrystalline solid solutions.

Nanocrystalline grains are observed during the mechanical alloying of dissimilar component powders. Klassen, Oehring, and Bormann<sup>[17]</sup> followed the phase formation and microstructural development during the mechanical alloying of Ti and Al powder blends of overall composition  $Ti_{25}Al_{75}$ . TEM revealed nanocrystalline grains of partially ordered  $L1_2$  phase with a crystallite size of 10–30 nm in the alloy layers at the interface between the pure Ti and Al lamellae at the very early stages of the milling process. The alloy phase that develops between the pure powder components consists of nanocrystalline grains, presumably because of the multiple nucleation events and the slow growth occurring at the relatively low temperatures (100–200°C above ambient) during milling. Trudeau et al.<sup>[18]</sup>

**Fig. 2** Crystallite size for FeTi intermetallic phase for low-energy (●) mechanical alloying of Fe and Ti powders, and (▲) mechanical milling of the FeTi compound powders. Source: From Ref.<sup>[18]</sup>.

prepared nanocrystalline FeTi by both low milling energy mechanical alloying (MA) of elemental Fe and Ti powders and mechanical milling (MM) of FeTi compound powders. Higher mill energies resulted in amorphization. The grain size of the MM Fe/Ti steadily decreases with milling time, while that for the MA Fe/Ti initially increases and then decreases to values essentially identical to those for the milled samples. This effect is illustrated in Fig. 2.

### Brittle Materials

The first materials subjected to mechanical alloying were combinations of ductile metals and brittle oxide powders, or with both components ductile metals. It was not clear that, if both components were brittle, the welding of the dissimilar powders believed to be required for the alloying to occur would take place. It might be expected that brittle components would simply fracture during milling and be reduced in size to the limit of comminution observed in the grinding of brittle mineral powders. However, it has been found that ball milling of nominally brittle materials can lead to alloying of brittle components, e.g., Si and Ge,<sup>[19]</sup> and the introduction of significant plastic deformation and high dislocation densities in brittle compounds, e.g.,  $Nb_3Sn$ .<sup>[20]</sup> Si and Ge are completely brittle at room temperature, and yet complete solid solutions of Si–Ge alloys were obtained across the binary phase diagram. Thus alloying on the atomic scale was observed by mechanical alloying of brittle components.  $Nb_3Sn$  is an extremely brittle intermetallic compound that elastically fractures until tested at temperatures

above about 1400°C. However, ball milling Nb<sub>3</sub>Sn can produce large amounts of plastic deformation, as observed by TEM of the milled powder. The dislocations so produced then induce a nanocrystalline grain structure similar to that formed in milled ductile metals. It is not yet clear how ball milling can produce large plastic deformation in materials that are very brittle under uniaxial stress conditions. It is suggested that the high hydrostatic stress component, which may exist in the powders during milling, can favor plastic deformation over fracture and allow a large dislocation density to be generated.<sup>[20]</sup> Mechanical attrition was also found to induce nanocrystalline microstructures in brittle ceramics, such as ZrO<sub>2</sub>, and ceramic powder mixtures, such as Fe<sub>2</sub>O<sub>3</sub>/Cr<sub>2</sub>O<sub>3</sub> and ZrO<sub>2</sub>/Y<sub>2</sub>O<sub>3</sub>.<sup>[3]</sup>

### Polymer Blends

The application of mechanical attrition to polymeric materials was initiated by Shaw.<sup>[21]</sup> To fracture the polymer particulates, and on the microscopic level the polymer chains, milling was conducted at temperatures below the glass transition temperature of the given polymer. Shaw's group has studied a number of homopolymers such as polyamide, polyethylene, acrylonitrile-butadiene-styrene, polypropylene, and polystyrene. Refinement of the microstructure typically occurred and milling-induced structural and property changes were noted that were very material-specific. Subsequently, others have studied milling-induced changes in the structure of several semicrystalline and amorphous homopolymers.<sup>[22]</sup> For example, in poly(ethylene terephthalate) (PET), milling promotes an oriented amorphous morphology in both high- and low-crystallinity PET. Molecular weight, glass transition temperature, and impact strength have been used to probe the milling-time-dependent molecular and property evolution of several homopolymers, e.g., poly(methylmethacrylate) (PMMA) and polyisoprene (PI). Milling of PMMA resulted in monotonic decreases in molecular weight and glass transition temperature, reflecting the milling-induced scission of the polymer chains. PI exhibited much different behavior in that the decrease in glass transition temperature,  $T_g$ , given by  $\Delta T_g = T_{g,0} - T_g(t_m)$ , where  $T_{g,0}$  is the glass transition temperature of the unmilled polymer, first increased and then decreased, as illustrated in Fig. 3. In this case, cryomilled PI does not exhibit a monotonic increase in  $\Delta T_g$ , but instead shows a sharp maximum at relatively short milling times (2 h), followed by a drop to almost zero before again increasing slightly for longer milling times. This unusual, but reproducible, behavior strongly suggests that the PI chains undergo chemical crosslinking during

Fig. 3 Dependence of  $\Delta T_g$  on milling time,  $t_m$ , for cryomilled polyisoprene. Source: From Ref.<sup>[22]</sup>.

cryomilling. In such a case, we imagine a dynamic competition between chains breaking (causing a decrease in molecular weight) and crosslinking (promoting an increase in molecular weight) under the non-equilibrium conditions of milling. Sol-gel analysis and Fourier transform infrared (FTIR) spectroscopy yielded further evidence for milling-induced crosslinking in PI. Mechanical attrition was also performed at cryogenic temperatures to incorporate PI into PMMA.<sup>[23]</sup> A number of experimental techniques were used to study the structure of these normally immiscible polymer mixtures. TEM clearly showed that the solid-state blending by mechanical attrition of polymeric materials can yield nanoscale dispersions of immiscible polymers. The strong evidence for free radical formation and crosslinking induced by milling suggests many possibilities for the design of novel new polymeric materials with nanoscale microstructures. Incorporation of inorganic dispersoids in polymeric materials at the nanoscale by mechanical attrition is an area of research not yet fully explored.

### Nanocomposites

Nanoscale precipitates or dispersoids used to strengthen structural materials have been commonly used for about a century. However, the combination of nanoscale second phases in a nanocrystalline matrix are new microstructures and mechanical attrition is a particularly suited synthesis method for such materials. Because equilibrium solid solubility limits can be significantly enhanced by mechanical attrition of systems of limited mutable solubilities<sup>[24]</sup> to form nanocomposites, the immiscible nature of the component phases must be strong. Metals with very different atomic sizes

such as Pb and Al can form nanocomposites<sup>[25]</sup> as well as covalently or ionic bonded compounds in metallic matrices, such as  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and AlN in Fe.<sup>[26]</sup>

Metalloid second phases in nanocrystalline grain size matrices have been produced via the method of cryomilling. This technique of reactive milling of metals in liquid nitrogen was first developed by Huang, Vallone, and Luton<sup>[27]</sup> for Al, and has since been applied to several other metallic materials. The cryomilling of elemental Al and Ni powders in liquid nitrogen resulted in a nanoscale grain size for the Ni-base matrix of about 6 to 11 nm. Continued cryomilling in nitrogen resulted in a reaction between N, O, and the Al, which depleted the Al content of the matrix until, at long cryomilling times (170 h), the structure consisted of nanocrystalline Ni with AlN and  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> nanoscale dispersions. Similar to the results they obtained from their work on Al, the presence of the nanoscale dispersoids resulted in a marked inhibition of grain growth even on annealing at high temperatures. The Ni-based nanocrystalline grain size containing the nitride and oxide dispersoids maintained a nanoscale grain structure with limited grain growth (grain size distribution of mostly about 11 nm, with some grains up to 300 nm) after annealing at 1373 K. The same material milled in argon was found to have extensive grain growth to about 1  $\mu$ m grain size after annealing at this temperature. These results demonstrated the effectiveness of nanoscale second phases in a nanoscale matrix to impede grain growth.

## MECHANISMS FOR NANOCRYSTAL SYNTHESIS BY MECHANICAL ATTRITION

### Single-Phase Metals by Mechanical Attrition

The first description of the evolution of a nanoscale grain structure during mechanical milling of elemental metals was given by Fecht and coworkers and summarized, for example, in Ref.<sup>[5]</sup> The basis of this first model was a study of the nanocrystallization of AlRu and Ru by mechanical attrition.<sup>[28]</sup> The structure/microstructure of AlRu as a function of milling time was followed by analysis of X-ray line broadening to estimate average grain size and lattice strain and TEM and high-resolution TEM (HRTEM) to directly observe the microstructural development. The TEM and HRTEM studies showed that, at the early stages of milling, the deformation was localized within shear bands that are approximately 0.5–1  $\mu$ m wide. The shear bands contain a high dislocation density. At a given strain, these dislocations begin to annihilate and recombine to small-angle grain boundaries separating individual cells or grains. Small grains, 8–12 nm in diameter, observed within the shear bands and electron

diffraction patterns suggest that the misorientation angles between the grains are relatively small. At longer milling times, the grain size steadily decreased, consistent with the X-ray results, and the shear bands coalesced. The small-angle boundaries were replaced by higher-angle boundaries, implying grain rotation, as reflected by the disappearance of texture in the electron diffraction patterns, as well as the random orientation of the grains observed from the lattice fringes in HRTEM. Fecht summarized the observed phenomenology of nanocrystallization by mechanical attrition into the following three stages:

- Stage 1. Deformation localization in shear bands containing a high dislocation density.
- Stage 2. Dislocation annihilation/recombination/rearrangement to form a cell/subgrain structure with nanoscale dimensions—further milling extends this structure throughout the sample.
- Stage 3. The orientation of the grains becomes random, that is, low angle grain boundaries disappear as high angle grain boundaries replace them, by presumably grain boundary sliding, rotation.

From evidence of the atomic-level lattice strain and the stored enthalpy as a function of reciprocal grain size (or milling time), it was concluded that two different regimes can be distinguished, i.e., dislocation vs. grain boundary deformation mechanisms.<sup>[5]</sup> The lattice strain in the fcc elements studied by Eckert et al.,<sup>[6]</sup> milled in a high-energy shaker mill, was found to increase continuously with decreasing grain size, and reach a maximum value at the smallest grain size. This is in contrast to the earlier observation on Ru and AlRu, which indicated a maximum in strain vs.  $1/d$ ,<sup>[29]</sup> and the more recent study of Oleszak and Shingu<sup>[8]</sup> on a low-energy mill, which also shows a broad maximum in strain vs.  $1/d$  for a number of elements including several fcc elements. The lattice strain values available from the literature are plotted against reciprocal grain size,  $1/d$ , in Fig. 4. With the exception of Ru, the data increased lattice strain with  $1/d$  appear to fall on a common relatively narrow band before decreasing from the maximum strain values. However, these data are obtained from several groups using mills with various energy levels and possible differences in milling temperature. It has been demonstrated<sup>[12]</sup> that lower milling temperature resulted in larger values for lattice strain for Cu and Ni. However, the data from the low-energy mill<sup>[8]</sup> should be self-consistent and exhibit interesting behavior. That is, the strain rises with decreasing grain size, reaches a maximum, and then decreases to low values for the smallest nanocrystalline grain sizes. A maximum in strain with  $1/d$  was previously explained by either a change in deformation mechanism from dislocation generation and

Fig. 4 Lattice strain vs. reciprocal grain size. Source: From Ref.<sup>[2]</sup>.

movement to grain boundary sliding, grain rotation,<sup>[28]</sup> or, in brittle intermetallics to fracture after the strain maximum is reached.<sup>[18]</sup> A problem with the first mechanism is that the nanocrystalline grain size continues to decrease after the strain maximum is reached, and grain boundary sliding and rotation presumably cannot result in grain size reduction. There is no clear evidence at present in the elements for the fracture mechanism, which would also presumably result in a finer particulate distribution.

Additional information to help explain the mechanism of nanocrystalline formation comes from measurements of stored enthalpy. Maxima in stored enthalpy vs.  $1/d$  are typically observed.<sup>[6,8,29]</sup> However, the maximum in stored enthalpy is often found at smaller grain sizes than the strain maximum, as illustrated in Fig. 5 for W.<sup>[8]</sup> Here the maximum in strain occurs at  $d = 8.3$  nm, while the maximum in stored enthalpy is at  $d = 5.5$  nm. Several suggestions have been offered to explain the maxima in stored enthalpy with  $1/d$ , including decreasing strain<sup>[8,29]</sup> or impurity pickup during milling.<sup>[29]</sup> The latter is an unlikely explanation for samples obtained by low-energy milling,<sup>[8]</sup> where metallic impurity contamination is negligible. It is stated that the stored enthalpy comes mainly from grain boundaries<sup>[28,29]</sup> and grain boundary strains. Stress relaxation may be responsible for the maxima,<sup>[8]</sup> but, as noted above, the strain and stored enthalpy maxima do not necessarily coincide.

While the general concepts described above for synthesis of elemental metal nanocrystalline structures by mechanical attrition are likely to have some validity,

Fig. 5 Stored enthalpy ( $\Delta H$ ) and lattice strain ( $\epsilon$ ) vs. reciprocal grain size for W. Source: From Refs.<sup>[2,8]</sup>.

questions still remain especially regarding the maxima in lattice strain and stored enthalpy, and the mechanism of grain refinement. Several recent experimental studies as well as suggested alternate mechanisms will now be discussed.

Recent studies of the synthesis of nanocrystalline Zn by milling at liquid nitrogen temperatures (cryomilling) have provided evidence for an alternate mechanism for making nanoscale grains.<sup>[30,31]</sup> In most previous studies, the progress of nanocrystallization as a function of milling time was followed by X-ray diffraction line broadening analysis, which gives an average grain size. The grain size so determined typically exhibits monotonically decreasing values with milling time. This is also the case for cryomilled Zn, as illustrated in Fig. 6. This average grain size decreases rapidly for the early milling times, and then saturates to a value of about 20 nm for the longer times.

Fig. 6 Average grain size for cryomilled Zn vs. milling time. Source: From Ref.<sup>[30]</sup>.

with milling time, an extensive study using TEM was carried out.<sup>[30]</sup> It was surprising to observe a large fraction of very small grain sizes (less than 5 nm) even in the very early stages (e.g., 0.5 h) of cryomilling. The grain size distribution was found to be essentially bimodal for the shorter milling times, as shown in Fig. 7A and a for 0.5 h of milling, and then collapsed to one peak at longer milling times, and finally narrowed to a tighter distribution at the longest times, as seen in Fig. 7E and e for a milling time of 12 h. These distributions were determined from dark-field TEM micrographs, as shown in Fig. 8A and B for the samples milled 0.5 and 12 h, respectively. From Figs. 7 and 8, it is observed that at short milling times,

**Fig. 7** The number fraction and volume fraction of grain size at cryomilling times: 30 min (A, a) and 12 h (E, e). *Source:* From Ref.<sup>[30]</sup>.

**Fig. 8** (A) TEM dark field image for Zn cryomilled for 30 min. (B) TEM dark field image for Zn cryomilled for 12 h. *Source:* From Ref.<sup>[30]</sup>.

grains of about 250 nm size exist together with small grains of less than 10 nm. It was suggested that the very small grains formed at the early milling times might have been caused by a dynamic recrystallization (DRX) phenomenon. Dynamic recrystallization refers to the occurrence of crystallization during deformation. The mechanisms and transformation kinetics for both static and dynamic recrystallization have been reviewed by Doherty et al.<sup>[32]</sup> It appears that DRX can occur as a nucleation and growth process, or as a recovery process. Many issues related to the transformation kinetics for DRX remain unresolved, and the underlying mechanisms are not well understood. However, it is assumed that the high dislocation densities possible by deformation at low temperatures and the nucleation sites probably provided by shear banding are consistent with cryogenic temperature milling of, e.g., Zn, in the high strain, high strain rate deformation which occurs. Evidence for the possibility of dynamic

**Fig. 9** Hardness vs. milling time for Zn milled at 100 K (solid circles) and at room temperature (solid triangles). The relative densities for the cryomilled samples are indicated by open squares. *Source:* From Ref.<sup>[33]</sup>.

recrystallization playing a role in the synthesis of nanocrystalline grain sizes in metals is dramatically observed in the oscillatory hardness behavior with cryomilling time in Zn.<sup>[33]</sup> This oscillatory hardness behavior is illustrated in Fig. 9. The dramatic oscillatory hardness changes with milling times at cryogenic temperatures are not reflected in the hardness data for samples milled at room temperature. They are also not related to any artifact, such as porosity, as shown by the essentially constant, and nearly theoretical, density of the samples. Transmission electron microscopy showed that large variations in the dislocation density and grain-size distribution occurred during cryomilling. The observations suggest that dynamic recrystallization takes place in larger grains (>50 nm), when the dislocation density due to strain hardening reaches a critical level to nucleate DRX. A reaction-rate model was developed which accounts for the DRX effect and the observed oscillations in hardness. Good agreement was obtained with the experimental data. These results imply that in special circumstances, i.e., where conditions are right to nucleate DRX, the dynamic recrystallization reaction may also contribute to the synthesis of a nanoscale grain microstructure. In analogy to “continuous recrystallization,”<sup>[32]</sup> the mechanism proposed by Fecht and coworkers, in which dislocation structures continuously rearrange themselves during deformation in a recovery-like fashion that ends in high-angle boundaries, nanocrystalline grains, can sometimes be also formed by a “discontinuous” DRX process.

He and Lavernia<sup>[34]</sup> offered an alternative explanation for the synthesis of nanoscale microstructures

in cryomilled Inconel 625 alloy. This Ni-base alloy was milled in liquid nitrogen to form a nanocrystalline grain structure. TEM observations indicated that grains in the cryomilled powder were deformed into elongated grains containing a high density of deformation faults. With continued milling, the elongated grains fractured into small nanoscale fragments. The occurrence of the elongated grains and their subsequent fragmentation were attributed to repeated strain fatigue and fracture caused by the cyclic impact loading in random directions, along with cold welding. A high density of mechanical nanoscale twins was also observed.

While most of the studies on the development of nanocrystalline grain structures by mechanical attrition have involved observing the microstructure as a function of milling time, and presumably, total average strain, Tao et al.<sup>[35]</sup> recently investigated the microstructure of a pure Fe plate that had been subjected to surface mechanical attrition. In this case, the milling balls were impacted on the surface of the Fe plate by vibratory motion, such that the surface layer was subjected to high-strain-rate plastic deformation. The degree of plastic deformation was highest at the surface of the plate and decreased, eventually to zero, as distance from the surface into the plate increased. The structure and microstructure of the deformed Fe was then studied by X-ray diffraction line broadening analysis as the plate was progressively etched, layer by layer, and by scanning electron microscopy (SEM), TEM, and HRTEM observations of the cross sections of the surface layers. X-ray diffraction results showed that the grain size was a minimum at the surface and increased with depth, while the microstrain was a maximum at the surface and dropped to about zero at a depth of 60  $\mu\text{m}$ . From the electron microscopy, the surface-treated layer could be subdivided into several sections in terms of grain (or cell) size. From the top surface these were:

- Section 1. Nanostructured regime:  $\sim 0\text{--}15\ \mu\text{m}$ ;
- Section 2. Submicron-sized regime:  $\sim 15\text{--}40\ \mu\text{m}$ ;
- Section 3. Micron-sized regime:  $\sim 40\text{--}60\ \mu\text{m}$ .

Beyond a depth of 60  $\mu\text{m}$ , the original Fe matrix showed some evidence of plastic deformation but no grain refinement. At the regions adjacent to the strain-free matrix, homogeneously distributed dislocation lines are observed, and the dislocation density increases as the distance from the surface decreases. In addition, dense dislocation walls (DDWs) are observed, with spacing in the micron range and parallel to each other along  $\{110\}$  planes. Dislocation tangles are also observed and in some regions the dislocation density is high. With decreasing depth, into Section 3, most original grains are subdivided into micron-sized

cells, which are either roughly equiaxed or lamellar. The misorientation of these cells of DDWs are small, typically less than  $1^\circ$ . At still smaller depths, that is in Section 2, the cell sizes are found to decrease with elongated cells several microns long and about 200–400 nm thick. Some equiaxed cells are also seen that are  $\sim 200$ – $500$  nm in size. Finally, near the surface, where the deformation strain and strain rates are maximum, nanocrystalline microstructures are observed. Equiaxed nanocrystalline grains are observed near the surface, while at the bottom of Section 1, lamellar nanoscale grains are observed. However, inside the lamellar grains, smaller equiaxed grains are also present. Based on these extensive microstructural observations, the sequence of nanocrystalline formation was summarized as follows. Formation of DDWs and dislocation tangles (DTs) first occur, then the DDWs and DTs transform into subboundaries with small misorientations. Finally, the subboundaries and subgrains evolve into nanocrystalline grains with large misorientation angles between them. It was suggested that, for the synthesis of nanocrystalline grains during plastic deformation, high strain rates were necessary as well as large strains. This suggestion is consistent with observations of plastic-deformation-induced grain refinement at high strains, while lower strain rates such as equal channel angular pressing or cold rolling typically produce grain sizes no smaller than about 100–200 nm. However, it may be at variance with the results of low-energy milling experiment, where similar minimum grain sizes have been observed to those produced by high-energy milling.<sup>[8]</sup> More studies along the lines of the above are needed to clarify the mechanism for synthesis of nanocrystalline metals by mechanical attrition.

### Nanocrystallization Mechanisms for Milling of Dissimilar Elements

The proposed mechanism for nanocrystallization on milling of dissimilar elements that form an intermediate phase, e.g., TiAl from Ti and Al powders,<sup>[17]</sup> was the biasing of nucleation vs. growth of the new phase at the relatively low temperatures of milling, as described earlier in this paper. However, milling of dissimilar metals that do not form intermediate phases can also form nanoscale microstructures and the mechanism must be different. Zghal et al.<sup>[36]</sup> reported the results of milling the normally immiscible Cu–Ag and Ni–Ag systems. The Cu–Ag microstructure after milling at lower temperatures exhibits a pronounced texture and a complex microstructure. Milling at higher temperature produced small equiaxed nanoscale grains, which were the result of dynamic recrystallization. In the case of Ni–Ag, which has a larger positive

heat of mixing than Cu–Ag, complete mixing was not possible, and a nanocomposite was formed. It was suggested that, as texture was not observed in the Ni-rich phase, which featured smaller grain size (5–10 nm), full mixing of the components cannot take place because of the differences in their mechanical properties.

More studies are needed to clarify the diverse possible mechanisms for nanocrystallization by mechanical attrition of dissimilar powders.

### PROBLEMS: CONTAMINATION AND POWDER CONSOLIDATION

A serious problem with the milling of fine powders is the potential for significant contamination from the milling media (balls and vial) or atmosphere. If steel balls and containers are used, iron contamination can be a problem. It poses a most serious risk for the highly energetic mills, e.g., the Spex shaker mill, and depends on the mechanical behavior of the powder being milled, as well as its chemical affinity for the milling media. For example, milling Ni to attain the minimum grain size in a Spex mill resulted in Fe contamination of 13 at.%, while the Fe contamination in nanocrystalline Cu similarly milled was only  $\leq 1$  at.%.<sup>[16]</sup> Lower-energy mills result in substantially less, often negligible, Fe contamination. Other milling media, such as tungsten carbide or ceramics, can be used, but contamination from such media is also possible. Interstitial element (oxygen, nitrogen) contamination can be controlled by milling and subsequent powder handling in a pure inert gas atmosphere, with care taken that the milling vial is leak-free during processing.

Powder consolidation to theoretical density of nanocrystalline materials prepared by mechanical attrition without significant coarsening is necessary for many property measurements, e.g., mechanical behavior, and for applications requiring bulk materials. There is no room in this paper to adequately review the escalating efforts in this important field. However, a number of successes have been documented by both conventional and innovative methods and are reviewed by Groza.<sup>[37]</sup> For the special case of very ductile, relatively low melting temperature metals such as Zn and Al, it has been found that, in the absence of a process control agent during milling, cold welding can dominate the process and the powders can be “consolidated” into spherical-shaped balls that can be up to 6–8 mm in diameter.<sup>[38]</sup> Thus in situ consolidation can be attained in these cases during milling. Disks can be formed from the spherical samples via compression. Such disks are suitable for mechanical tests such as miniaturized disk bend tests or small-size tensile samples.

## CONCLUSION

Mechanical attrition of powders is a simple and versatile method to prepare nanocrystalline microstructures in a variety of materials including metals, ceramics, polymers, intermetallics, and composites. The mechanism for formation of nanoscale grains by severe plastic deformation induced by ball milling, in general, involves the competition between defect production and defect recovery by thermal processes. The details by which this occurs are still not completely defined. In most cases, a continuous buildup of dislocation density and the rearrangement of dislocations into first cells, and then small equiaxed grains, occur. In some cases, there is evidence for discontinuous dynamic recrystallization. More systematic TEM studies on a variety of materials are needed to confirm the mechanism. Problems of powder contamination during processing must be considered, but can be minimized. Consolidation of the powders with nanoscale microstructures into bulk structures is a topic that requires further attention.

## INTRODUCTION

Internal interfaces in materials are extended defects, such as grain boundaries and interphase boundaries, which can be found in almost every natural or artificially produced material or man-made structure.<sup>[1]</sup> In general, the correlation between the atomic structure and the energy of interfaces can be described by their respective excess free volume,<sup>[2]</sup> which can be minimized by the formation of closely packed structural units of atoms so that interfaces with low index planes and low index atomic rows are parallel to each other.<sup>[3,4]</sup> However, the experimental evidence concerning structure–energy correlations of internal interfaces, in particular under thermodynamic equilibrium conditions where entropic effects should be taken into account, remains unclear because of the inherent experimental difficulties and the generally small interface-to-volume ratio in conventional polycrystals.

Decreasing the grain size of a material to a few nanometers leads to a drastic increase of the number of grain boundaries (or other internal interfaces) reaching typical densities up to  $10^{19}$  interfaces per cubic centimeter. The large number of atoms located in these interfaces in comparison with the crystalline part scales roughly with the reciprocal grain size and corresponds approximately to  $3 \delta/d$ ,  $\delta$  being the width of the interface, typically 0.8–1.2 nm.<sup>[5]</sup> For example, for a material with a grain or domain size of 5 nm, about 50% of the overall atoms deviate from ideal lattice site positions and become influenced by the grain boundaries. At the same time, the energy (and other properties) of the material is being increased in proportion to the level of atomic disorder of the material, i.e., in proportion to the overall grain boundary area. Nanostructured materials have therefore attracted considerable scientific interest for more than a decade because of their unusual and sometimes unexpected physical (electronic, magnetic, mechanical, optical) and chemical (catalytic) properties.<sup>[6]</sup>

Besides the synthesis of clusters, thin films, multilayers, and coatings from the gas or liquid phase, chemical methods such as sol–gel processes and electrodeposition are common methods of synthesizing

nanostructured materials. As a versatile alternative, however, mechanical methods have been developed which allow to fabricate nanostructured materials in large quantities with a broad range of chemical compositions and atomic structural arrangements.<sup>[7,8]</sup> These methods can, for example, be applied to powder samples, thin-foil sandwiches, and to the surface of bulk samples in order to produce nanostructures at surfaces as discussed below. As a result, a wide range of metals, alloys, intermetallics, ceramics, and composites can be prepared in an amorphous, nanocrystalline, or quasicrystalline state. Because of the broad range of possible atomic structures very different properties in comparison with conventional materials are obtained. For example, nanostructured particles prepared by mechanical attrition can exhibit unusually high values in hardness,<sup>[9,10]</sup> enhanced hydrogen solubility,<sup>[11]</sup> giant-magneto-resistance effects,<sup>[12]</sup> magnetic spin-glass behavior,<sup>[13]</sup> etc.

## EXPERIMENTAL

A variety of mechanical milling devices have been developed for different purposes.<sup>[14]</sup> The basic process of mechanical attrition is illustrated in Fig. 1. Powder particles with typical particle diameters of about 20–100  $\mu\text{m}$  are placed together with a number of hardened steel or WC-coated balls in a sealed container, which is shaken violently. Consequently, plastic deformation at high strain rates ( $\sim 10^3$ – $10^4 \text{ sec}^{-1}$ ) occurs within the particles and the average grain size can be reduced to a few nanometers after extended milling. The temperature rise during this process is modest and is generally estimated to be  $\leq 100$  to  $200^\circ\text{C}$ . The collision time corresponds to typically 2 msec.

High-energy milling forces can be obtained by using high frequencies and small amplitudes of vibration. Ball mills (e.g., SPEX model 8000), which are preferable for small batches of powder, i.e.,  $\approx 10 \text{ cm}^3$ , are sufficient for research purposes. As the kinetic energy of the balls is a function of their mass and velocity, dense materials (steel or tungsten carbide) are preferable to ceramic balls. During mechanical attrition contamination by

Fig. 1 Schematic sketch of the process of mechanical attrition and the corresponding shear action of metal powders.

the milling tools (Fe) and atmosphere (trace elements of  $O_2$ ,  $N_2$  in rare gas) can be problematic. By minimizing the milling time and using the purest metal powders available, a thin coating of the milling tools by the respective powder material is generally obtained, which reduces Fe-contamination levels of less than typically 1 at.%. Atmospheric contamination can be minimized or eliminated by sealing the vial with a flexible “O”-ring after the powder has been loaded in an inert gas glove box. Small experimental ball mills can also be enclosed completely in an inert gas glove box. As a consequence, oxygen and nitrogen contamination can be limited to less than 300 ppm. In this respect, the nanoscaled powder material obtained has often a higher purity than materials synthesized by alternative methods, such as chemical processes or inert gas evaporation and condensation. In addition, the structural contributions of small pores occurring during compaction of small clusters can be safely neglected.<sup>[15]</sup>

An alternate route to producing samples with high levels of both plastic deformation and interfacial area is cold rolling of layered elemental sheets.<sup>[16]</sup> Each deformation cycle consists typically of rolling the multilayered sandwich to a thickness of approximately 80  $\mu\text{m}$  and subsequent folding as shown in Fig. 2. Here the large increase in interfacial area is created internally with absolutely negligible contamination at ambient temperature.

As a further example of more technical relevance, the development of high-speed ICE trains reaching velocities of more than 300 km/hr is also a materials challenge concerning the mechanical integrity and safety required for the railway tracks (high-strength steel with composition Fe–0.8 at.% C–1.3 at.% Mn).<sup>[17]</sup> In particular, the interaction and slip between wheel and rail has to be optimized and is controlled by sophisticated electronics. On the steel surface where the local pressure typically is exceeding 1.0–1.5 GPa, solid-state transformations have been observed which are caused by friction-induced shear forces and have strong similarities with mechanical attrition of powder samples.

Fig. 2 Schematic sketch of the process of cold rolling of elemental foils.

## EXPERIMENTAL RESULTS

### Nanostructure Formation

During mechanical milling or attrition the metal powder particles are subjected to severe plastic deformation from collisions with the milling tools. Consequently, plastic deformation at high strain rates ( $\sim 10^3$ – $10^4 \text{ sec}^{-1}$ ) occurs within the particles and the average grain size can be reduced to a few nanometers after extended milling. As such, the metal particle is plastically deformed with most of the mechanical energy expended in the deformation process being converted into heat, but the remainder being stored in the metals, thereby raising its internal energy.<sup>[18,19]</sup>

The microstructural changes as a result of mechanical attrition can be followed by X-ray diffraction methods averaged over the sample volume. The X-ray diffraction patterns exhibit an increasing broadening of the crystalline peaks as a function of milling time. The peak broadening is caused by size as well as internal strain effects.<sup>[20,21]</sup> The average coherently diffracting domain size (grain or crystal size) and the microstrain as a function of milling time are obtained from the integral peak widths assuming Gaussian peak shapes. Based on the method of X-ray analysis applied (Scherrer formula,<sup>[22]</sup> Williamson and Hall method at full width at half maximum, or integral peak width at half maximum,<sup>[23]</sup> Warren–Averbach analysis,<sup>[24]</sup> etc.) the weighting of the grain size distribution is different and therefore the average grain size can vary by a factor of two. Further evaluation by TEM and small angle X-ray or neutron diffraction improves the accuracy of the data.

After corrections for  $K_z$  and instrumental broadening, the line broadening due to the small crystal size is constant in  $K$ -space and is given by  $\Delta K = 0.9 (2\pi/d)$ , where  $d$  is the average domain or grain diameter. The strain broadening corresponds to  $\Delta K = A \langle e^2 \rangle^{1/2} K$  with  $A$  being a constant depending on the strain distribution ( $A \approx 1$  for a random distribution of dislocations<sup>[25]</sup> and  $\langle e^2 \rangle^{1/2}$  being the rms strain). Additional defects which might contribute to the peak broadening,

**Fig. 3** The average grain size and microstrains as a function of milling time for iron powder determined from X-ray line broadening.

such as stacking faults, can be safely neglected in all cases discussed here. However, for some metals with very small stacking fault energies, e.g., Co, the contribution of stacking faults to the peak broadening can be considerable, but is clearly the exception.

As a result, it is generally found that in the very beginning mechanical attrition leads to a fast decrease of the average grain size to 40–50 nm. Further refinement occurs slowly to about 10–15 nm after extended milling. The average atomic level strain is reaching values up to 0.7% as shown in Fig. 3 for the milling of Fe powders.

From a combination of X-ray, electron, and neutron diffraction, the elemental processes leading to the grain size refinement include three basic stages:<sup>[26]</sup>

- i. Initially, the deformation is localized in shear bands consisting of an array of dislocations with high density (up to  $10^{16}$  per  $m^2$ ). Here the dislocation cell size dimensions are basically a function of the acting shear stress  $\tau$  resulting in an average cell size dimension  $L$  of  $L = 10Gb/\tau$  with  $G$  being the shear modulus and  $b$  the Burgers vector.
- ii. At a certain strain level, these dislocations annihilate and recombine to small angle grain boundaries separating the individual grains. The subgrains formed via this route are already in the nanometer-size range.
- iii. The orientations of the single-crystalline grains with respect to their neighboring grains become completely random. Thus the microstructure becomes identical with the microstructure of samples produced by the noble gas condensation and compaction and exhibiting a largely reduced number of internal pores.

### Extended Solid Solutions and Metallic-Glass Formation

Extended solid solutions far beyond the thermodynamic equilibrium have generally been noted in the

course of mechanical milling of alloys. In addition, for phase mixtures with negative enthalpies of mixing and large (>15%) atomic size mismatch solid-state amorphization is observed. During this process long-range solute diffusion and solute partitioning are suppressed and therefore highly metastable amorphous and nanocrystalline states become accessible.

For example, during mechanical alloying of 75 at.% Zr and 25 at.% Al the formation of a supersaturated hcp ( $\alpha$ -Zr) solid solution was observed prior to the solid-state-amorphization reaction.<sup>[27]</sup> However, in all cases of binary alloys it remained unclear whether indeed a metallic glass has been formed or just a material with “X-ray amorphous structure”. More recently, a similar phase transformation sequence has been investigated in a mechanically alloyed multicomponent elemental  $Zr_{60}Al_{10}Ni_9Cu_{18}Co_3$  powder mixture with an alloy composition that is known to form a bulk metallic glass when cooled from the liquid state.<sup>[28]</sup> These multicomponent alloys are considerably more stable than binary alloys and can be heated above the glass transition temperature before crystallization sets in. The X-ray spectra at different stages of the milling process are characterized by the successive disappearance of the elemental Al, Co, Cu, and Ni peaks and a simultaneous shift of the Zr peaks to higher scattering angles, corresponding to a decrease in the lattice constant of the hcp-Zr as a result of the rapid dissolution of the smaller atoms, such as Cu, Ni, Co, and Al in the ( $\alpha$ -Zr) matrix<sup>[29]</sup> as shown in Fig. 4.

An alternate route to producing samples with high levels of both plastic deformation and interfacial area is by cold rolling of layered elemental sheets in an inert gas atmosphere with subsequent folding between each deformation cycle. In this case, the large increase in interfacial area is created internally with negligible contamination.

**Fig. 4** X-ray spectra for mechanically alloyed  $Zr_{60}Al_{10}Ni_9Cu_{18}Co_3$  powder samples exhibiting the transformation from the initially crystalline powder mixture to an amorphous glass-like structure.

**Fig. 5** XRD profiles showing development of a metallic glass by cold rolling of elemental foils of Zr, Al, Cu, and Ni (x: Zr, o: Al, +: Cu, ◆: Ni).

In contrast to mechanical alloying of powder samples the uncertainty in the temperature during processing is removed as the sample is in firm contact with the massive rolls and deformation can be performed at a low strain rate in order to maintain ambient temperatures.

This approach has been used to examine amorphous phase formation in several binary alloys such as Zr–Ni and Cu–Er.<sup>[30,31]</sup> In the prior work on amorphous phase formation, deformation rates in excess of  $1 \text{ sec}^{-1}$  were employed and some annealing was needed to complete the amorphization reaction.<sup>[32]</sup> In contrast, fully amorphous foils of a multicomponent  $\text{Zr}_{65}\text{Al}_{7.5}\text{Cu}_{17.5}\text{Ni}_{10}$  alloy have been synthesized at ambient temperatures from a layered array of individual elemental sheets by repeated low strain rate ( $0.1 \text{ sec}^{-1}$ ). Fig. 5 exhibits the X-ray diffraction patterns from the Zr–Al–Ni–Cu foils taken after 10, 40, 80, and 120 deformation cycles. High resolution TEM analysis exhibits further evidence that a true amorphous phase has been formed when some nanocrystallites of Zr are still present after 80 cycles as shown in Fig. 6A. The sample becomes fully amorphous after 120 cycles (Fig. 6B). However, structural features and corresponding contrast variations of the order of about 2 nm (Fig. 6B) are apparent and typical for a small-scale phase separation.

### Thermal Stability

As a result of the cold work considerable energy has been stored in the powder particles. Therefore thermodynamically these materials are far removed from their equilibrium configuration and a large driving force toward equilibrium exists. The stored energy is released during heating to elevated temperatures due to recovery, relaxation processes within the grain boundaries, and grain

**Fig. 6** High-resolution TEM micrograph of a cold-rolled multilayered sample exhibiting a remaining nanocrystalline Zr-rich crystallite surrounded by an amorphous matrix (A) after 80 cycles of deformation and (B) a fully amorphous sample after 120 cycles.

growth. As a consequence, during annealing at elevated temperatures, relaxation and grain-growth processes will occur leading to a concomitant increase of the grain size.

This behavior has been investigated for a number of materials and presented here in detail for iron. For extended periods of milling time a fast decrease of the average grain size to nanometer dimensions is observed with a stationary average grain size  $d = 15 \text{ nm}$  and 0.7% microstrain as mentioned above. The enthalpy release during differential scanning calorimetry (DSC) heating experiments spreads over the entire temperature range of the scan as shown in Fig. 7. The very broad

**Fig. 7** Exothermal DSC heating scan at 10 K/min of iron powder after mechanical attrition for 5 and 25 hr showing two stages of heat release (below and above ca. 550 K).

signal does not exhibit any distinct peaks but a further increase of the exothermic signal for  $T > 550$  K.

X-ray diffraction of powder samples annealed for 80 min at each temperature revealed the evolution of grain size and strain as a function of annealing temperature as shown in Fig. 8. The microstrain is decreasing rapidly below 550 K whereas the grain size remains nearly constant in this range. As such, the enthalpy release during the first exotherm in Fig. 7 is only related to relaxation and not to grain growth. Grain growth starts to become significant above about 570 K. Furthermore, it has been found that after a fast increase at early times the average grain size  $d$  changes from 15 to about 30–40 nm. The average grain size remains constant for  $t \geq 2400$  sec and reaches values of 100–200 nm at temperatures about 870 K.

As such, two regimes with and without grain growth can be clearly distinguished. As the influence of lattice point defects and lattice dislocations is negligible, the enthalpy release can be clearly assigned to the existence

**Fig. 8** Dependence of the stationary grain size and microstrain of (initially) nanocrystalline Fe-powder milled for 25 hr on annealing as a function of temperature.

**Fig. 9** Isothermal exothermic DSC curve at 500°C of nanocrystalline iron (upper part) and plot of  $(dH/dt)^{-2/3}$  vs. time (lower part).

of grain boundaries. The reduction of the microstrains is probably caused by grain boundary relaxation and annihilation of secondary grain boundary dislocations. Based on elastic theory it is estimated that this contribution to the overall energy is less than about 10%.

Further isothermal DSC measurements allow to analyze the grain-growth processes in nanocrystalline Fe. For example, the isothermal DSC curve shown in the upper part of Fig. 9 was measured at 770 K after annealing the sample at 670 K and heating to 770 K at a rate of 50 K/min. A monotonically decreasing signal typical for grain growth is observed. Similar signals are observed at 470, 570, and 670 K and clearly differ from those measured in isothermal recrystallization processes controlled by nucleation and growth in conventional polycrystalline metals which are described by Johnson–Mehl–Avrami-type models.<sup>[33]</sup> Fig. 9 does not exhibit the expected maximum related to an incubation time for nucleation, but shows only a decrease in the signal.

Furthermore,  $(dH/dt)^{-2/3}$  should scale linearly with time when normal parabolic grain-growth behavior is assumed.<sup>[34]</sup> This assumption is well approximated for  $t < 1200$  sec as shown in the lower part of Fig. 9. The upper part of Fig. 9 includes a fit to the measured DSC signal assuming parabolic grain growth and a grain boundary energy of  $1.2 \text{ J/m}^2$  in agreement with theoretical estimates for fully relaxed large-angle grain boundaries in bcc-Fe.<sup>[35]</sup>

## DISCUSSION

### Elemental Metals

The energies finally stored during mechanical attrition largely exceed those resulting from conventional cold working of metals and alloys (cold rolling, wire drawing, extrusion, etc.). During conventional deformation, the excess energy is rarely found to exceed

1–2 kJ/mol and therefore is never more than a small fraction of the enthalpy of fusion  $\Delta H_f$ . In the case of mechanical attrition, however, the energy determined can reach values typical for crystallization enthalpies of metallic glasses corresponding to about 40%  $\Delta H_f$ .<sup>[36]</sup>

A simple estimate demonstrates that these energy levels cannot be achieved by the incorporation of defects which are found during conventional processing. In the case of pure metals, the contribution of point defects (vacancies, interstitial) can be safely neglected because of the high recovery rate at the actual processing temperature. Even taking nonequilibrium vacancies into account which can form as a consequence of dislocation annihilation up to concentrations of  $10^{-3}$ , such contributions are energetically negligible in comparison.

The maximum dislocation densities that can be reached in heavily deformed metals are less than  $10^{16} \text{ m}^{-2}$  which would correspond to an energy of less than 1 kJ/mol. Therefore it is assumed that the major energy contribution is stored in the form of grain boundaries and related strains within the nanocrystalline grains which are induced through grain boundary stresses.

Other detailed studies are obtained from cold rolling and torsion,<sup>[37]</sup> wire drawing,<sup>[38]</sup> and cyclic deformation<sup>[39]</sup> processes resulting in an asymptotic saturation of the flow stresses. This is considered as a result of the simultaneous occurrence of dislocation multiplication and annihilation leading to a saturation of the dislocation density. In particular, under cyclic deformation slip becomes highly localized in so-called persistent slip bands (shear bands). These lie parallel to the primary glide plane and are separated by regions containing the original matrix structure. These bands consist of dense walls of dislocations, largely screw dislocations having a density  $\sim 10^{13} \text{ m}^{-2}$ . The closest spacing between screw dislocations of opposite sign is  $\sim 50 \text{ nm}$ , the minimum distance before annihilation occurs. For edge dislocations which are more relevant for the deformation of fcc crystals this critical annihilation length is found to be 1.6 nm for Cu. As such, it has been concluded that the annihilation of dislocations can set a natural limit to the dislocation densities which can be achieved by plastic deformation (typically less than  $10^{13} \text{ m}^{-2}$  for screw dislocations and  $10^{16} \text{ m}^{-2}$  for edge dislocations).<sup>[7]</sup> Steady-state deformation is observed when the dislocation multiplication rate is balanced by the annihilation rate.

It is expected that the shear modulus of the grain boundary regions is lowered by about 40% when the “volume-fraction” of the grain boundaries becomes comparable to that of the crystals.<sup>[1,38,39]</sup> Localized deformation then proceeds by the dilatation of the grain-boundary layers similar to superplastic behavior<sup>[40]</sup> with the undeformed crystallites moving in a “sea” of dilated grain boundaries.

## Extended Solid Solutions

Mechanical attrition has also gained much attention as a nonequilibrium process resulting in solid-state alloying reactions beyond the equilibrium solubility limit for a broad range of alloys, intermetallics, ceramics, and composites.<sup>[41,42]</sup> In the case of mechanical attrition of a binary powder mixture, amorphous phase formation can occur by intermixing of the atomic species on an atomic scale, thus driving the crystalline solid solution outside of its stability range against “melting” resulting in solid-state amorphization.<sup>[43]</sup> This process is considered as a result of both mechanical alloying<sup>[44]</sup> and the incorporation of lattice defects into the crystal lattice.<sup>[45]</sup>

The formation of extended solid solutions during mechanical attrition of systems with negative heat of mixing can be explained in terms of milling-induced interdiffusion reactions.<sup>[46]</sup> In this regard the action of deformation (i.e., “driven system”) and especially shearing processes in causing atomic-scale mixing has been clarified recently.<sup>[47]</sup> This can be considered as an athermal process that yields a high level of homogenization of the component atoms provided that sufficient deformation is applied. In fact, Monte Carlo simulations indicate that deformation can yield a solid solution even in alloy systems with a positive enthalpy of mixing. In this case, the driven system action, characterized by a “forcing parameter” as the frequency ratio between forced and thermally activated jumps, results in a behavior that is similar to that resulting from an enhanced diffusivity characteristic of a high-temperature, high-entropy state with extended solubilities.

An alternate route to producing samples with high levels of both plastic deformation and interfacial area is by cold rolling of layered elemental sheets which are folded between each deformation cycle. In this case, the large increase in interfacial area is created internally with absolutely negligible contamination. Similarly, in contrast to mechanical attrition the uncertainty in the temperature during processing is removed as the sample is in firm contact with the massive rolls and deformation can be performed at a low strain rate to maintain ambient temperatures. This approach has been used to examine amorphous-phase formation in several binary alloys such as Zr–Ni,<sup>[48]</sup> Cu–Er,<sup>[49]</sup> and Al–Pt<sup>[50]</sup> and also for the preparation of bulk Fe/Ag nanomultilayers with giant magnetoresistance.<sup>[51]</sup>

In the prior work on amorphous-phase formation, deformation rates in excess of  $1 \text{ sec}^{-1}$  were employed and some annealing was needed to complete the amorphization reaction. Fully amorphous foils of a multicomponent  $\text{Zr}_{65}\text{Al}_{17.5}\text{Cu}_{17.5}\text{Ni}_{10}$  alloy have been synthesized at ambient temperatures from a layered array of individual elemental sheets by repeated low-strain-rate ( $0.1 \text{ sec}^{-1}$ ) cold rolling.<sup>[52]</sup> Fig. 5 shows

**Fig. 10** Schematics of solid-state amorphization reaction at an intermediate stage.

X-ray diffraction patterns from the Zr–Al–Ni–Cu foils taken after 10 (A), 80 (B), and 120 (C) deformation cycles. High-resolution TEM analysis exhibits further evidence that a true amorphous phase has been formed as shown in Fig. 6.

The detailed X-ray and electron diffraction experiments revealed that the crystal-to-glass transition was preceded by a rapid solution of smaller atoms such as Cu, Ni, Co, and Al in the  $\alpha$ -Zr matrix to supersaturation levels with a concomitant reduction in grain size to values below 30 nm as schematically shown in Fig. 10.

As a final product, a fully amorphous Zr–Al–Ni–Cu–Co samples were obtained with structural and thermal properties identical to a metallic glass of the same composition produced by liquid undercooling. Fig. 11 exhibits a high-resolution TEM image of a fully amorphous, metallic glass with identical composition produced from the liquid state. Whereas structural features on the scale of 2 nm have been observed in the amorphous phase formed in the solid state (Fig. 6B), such contrast variations typical for small-scale phase separation have not been observed by cooling from the liquid phase. This structurally homogeneous state is thermodynamically closer to the equilibrium, albeit metastable.

Surprisingly, thermal analysis of cold-rolled amorphous samples and amorphous powder samples prepared by mechanical alloying also reveals a distinct glass transition at  $T_g = 647$  K and about 620 K, respectively, as shown in Fig. 12 (followed by a sharp exothermic crystallization peak at 745 K which is not shown here). As such, it is worthy to note that very similar to amorphization reactions observed in mechanically alloyed Zr-based powder mixtures of similar composition the initial stage of cold rolling is characterized by the dissolution of solute into Zr along

**Fig. 11** High-resolution TEM micrograph of a glassy  $Zr_{60}Al_{10}Ni_9Cu_{18}Co_3$  alloy slowly (10 K/sec) cooled from the liquid state.

with a reduction in grain size to about 30 nm before the onset of the crystal-to-glass transition. The formation of similar amorphous phases from two inherently different initial states, i.e., the solid and the liquid state, suggests that compositionally induced static disorder in a mechanically driven system can lead to the same final glassy state which is conventionally derived from freezing the dynamic disorder of a liquid out to a glass.

### Nanocrystallization of Surfaces

Many microscopic processes occurring during mechanical attrition and mechanical alloying of powder particles exhibit common features with processes relevant in tribology and wear. For example, the effects of work hardening, material transfer, and erosion during wear

**Fig. 12** Thermal analysis exhibiting the difference in heat capacity of the sample material  $Zr_{60}Al_{10}Ni_9Cu_{18}Co_3$  in comparison with the thermodynamically stable crystalline configuration for amorphous mechanically alloyed powder, bulk metallic glass, and foil stacks (black squares: mechanically alloyed powder, open circles: liquid cooling, closed circles: cold rolling).

situations result in similar microstructures of the wear surface as observed during mechanical attrition.<sup>[53,54]</sup> In particular, during sliding wear, large plastic strains and strain gradients are created near the surface. Typical plastic shear strain rates can correspond here to several  $10^3 \text{ sec}^{-1}$ .

Close to the surface of wear scars as well as in the wear debris of Cu, nanocrystalline structures have been observed by high-resolution electron microscopy with an average grain size of 4–5 nm.<sup>[55]</sup> Within the interior of the grains no defects were observed suggesting that most of the defects are absorbed by the grain boundaries because of their proximity. However, this type of plastic deformation at high strain rates does not seem to be limited to metals and alloys,<sup>[56]</sup> but has been observed in ceramics<sup>[57]</sup> and diamond<sup>[58]</sup> as well.

During sliding wear a special tribo layer develops on the surface of a sliding component being subjected to large plastic strains. This surface layer often is called the Beilby layer which, for a long time, was thought to be amorphous because its microstructure could not be resolved with the instruments commonly used.<sup>[59]</sup> There are indeed some systems in which truly amorphous layers are produced by sliding,<sup>[60]</sup> but in most cases the subsurface layer with a thickness of several micrometers has a nanocrystalline structure.

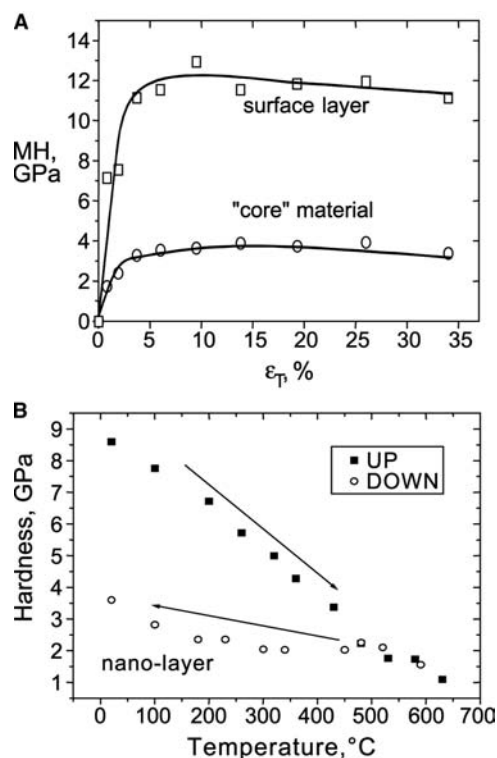

Corresponding X-ray diffraction and TEM results indicate that the average grain size of the extremely deformed surface layer corresponds to about 20 nm,

**Fig. 13** TEM bright field images (A) of the nanostructured surface layer and (B) the initial pearlitic steel sample.

whereas a gradient in grain size is observed further away from the surface reaching values up to 200 nm.<sup>[61]</sup> For example, Fig. 13 exhibits TEM micrographs and the corresponding diffraction patterns of the initial pearlitic structure (A) in comparison with the nanocrystalline layer near the surface (B).

Corresponding X-ray diffraction and TEM results indicate that the average grain size of the extremely deformed surface layer is decreased to about 20 nm, whereas a gradient in grain size is observed further away from the surface where values up to 200 nm are reached.<sup>[62,63]</sup> As a consequence, hardness measurements have been performed by nanoindentation and conventional methods as shown in Fig. 14A and B as a function of deformation and also temperature. This remarkable increase in hardness and mechanical strength of regions near the surface by a factor of 4–5 is clearly related to the fact that the average grain size is drastically decreased by the continuous deformation process as found by TEM analysis and X-ray diffraction. The apparent hysteresis seen in Fig. 14B is an indication that the microstructure is drastically changed during thermal annealing resulting in considerable grain growth and (re-) precipitation of Fe-carbides and concomitant mechanical softening.<sup>[64]</sup>

Millman.

## CONCLUSION

Severe plastic deformation, which can be achieved by a number of different methods, leads to a refinement of the microstructure to a nanometer scale. The correlation of structural and thermal analysis reveals that the defect structure after long milling times is composed of a network of large angle grain boundaries. These grain boundaries are formed by reorganization of dislocations produced in the initial step of the deformation process. Because of the high density of grain boundaries and the large amounts of stored enthalpy, relaxation processes of the heavily deformed structure and grain growth start at rather low temperatures. In some cases with large chemical driving force (large negative enthalpies of mixing, "deep eutectics") the formation of a glass-like state with a distinct glass transition temperature is observed. However, this state obtained by solid-state processing exhibits a distinct underlying disordering on the scale of 2 nm not observed in glassy alloys with identical composition produced from the liquid.

Furthermore, many microscopic processes occurring during mechanical attrition and mechanical alloying of powder particles exhibit common features with processes relevant in tribology and wear. For example, the effects of work hardening, material transfer, and erosion during wear situations result in similar nanostructured layers of a wear surface as observed during mechanical attrition. Typical plastic shear strain rates can correspond here to several  $10^3$ . As such, the study of extreme plastic deformation processes not only is opening new processing routes for a variety of advanced nanostructured materials but also improves the understanding of technologically relevant deformation processes, e.g., surface wear, on a nanoscopic level which often limit the lifetime of technical components.

## INTRODUCTION

Supercritical fluid (SCF) approach is a novel and emerging technology to generate nanomaterials in small areas, high-aspect-ratio structures, complicated surfaces, and poorly wettable substrates with high uniformity, high homogeneity, and minimum environmental problems.

Through hydrogen reduction of metal- $\beta$ -diketone complexes in supercritical CO<sub>2</sub>, a rapid, convenient, and environmentally benign approach has been developed to synthesize a variety of nanostructured materials: 1) metal (Pd, Ni, and Cu) nanowires and nanorods sheathed within multiwalled carbon nanotube (MWCNT) templates; 2) nanoparticles of palladium, rhodium, and ruthenium decorated onto functionalized MWCNTs. These highly dispersed nanoparticles are expected to exhibit promising catalytic properties for a variety of chemical or electrochemical reactions; 3) Cu, Pd, or Cu-Pd nanocrystals deposited onto SiO<sub>2</sub> or SiC nanowires (NWs). Different types of nanostructures were achieved, including nanocrystal-NW, spherical aggregation-NW, shell-NW composites, and “mesoporous” metals supported by the framework of NWs.

## BACKGROUND

Supercritical fluid synthesis and processing of nanostructured materials have attracted an increased attention during the past decade.<sup>[1–6]</sup> SCFs exhibit a novel hybrid of liquid-like and gas-like properties. They have appreciable densities and can dissolve solid compounds like liquid solvents yet they have low viscosities, low surface tension, and high diffusivities like gases. As a result of their high compressibility, SCFs offer a convenient means of accessing a wide range of solvent properties without physically changing the

solvent. Because of these unusual properties, the synthesis and processing of nanostructured materials using SCFs show significant advantages over conventional processes: 1) SCFs facilitate permeation, diffusion, and penetration to small areas, high-aspect-ratio structures, complicated surfaces, and poorly wettable substrates to attain high uniformity and homogeneity, therefore being capable of fabricating nanostructured materials which are difficult to accomplish through traditional methods; 2) SCFs allow higher concentrations of starting materials than chemical vapor deposition (CVD) does and provide diffusivities higher than liquid solvents do, therefore SCF synthesis and processing could be very fast; 3) the solvent strength of a SCF can be varied by manipulation of fluid temperature and pressure, thus allowing a degree of control and rapid separation of products which is not possible using conventional solvents; and 4) some SCFs, such as supercritical CO<sub>2</sub> (scCO<sub>2</sub>), leave no solvent residues and are recyclable, thus being environmentally benign. Furthermore, unreacted materials, by-products, and contaminants in SCFs can be easily removed from the system; therefore products of high purity can be obtained. The synthesis and processing of nanostructured materials such as nanoparticles, nanowires, nanorods, nanotubes, nanocomposites, and thin solid films with nanoscale thickness have been achieved through a number of SCF physical and chemical transformations in which a SCF can act as a medium either for transporting solute species or for chemical reactions, or both. In some cases, the SCF itself can also take part in the reactions. Table 1 summarizes the typical SCF approaches to a variety of nanostructured materials.<sup>[1–6]</sup> The aim of this entry is to show how to use SCFs in the synthesis and processing of nanostructured materials templated by MWCNTs and nanowires (NWs).

**Table 1** Typical SCF approaches to nanostructured materials

	Nanoparticles, nanowires, nanorods nanotubes, nanocomposites	Thin films
Physical transformation	Rapid expansion of supercritical solutions (RESS)	Physical RESS deposition
	Supercritical-assisted nebulization and atomization	Physical deposition in SCFs
	Physical impregnation in SCFs without expansion

Because of their exceptional electrical and mechanical properties caused by quantum confinement effects, one-dimensional carbon nanotubes (CNTs) and NWs have stimulated a growing interest over the past decade for their application potential as interconnects and building blocks for functional nanodevices.<sup>[7–10]</sup> CNTs also have other possible uses including storage of hydrogen and other gases, membrane materials for batteries and fuel cells, anodes for Li-ion batteries, capacitors, and chemical filters.<sup>[11–13]</sup> Modification of CNTs and NWs to produce nanocomposites provides an attractive strategy to expand, improve, or alter their properties and functions as well as their promising applications.<sup>[14–25]</sup>

Because of their small size, high chemical stability, high-aspect-ratio cavities, and large surface-area-to-volume ratio, CNTs have been considered as templates for confining and directing the growth of metallic nanowires, nanorods or tubular structures, or as supports for metal nanoparticles which can be impregnated in the cavities or attached to the external walls of the CNTs.<sup>[26–36]</sup> The produced metal/CNT composites can be used as catalysts, sensors, semiconductor devices, data storage, and processing devices, contrast agents in magnetic resonance imaging, new reinforced metal-nanofiber materials, and in xerography.<sup>[26,27,35,37–41]</sup> Metal impregnation in the hollow interiors of the CNTs can be achieved in situ during

CNT growth by incorporating the metals or metal precursors along with the carbon source. Although Fe, Co, Ni, Ti, Cu, and certain lanthanide and transition-metal carbides have been successfully trapped in CNTs using this method, harsh conditions such as high temperature or arc evaporation are usually required, and impurities could be produced as encapsulated carbon clusters and soot.<sup>[42–44]</sup> Capillary drawing of low-melting metals into cavities of CNTs provides a simple approach for metal loading,<sup>[28,45]</sup> however, CNTs are not wetted by liquids with surface tensions higher than 100–200 mN m<sup>-1</sup>, thereby excluding most metals and other elements in the periodic table.<sup>[46]</sup> The most promising and flexible approach to metal loading is then to deposit metals into the cavities or onto the external walls of CNTs through a chemical reaction such as CVD or wet chemical process.<sup>[13,15,26,29–32,35,36,47–55]</sup> However, by virtue of the small inner diameter and the extremely high aspect ratio of CNTs, this approach requires high temperatures or extensive reaction times for filling metals into the inner cavities of CNTs, and, consequently, the percentage of filled CNTs often is low. The CVD procedure may suffer from the limited volatility of metal precursors and the resulting low-vapor-phase concentration and mass-transfer-limited reactions, in addition to the high temperature for the decomposition or reduction of metal precursors. In the case of wet

chemical procedures, a hindrance could be the slow process for concentrating and impregnating reactants into the cavity of CNTs. As the pristine surface of the CNTs is rather inert and poorly hydrophilic, this approach also results in unsatisfactory adhesion and coverage control of metal nanoparticles coated onto the outer walls of CNTs, and metal agglomeration into fewer larger particles as well.<sup>[53,54]</sup> For most of the catalytic applications, catalyst particles loaded on the exterior of the CNTs are preferred because they are more accessible to the reactant molecules than those encapsulated inside the internal channels. In order to obtain a specific nucleation of metals on the outer surface with good adhesion and control, functionalization of CNTs before metal deposition is required and can be accomplished by chemical treatments using a myriad of oxidants, such as HNO<sub>3</sub>, KMnO<sub>4</sub>, OsO<sub>4</sub>, HNO<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub>, and RuO<sub>4</sub> to generate -COOH, -OH, and other functional groups on the external walls of CNTs.<sup>[15,31,32,36,55,56]</sup> Also, one-step or two-step sensitization-activation methods have been used for introducing catalytic nuclei (often Pd-Sn alloys or Pd nuclei) to the otherwise non-catalytic CNT surface to achieve a better metal loading through electroless deposition.<sup>[13,30]</sup> However, the known wet chemical processes usually involve tedious and time-consuming treatment of CNTs and generate aqueous wastes.

Considerable efforts have also been spent to the modification of NWs to produce hybrid nanocomposites, in which NWs were decorated with nanoparticles, or sheathed by thin films, shells, and molecular layers, and most methods for modifying are solution-based.<sup>[17-25]</sup>

Based on hydrogen reduction of metal- $\beta$ -diketone complexes in supercritical CO<sub>2</sub>, we have developed a rapid, direct, and clean approach for the modification of MWCNTs and NWs to achieve nanocomposites as follows: metal nanowires or nanorods sheathed within MWCNT templates, MWCNTs decorated with catalytic metal nanoparticles, NWs decorated with metal nanocrystals, spherical aggregations of metal nanocrystals strung up by NWs, NWs wrapped by metallic shells, and "mesoporous" metals supported by the framework of NWs.<sup>[57-59]</sup>

### HYDROGEN REDUCTION OF METAL- $\beta$ -DIKETONE COMPLEXES IN SCCO<sub>2</sub>

Hydrogen reduction of metal precursors such as metal- $\beta$ -diketone complexes in scCO<sub>2</sub> has proven to be one of the most successful approaches for synthesizing sterically stabilized metal nanocrystals.<sup>[60,61]</sup> ScCO<sub>2</sub> reactions and particle nucleation occur in the presence of organic capping ligands, which bind to the surface of the agglomerates to form monolayers and quench further growth, providing size control and nanocrystal

stabilization. Moreover, the steric stabilization of nanocrystals in scCO<sub>2</sub> varies with the tunable density and solvation power of scCO<sub>2</sub>, enabling reversible stabilization and destabilization of colloidal dispersion, which could improve many aspects of nanocrystal processing, such as size-selective separation, synthesis, and self-assembly. Robust, highly crystallized, relatively size-monodisperse, and sterically stabilized silver, iridium, and platinum nanocrystals ranging in diameter from 20 to 120 Å were synthesized in scCO<sub>2</sub> by reducing metal- $\beta$ -diketone complexes with H<sub>2</sub> in the presence of fluorinated thiol ligands.

Hydrogen reduction of metal- $\beta$ -diketone complexes in scCO<sub>2</sub> has also been demonstrated as an effective method to deposit metal films into high-aspect-ratio structures of inorganic and polymer substrates as well as into mesoporous solids.<sup>[62-67]</sup> Herein a metal- $\beta$ -diketone complex is dissolved into scCO<sub>2</sub> and a heated substrate (or mesoporous solid) is exposed to the solution. H<sub>2</sub> is then mixed into the solution and initiates a chemical reaction involving the precursor, thereby yielding metal films onto the substrate.

Likewise, hydrogen reduction of metal- $\beta$ -diketone complexes in scCO<sub>2</sub> can be applied to the modification of MWCNTs and NWs using a typical experimental set-up shown in Fig. 1.<sup>[57-59]</sup> The MWCNTs have diameters of about 20–30 nm and lengths of about 2–3  $\mu$ m. Two types of NWs, SiO<sub>2</sub>, and SiC NWs, 40 to 110 nm in diameter, several tens of micrometers in length, and randomly oriented on silicon substrates, were subjected to modification. MWCNTs, SiO<sub>2</sub>, or SiC NWs on silicon substrates were loaded in a 3.47-mL high-pressure stainless steel reactor along with a metal- $\beta$ -diketone complex. Following precursor loading, valve V<sub>1</sub> was closed while valves V<sub>2</sub>, V<sub>3</sub>, and V<sub>4</sub> were opened and H<sub>2</sub> at 3 atm was allowed to flow through the reactor for 5 min to expel the air inside. Valves V<sub>2</sub>, V<sub>3</sub>, and V<sub>4</sub> were then closed, and V<sub>1</sub> was opened to charge the H<sub>2</sub>-CO<sub>2</sub> mixer with 80 atm

Fig. 1 Schematic drawing of the experimental apparatus.

of CO<sub>2</sub>. After mixing of H<sub>2</sub> and CO<sub>2</sub>, valve V<sub>3</sub> was opened forcing the mixture into the reactor. Valves V<sub>1</sub> and V<sub>3</sub> were then closed for the dissolution of the precursor in the CO<sub>2</sub> solution. To ensure complete dissolution, the reactor was left undisturbed for 30 min. After that, the reactor was heated gradually to the desired temperature and kept at this constant temperature for 5–10 min. After the reaction, the reactor was cooled to 35°C and vented slowly by opening V<sub>4</sub>. Neat CO<sub>2</sub> flow was used to flush the reactor twice to remove the possible unreacted species and by-products. The reactor was then opened to recover the modified MWCNTs or NWs.

## METAL NANOWIRES AND NANORODS SHEATHED WITHIN MWCNTS

Unfunctionalized MWCNTs were used as the templates for confining and directing the growth of metal nanowires and nanorods caused by the hydrogen reduction of metal- $\beta$ -diketone complexes in scCO<sub>2</sub>. The metal- $\beta$ -diketone complexes used were M(hfa)<sub>2</sub>·xH<sub>2</sub>O (M=Pd, Ni, and Cu; hfa=hexafluoroacetylacetonate), and the temperatures of hydrogen reduction were 80–150°C, 250°C, and 250°C for filling palladium, nickel, and copper into MWCNTs, respectively. Transmission electron microscopy (TEM) observation of many different views of the product revealed several forms of foreign materials inside the MWCNTs. The amount of filled MWCNT out of the total number of nanotubes is estimated at about 10%. Fig. 2A and B shows the TEM images of

**Fig. 2** TEM images of metal nanowires or nanorods impregnated in MWCNT templates. (A,B) Palladium. (C) Nickel. (D) Copper. *Source:* From Ref.<sup>[57]</sup>.

nanowires or nanorods sheathed within carbon nanotubes. The nanowires are 7–9 nm in diameter and can be more than 200 nm in full length. The diameter of nanowires corresponds to the inner diameter of the MWCNTs and varies along the wires due to the fluctuation in the MWCNT diameter. The nanowires can be straight or curved, depending upon the curvature of the CNT wrapping. Fig. 2B also shows several segments of nanowires or nanorods that have been filled into the MWCNT. A typical energy dispersive X-ray spectrum (EDS) conducted on an individual nanowire or nanorod in the TEM is shown as an inset in Fig. 2B. It confirms that the nanowires and nanorods were made purely of palladium. Similarly, nanowires and nanorods of nickel or copper can also be developed within the channels of MWCNT templates, as shown in Fig. 2C and D.

Fig. 3A shows a high-resolution transmission electron microscopy (HRTEM) image of a Pd nanorod sheathed by a MWCNT, revealing that the Pd nanorod is composed of segments of single crystals. The region marked by a dashed square in Fig. 3A was further enlarged and is shown in Fig. 3B. Fourier transform and Fourier filtered HRTEM image are shown as insets in Fig. 3B. The HRTEM image processing indicates that this segment of Pd nanorod possesses the face centered cubic (fcc) structure with a measured lattice constant of 0.38 nm, which is comparable with the reported lattice constant of 0.3887 nm.

Similar to CVD and some wet chemical processes for MWCNT decoration, nucleation of metals as nanoparticles on the outside of MWCNTs occurred unavoidably in supercritical CO<sub>2</sub> along with metal filling. As has been reported, the defects in the MWCNT structure can provide favored sites for nucleation and growth of particles. Therefore besides the pure nanowire (or nanorod)/MWCNT composites, nanowire (or nanorod)/MWCNT/nanoparticle composites are also observed. As shown in Fig. 3A, a couple of palladium nanoparticles were attached to the exterior surface of the MWCNT sheathing the nanowire. Based on our experiment, we can somehow adjust the outside or inside loading preference of a metal by functionalization of MWCNTs. Metal deposition occurs only on the external walls of functionalized MWCNTs.

## MWCNTS DECORATED WITH CATALYTIC METAL NANOPARTICLES

### Functionalization of MWCNTs

The functionalization of MWCNTs was performed by dispersing and refluxing 0.5 g of MWCNTs in 40 mL of concentrated H<sub>2</sub>SO<sub>4</sub>–HNO<sub>3</sub> mixture (1:1 v/v ratio) for 6 hr to form a dark-brown suspension. The reaction

**Fig. 3** (A) HRTEM images of a Pd nanorod sheathed within a MWCNT, revealing that the Pd nanorod is crystalline with a fcc structure, (B) enlarged section of (A) showing that the imaging zone axis is [110]. *Source:* From Ref.<sup>[57]</sup>.

mixture was then diluted with distilled water to 200 mL and stirred for several hours, cooled down to room temperature, and filtered. The recovered black solid was washed several times with distilled water and finally dried at room temperature in vacuum. Previous X-ray photoelectron spectroscopy (XPS) and diffraction reflectance infrared Fourier transform (DRIFT) studies revealed that the surfaces of functionalized MWCNTs become covered with carboxylic ( $-\text{COOH}$ ), Carbonyl ( $>\text{C}=\text{O}$ ), and hydroxyl ( $-\text{COH}$ ) groups.<sup>[31,32,68]</sup> These functional groups have been demonstrated to provide favorite nucleation sites for metal nanoparticle growth and to stabilize the nanoparticles by increasing the nanoparticle–CNT interaction.

### Functionalized MWCNTs Decorated with Catalytic Palladium Nanoparticles

Modification of 10 mg of functionalized MWCNTs was carried out through hydrogen reduction of  $\text{Pd}(\text{hfa})_2 \cdot x\text{H}_2\text{O}$  at  $80^\circ\text{C}$ . A bright field TEM micrograph of the MWCNTs after  $\text{scCO}_2$  deposition using 10 mg of  $\text{Pd}(\text{hfa})_2 \cdot x\text{H}_2\text{O}$  is shown in Fig. 4A. Well-dispersed, spherical particles were anchored onto the external walls of MWCNTs, and the size range of these particles was about 5–10 nm. A selected area electron diffraction (SAED) pattern on a nanoparticle is shown as an inset in Fig. 4A, and the bright rings with occasional bright spots signify the crystalline nature

**Fig. 4** TEM images and EDX spectroscopy of MWCNTs decorated with Pd nanoparticles after hydrogen reduction of (A) 10 mg, (C) 20 mg, (D) 30 mg and (E) 50 mg  $\text{Pd}(\text{hfa})_2$ . *Source:* From Ref.<sup>[58]</sup>.

**Fig. 5** (A) TEM and (B) HRTEM images of MWCNTs decorated with Rh nanoparticles.

of the nanoparticle. EDS examination confirmed the presence of Pd in the nanoparticles decorating MWCNTs (Fig. 4B). For comparison, a commercial Pd on activated carbon catalyst sample was also examined by TEM, and the results showed numerous very large Pd particles irregularly distributed on carbon surfaces. The MWCNT appears to provide a unique template for decoration of nanometer-sized Pd metal particles on the carbon surfaces. By increasing the amount of Pd(hfa)<sub>2</sub> precursor, the loading density of Pd nanoparticles on the outer walls of CNTs can be increased (Fig. 4C to E).

#### Functionalized MWCNTs Decorated with Catalytic Rhodium Nanoparticles

Rh(acac)<sub>2</sub>·xH<sub>2</sub>O (acac=acetylacetonate) was used as the metal precursor in the hydrogen reduction reaction for loading Rh nanoparticles onto functionalized MWCNTs. The adopted temperature for the reduction was 250°C. A representative TEM image of MWCNTs decorated with Rh nanoparticles is displayed in Fig. 5A. A high and homogeneous dispersion of nanoparticles with a uniform distribution of particle sizes centered around 3–5 nm can be distinguished. The nanoparticles are comparable in size to the diameter of MWCNTs and are crystalline in nature as indicated by the SAED pattern given as an inset in Fig. 5A. The HRTEM image shown in Fig. 5B verifies that Rh nanoparticles are crystallites with visible lattice fringes.

#### Functionalized MWCNTs Decorated with Catalytic Ruthenium Nanoparticles

Decoration of Ru nanoparticles onto functionalized MWCNTs was performed by using Ru(acac)<sub>3</sub>·xH<sub>2</sub>O as the metal precursor for hydrogen reduction at 250°C. Fig. 6 presents the TEM images of highly dispersed Ru nanoparticles attached on MWCNTs, with

very tiny diameters around 1 nm and a uniform distribution throughout the full length of MWCNTs. The SAED pattern exhibits a set of diffraction rings from Ru metal. The diffraction did not appear as clear spots, but as concentric rings, each of which consists of a large number of very small spots, suggesting that the nanoparticles are composed of many fine crystallites. EDS spectrum of the nanocomposite shows emission from Ru, indicating the chemical identity of nanoparticles as Ru containing.

#### Chemical States of Metal Nanoparticles Decorated onto Functionalized MWCNTs

The chemical composition of the nanoparticles deposited onto functionalized MWCNTs was analyzed by XPS. Survey XPS spectra of the decorated MWCNTs provide results similar to those from EDS. In addition to peaks of C, O, and Si resulting from the MWCNTs and background (MWCNTs were dispersed onto silicon substrates for XPS analysis), each survey XPS spectrum shows strong peaks of Pd,

**Fig. 6** TEM image of highly dispersed Ru nanoparticles attached on MWCNTs.

Rh, or Ru. No other heterolement including fluorine was detected, implying no byproducts or unreacted precursors are present in the nanocomposites.

The states of MWCNT-supported palladium, rhodium, and ruthenium nanoparticles can be more clearly identified through high-resolution XPS analysis. A typical high-resolution Pd<sub>3d</sub> XPS spectrum of the Pd-decorated MWCNTs is shown in Fig. 7A. The binding energies, 335.3 eV for Pd<sub>3d5/2</sub> peak and 340.6 eV for Pd<sub>3d3/2</sub> peak, are in accordance with those reported for Pd<sup>0</sup>.<sup>[69]</sup> Furthermore, the peaks are asymmetric, having a line shape typical of metallic Pd.<sup>[69]</sup> All these imply that the palladium in the nanoparticles is zero-valent. No significant changes were observed in the binding energies or intensities of the Pd<sub>3d</sub> XPS core levels after exposing the palladium-decorated MWCNTs to air for 1 month, which demonstrates the stability of the palladium nanoparticles.

Fig. 7B displays the high-resolution Rh<sub>3d</sub> core level XPS spectrum of MWCNTs coated with Rh nanoparticles. The spectrum shows a low-energy band Rh<sub>3d5/2</sub> at 307.3 eV, and a high-energy band Rh<sub>3d3/2</sub> centering at 312.1 eV. As the Rh<sub>3d5/2</sub> and Rh<sub>3d3/2</sub> peaks for rhodium metal lie at 307.2 and 312.0 eV, respectively,<sup>[69]</sup> this indicates that Rh is also in the zero-valent state in Rh nanoparticle-MWCNT composites.

For MWCNTs decorated with ruthenium nanoparticles, the high-resolution Ru<sub>3d</sub> XPS spectrum has been obscured by the C<sub>1s</sub> spectrum. The deconvoluted spectrum shown in Fig. 7C gives broad bands that can be curve-fitted into two pairs of Ru<sub>3d</sub> peaks, therefore two chemically different Ru entities can be identified: the dominant pair with a Ru<sub>3d5/2</sub> peak at 279.8 eV corresponds well with the 3d5/2 and 3d3/2 lines of element Ru<sup>0</sup>, indicating that the majority of ruthenium loaded on MWCNTs is present as metallic Ru; the minor pair showing a Ru<sub>3d5/2</sub> peak at 280.8 eV can be assigned to Ru oxides. The presence of Ru oxides is responsible for the strong interaction between highly dispersed Ru nanoparticles and oxygen-containing groups on the functionalized MWCNTs and could also be resulted from the slight oxidation of Ru nanoparticles upon exposure of samples to ambient air.

### Promising Applications of the Metal-MWCNT Nanocomposites in Catalysis

Chemistry in ecologically benign solvents is of increasing interest in recent years. Most solvents used in organic syntheses for heterogeneous or homogeneous catalysis are coming under close scrutiny because of their toxicity and waste generation. There is a great push in industry today to replace these solvents with environmentally friendly solvents such as liquid or supercritical CO<sub>2</sub>. We have recently reported that

**Fig. 7** High-resolution (A) Pd<sub>3d</sub>, (B) Rh<sub>3d</sub>, and (C) Ru<sub>3d</sub> XPS spectra of MWCNTs decorated with Pd, Rh, or Ru nanoparticles.

palladium nanoparticles dispersed by a water-in-CO<sub>2</sub> microemulsion are very effective catalysts for hydrogenation of a number of olefins.<sup>[70]</sup> However,

separation of products from the surfactants and reuse of the catalyst are potential technical difficulties associated with the microemulsion technique. Developing effective heterogeneous catalysts that can be reused for chemical synthesis in liquid or supercritical CO<sub>2</sub> is currently of great interest to the chemical industry. The Pd nanoparticle–MWCNT composite may provide an effective catalyst for chemical synthesis in a green solvent that allows easy separation of products and minimizes waste solvent generation.

The catalytic capability of the Pd–MWCNT composite was tested for hydrogenation of a CO<sub>2</sub>-soluble olefin *trans*-stilbene in liquid CO<sub>2</sub>:

In this test, stilbene was dissolved in a mixture of 5 atm H<sub>2</sub> and 100 atm of CO<sub>2</sub> to make a 0.033 mol/L solution. The solution was pumped into a 6.94-mL stainless steel vessel loaded with 5 mg of the Pd–MWCNT composite (reported in Fig. 4C) at room temperature (23°C). Ultrasonication was applied to the vessel for 10 sec to disperse the catalyst. The product was trapped in CDCl<sub>3</sub> at different times and analyzed by proton NMR (Bruker, AMX 300). According to our NMR results, conversion of stilbene to 1,2-diphenylethane was about 80% and 96% after 5 and 10 min of reaction, respectively.

A number of noble metal–carbon fiber or metal porphyrin–graphite composites have been demonstrated to catalyze electrochemical reactions significantly.<sup>[13,71,72]</sup> The Pd–MWCNT nanocomposite was also tested for its electrocatalytic activity in oxygen reduction that is

**Fig. 8** Cyclic voltammograms of oxygen reduction in 1.0 M H<sub>2</sub>SO<sub>4</sub>. Source: From Ref.<sup>[58]</sup>.

important in fuel cell applications. For comparison, graphite powder, MWCNTs, and Pd–MWCNT (Fig. 4C) were mixed individually with mineral oil to make three different carbon paste working electrodes. Cyclic voltammetry measurements were conducted at room temperature in a three-compartment electrochemical cell. The electrolyte was 1.0 M H<sub>2</sub>SO<sub>4</sub> saturated with oxygen. The potential was cycled between +0.60 and -0.10 V at 40 mV/sec. As shown in Fig. 8, essentially no O<sub>2</sub> reduction was observed over the potential window for the carbon paste electrodes of bare MWCNT and graphite powder. In contrast, for the Pd–MWCNT electrode, a very large O<sub>2</sub> reduction wave was observed at potentials characteristic for Pd electrocatalysis. The enhancement of the cathodic current indicates a high electrocatalytic activity of the Pd–MWCNT electrode for the reduction of oxygen.

The highly dispersed Rh and Ru nanoparticles on MWCNTs are also expected to be potential catalysts for a variety of reactions.<sup>[26,73]</sup> As a catalyst for the hydrogenation of *trans*-cinnamaldehyde and the hydroformylation of hex-1-ene in the liquid phase, Rh-supported MWCNTs were found to be very selective toward C=C double-bond hydrogenation and the production of linear and branched aldehydes, respectively.<sup>[73]</sup> However, Ru nanoparticles anchoring on MWCNTs showed an unexpected increase in selectivity (up to 92%) for cinnamyl alcohol in liquid-phase hydrogenation of cinnamaldehyde.<sup>[26]</sup>

## METAL–NW NANOCOMPOSITES

### Metal–SiO<sub>2</sub> NW Composites

Modification of SiO<sub>2</sub> NWs was performed by hydrogen reduction of Cu(hfa)<sub>2</sub>·xH<sub>2</sub>O in scCO<sub>2</sub> at 250°C and 80°C, respectively. Typical SEM images of SiO<sub>2</sub> NWs after copper deposition are shown in Fig. 9, and three types of nanostructures are clearly visible. When a lower precursor concentration (2.0 × 10<sup>-3</sup> mol/L) was used in the experiment, discrete Cu nanoparticles were found to randomly anchor to the SiO<sub>2</sub> NWs (inset of Fig. 9A). As the concentration of the precursor increased to 2.7 × 10<sup>-2</sup> mol/L, the NWs became thicker after coating, wrapped by shells of densely packed Cu nanoparticles. The average outside diameter of the wire-shell composite structures can be up to 400 nm, indicating that the shells were composed of multilayers of Cu nanoparticles. The rough surfaces of the composites suggested that the copper coating was polycrystalline. We believe that the Cu nanoparticles were nucleated in the SCF medium and then deposited onto the SiO<sub>2</sub> NW surfaces to form the coated layer. Noticeable from the SEM images is also the aggregation of the Cu nanocrystals to form larger structures, most of which were sphere-like

**Fig. 9** SEM images of SiO<sub>2</sub> NWs after copper deposition from supercritical CO<sub>2</sub> solutions of (A)  $2.0 \times 10^{-3}$  (B)  $2.7 \times 10^{-2}$  mol/L Cu(hfa)<sub>2</sub>. Source: From Ref.<sup>[59]</sup>.

and “strung” up by the NWs. The inset in Fig. 9A shows a TEM image of a nanoparticle-decorated NW. Cu nanoparticles with different sizes, ranging from several to 50 nm in diameter, strung onto the SiO<sub>2</sub> NWs.

### Metal Alloy–SiC NW Composites

In principle, a number of metal precursors can be used as starting materials as long as they are soluble in CO<sub>2</sub>, and metals other than palladium and copper, or metal alloys can be coated on the SiO<sub>2</sub> NWs to form nanocomposites. Furthermore, NWs suitable for the SCF fabrication process are not limited to SiO<sub>2</sub>. Such hydrogen reduction of metal precursors in supercritical CO<sub>2</sub> may provide a general and clean process to modify NWs with metallic nanoparticles. Fig. 10 describes Cu–Pd alloy nanoparticles attached to SiC NWs through hydrogen reduction of a mixture of Cu(hfa)<sub>2</sub>·xH<sub>2</sub>O (95%) and Pd(hfa)<sub>2</sub>·xH<sub>2</sub>O (5%) in scCO<sub>2</sub> at 80°C. Some aggregated balls of metals are also observed.

### CONCLUSION

SCF approach is a novel and emerging technology to generate nanomaterials in small areas, high-aspect-ratio

structures, complicated surfaces, and poorly wettable substrates with high uniformity, high homogeneity, and minimum environmental problems.

Through hydrogen reduction of metal-β-diketone complexes in supercritical CO<sub>2</sub>, a rapid, convenient, and environmentally benign approach has been developed to synthesize a variety of nanostructured materials: 1) metal (Pd, Ni, and Cu) NWs and nanorods sheathed within MWCNT templates; 2) nanoparticles of palladium, rhodium, and ruthenium decorated onto functionalized MWCNTs. These highly dispersed nanoparticles are expected to exhibit promising catalytic properties for a variety of chemical or electrochemical reactions; 3) Cu or Cu–Pd nanocrystals deposited onto SiO<sub>2</sub> or SiC NWs. Different types of nanostructures were achieved, including nanocrystal-NW, spherical aggregation-NW, shell-NW composites, and “mesoporous” metals supported by the framework of NWs.

### ACKNOWLEDGMENTS

This work was supported by a LDRD program at Pacific Northwest National Laboratory (PNNL) and the Idaho-NSF-EPSCoR and ARO-DEPSCoR

## INTRODUCTION

The discovery of X-rays in 1895 by W.C. Röntgen gave materials science and engineering a powerful research tool. Investigations with X-rays are non-destructive and often very fast, which explains their widespread use. There are mainly two fields of application, namely chemical analysis by means of X-ray fluorescence spectrometry (XRF) and structure determination by means of X-ray diffractometry (XRD). The first field deals with the use of multilayer mirrors for the detection of even very small amounts of an element in a specimen. In the second field, multilayer mirrors are employed to obtain structural information, e.g., on the crystal structure, the texture of materials, or phase formation. Diffractometry is also used to determine the crystal lattice spacing of a structure, to estimate the grain size in nanocrystalline materials, to observe structural transformations, to measure the internal strain in materials, or to identify new structures, e.g., in protein crystallography. X-ray investigations can be improved by using state-of-the-art X-ray optics. There are various types of X-ray optical elements, e.g., crystals, mono-/multilayer mirrors, zone plates, capillaries, or X-ray lenses. Here, multilayer mirrors will be presented as powerful X-ray optics for XRF and XRD, especially X-ray reflectometry (XRR). State-of-the-art physical vapor deposition technologies enable us to produce very precise and accurate multilayer mirrors. They consist of alternating layers of

high-Z and low-Z (heavy and light elements) materials with a double-layer thickness or period  $d$  in the nanometer range. In the field of X-ray optics, multilayer mirrors are competitive elements to improve the performance of complete X-ray optical systems by collimation, beam shaping, beam guidance, and monochromatization.

## OVERVIEW

In the electromagnetic spectrum, X-rays occupy the region between gamma and ultraviolet rays, ranging from hard X-rays via soft X-rays to extreme ultraviolet radiation (EUV). In this region the wavelength  $\lambda$  of X-rays is expressed in nanometers, e.g.,  $1 \text{ nm} = 10^{-9} \text{ m} = 10 \text{ \AA}$ .<sup>[1]</sup> To convert wavelengths into photon energy  $E$ , the relationship  $\hbar\omega\lambda = 1239.842 \text{ eV nm}$  can be applied.<sup>[2]</sup> Since the discovery of X-ray diffraction in 1912, it has been possible to investigate the structure of materials with atomic resolution.<sup>[3]</sup> The success of X-ray investigations depends on the properties of the optical system; this fact has driven forward the development of various sources, optics, and detectors. During the last 30 years, new X-ray sources such as synchrotron facilities have been built to achieve sufficient intensity and collimation. For these sources, now various X-ray optics are available, e.g., crystals, grazing-incidence mirrors, zone plates, X-ray lenses, and multilayer mirrors. The use of the state-of-the-art

X-ray optics can dramatically improve the outgoing X-ray beam,<sup>[4]</sup> and it can open up totally new methods for the investigation of materials.<sup>[5]</sup> Here, multilayer mirrors will be introduced and discussed as powerful X-ray optical elements in chemical analysis and structure determination. A multilayer consists of alternating layers of high-Z and low-Z materials with a double-layer thickness or period  $d$  in the order of nanometers (2–10 nm). In XRF, multilayer mirrors<sup>[6]</sup> have been used as analyzer crystals to measure the elemental composition of a material, especially to detect light elements by means of wavelength-dispersive XRF.<sup>[7]</sup> They work as a filter for a distinct emission line of the stimulated fluorescence radiation of a specimen. Because of the low atomic number of light elements, the fluorescence yield is poor.<sup>[8]</sup> Some improvements are still possible because of advanced deposition techniques, which make more exotic materials available as thin films. Furthermore, not only the peak reflectivity but also the background suppression originating from the matrix elements plays an important role in reducing the measuring time. Their optimization leads to an improved lower limit of detection (LLD). In this section, improvements for the detection of boron, carbon, and aluminum will be presented and discussed. In XRD, laterally graded multilayers on figured substrates for beam conditioning were introduced by Göbel and Schuster.<sup>[9–12]</sup> The layer thickness gradient fulfills Bragg's law for the X-ray wavelength of interest across the whole mirror length. Therefore, such a graded multilayer acts both as a monochromator and as a beam shaper for X-rays. A divergent "white" beam from an X-ray source is converted into a parallel monochromatic beam by a parabolically curved, laterally graded multilayer mirror ("Göbel-Mirror"). These multilayer mirrors combine the advantages of perfect single crystals (with large incidence angle but low acceptance angle) and total-reflection mirrors (with high reflectivity but small incidence angle). The use of high-precision prefigured optical substrates has led to a new generation of curved graded multilayer mirrors that achieve peak reflectivities higher than 70% at Bragg angles between 0.5° and 3°. Therefore, multilayer mirrors have attained an important and preferential role as optical elements for X-ray laboratory equipment.

## XRF

### La/B<sub>4</sub>C Multilayer for the Detection of Boron (B-K $\alpha$ : $E = 183 \text{ eV}/\lambda = 6.775 \text{ nm}$ )

To fabricate multilayer mirrors, alternating stacks of two different materials are deposited by magnetron sputtering onto a substrate in a vacuum system at an

Ar working pressure of 0.1–0.5 Pa. The as-deposited La/B<sub>4</sub>C multilayers (Fig. 1) are of good structural quality: Each of the 50 double layers is smooth, and the double-layer thickness (approximately 10 nm) is uniform over the whole stack. The small-angle Bragg peaks (inset of Fig. 1) indicate that the layer roughness is less than 0.5 nm. At higher magnification, the interdiffusion appears to be broader at the B<sub>4</sub>C-on-La interface than at the La-on-B<sub>4</sub>C interface. These results are consistent with the XRR data, which show that the small-angle Bragg peaks are less intense than expected. This could be explained by the chemical interdiffusion at each interface. Furthermore, the electron diffraction of a small area indicates that both layers are amorphous.

Figure 2 shows a comparison of the measured reflectivities of the Mo/B<sub>4</sub>C multilayer previously used for B detection<sup>[14,15]</sup> and the newly developed La/B<sub>4</sub>C multilayer. For this comparison, s-polarized radiation with photon energies of 50–250 eV at a fixed incidence angle of 24.5° was used at a synchrotron reflectometer (Beamline G1 at HASYLAB, DESY in Hamburg).<sup>[16]</sup> Both multilayers consist of 40 pairs each, with a period of approximately 8.5 nm. Fig. 2 shows the reflectance vs. photon energy of 50–250 eV at a fixed incidence

**Fig. 1** Cross-section TEM image of a La/B<sub>4</sub>C multilayer, 50 double layers are visible with a period of approximately 10 nm. La layers: dark; B<sub>4</sub>C layers: bright. Two different electron diffraction patterns with different magnification are shown in the inset. The surrounding spots of the Si substrate can be seen on the left inset. *Source:* For experimental details, see Ref.<sup>[13]</sup>.

**Fig. 2** Experimental reflectivity vs. photon energy at a fixed incidence angle of 24.5°: comparison of La/B<sub>4</sub>C and Mo/B<sub>4</sub>C multilayers, using synchrotron radiation. Source: For experimental details see Ref.<sup>[13]</sup>.

angle of 24.5°. The first-order Bragg peak of both multilayers is determined at 183 eV, but the reflectivities obtainable at this energy are different. The higher peak intensity of 53% occurred for the La/B<sub>4</sub>C multilayer whereas the reflectivity for the Mo/B<sub>4</sub>C multilayer was only 38%. Moreover, it is remarkable that the La/B<sub>4</sub>C multilayer showed less reflectivity in the range below 100 eV, which is important for Si-L radiation at 90 eV. So, the improved suppression of unwanted Si fluorescence radiation in the case of the La/B<sub>4</sub>C multilayer is a clear advantage because it decreases the background in the XRF measurement of boron within a silicon matrix. This is crucial for applications in the semiconductor industry. Furthermore, La/B<sub>4</sub>C showed a superior suppression of O-K fluorescence radiation.<sup>[17]</sup> The latter experiments reveal that over the whole angular range (0°–30°) the reflectivity at 525 eV is lower for La/B<sub>4</sub>C than for Mo/B<sub>4</sub>C. The better suppression of fluorescence radiation of oxygen and silicon leads to the assumption that La/B<sub>4</sub>C should be the superior boron analyzer for samples consisting of these elements. On the other hand, Fig. 2 shows another peak at 115 eV, which is because of the lanthanum absorption edge, which in turn leads to an enhanced XRF background if the investigated sample emits radiation at this energy. This enhanced background may occur if the sample contains phosphorus (L emission line at 120 eV).

The patented<sup>[18]</sup> La/B<sub>4</sub>C multilayer mirror is particularly suited for the detection of boron. Fig. 3 illustrates its performance by means of the XRF spectra of a sample with a high boron content (B<sub>4</sub>C plate) using the La/B<sub>4</sub>C and Mo/B<sub>4</sub>C multilayers as analyzers. Fig. 4 demonstrates the superiority of this mirror with respect to samples having a low boron content. A 707-nm thick borophosphosilicate glass (BPSG) film containing 5% B and 2.95% P was used

**Fig. 3** X-ray fluorescence measurements of a B<sub>4</sub>C specimen (high boron concentration) using La/B<sub>4</sub>C and Mo/B<sub>4</sub>C multilayers as analyzers. Performed by means of wavelength-dispersive XRF. The boron peak at approximately 24.5° is increased for the new multilayer. Source: From Ref.<sup>[13]</sup>.

as a sample. BPSG is important in semiconductor manufacturing; it is used in the process of wafer-flattening.<sup>[19]</sup> Consequently, the new La/B<sub>4</sub>C multilayer mirror offers a clear improvement in the detection of boron, irrespective of its concentration.

To quantify the improvement achieved in XRF applications, the LLD is determined using the following formula:  $LLD = 3 \cdot c(B) / (p - b) \cdot \sqrt{b} / 100s$ , where  $c(B)$  is the boron content, and  $p$  and  $b$  are the intensities of the peak and background, in counts per second. Table 1 shows the results for both test samples with different analyzers. The determination of the LLD reveals that there is an improvement of approximately 29% for the La/B<sub>4</sub>C multilayer as well as for the sample with a low boron content and a significant phosphorus content.

**Fig. 4** XRF measurements of a BPSG specimen (low boron concentration) using La/B<sub>4</sub>C and Mo/B<sub>4</sub>C multilayers as analyzers. Performed by means of wavelength-dispersive XRF. The boron peak at approximately 24.5° is increased for the new multilayer. Source: From Ref.<sup>[13]</sup>.

**Table 1** LLD of Mo/B<sub>4</sub>C and La/B<sub>4</sub>C multilayers using B<sub>4</sub>C and BPSG as test samples with high and low boron content, respectively

Analyzer	B <sub>4</sub> C LLD (ppm)	BPSG LLD (ppm)
Mo/B <sub>4</sub> C	344	896
La/B <sub>4</sub> C	243	634

LLD =  $3 \cdot c(B) / (p - b) \cdot \sqrt{b/100s}$ , where  $c(B)$  is the boron content, and  $p$  and  $b$  are the intensities of the peak and the background, in counts per second. The unit of the LLD is ppm.

Source: From Ref.<sup>[13]</sup>.

To summarize, the higher peak reflectivity and the better suppression of unwanted radiation lead to this improvement of boron detection. Thus, La/B<sub>4</sub>C has replaced Mo/B<sub>4</sub>C in multilayer mirrors used in X-ray optical applications below 190 eV. Further XRR investigations have shown that the La/B<sub>4</sub>C multilayers remain stable after 30 min of annealing at 150°C and their X-ray optical properties do not change. After annealing at 780°C for 30 min, the reflectivity of the multilayer stack is reduced. However, the existence of many Bragg orders shows that the multilayered structure of the whole stack is still present but slightly rougher. Moreover, transmission electron microscopy (TEM) investigations show that crystallization of the layers and grain coarsening take place. This thermal stability makes the La/B<sub>4</sub>C multilayers promising for synchrotron applications. The use of La/B<sub>4</sub>C multilayers for normal-incidence applications at X-ray wavelengths above the boron edge would be interesting for future EUV lithography, bearing in mind that the calculated normal-incidence reflectivity of an ideal La/B<sub>4</sub>C multilayer mirror would be 80% at a wavelength of 6.6 nm.

### Multilayers for the Detection of Carbon (C-K $\alpha$ : $E = 277 \text{ eV}/\lambda = 4.476 \text{ nm}$ )

For the detection of carbon at photon energy of 277 eV, various multilayer combinations have been developed and investigated. Previously, V/C and Ti/C had been considered for this energy. As shown by theoretical calculations, it is possible to improve the reflectivity at this photon energy by replacing the V or Ti layer with one of their alloys. The best results are achieved with oxides and nitrides (Table 2). This procedure promises an improved

**Table 2** Calculated reflectivity of various ideal multilayers with a  $d$ -spacing of 6 nm and a thickness ratio of  $\Gamma = 0.4$  at a photon energy of 277 eV

Multilayer	V/C	VC/C	VN/C	VO/C	Ti/C	TiC/C	TiN/C	TiO <sub>2</sub> /C
Reflectivity (%)	41.3	40.6	48.7	48.5	39.2	39.8	49.4	51.2

Source: From Ref.<sup>[20]</sup>.

absorption-to-dispersion ratio because the use of alloys reduces the density. Furthermore, the absorption edge of N and O is close, but not too close, to the C edge.

Figure 5 shows the energy scans of some of the multilayers (Table 2), which were deposited by magnetron sputtering and examined by synchrotron radiation. The peak reflectivities measured at 277 eV are 29.4% and 37.1% for the V/C and the TiO<sub>2</sub>/C multilayers, respectively. These results are lower than the calculated values for ideal multilayers. However, the expected advantage of the oxides shown is confirmed experimentally. The energy scans in Fig. 5 also reveal the differences between the two multilayers at energies of 450–525 eV. The V/C multilayer has an enhanced reflectivity at around 525 eV, which is because of the V-L edge. This reflectivity is undesired because it may lead to unwanted background radiation in samples containing oxygen (525 eV). Therefore, it can be concluded that V as a multilayer material is unfavorable if the sample contains oxygen. For the promising TiO<sub>2</sub>/C multilayer, the Ti-L edge is located at about 450 eV, which is sufficiently far away from the O-K emission line at 525 eV. Note that the difference in reflectivity between the two multilayers at 525 eV is more than one order of magnitude. Therefore, in the case of the Ti-based multilayer a lower background is expected. A second effect leading to an improved background is the reduction in density and absorption of the oxide or nitride multilayers. To check the performance of various carbon analyzers, XRF measurements with a graphite sample have been carried out and confirmed the above assumptions. The TiO<sub>2</sub>/C multilayer clearly has the best background suppression (Fig. 6). Consequently, compared to the carbon detection limit for V/C (181 ppm), the improvement for TiO<sub>2</sub>/C (128 ppm) is about 29% and that for TiN/C (146 ppm) about 19%.

### Multilayers for the Detection of Aluminum (Al-K $\alpha$ : $E = 1487 \text{ eV}/\lambda = 0.834 \text{ nm}$ )

The improvement of the detection limit of Al in samples with high Si contents is again of relevance for the semiconductor industry. Because Si (1740 eV) is a neighbor of Al in the periodic table of elements, their emission lines are not so well separated. Besides, a high Si content in the specimen causes an enhanced XRF background around the Al emission line. Usually, in

**Fig. 5** Experimental reflectivity vs. photon energy at a fixed incidence angle of  $21.5^\circ$ : comparison of  $\text{TiO}_2/\text{C}$  and  $\text{V}/\text{C}$  multilayers. *Source:* From Ref.<sup>[20]</sup>.

XRF spectrometers the  $\text{W}/\text{Si}$  multilayer is employed for this energy range. The multilayer exhibits rather broad Bragg peaks, which result in relatively poor background suppression. The first attempt to reduce the background was the replacement of the reflector  $\text{W}$  with the lighter compound  $\text{WSi}_2$ . The lower density of  $\text{WSi}_2$  ( $9.8 \text{ g/cm}^3$ ) compared to that of  $\text{W}$  ( $19.3 \text{ g/cm}^3$ ) gave rise to lower absorption and narrower Bragg peaks. The theoretical reflectivities given in Fig. 7 confirm these considerations, although the  $\text{Al}$ -peak reflectivity is reduced. In a second attempt,  $\text{W}$  was replaced with  $\text{Ta}$  ( $16.6 \text{ g/cm}^3$ ). As  $\text{Ta}$  has a suitable absorption edge close to  $1740 \text{ eV}$ , the calculated reflectivity of  $\text{Ta}/\text{Si}$  is even more reduced around the  $\text{Si}$  emission line. The  $\text{Al}$ -peak reflectivity is only reduced slightly. The XRF measurements (Fig. 8) have been carried out with a  $12\text{-nm}$   $\text{Al}$  film on a  $\text{Si}$  wafer, using  $\text{W}/\text{Si}$ ,  $\text{WSi}_2/\text{Si}$ , and  $\text{Ta}/\text{Si}$  multilayer analyzers. As expected, the reflectivities of the  $\text{WSi}_2/\text{Si}$  and  $\text{Ta}/\text{Si}$  multilayers at the  $\text{Si}$  emission line have been reduced compared

**Fig. 6** XRF measurements of a graphite sample using  $\text{V}/\text{C}$ ,  $\text{TiN}/\text{C}$ , and  $\text{TiO}_2/\text{C}$  multilayers as analyzers. *Source:* From Ref.<sup>[20]</sup>.

**Fig. 7** Theoretical reflectivity vs. photon energy for the three multilayers,  $\text{Ta}/\text{Si}$ ,  $\text{WSi}_2/\text{Si}$ , and  $\text{W}/\text{Si}$ , each of them with  $4\text{-nm}$  double-layer spacing, calculated using Henke's optical constants. *Source:* From Ref.<sup>[20]</sup>.

to those of  $\text{W}/\text{Si}$ , and additionally, the signal-to-background ratio around the  $\text{Al}$  line has been improved. The  $\text{Al}$  detection limits of  $\text{W}/\text{Si}_2$  and  $\text{Ta}/\text{Si}$  are improved by  $42\%$  and  $60\%$ , respectively, compared to those of  $\text{W}/\text{Si}$ .<sup>[21]</sup> These results confirm the assumption that the neighboring  $\text{Si}$  radiation contributes to the background at the  $\text{Al}$  line. Finally, for the measurement of low  $\text{Al}$  concentrations in  $\text{Si}$ -rich specimens,  $\text{Ta}/\text{Si}$  provides the best performance because of the decisive signal-to-background ratio around the  $\text{Al}$  emission line.

## XRD

In this entry, the applications of multilayer mirrors in XRD will be reviewed in a more general way. Today, multilayer mirrors are available for almost all X-ray sources. The percentage of multilayer mirrors for the

**Fig. 8** X-ray fluorescence measurements of a  $12\text{-nm}$  thick  $\text{Al}$  coating on silicon wafer, using  $\text{Ta}/\text{Si}$ ,  $\text{WSi}_2/\text{Si}$ , and  $\text{W}/\text{Si}$  multilayers as analyzers. The different peak positions are because of slightly different double-layer spacings. *Source:* From Ref.<sup>[20]</sup>.

Cu-K $\alpha$  wavelength ( $\lambda = 0.1541 \text{ nm}/E = 8048 \text{ eV}$ ) is approximately 85% of the whole market. Mo, Co, and Cr multilayer mirrors have market shares of 5%, 6%, and 4%, respectively. Thus, a lot of work has been devoted to the improvement of the peak reflectivity and spectral resolution of X-ray optics using copper radiation. However, most multilayer mirrors share a large number of important properties. First, we will report on the design, substrate specifications, and requirements for X-ray optics. Additionally, the optimization will be described, especially the selection of materials. Then, the characterization of curved graded multilayer mirrors will be presented. Finally, we will look at various applications of this state-of-the-art technology.

### Multilayer Mirrors for XRD

The design of laterally graded multilayer mirrors is described in detail by Schuster et al.<sup>[22]</sup> To summarize briefly, there are three major mirror types for the use in XRD: parabolic, elliptic, and planar. As mentioned above, a parabolic mirror collects the divergent beam from a source (located at the focus of the parabola), and then it generates parallel beams (Fig. 9). A concave elliptic mirror converts a divergent beam from a source into a convergent beam. When the source is positioned at the first focus, the outgoing beam is directed into the second focus of the ellipse. A planar mirror is the simplest optical system, because its reflecting surface does not change the inclination laterally. However, provided the multilayer period and its gradient fit perfectly to the shape of the mirror, a high peak reflectivity can be achieved.

### Substrate Specifications for Figured Multilayer Mirrors for Use in XRD

For the fabrication of X-ray mirrors various substrate materials are used, for instance single-crystalline pure silicon, fused silica, and quartz. Before deposition, it is important to have a surface with low roughness,

**Fig. 9** Parabolically curved and laterally graded multilayer mirror (known as Göbel mirror) attached to an X-ray tube. The divergent beam from the X-ray tube is converted into a parallel beam. The resulted beam in the sample direction is also monochromatic.

small slope errors, and a good long-term stability. There are different methods to achieve such a substrate surface and a figured X-ray optics. With the first method, the multilayers are deposited on flat and smooth substrates. These are often silicon wafers that are commercially available at a reasonable price and have an excellent surface quality. The rms roughness is below 3 Å. To reach the desired shape, the wafer with the multilayer on top is pressed onto a negative form. This curvature of the mirror is fixed with a glued backing plate. The advantage of this technique is the low risk involved. Typical slope errors are 15 arcsec rms. A second method for the fabrication of multilayers is possible provided the deposition process is stable and reproducible: Before deposition, prefigured fused quartz substrates are processed by mechanical and ion-beam polishing to achieve the desired shape. Their surface roughness is below 2.5 Å, and the typical slope error of these substrates is below 1.7 arcsec rms. This is by about a factor of 10 better than with the first method.

### XRD Multilayer Requirements

The multilayer mirrors for XRD are designed to achieve high reflectivity, good beam uniformity, low divergence, and high spectral purity.<sup>[23]</sup> Here, we will consider the requirements for parabolically figured multilayer mirrors. Such a mirror is able to convert a divergent beam from a source into a parallel beam. Therefore, the multilayer period  $d$  has to fulfil the dispersion-corrected multilayer Bragg equation:

$$d = \frac{\lambda}{2 \left( 1 - \frac{\delta}{\sin^2 \Theta} \right) \sin \Theta}$$

where  $\delta$  ( $< 10^{-4}$ ) is the mean decrement of the refractive index of the multilayer, and  $\Theta$  is the parabola-dependent Bragg angle of the multilayer;  $p$  is the parabola parameter, and  $x$  is the coordinate extending from the vertex along the parabola symmetry axis. After including the parabola equation, the angle of incidence is given by  $\Theta(x) = \text{arccot} \sqrt{2x/p}$ . Please note that there is now a clear dependence between the multilayer period  $d$  and position  $x$ , which is an important issue concerning the quality of a parallel beam X-ray optics. The requirements for elliptical and planar multilayer mirrors are given in Ref.<sup>[22]</sup>.

### Optimization of Multilayer Mirrors (Selection of Materials)

The performance of a multilayer mirror depends on the selection of the two materials (spacer with low  $Z$  and

reflector with high  $Z$ ), as discussed by Spiller.<sup>[23]</sup> Ideally, a pair with a high X-ray optical contrast  $\Delta\delta$  and small absorption coefficients is chosen. However, the measured performance is often lower than that expected from the theory; this may be because of errors in layer thickness, uncertainties in the optical constants, contamination, and interdiffusion or intermixing at the interface of the materials. Simulations are useful to find the best combination of materials. Atomic scattering factors for all elements<sup>[24]</sup> and their optical constants are available on the Internet at [http://www-cxro.lbl.gov/optical\\_constants/](http://www-cxro.lbl.gov/optical_constants/) for energies up to 30 keV and at <http://physics.nist.gov/PhysRefData/Xcom/Text/XCOM.html> for energies up to 100 GeV. With IMD (software for modeling the optical properties of multilayer films)<sup>[25]</sup> it is also possible to simulate the theoretical reflectivity of a multilayer mirror (Fig. 7). Intensities of specular reflected X-rays can be computed based on the Fresnel equations including interfacial roughness and/or diffuseness.<sup>[26–28]</sup> With these simulations, the quality of multilayers can be checked, and therefore, thin film growth can be controlled to achieve atomic sharp interfaces and high reflectivity. For instance, a promising combination should have a small transition zone and low roughness between the materials. Furthermore, TEM investigations are carried out to explain the microstructure at the interface of various magnetron sputtered multilayers.<sup>[29,30]</sup> To reduce the interdiffusion at the interfaces, barrier layers are incorporated, e.g., in Mo/Si multilayers for EUV applications.<sup>[31,32]</sup>

### Characterization of Multilayer Mirrors for XRD

Reflectivity measurements are the first step to determine double-layer spacing (or period), roughness, and density of each layer of the multilayer. In Fig. 10, a parabolic mirror designed for Cr- $K\alpha$  radiation is shown. In this energy range, absorption and dispersion are higher; so the number of periods is reduced to 70 layer pairs. The reflectivity curves are measured at three positions (or focal distances) of a graded Cr/C multilayer. The average peak reflectivity is about 74%, which is a high value for Cr- $K\alpha$  radiation, and enables many applications.

Figure 11 shows a typical variation in double-layer spacing  $d$  across a parabolically curved graded W/Si multilayer measured by XRR. The solid line gives the ideal curve with a period of 4.88 nm at 150 mm and a gradient of  $1.95 \times 10^{-8}$ . So the high accuracy and high precision are evident. The applied magnetron sputtering process is highly reproducible; therefore, it allows the fabrication of multilayers with a period within a 1% tolerance range around the desired values.

**Fig. 10** Reflectivity vs. incidence angle across a Cr/C multilayer at different focal distances,  $f = 75, 90,$  and  $105$  mm. The  $d$ -spacings are 4.88, 5.34, and 5.90 nm, measured with Cr- $K\alpha$  radiation by means of XRR. The multilayer has 70 Cr/C pairs and a thickness ratio of  $\Gamma = 0.5$ . Source: From Ref.<sup>[22]</sup>.

Please note that the difference in  $d$ -spacing over a distance of about 10 mm equals one atom.

The beam uniformity was checked by coupling the parallel beams to a channel-cut monochromator (for experimental details, see Refs.<sup>[33–35]</sup>). Because of the extremely small acceptance angle of the monochromator, the quality and also the imperfections of the mirrors are obvious. The typical width of the parallel beam after a multilayer mirror is approximately 1 mm. The intensity deviation over the beam width is less than 20% because of the small period error of the multilayer and small slope error of the curved mirror. The beam divergence can be measured with a rocking curve on the Si(004) reflection. The typical full

**Fig. 11** Double-layer spacing  $d$  vs. focal distance  $f$  across a parabolically curved graded W/Si multilayer measured by means of XRR (full squares). The solid line gives the ideal period based on the focal distance. To guide the eye, the two sidelines indicate a tolerance band of  $\pm 1\%$  around the ideal curve. Source: From Ref.<sup>[33]</sup>.

**Fig. 12** Suppression of Cu-K $\beta$  radiation: diffraction measurements around Si(004) carried out with various parabolic multilayers (Ni/B<sub>4</sub>C, WSi<sub>2</sub>/Si, and W/Si) in the incident beam path. *Source:* From Ref.<sup>[36]</sup>.

width at half maximum (FWHM) of a rocking curve is about 0.03° for WSi<sub>2</sub>/Si and Ni/B<sub>4</sub>C multilayer mirrors.

With many XRD applications, monochromatic radiation is required for the investigation of a specimen. Therefore, K $\beta$  radiation and Bremsstrahlung should be suppressed. The K $\beta$  suppression was examined by measuring a  $\theta$ -2 $\theta$  scan around the Si(004) reflection from a single-crystalline Si wafer. As shown in Fig. 12, W/Si multilayer mirrors have a relatively poor suppression of Cu-K $\beta$  and W-L $\beta$  lines, whereas WSi<sub>2</sub>/Si and Ni/B<sub>4</sub>C multilayer mirrors offer an improved spectral purity. Furthermore, the thermal stability of WSi<sub>2</sub>/Si multilayers is superior to that of W/Si multilayers.<sup>[37]</sup> Consequently, the K $\beta$ -to-K $\alpha$ 1 intensity ratio achieved (or suppression factor) is better than 1:2000. The normalized K $\beta$ -to-K $\alpha$ 1 intensity ratios for the W/Si, WSi<sub>2</sub>/Si, and Ni/B<sub>4</sub>C multilayers are about 1:0.28:0.21. An additional check of the monochromatization by means of a quartz powder specimen confirmed this result.<sup>[33]</sup>

Table 3 summarizes the intensity gain factors obtained from various parabolically curved graded multilayer mirrors by coupling the parallel beam to a channel-cut monochromator. The details of the

**Table 3** Intensity gain factors (mirror length 60 mm, focal distance from the center of each mirror 150 mm, thickness ratio of  $\Gamma = 0.5$ , 50 layer pairs for W/Si, and 100 layer pairs for the other material combinations)

Year	Multilayer	Intensity gain factors
1995	W/Si	6
1997	W/Si	11
1997	WSi <sub>2</sub> /Si	12
1999	Ni/B <sub>4</sub> C	16

*Source:* From Ref.<sup>[33]</sup>.

experimental setup are described in Ref.<sup>[34]</sup>. The parallel beams lead to a considerable increase in the throughput when coupled to these low-acceptance channel-cut monochromators. Compared to a configuration without a multilayer mirror, an intensity gain factor of 6 has been achieved using a bent and glued multilayer mirror. Please note that the small acceptance angle of the channel-cut monochromator leads to a conservative gain factor. In diffraction experiments, the gain factor is expected to be higher because of the larger acceptance angle. As can be seen in Table 3, the use of prefabricated quartz substrates can improve the intensity gain factor from 6 to 11 when W/Si multilayer mirrors have been used. This setup also allows a comparison between various multilayer materials. WSi<sub>2</sub>/Si multilayer mirrors show an intensity gain factor of about 12. A further intensity improvement has been obtained applying Ni-based multilayer mirrors, which have a gain factor of approximately 16. The theoretical limit is in the range of 20–25, depending on the multilayer materials.<sup>[38]</sup> The photon flux of these parallel beam X-ray optics is approximately  $3 \times 10^9$  cps for Cu-K $\alpha$  radiation at a source-to-detector distance of 435 cm and with an X-ray generator operated at 40 kV and 40 mA.

### Applications of Multilayer Mirrors in XRD

The previously mentioned features of multilayer mirrors namely high reflectivity, good beam uniformity, low divergence, and good spectral purity are the basis for their success in the market and numerous applications. Today, approximately 50% of all XRD instruments are equipped with graded multilayer mirrors, and this number is still increasing. The above mentioned gain factor of more than one order of magnitude can be displayed in XRR. The upper reflection curve in Fig. 13 was measured with an incident beam Göbel mirror for Cu-K $\alpha$  radiation and the lower curve without the Göbel mirror but with a graphite diffracted beam monochromator to suppress the influence of Cu-K $\beta$  radiation. The measurements were carried out with a Bruker AXS D8 Advance Diffractometer equipped with a reflectometry stage with a knife-edge collimator. The distance between the knife-edge and the specimen was 10  $\mu$ m. All other measurement conditions were identical. The specimen was a V/C multilayer with 40 pairs and a period of 6.5 nm. The two measurements were plotted without normalizing in units of counts per second. Please note that the primary intensity provided by the Göbel mirror is more than one order of magnitude. Consequently, it is possible to investigate more Bragg orders. In another measurement, a dynamic range of nine orders of magnitude was achieved by measuring the native oxide

**Fig. 13** Cu-K $\alpha$  reflectivity curves of a V/C-multilayer film, 6.5-nm  $d$ -spacing and 40 pairs, measured with an incident beam Göbel mirror and with a secondary monochromator, respectively. *Source:* From Ref.<sup>[39]</sup>.

layer on top of a silicon wafer. Such a dynamic range is not achievable with conventional diffractometers, only at synchrotron sources and nowadays in the laboratory with Göbel mirrors. The high intensity also allows diffuse XRR (cf. Ref.<sup>[20]</sup>). Here, we also describe a comparison between conventional Bragg–Brentano geometry and parallel beam geometry with respect to the effect of peak broadening. In the first case, the position of the specimen with reference to the center of the diffractometer has to be adjusted very accurately; otherwise, the measured peaks of the diffraction pattern will be influenced, showing peak broadening with increasing deviation. The peak width plays an important role in considering the grain size in powder measurements or the internal stress of a coating. The use of parallel beams allows to avoid these problems. There is no sensitivity to sample displacement, which leads to peak broadening and to peak shifts because of defocusing.<sup>[20,40]</sup> Therefore, it is possible to do measurements with variable-temperature attachments and to investigate samples with low absorption (e.g., plastics) or with irregularly shaped surfaces, for example, an ancient statue.<sup>[10]</sup>

The resolution of XRR measurements can be improved by the use of a different wavelength, as shown in Fig. 14. The reflectivity of a V/C multilayer is measured with Cu and Cr radiation. For each measurement a Göbel mirror that has been optimized for the selected wavelength is used. In the measurement using Cr-K $\alpha$  radiation ( $E = 5415 \text{ eV}/\lambda = 0.2290 \text{ nm}$ ) the Kiessig fringes are clearly resolved between the main order reflections from the multilayer; when employing Cu radiation, they are not resolved. The Kiessig fringes are because of the total film thickness of about 260 nm. Their number between the main order reflections equals the number of bilayers minus 2. Thus, it is possible to determine the number of bilayers

**Fig. 14** Reflectivity measurements of a V/C-multilayer film, 6.5-nm  $d$ -spacing and 40 pairs, obtained with Cu-K $\alpha$  (40 kV, 40 mA) and Cr-K $\alpha$  (35 kV, 35 mA) radiation, respectively, and using Göbel mirrors optimized for these wavelengths ( $2\theta$  step size:  $0.004^\circ$ , scan speed: 1 step/s, total measurement time: 35 min 25 s). *Source:* From Ref.<sup>[39]</sup>.

( $N = 40$ ). This example demonstrates the higher resolution that is achievable with a change to another wavelength.

## CONCLUSIONS

In the field of XRF, nanostructured multilayer mirrors are applied in the detection of light elements. The recently developed multilayer mirrors for the detection of boron, carbon, and aluminum presented and discussed here achieve a much lower and consequently better LLD. This improvement is not only because of higher reflectivity but also because of lower background. In the field of XRD, significant progress has been made in the design and fabrication of curved graded multilayer mirrors that are employed to achieve high reflectivity, good beam uniformity, low divergence, and high spectral purity. A typical XRD multilayer mirror displays the following properties, depending on the materials used: reflectivity  $>70\%$ , Bragg angle:  $0.8^\circ$ – $2^\circ$ , Bragg peak width:  $0.03^\circ$ – $0.06^\circ$ , rms slope error  $<0.01^\circ$ , total divergence  $<0.033^\circ$ . The application of X-ray multilayer mirrors is currently expanding in new fields where the X-ray intensities are weak.<sup>[41–43]</sup> Today, the characterization of thin films and layer stackings is also possible using specular XRR at Cr wavelength. Moreover, measurements with diffuse XRR can be performed with a quality previously confined to synchrotron radiation sources. In protein crystallography and life sciences, very small crystals, large unit cells, and anisotropic structures can be investigated by means of XRD. In addition, these powerful multilayer mirrors coupled to low-power X-ray tubes can lead to the development of

new, small, and transportable instruments with significant X-ray intensity. Finally, the recent developments and applications in X-ray optics should be mentioned here. In protein crystallography, elliptically bent focusing multilayer mirrors are employed, especially in single crystal diffraction. Two-dimensional focusing is possible when two mirrors are combined in a Montel scheme.<sup>[20]</sup> Larger X-ray optics are required for beam alignment, beam guidance, and monochromatization in the soft X-ray range at free electron lasers. For this application (50–200 eV), amorphous carbon coatings are used as a 500-mm long total-reflection mirror. These monolayers exhibit a uniformity of better than 2% in thickness over the whole length.<sup>[44,45]</sup> Depth-graded multilayer mirrors used as optical elements at synchrotrons provide a broad and well-defined reflectivity profile.<sup>[46]</sup> Thus, the use of nanostructured multilayer mirrors for X-ray optical applications is still growing in many directions.

## ACKNOWLEDGMENTS

# Nanostructured Silica and Silica-Derived Materials

Ho-Cheol Kim  
Geraud Dubois

IBM Almaden Research Center, San Jose, California, U.S.A.

## INTRODUCTION

Silicates are the most commonly found minerals as they are compounds of silicon and oxygen, which together make up almost 75% of the earth's crust. Consequently, silicates are a basic building block of various natural or artificial structures. With emerging interests in nanoscale science and technology, silicate materials containing nanometer-sized structures have been studied and their new and interesting physical, chemical, and biological phenomena are begun to be understood. The control of silica material structures at a nanoscopic level attracts a great deal of interest among the scientific community in the last decade and remains an ongoing challenge. While various kinds of silica polymeric materials have been known for years, new morphologies have recently appeared, such as spherical hollow spheres, transparent films, mesoporous materials with narrow pore size distribution, and nanoporous thin films. In this entry, we discuss some old and new aspects of the synthesis of silica polymeric nanostructures, as well as their use in emerging technologies.

## SILICA NANOPARTICLES

In 1968, Stöber and Fink<sup>[1]</sup> hydrolyzed a dilute solution of tetraethylorthosilicate (TEOS) in ethanol at high pH and obtained uniform spheres of amorphous silica whose sizes could be varied from 10 nm to 2  $\mu$ m simply by changing the concentrations of the reactants. Examples of dense silica nanoparticles synthesized according to the Stöber process are depicted in Fig. 1.

This method was later improved by many others and appears to be the simplest and most effective route to monodispersed silica spheres.<sup>[2]</sup> Two types of reactions occur in the formation of silica particles: silanol groups are formed by hydrolysis of alkoxy silane groups and siloxane bridges are formed by a condensation polymerization reaction.

Recent mechanistic studies suggest that several types of micrometer-sized colloidal particles prepared by the precipitation method are in fact, the result of

aggregation of much smaller subunits, or nanometer-sized primary particles, rather than continuous growth by diffusion of species from the solution to the nucleating surfaces.<sup>[3]</sup> In some cases, a broad range of size distribution was observed during the period of growth, indicating the occurrence of multiple nucleation events.<sup>[4]</sup> The uniformity of size in the final product may be achieved through a self-sharpening growth process during which small particles grew more rapidly than larger ones.

The surfaces of these silica colloids are typically terminated with three silanol types: free or isolated silanols, hydrogen-bonded or vicinal silanols, and geminal silanols (Scheme 1).

Silica nanoparticle surfaces can be rendered non-polar by post-treatment with hexamethyldisilazane (commonly used in industry for the manufacture of hydrophobic fumed silica), alkoxy silanes, or alcohols (esterification).<sup>[5–7]</sup> The treated silica nanoparticles can then be dispersed in various non-alcoholic solvents, such as methyl isobutyl ketone, cyclohexane, n-octane, or diethyl ether. Protected and unprotected monodispersed silica colloidal spheres are commercially available in large quantities from Nissan Chemical Industries, a company that has produced silica colloids for many years and whose monodispersed products are marketed under the trade name Snowtex<sup>®</sup>. Those readers with interest in the applications of monodispersed colloidal silica spheres can find a recent survey by Xia et al.<sup>[8]</sup>

Whereas dense silica particles have been known since 1956, spherical silica materials with hollow interiors have drawn interest in recent years because of their potential uses as low-density capsules for controlled-release drugs, dyes and inks, development of artificial cells, protection of proteins, or enzymes, and catalysis.<sup>[9]</sup> Many procedures for the generation of hollow silica spheres exist, including layer-by-layer deposition on (sub)micrometer-sized latex particles,<sup>[10]</sup> interfacial synthesis,<sup>[11]</sup> the use of hybrid polystyrene/siloxane latex particles,<sup>[12,13]</sup> and more recently, the controlled precipitation of silicic acid on functionalized polystyrene latexes<sup>[14]</sup> or the liquid phase deposition of silica onto fullerene surfaces.<sup>[15]</sup> Two major requirements

**Fig. 1** Scanning electron microscope pictures of dense silica nanoparticles (left: 50 nm diameter; right: 150 and 200 nm diameter).

**Scheme 1** Surface silanol types.

of any of these synthetic methods are to ensure a homogeneous deposition of silica and to prevent multiparticle aggregation. Hereafter we describe two of the aforementioned strategies as examples for the synthesis of spherical silica particles with hollow interiors. The first approach is divided in two steps as shown in Scheme 2. First, 3-(trimethoxysilyl) propyl methacrylate (MPS) is covalently attached to the surface of polystyrene latex particles leading to silanol-functionalized particles. Then, the silanols are used to nucleate the deposition of a silica layer onto the hybrid particles' surface by reaction with TEOS in aqueous basic alcoholic suspensions. Using this process, stable non-aggregated suspensions of hollow silica nanoparticles with 20 nm thick shells are produced as illustrated by the transmission electron microscope (TEM) images in Fig. 2. It is notable that

dense silica particles are not detected, indicating that the polycondensation reaction only takes place at the seed surface.

The second approach involves the slow controlled precipitation of silica from a sodium silicate solution onto polystyrene latexes bearing amine functionalities or amine and carboxylate groups (zwitterionic surface). Control of the sodium silicate solution pH is critical. A pH of 9.7 ensures a homogeneous coating of the latex particles in 24 hr and minimizes the non-templated precipitation of silica particles (Scheme 3). Interestingly for this approach, deposition of the coated particles on a surface from aqueous solution by slow evaporation leads to highly organized hexagonal lattices. The voids between adjacent spheres are still open, indicating that the organized array is indeed formed by the stacking of silica coated spheres (Fig. 3).

For both strategies, the latex core is removed by calcination in a final step leading to the formation of hollow silica spheres with theoretically closed central pores, the pore size being dictated by the size of the starting polymeric core. While closed cell porosity is advantageous in the case of hollow silica nanoparticles for the applications mentioned previously, other applications benefit more from open porosity and high

**Scheme 2** Formation of hollow silica beads.

surface area. These include ion exchange, gas adsorption, heterogeneous catalysis, hydrogen and or methane storage, and many others.

## NANOPOROUS MEDIA

Porous media are very useful in numerous applications for every day life. When the pore size reaches several nanometers, they can find potential applications in state-of-the-art technologies including electronics, optics, biotechnology, and so on. Porous materials may be fully crystalline (zeolites), ordered on a mesoscopic length scale but amorphous on an atomic length scale (surfactant-templated materials), or fully disordered (silica gels).<sup>[16,17]</sup> While the engineering of micro structure has been achieved in the case of zeolites for more than 50 years, precise control of the pore size distribution and the shape and volume of the void spaces for mesoporous silicates only emerged in the early 1990s with the synthesis of the so-called M41S periodic mesoporous silica.<sup>[18]</sup> In the synthesis of this material (Scheme 4), the hydrolysis and polycondensation of the silica precursor was templated by micelles preformed from a surfactant, an amphiphilic molecule that self-organizes in aqueous media into supramolecular arrays due to polarity differences between the lyophobic head group and lyophilic tail. While a

structure-directing agent (surfactant) is used for the synthesis of both zeolites and M41S materials, only in the latter case is a true template mechanism operative as a direct correlation of the surfactant array size and shape to final pore size and geometry is observed. The pores of these solids are classified according to size: pores size below 2 nm are called micropores, those in the range 2–50 nm are denoted mesopores, and those above 50 nm are macropores.<sup>[19,20]</sup>

Depending upon the nature of the surfactant (e.g., cationic, anionic, neutral, zwitterionic, bolaamphiphile, Gemini, divalent, and commercially available polymers), different mesophases are obtained: MCM-41 (hexagonal), MCM-48 (cubic), MCM-50 (lamellar), SBA-1, SBA-6, HMS, MSU-n, MSU-V, and many others.<sup>[21]</sup> When a charged surfactant is used, calcination of the as-synthesized material is mandatory to fully remove the template, whereas in the case of a neutral surfactant washing is sufficient. This neutral templating route allows the direct synthesis of hybrid organic–inorganic mesoporous materials where an organic molecule can be incorporated either in the channels or inside the walls.<sup>[22,23]</sup> These organically functionalized silicas present a very high surface area and tightly controlled porosity with a loading of organic groups that can be varied over a large range.

In the semiconductor industry, scientists have recently drawn inspiration from the molecular templated

**Scheme 3** Silica coating of amino-functionalized latex particles.

**Fig. 3** Scanning electron microscope image of an organized multilayer of 200-nm-sized coated spheres after calcinations. With the chosen acceleration voltage, the complete coating is not visible in this case.

synthesis of mesoporous solids to develop materials with low dielectric constant (low  $k$ ) for advanced microelectronics. As electronic devices get smaller and smaller, improvements in back end of the line (BEOL) interconnect performance require the reduction of resistance and capacitance, hence, new insulating materials having lower dielectric constant are needed.<sup>[24]</sup> Fig. 4 represents a typical BEOL structure containing multilayers of hard mask, dielectrics, etch stop, and cap coating. For over 30 years, silicon dioxide ( $\text{SiO}_2$ ) has been the dielectric insulator of choice for the semiconductor industry due to its excellent dielectric breakdown strength, a high modulus, good thermal conductivity, and excellent adhesion to other materials. However,  $\text{SiO}_2$  is being replaced with materials

possessing lower permittivity to achieve reduced capacitance for next technology generations. For example, at the 65 nm technology generation, the target effective dielectric constant ( $k_{\text{eff}}$ ) according to the 2001 International Technology Roadmap for Semiconductors is 2.3–2.6.<sup>[25]</sup> The  $k_{\text{eff}}$  is a composite value comprised of the dielectric, hard mask, barrier cap layer, and etch stop layer as schematically shown in Fig. 4. To achieve this ultra low dielectric constant, materials with  $k < 2.2$  will be required. Porous structure is unavoidable choice for dielectric material in order to attain sufficiently low dielectric constants.

The incorporation of nanosized pores into a matrix structure leads to a significant decrease in the dielectric constant of the bulk material since the dielectric

**Scheme 4** General mechanism for the formation of M41S materials.

Fig. 4 A typical structure of multilayered BEOL.

constant of air is about one. The dielectric constant of the material can therefore be adjusted by simply varying the level of nanoporosity. Among a variety of method to generate nanoporosity in organic or inorganic films, an approach developed in IBM, known as the so-called *sacrificial porogen approach*, has been recognized as a simple and effective route to thin films containing nanometer sized pores.<sup>[26–31]</sup> It utilizes phase separation of two component systems where one component (e.g., organosilicates matrix) crosslinks into a network effectively limiting domain growth and coarsening of the porogen phase (an organic, labile polymeric component) that is ultimately expelled from

the film by thermal decomposition. Fig. 5 depicts the schematics of pore generating process. The morphology of nanohybrid, where the phase separated porogen domain is entrapped within crosslinked organosilicate matrix, and hence the pore morphology is strongly dependent on the interaction between porogen and matrix material, and molecular weight, molecular architecture, and loading level of the porogen.

This process is able to generate various morphology and dimensions of the pores. Two distinctive pore morphologies could be observed depending on the phase separation kinetics. As shown in the right side of Fig. 5, when the porogen and matrix undergo the liquid–solid phase separation caused by the crosslinking of the matrix material, which is a typical nucleation and growth (NG) process, random shapes of pores with broad size distribution are obtained. Porogens of homopolymers or copolymers with linear or branched molecular architectures show NG type phase behavior. In contrast, well-defined, quite-ordered pore structure with narrow size distribution is obtained when preassembled porogens template the porous structure.<sup>[32]</sup> By the definition of templating (TP), the procedure involves a preassembled mould with the specific morphology that can be transferred to the final porous structure. As shown by the cross-sectional TEM images in Fig. 6, microstructures of pores

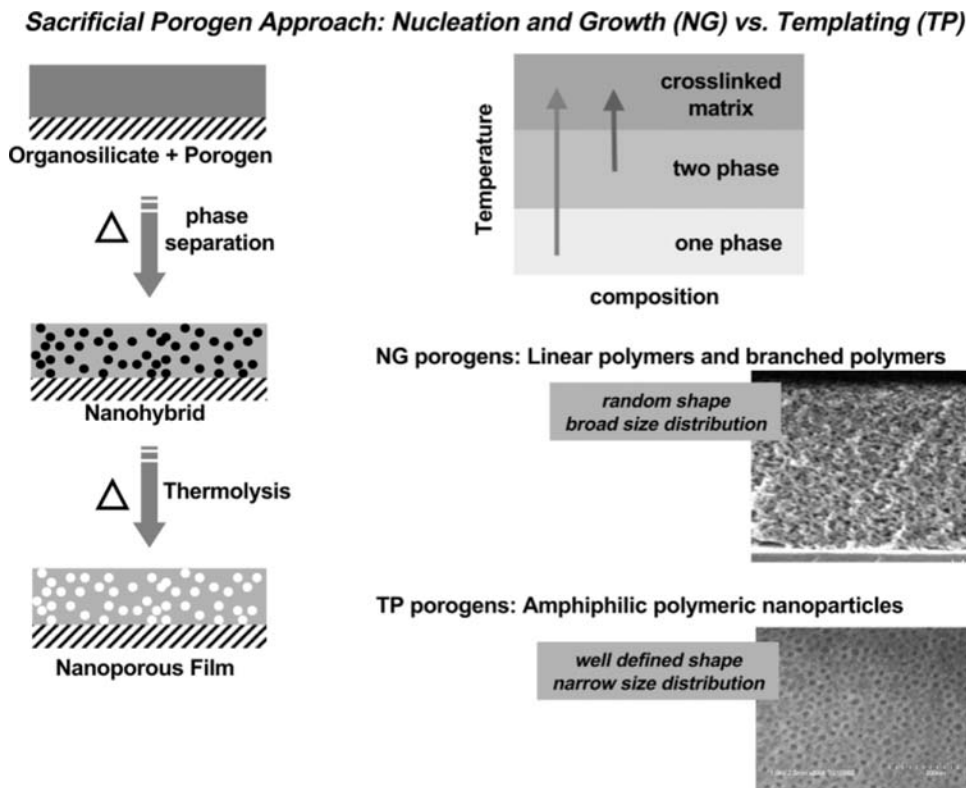

Fig. 5 Schematics of the sacrificial porogen approach to nanoporous organosilicates. Two distinct microstructures of pores are observed with different molecular architectures of porogens as shown in the right side.

**Fig. 6** Transmission electron microscope images of porous thin films generated by two different routes. Left: NG; Right: TP.

generated by two routes are very different. TP process (right-side image of Fig. 6) provides well-defined regular pore structures while NG process (left-side image of Fig. 6) gives random structures of pores.

In addition to the low dielectric constant, the nanoporous organosilicate thin films have a number of interesting properties which make them very attractive for many potential applications including optical components, catalyst supports, separation media, high density biosubstrates, and so on. Due to the nanoscopic dimensions of pores, these materials are optically homogeneous within visible wavelength of light. As shown in Fig. 7, for example, the refractive index of thin films of organosilicates also can be easily controlled over broad ranges (1.16–1.35 for this example) by simply varying the amount of porogen loadings.

**Fig. 7** Refractive index of porous organosilicate thin films as a function of porosity.

One simple application of this controllable refractive index is optical coating on glass to enhance transmission of light (i.e., antireflection effect).<sup>[33,34]</sup> With a single layer of homogeneous dielectric material coating on a substrate, antireflection effect can be achieved if  $n_2^2 = n_1 n_3$  and  $h = \lambda/4$ , where  $h$  is coating thickness,  $\lambda$  is the wavelength of incident light,  $n_1$ ,  $n_2$ , and  $n_3$  are the refractive indices of substrate, dielectric material, and air, respectively. A dielectric material of  $n_2 = 1.22$  is required for glass substrate ( $n_1 \sim 1.5$ ,  $n_3 \sim 1$ ), which is not attainable with pure solid dielectric materials as the lowest  $n_2$  of dielectric materials is about 1.35 (cryolite,  $n_2 = 1.38$  for  $\text{MgF}_2$ ).<sup>[35]</sup> Fig. 8 shows the optical transmission spectra of glass slides coated with  $\sim 60$  nm of nanoporous poly(methylsilsesquioxane) (PMSSQ) generated from 50 wt% porogen loading ( $n \sim 1.22$ ). Compared to the uncoated glass, single and double sided nanoporous coatings increase the optical transmission through the glass from  $\sim 91.7\%$  to  $\sim 94.4\%$  and  $\sim 98.2\%$ , respectively. In addition, thin films of the nanoporous film with optical thickness ranging within visible wavelength are found to be robust.

Due to the nanoscopic dimension of pores and intrinsic hydrophobicity of PMSSQ, the porous PMSSQ films show very selective sorption behavior. A quartz crystal microbalance (QCM) combined with reflectance infrared spectroscopy (IR) study revealed this selectivity.<sup>[36]</sup> With organic liquids having surface tension below the critical value (38–48 dyne/cm), the extent of sorption increased with porosity of PMSSQ films. Extremely low amounts of sorption were measured with the liquids having a surface tension higher than the critical value. The selective sorption behavior can be interpreted by capillary condensation resulting from the lowered vapor pressure in the nanoscopic pores and the experimental data are in good agreement with calculations using the Kelvin equation.

Fig. 8 Antireflection effect of nanoporous thin films coated on a glass slide.

The nanoporous PMSSQ thin films show potentials as biosubstrates when the hydrophilicity is controlled. A wide range of surface hydrophilicity can be obtained by a simple UV/ozone treatment on nanoporous PMSSQ films. Although the precise mechanism of UV/ozone treatment has remained unclear in literature, it has been widely used for a variety of etching/cleaning applications in the microelectronics industry. It is known that ozone is dissociated by absorption of 253.7 nm radiation or thermal heating into atomic oxygen which is postulated to be the predominant etchant species. Over the temperature range from room temperature to  $\sim 300^{\circ}\text{C}$ , organic materials are broken down into simple volatile oxidation products such as carbon dioxide, water, etc.<sup>[37,38]</sup> Fig. 9 shows water contact angles on dense PMSSQ surface as a function of UV/ozone treatment time at  $30^{\circ}\text{C}$ . The treatment gives surfaces having water contact angles ranging from  $105^{\circ}$  to  $25^{\circ}$  with increasing treatment time.

Since biosystems are based on aqueous environment, controlled hydrophilicity of solid surface is very useful for numerous applications in biotechnology including microarrays, affinity separation channels, etc. The ability to control surface hydrophilicity is applicable for pattern generation by limiting the area of UV/ozone treatment using a mask. Hydrophilic patterns in hydrophobic matrix can be obtained since only the area exposed both to UV and ozone becomes hydrophilic while masked areas remain as hydrophobic. Fig. 10 shows the patterning process and an optical micrograph of a patterned surface where hydrophilic area (diameter =  $250\ \mu\text{m}$ ) is decorated with a fluorescent dye (6-FAM amidite). Due to the porous, three-dimensional structure of the matrix, the patterned substrate has higher number density of functional groups than flat surface, which results in ten times higher fluorescence intensity than the corresponding flat silicon wafer surface. The arrays

of patterns containing high surface area are desirable to reduce the overall size of an array while maximizing the number of reaction sites within the pattern and minimizing the required reagent and sample volume.<sup>[39–41]</sup>

## CONCLUSIONS

Silicates with controlled nanoscopic structures are very attractive for a variety of potential applications due to their novel and interesting physical, chemical, and biological properties. Effort continues to explore new nanostructures, to optimize properties, and to utilize them for numerous end-uses, including optical components, electronics, separation media, catalysis, and biotechnology.

## INTRODUCTION

The mass–strength ratio is of exceptional importance for different applications. Critical parts of various moving vehicles from satellites to aircrafts to cars depend on strength and toughness of the materials they are made of, while strict limitations on the weight of the different components are placed by the launch technology. Single-walled carbon nanotubes (SWNT) present significant potential as the basic material for space applications. The exceptional mechanical properties of SWNTs<sup>[1–6]</sup> have prompted intensive studies of their composites. These qualities can also be used in a variety of other technologies from automotive to military and medical. However, the present composites have shown only a moderate strength enhancement when compared to other hybrid materials.<sup>[7–9]</sup> Although substantial advances have been made,<sup>[10]</sup> the mechanical characteristics of SWNT-doped polymers are noticeably below their highly anticipated potential. Pristine SWNTs are well known for poor solubilization, which leads to phase segregation of composites. Severe structural inhomogeneities

result in the premature failure of the hybrid SWNT–polymer materials. The connectivity with and uniform distribution within the matrix are essential structural requirements for the strong SWNT composites.<sup>[11–13]</sup> Here we show that a new processing approach based on sequential layering of chemically modified nanotubes and polyelectrolytes can greatly diminish the phase segregation and render SWNT composite highly homogeneous. Combined with chemical cross-linking, this processing leads to drastically improved mechanical properties. The tensile strength of the composites is several times higher than that of SWNT composites made via mixing; it approaches values seen for hard ceramics. The universality of the layering approach applicable to a wide range of functional materials makes possible successful incorporation of SWNT into a variety of composites, imparting them required mechanical properties.

The thin-film membranes that are obtained as a result of the layer-by-layer process can be used as an intermediate or as a component of ultrastrong laminates. At the same time, the prepared membranes can also be utilized in the as-prepared form for space and

biomedical technologies because of the combined strength and multiple functionalities of the SWNT membranes.

## RESULTS AND DISCUSSION

Single-walled carbon nanotube composites are typically prepared by blending, in situ polymerization, and extrusion. After extensive surface modification, such as grafting or polymer wrapping,<sup>[12–14]</sup> the phase segregation from a macromolecular matrix is smaller than for pristine SWNT, but still remains high owing to vastly different molecular mobilities of both components. Very intense research on appropriate surface modification of SWNT is currently under way in many groups around the world. Nevertheless, most common loadings of nanotubes in the polymer matrix are within the 1–15 wt.% range, whereas more than 50% of the SWNT content is needed for materials with special mechanical performance without compromising the homogeneity of the composite at the nanometer level. This high loading of the nanotubes is particularly important when both electrical and mechanical qualities of the nanotubes are going to be utilized.

The phase segregation between dissimilar materials can be circumvented by applying a new deposition technique often called layer-by-layer assembly (LBL).<sup>[15]</sup> It is based on the alternating adsorption of monolayers of individual components attracted to each other by electrostatic and van der Waals interactions and can be carried out with a variety of polyelectrolytes and other compounds with high molecular weight. The immobilization of the macromolecular compounds and strong interdigitation of the nanometer-thick film allows for the close-to-perfect molecular blending of the components.<sup>[16,17]</sup>

The SWNT–polyelectrolyte composites produced in this study were assembled onto a solid support via alternate dipping of a solid substrate (glass slides, Si wafers) into dispersions of SWNT and polyelectrolyte solutions.<sup>[18–20]</sup> The individual assembly steps, i.e., adsorption of SWNT and polyelectrolyte monolayers, were interlaced by rinsing steps to remove the excess of assembling materials. When the LBL procedure was complete, the multilayer films were lifted off the substrate to obtain uniform freestanding membranes, which can be handled as regular composites.<sup>[21]</sup> Such films make possible straightforward testing of their mechanical properties. It is important to note that large-area membranes for space telescopes and similar applications can similarly be made by deposition on the substrates of appropriate size.

Single-walled carbon nanotubes were produced by laser ablation and subsequently purified via acid treatment. They were manufactured by laser vaporization

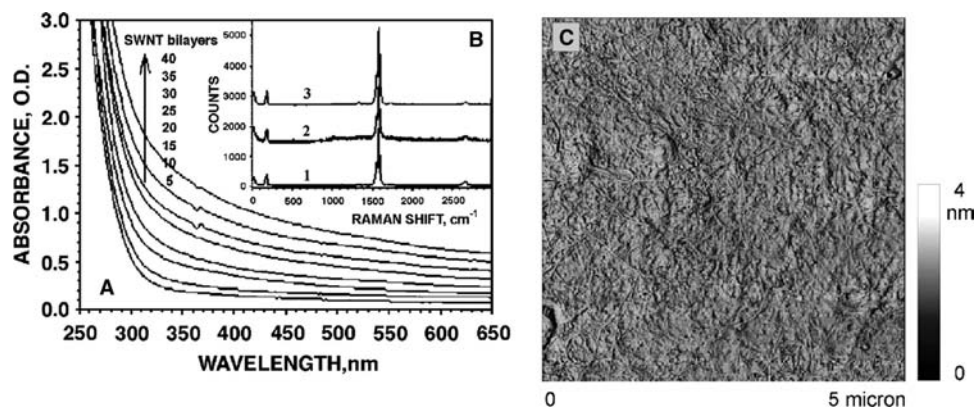

of carbon rods doped with Co, Ni, and FeS in an atmosphere of Ar:H<sub>2</sub>. It needs to be pointed out that the standard SWNT products made by HiPCO and other methods contain significant amount of soot, graphite flakes, and remnants of the catalyst, which need to be removed before the assembly. The quality of the dispersion directly affects the mechanical performance of the resulting composite.

A suspension of SWNT raw material was refluxed in 65% HNO<sub>3</sub> and subsequently purified by centrifugation. Supplemented by sonication, this treatment results in the partial oxidation of ca. 5% of the total number of carbon atoms both in caps and walls of SWNT.<sup>[22]</sup> A similar type of dispersion can also be made following other methods, such as polymer wrapping the nanotubes and chemical derivatization. Optimization of the aqueous nanotube dispersions should be considered as one of the most critical direction of the optimization of the carbon nanotube composites and speed and quality of their processing in the composites.

The presence of carboxylic acid groups affords the preparation of metastable SWNT dispersions after 1-min sonication in deionized water without any additional surfactant. Thus-prepared, negatively charged SWNT with a zeta potential of  $-0.08$  V can be layer-by-layer assembled with positively charged polyelectrolyte, such as branched poly(ethyleneimine) (PEI; Mw = 70,000) (Fig. 1). Because the overall negative charge of the SWNT used here was fairly small, a layer of SWNT was replaced with a layer of poly(acrylic acid) (PAA; Mw = 450,000) after every fifth deposition cycle (Fig. 1). These additional layers improve the linearity of the deposition process and present a convenient chemical anchor for subsequent chemical modification. For the same reasons, a single PEI/PAA bilayer was deposited on a bare glass or Si

**Fig. 1** Common polyelectrolytes used for LBL process.

**Fig. 2** Structural characterization of SWNT multilayers. (A) Sequential UV-vis spectra of a glass substrate in the course of the LBL deposition of SWNT. The spectra were taken for a total number of (PEI/SWNT) bilayers indicated in the graph. substrate before the SWNT assembly. The assembly conditions of the entire procedure (pH, ionic strength, concentrations, etc.) were optimized so that the dipping cycles can be repeated as many times as needed with linear growth of the multilayers (Fig. 2A). This enables the preparation of films with any desirable thickness and architecture tailored to different applications. The ionic conditions of LBL assembly were the following: 1% solution of PEI at pH 8.5; 1% PAA at pH 6 (pH 3 for wafer coating); SWNT at pH 6.8. All solutions were made in 18 MΩ deionized (DI) water without addition of any extra salt or other low molecular weight electrolyte. Deionized water was also used for rinsing at pH 8.5, adjusted by NaOH. Wafers and glass slides were cleaned in piranha solution, rinsed with DI water, sonicated for 15 min, and again thoroughly rinsed with DI water. After that, they were coated with a precursor layer: PEI (10 min) + PAA (15 min, pH 3), followed by the deposition of (PEI/SWNT)<sub>5</sub>. The layer sequence of (PEI/PAA)-(PEI/SWNT)<sub>5</sub> was repeated until the desirable thickness was obtained. Exposure times of 10 and 60 min was used for polyelectrolytes and SWNT baths, respectively.<sup>[18,19]</sup>

Multilayer stacks with a cumulative structure of [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>6</sub> and [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>8</sub> containing 30 and 40 (PEI/SWNT) bilayers, respectively, were typically used in this study.

We are currently investigating other methods of SWNT dispersion in water to avoid excessive damage to the SWNT wall, for example, wrapping the nanotubes with copolymers, which can work equally well on the SWNT and multiwalled carbon nanotubes (MWNT). For some applications, MWNTs can be the preferred materials because of their lower cost.

Similarly to other polyelectrolyte LBL systems,<sup>[15]</sup> a submonolayer of SWNT is deposited in each

deposition cycle. The final morphology of the multilayers can be described as a mixture of individual carbon nanotubes and their 4–9-nm bundles intricately interwoven together in a fine fabric (Fig. 2C). Two important structural characteristics should be pointed out. Single-walled carbon nanotubes uniformly cover the entire surface of the substrate without any evidence of phase separation. Also, the presence of oxidized flat graphite sheets and other forms of carbon colloids in our experiments was very small. Both these factors contributed to the mechanical properties of the composites. The quality of the nanotube material was also assessed by Raman spectroscopy. (Raman measurements were performed in a backscattering configuration with 50 mW of 514.5-nm laser light incident on the samples). The characteristic Raman peaks for SWNTs, e.g., the radial breathing mode at  $\sim 182 \text{ cm}^{-1}$  and the tangential C–C stretching modes located at  $\sim 1560 \text{ cm}^{-1}$  (G1 mode) and  $\sim 1583 \text{ cm}^{-1}$  (G2 mode), were very sharp and narrow, indicating the high uniformity of the SWNT and low level of impurities present in the films. A barely visible peak at  $\sim 1340 \text{ cm}^{-1}$  (D mode) revealed the presence of residual amounts of disordered carbon structures. Using the correlation between the frequency of the radial breathing mode,  $\nu$ , and the SWNT diameter,  $d$ , expressed as  $d = 223.75/\nu$ ,<sup>[23]</sup> a value of  $d = 1.2 \text{ nm}$  is obtained, which is in a good agreement with the SWNT diameters obtained from atomic force microscopy (AFM) images of many individual nanotubes. From these images, the length of the nanotubes was estimated to be 2–7  $\mu\text{m}$ .

Poly(ethyleneimine) was utilized as the LBL partner of SWNT because of the terminal -NH<sub>2</sub> and backbone -NH- groups in the main chain and branches suitable for the subsequent chemical modification of the composite.<sup>[24]</sup> The PEI chains can be cross-linked 1) with

each other and 2) with carboxyl groups on SWNT and PAA. Chemical stitching increases the connectivity of the polyelectrolyte matrix with SWNT, and therefore, the load transfer in the composite.<sup>[13]</sup> We used here the combination of both modification pathways. Partial covalent SWNT-PEI-PAA cross-linking was achieved by heating the films to 130°C after the deposition of each layer, resulting in amide bonds between a variety of protonated and non-protonated functional groups of PEI, PAA, and SWNT complementing the intrinsic ionic cross-linking of the LBL films.<sup>[25]</sup> Subsequently, the film was exposed to glutaraldehyde at room temperature. The sample was cross-linked in 0.5% glutaraldehyde solution in phosphonate buffer (0.054 M Na<sub>2</sub>HPO<sub>4</sub>, 0.013 M NaH<sub>2</sub>PO<sub>4</sub>, pH 7.4) for 1 hr at room temperature. To remove unreacted glutaraldehyde, the film was rinsed with tap water for 3 × 10 min and then with DI water the same number of times. This reaction produces a tight network of polymeric chains and nanotubes connected by dialdehyde linkages. It was found that if only 1% of all carbon atoms of SWNT are chemically bonded to the polymer matrix, such cross-linking drastically increases the shear between them by an order of magnitude.<sup>[13]</sup> Therefore a 5% density of -COOH groups on the SWNT surface cited above should be sufficient to obtain good connectivity with the polyelectrolyte matrix. Note that these groups are not completely utilized at the moment because of the relatively low temperature of the amide bond cross-linking step.

The mechanical properties of the LBL-assembled SWNT thin films were studied in their freestanding form prepared by the chemical delamination from the substrate.<sup>[21]</sup> Multilayers of SWNT were separated from the silicon wafers by immersion into 0.5% aqueous HF for 3 min. The Raman scattering spectrum of the separated film is almost identical to that of the supported film and original nanotubes (Fig. 2B), demonstrating that the structure of SWNT remains mostly unaltered during cross-linking and delamination.

The breathing mode frequency shifts from 185 cm<sup>-1</sup> in the assembled film to 182 cm<sup>-1</sup> in the cross-linked, self-standing films, indicating a small expansion of the tube diameters.<sup>[18,19]</sup>

The delaminated thin films (Fig. 3A) can be easily handled in a variety of ways. They can be made of any desirable size or shape determined only by the dimensions of the substrate. The films that we routinely prepare in this study were ca. 1 × 3 cm. Assemblies with a structure of [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>6</sub> and [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>8</sub> displayed an SWNT content of 50 ± 5 wt.% as calculated from carbon and nitrogen energy-dispersive X-ray analysis (EDAX) peak integrals. Previously reported composites made with modified SWNT revealed strong inhomogeneities even at SWNT loadings as low as 6–8%.<sup>[8,9]</sup> The cross-sectional image of the freestanding film (Fig. 4A,B) clearly demonstrates the absence of micron-scale inhomogeneities although the occasional inclusion of round 30–60 nm particles can be seen (possibly dust). The slight variations in the gray-scale contrast between different strata show the actual variations in SWNT distribution within the sample. They originate from small deviations in SWNT adsorption conditions, such as dispersion concentration and pH, during the buildup procedure. In scanning electron microscopy (SEM) (Fig. 3A), the surface of the sample also appears smooth and continuous. Typically, the separation of single-walled or multiwalled carbon nanotubes and their bundles in mixed polymer composites can be observed as whiskers clearly visible in transmission electron microscopy (TEM) and SEM images.<sup>[4,26]</sup> The TEM examination of the initial stages of rupturing showed that virtually no fiber pullout occurs in the LBL multilayers (Fig. 3B). This can be contrasted by extensive nanotube pullout reported before by several groups.<sup>[4,26]</sup> For many TEM images obtained in different areas of the self-standing films, we were able to observe only one SWNT bundle bridging the break region (Fig. 3C). The same image also shows two

**Fig. 3** Electron microscopy of the rupture region in SWNT multilayers. (A) Scanning electron microscopic image of the surface and broken edges of [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>8</sub>. (B, C) Transmission electron microscopic images of ruptured areas of the freestanding films. The arrows indicate the likely stubs of the broken nanotube bundles. They were identified as such because 1) their diameters are both equal to that of the actual SWNT bundle bridging the gap and 2) their mutual positioning presents a virtually perfect match with the expected location of the ends of a bundle broken during gap opening.

**Fig. 4** Transmission electron microscopic examination of the homogeneity of the SWNT LBL film. Survey (A) and close-up (B) TEM images of SWNT film cross sections. The top and bottom sides of the film are slightly different in roughness: The one that was adjacent to the flat substrate is smoother than the “growth” surface of the film. *Source:* From Refs.<sup>[18,19]</sup>

broken carbon fiber stubs embedded in the walls of the crack (marked by arrows in Fig. 3C). In total, the microscopy results indicate the efficient load transfer in the LBL composite. Similar films are currently prepared from the multiwalled carbon nanotubes utilizing the polymer wrapping (Fig. 5).

The mechanical properties of the layered composites were tested on a custom-made thin-film, tensile-strength tester (McAllister Inc.) recording the displacement and applied force by using pieces cut from [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>6</sub> and [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>8</sub> freestanding films. The tester was calibrated on similar pieces made from cellulose acetate membranes and Nylon threads. [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>6</sub> and [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>8</sub> samples had an average TEM thickness of 0.75 and 1.0 μm, respectively. Their typical stress ( $\sigma$ ) vs. strain ( $\epsilon$ ) curves differed quite markedly from stretching curves previously seen for SWNT composites<sup>[10]</sup> and for LBL films solely made from polyelectrolytes, (PEI/PAA)<sub>40</sub>, obtained by the same

**Fig. 5** Optical photograph of the free-standing LBL films made from multiwalled carbon nanotubes.

assembly procedure (Fig. 6B). They displayed a characteristic wave-like pattern, gradual increase of  $d\sigma/d\epsilon$  derivative, and the complete absence of the plateau region for high strains corresponding to plastic deformations (Fig. 6A). The latter correlates well with the enhanced connectivity of SWNT with the polymer matrix (Fig. 3). Other mentioned stretching features indicate the reorganization of the layered composite under stress. A process similar to the sequential breakage of cross-linked parts of coiled molecules (see AFM image in Fig. 2) observed in natural nanocomposites, such as seashells and bones,<sup>[27,28]</sup> is likely to be responsible for the wave-like pattern and the increase of the stretching curve slope. This statement can be substantiated by the AFM investigation of the single molecules of a polyelectrolyte adsorbed to the substrate (Fig. 7). Atomic force microscopy images of poly(diallyldimethylammonium) chloride (PDDA) (Fig. 7) polycation adsorbed to silicates revealed the actual conformation of macromolecules at the organic–inorganic interface. Similarly to PEI, this polyelectrolyte has a positive charge when adsorbed to silica or glass. Coiling of PEI is expected to be even stronger than that of PDDA because the latter has intrinsically strong propensity to form a rod-like structure because of its greater charge. The intentionally rarified submonolayers of polycation were made from  $2 \times 10^{-7}$  wt.% solutions to resolve single chains (Fig. 7A). These are intricately entangled to form a continuous film at higher concentrations. Adsorbed polyelectrolyte were found to be present in the film in different conformational states: extended (Fig. 7C),

**Fig. 6** Typical tensile-strength curves of the SWNT LBL films. Stress–strain dependence for (A) [(PEI/PAA)(PEI/SWNT)<sub>5</sub>]<sub>8</sub> and (B) a similar free-standing multilayer film solely made from polyelectrolytes. The dependence of the mechanical properties of the cross-linked LBL composites on humidity was tested in the range of relative humidity of 30–100%,  $T = 298^\circ\text{C}$ , and was found to be negligible. *Source:* From Refs.<sup>[18,19]</sup>

**Fig. 7** Atomic force microscopy of rarified PDDA films. (A) Overview of adsorbed PDDA molecules ( $2 \times 2 \mu\text{m}$ , mica). (B) Cluster of PDDA molecules ( $360 \times 230 \text{ nm}$ , Si wafer). (C) Fully extended PDDA chain ( $350 \times 170 \text{ nm}$ ). (D) Partially coiled PDDA chain ( $160 \times 80 \text{ nm}$ , mica). (E) Typical highly coiled conformation of PDDA chain ( $100 \times 110 \text{ nm}$ ). Source: From Ref.<sup>[29]</sup>.

partially coiled (Fig. 7D), and tightly coiled (Fig. 7E). The length of the macromolecules in extended conformation, 350–400 nm (Fig. 7C), coincides with that expected for poly(diallyldimethylammonium) chloride with  $M_w=200,000$ . As can be seen from Fig. 7A, most of the molecules (>75%) are present in the tightly coiled conformation. Moreover, the AFM examination of the clusters of the macromolecules molecules (Fig. 7B) demonstrates that this is apparently the preferential conformation of the polyelectrolyte in densely packed films made at higher concentrations used for multilayer preparation.<sup>[29]</sup>

Considering the complexity of the deformation process, the assessment of elastic and inelastic behavior in each part of the curve will be carried out upon detailed microscopic investigation. Meanwhile, the values of  $d\sigma/d\varepsilon$  exceeding 50 GPa should be noted.

The comparison with stretching curves of polyelectrolytes (Fig. 6B) shows that the incorporation of nanotubes in the LBL structure resulted in the transfer of the SWNT strength to the entire assembly. The stretching curves of the SWNT multilayers display a clear break point. The ultimate tensile strength,  $T$ , was found to be  $220 \pm 40 \text{ MPa}$  with some readings being as high as 325 MPa. This is several times to an order of magnitude greater than the tensile strength of strong industrial plastics with  $T = 20\text{--}66 \text{ MPa}$ .<sup>[30]</sup> It is also substantially higher than the tensile strength of carbon fiber composites made by mixing: Polypropylene filled with 50 vol.% carbon fibers has  $T = 53 \text{ MPa}$ .<sup>[31]</sup> A recent study on SWNT–poly(vinylalcohol) ribbons with axially aligned nanotubes reported a

tensile strength of 150 MPa.<sup>[10]</sup> The  $T$  values obtained for SWNT LBL films are in fact close to those of ultrahard ceramics and cermets such as tungsten monocarbide ( $T = 340 \text{ MPa}$ ), silicon monocarbide ( $T = 300 \text{ MPa}$ ), and tantalum monocarbide ( $T = 290 \text{ MPa}$ ).<sup>[30]</sup> Such strength and failure strain greater than in cermets (ca. > 1% in SWNT LBL vs. 0.2–0.6% in carbides) displayed by an organic composite is quite remarkable.

The tensile strength of single carbon nanotubes was experimentally determined to be between 13 and 50 GPa.<sup>[26,32]</sup> The lower values obtained for the SWNT multilayers should be mainly attributed to the contribution of polyelectrolytes and some uncertainty in the actual cross-section area at the break point and a degree of cross-linking. The mixing law predicts that polyelectrolyte matrix with  $T = 9 \text{ MPa}$  makes negligible contribution to the strength of the composite while taking about 50% of its volume fraction. [SWNT is  $d = 1.14 \text{ g/cm}^3$ . Because the density of the polyelectrolytes used for the preparation of the multilayers (i.e., PDDA  $d = 1.04 \text{ g/cm}^3$ ; PAA  $d = 1.14 \text{ g/cm}^3$ ) is almost the same, the volume fraction of SWNT in the composite can be considered to be equal to the mass fraction.] Additionally, the decrease of the mechanical strength of the nanotubes in the process of ionic functionalization (estimate 15%)<sup>[33]</sup> should also be considered as a factor affecting the strength of these composites. These issues are pointed out as means of further optimization of the multilayers. Tuning of their molecular structure and composition should lead to vast improvement of their mechanical properties that could possibly approach those of pristine carbon nanotubes.

It is also interesting to compare the  $T$  values for SWNT composite films to those obtained for other LBL films made with other inorganic components such as montmorillonite platelets, M, and nanoparticles, NP, for instance 8–10-nm magnetite nanoparticles. The freestanding films (PDDA/NP)<sub>40</sub> and (PDDA/NP/PDDA/M)<sub>40</sub> made according to Ref.<sup>[21]</sup> revealed  $T$  equal to 40 and 72 MPa, respectively. In conjunction with the tensile strength data (see above), it can be concluded that inorganic or SWNT components act as a molecular armor in the layered composites significantly reinforcing them. The molecular organization of the material made possible the transfer of a part of their strength to the entire assembly.

## CONCLUSION

The technology of the preparation of nanocomposites described above should be considered as an effective

tool in developing new ultrastrong materials. High structural homogeneity and interconnectivity of the structural components of the LBL films combined with high SWNT loading leads to significant increase of the strength of nanocomposites, being somewhat weaker than some other organic and carbon fiber materials but at the same time being far beyond their potential as ultrastrong composites. The described technique minimizes the structural defects originating from phase segregation and opens a possibility for the molecular design of layered hybrid structural materials from different polymers and other nanoscale building blocks. The prepared freestanding membranes can serve as a unique component for a variety of technologies. One of its great advantages over other technologies is the ability to prepare ultrathin ultrastrong membranes with minimal heterogeneity. We expect these composite materials to be used initially in high-value applications, most possibly as a critical part of a space or biomedical device. Once the carbon nanotubes become less expensive and the LBL processing becomes a routine operation, the same composites can be utilized in more high-volume products such as building construction materials and car components. At the same time, the less-expensive alternatives to the ultrastrong composites with comparable performance can be developed from carbon- or ceramics-based nanomaterials.

## INTRODUCTION

The discovery of carbon nanotubes by Ijima<sup>[1]</sup> initiated a new area of materials science. Following Ijima's discovery, Tenne et al.<sup>[2]</sup> later found layered sulfides (MoS<sub>2</sub> and WS<sub>2</sub>) to form nanotubes and other fullerene-type structures. Nanoparticles based on layered transition metal sulfides (LTMS) are of special interest because of their diverse applications. Layered transition metal sulfides have been extensively studied because of their crucial role in the petroleum and chemical industry. MoS<sub>2</sub>-based and WS<sub>2</sub>-based catalysts have been used for sulfur and nitrogen removal from petroleum feedstock.<sup>[3]</sup> In addition, MoS<sub>2</sub> is used as a lubricant additive.<sup>[4]</sup> Related compounds of TiS<sub>2</sub>, as well as MoS<sub>2</sub>, can work as cathodes in lithium nonaqueous batteries<sup>[5,6]</sup> and possess interesting and useful intercalation chemistry.<sup>[7]</sup> WS<sub>2</sub>, WSe<sub>2</sub>, TiS<sub>2</sub>, MoS<sub>2</sub>, MoSe<sub>2</sub>, and MoTe<sub>2</sub> are all semiconductors with unusual properties and potential electronic applications.<sup>[8]</sup>

The structure of MoS<sub>2</sub>, WS<sub>2</sub>, and ReS<sub>2</sub> consists of a two-dimensional layered closed-packed sulfur arrangement with a transition metal sandwiched between each layer. Weak van der Waals interlayer forces occur between stacked "sandwiches" that allow easy, low-strength shearing.<sup>[9,10]</sup> These materials are highly folded and distorted in nature, forming commonly known "rag" and "tubular" structures. Layered transition metal sulfide materials appear as morphological analogs of fullerenes exhibiting structures described as inorganic fullerenes (IFs), single sheets, folded sheets, nanocrystals, and nested IFs, also known as "onion crystals" or "Russian dolls."

Fullerene-related nanoparticles of MoS<sub>2</sub> can be obtained by electron beam irradiation,<sup>[11]</sup> laser ablation<sup>[12]</sup> of MoS<sub>2</sub> bulk powder, and arc discharge.<sup>[13]</sup> Scanning tunneling microscope electrical pulses over amorphous MoS<sub>3</sub> nanoparticles lead to the formation of closed MoS<sub>2</sub> shell IF (a few layers thick) and amorphous MoS<sub>3</sub>.<sup>[14]</sup> Inorganic fullerene nanoparticles have been synthesized recently by a variety of methods. Others

have reported the gas-phase synthesis of fullerene-like structures of WS<sub>2</sub><sup>[2]</sup> and MoS<sub>2</sub><sup>[15]</sup> and nested fullerenes of MoS<sub>2</sub>.<sup>[16]</sup> Complex WS<sub>2</sub> nanostructures have been obtained by template growth by Whitby et al.<sup>[17]</sup> The preparation and optical characterization of crystalline nanoparticles prepared by intercalation and ultrasonic fragmentation of bulk crystals have also been studied.<sup>[18–20]</sup> Divigalpitiya, Frindt, and Morrison<sup>[21–23]</sup> have reported the synthesis and preliminary characterization of composites based on single sheets of MoS<sub>2</sub>. Wilcoxon, Samara, and Newcomes<sup>[24]</sup> Wilcoxon and Samara,<sup>[25]</sup> and Parsapour et al.<sup>[26]</sup> have reported the growth of MoS<sub>2</sub> nanoparticles using micelle techniques.

## SYNTHESIS OF LAYERED TRANSITION METAL SULFIDES

A variety of methods have been used to synthesize LTMS. In general, poorly crystalline dichalcogenides are prepared by heating under hydrogen sulfide flow. The highly folded material is prepared by heating several grams of amorphous MoS<sub>2</sub> for 2 hr at 400°C in a stream of H<sub>2</sub> mixed with 15% H<sub>2</sub>S. As a result, the structure denoted as "poorly crystalline" and "raglike" LTMS is obtained.<sup>[27–29]</sup> The "rag" structure consists of stacked but highly folded and disordered MoS<sub>2</sub> layers (Fig. 1). The number of stacks and the dimensions of the layers can vary by changing the preparation conditions. The general reaction scheme of low-temperature metaphorical reaction in a solution is:

where T = transitional metal, X = salt anion (Cl, carboxylate, etc.), A = alkali-like cation (Li<sup>+</sup>, Na<sup>+</sup>, NH<sub>4</sub><sup>+</sup>, etc.), and Y = chalcogenides anion. Redox reactions tend to occur because the transition metal ions and the chalcogenides exist in several oxidation states:

**Fig. 1** Folded and disorder sheets of MoS<sub>2</sub>. *Source:* From Ref.<sup>[28]</sup>.

The great stability that the oxides and hydroxides lend to the transition metal salt eliminates the need for an aqueous environment. Moreover, hydroxylic solvents, in general, are very reactive and can serve as solvents for TX<sub>4</sub> or TX<sub>5</sub>. Poor reaction between hydrogen sulfide and the transition metal salt does not allow for direct synthesis of TY<sub>2</sub> species. This is why alkali chalcogenides must be used. Even in the absence of oxygen in air or water, the reaction of TiCl<sub>4</sub> with H<sub>2</sub>S is unfavorable at temperatures lower than 400°C. These are highly reactive ionic sources of chalcogenides and the reaction readily proceeds at room temperature. Lithium sulfide was found to be the most convenient source of sulfide ion:

For precipitation at room temperature, tetrahydrofuran and ethyl acetate are suitable solvents. Dark precipitates are obtained and easily filtered. Repeated washings with the solvent completely remove LiCl excess. To obtain crystalline TiS<sub>2</sub>, further heating at 400–600°C is required in a sealed quartz tube under an inert atmosphere. This example illustrates the synthesis of TiS<sub>2</sub> but it can be applied to any other transition metal sulfide.

WS<sub>2</sub>, ReS<sub>2</sub>, and OsS<sub>2</sub> can be prepared by heating amorphous sulfides at 400°C in a stream of H<sub>2</sub> mixed with 15% H<sub>2</sub>S. The structure of the ReS<sub>2</sub> poorly crystalline structure is the most likely material for the production of large amounts of nanotubes and fullerene-like materials. Recently, tetraalkylammonium thiomolybdates have been used to incorporate carbon into the extremely disordered materials and it is believed that this impurity increases the ability of the MoS<sub>2</sub> to fold.<sup>[30–32]</sup>

### NESTED INORGANIC FULLERENE ONION-LIKE STRUCTURE

Carbon fullerene Onion-like structures have been obtained under high electron irradiation using

**Fig. 2** Onion-like structures in MoS<sub>2</sub>. *Source:* From Ref.<sup>[11]</sup>.

transmission electron microscopy (TEM).<sup>[33]</sup> Tenne et al.<sup>[2]</sup> and Margulis et al.<sup>[34]</sup> have also observed fullerene Onion-like structures in layered materials including WS<sub>2</sub> and MoS<sub>2</sub>. Electron-irradiated MoS<sub>2</sub> crystals at 0.5 MeV energy were studied by Yacaman et al. using high-resolution electron microscopy. The irradiated MoS<sub>2</sub> crystals presented two main features: onion layers with fullerene-like structures, and others with their planes rotated with respect to each other by well-defined angles.<sup>[11]</sup> In the case of carbon, Onion-like structures tend to be rounded.<sup>[33]</sup> However, the layered materials Onion-like structures are faceted near the center and rounded at the edges, as illustrated in Fig. 2. MoS<sub>2</sub> layers in Onion-like structures are not evenly spaced (Fig. 3). Another interesting feature of these structures is illustrated in Fig. 4, where a relative

**Fig. 3** High-resolution transmission electron microscopy image of MoS<sub>2</sub> Onion-like structure. Fourier transform of the structure is shown in the inset. *Source:* From Ref.<sup>[11]</sup>.

**Fig. 4** Irradiated MoS<sub>2</sub> that illustrated a relative rotation of 10° by the layers on MoS<sub>2</sub> around an axis perpendicular to the image: (A) low magnification; and (B) high magnification. Source: From Ref.<sup>[11]</sup>.

rotation of the MoS<sub>2</sub> layers around an axis perpendicular to the basal plane can be clearly seen.

In a different approach, IFs such as IF-MoS<sub>2</sub> have also been synthesized using high-temperature methods that occur above 650°C. These methods involve such techniques as growth from the gas phase in which MoO<sub>3</sub> in the vapor phase is reacted with H<sub>2</sub>S in a carrier gas (Fig. 5). The gas-phase reactor synthesis has achieved great control over the nanoparticles growth parameters. This process consists of MoO<sub>3</sub> powder placed in the inner part of the reactor, (a) which is heated to 780°C. Molecular clusters (MoO<sub>3</sub>)<sub>3</sub> are formed and carried down through the reactor by N<sub>2</sub> gas. Hydrogen gas diffuses through the nozzles (c) from the outer reactor (b) and starts to react with the molecular clusters. The mild reduction conditions yield reduced MoO<sub>3-x</sub> clusters, which are less volatile and form MoO<sub>3-x</sub> nanosize particles at the low part of (a). The suboxide nanoparticles reach a size less than 5 nm before the sulfidization step. The coated oxide nanoparticles are swept by the carrier gas outside the reactor (a). Because the nanoparticles are surface-passivated, they land on the ceramic filter (d) and the oxide-to-sulfide conversion continues within the core without coalescence of the nanoparticles. The gas-phase reactor synthesis process generates pure IF-MoS<sub>2</sub> phase and the control over the size and shape of the nanoparticles is quite good.<sup>[35]</sup> A characteristic image of three IF nanoparticles produced in the gas-phase reactor is illustrated in Fig. 6.

MoS<sub>2</sub> fullerene-like nanoparticles can also be produced by a combination of sonochemistry and electrochemistry, recently termed sonoelectrochemistry. Sonoelectrochemical formation of nanoscale metal powders has been achieved by applying an electric current pulse to nucleate the electrodeposit, followed by a burst of ultrasonic energy that removes the metal particles from the sonic probe cathode.<sup>[36]</sup> Mastai et al. used the known process for cathodic electrodeposition of MoS<sub>2</sub> from solutions of thiomolybdate ions.

**Fig. 5** (A) Vertical gas-phase reactor for synthesis of MoS<sub>2</sub> fullerene-like nanoparticles: (a) inner tube; (b) middle tube; (c) nozzles; (d) external tube. (B) Closer look at the inner reactor (a). Source: From Ref.<sup>[35]</sup>.

**Fig. 6** "Russian doll" structures obtained by gas-phase synthesis. Source: From Ref.<sup>[15]</sup>.

Normally amorphous MoS<sub>2</sub> is deposited and becomes crystalline after heat treatment, forming a highly textured film.<sup>[36]</sup> Fig. 7 illustrates TEM images of the sonoelectrochemically prepared MoS<sub>2</sub> particles at different orientations with respect to the electron beam. The curved and closed nature of the structures can be observed at different angles. The authors could not state if the structures are made up of MoS<sub>2</sub> sheets entirely, are hollow, or contain a core of another material (i.e., MoO<sub>2</sub>, amorphous MoS<sub>2</sub>). However, the presence of MoS<sub>2</sub> planes inside the closed structures, but oriented in various directions (Fig. 7C),

**Fig. 7** Transmission electron microscopy images of the same MoS<sub>2</sub> particles taken with the sample rotated in the sample rotated in the direction of the electron beam at an angle of (A) +45°; (B) 0°; and (C) -45°. *Source:* From Ref.<sup>[36]</sup>.

suggests that the structures are hollow to some extent, as stated by Mastai et al.

They suggested an interesting mechanism to explain the closed curved structure. Amorphous MoS<sub>2</sub> is suspected to be formed by electrodepositing onto the sonic probe cathode. The deposit is then removed from the probe surface by a sonic shock wave. The deposit could be found in a spheroid or planar structure because nucleating electrodeposits are often nanoparticulates. The effect of the shock wave is not enough to crystallize the deposit according to the authors. They concluded that the cause of the crystallization, and possibly bending, which normally require high temperatures, is the collapse of cavitation bubbles. Cavitation bubble nucleation is favored at a surface, either of the sonic probe itself or of MoS<sub>2</sub>, which was previously removed from the probe surface. The bubble can then grow with the MoS<sub>2</sub> attached to it. During collapse, the high temperature at the surface of the bubble can cause crystallization.<sup>[36]</sup> The authors presented two cases to describe the crystallization of the particle. If the original amorphous particle was spheroidal, then the final crystallized particle is likely to maintain a related morphology. If the original particle, as removed from the probe, is closer to two-dimensional, curvatures and closures may occur around the collapsing bubble (the bubble then determines the shape of the structure), or the temperature from the bubble surface into the solution should cause a temperature gradient across the particle, which could also cause curvature. The closure is energetically preferred because of bond energy released by removing reactive edges. The less common nanotube formation could occur if the nucleated deposit were filamentary, or, more likely, if the bubble collapse occurred at the electrodeposit that was still on the electrode surface.<sup>[36]</sup> In that case, the effect of the bubble collapse is asymmetric, which could lead to an asymmetric-shaped structure of the final product. Sonochemical reactions that take place inside the collapsing bubble result always in amorphous products because of fast cooling rates ( $>10^{10}$  K/sec).<sup>[36]</sup>

On the other hand, amorphous or crystalline materials are produced by aqueous ionic reactions that take place in the 2000-nm ring surrounding the collapsing bubble. When operated separately, electrochemistry or sonochemistry yields amorphous MoS<sub>2</sub>. The proposed mechanism, involving the collapse of the cavitation bubble, logically explains the crystallization of this amorphous compound and (bending and closure) considers that the amorphous particle is not already related to the final shape and size.

Ultrasonic radiation not only induces crystallization and shape control reactions, but it can also induce chemical reactions. The combination of electrochemical and sonic processes provides many experimental

variables, which allow to control particle size and shape distribution, and will probably be applicable to the formation of closed structures of other layered compounds that can be prepared by electrochemical techniques.<sup>[36]</sup>

## MOS<sub>2</sub> NANOTUBES

Microtubes of MoS<sub>2</sub> have been grown by Remskar et al.<sup>[37]</sup> MoS<sub>2</sub> nanotubes produced using a template have been reported by Zelenski and Dorhout.<sup>[38]</sup> A low-temperature method developed by Prasad, Diemann, and Muller<sup>[39]</sup> produced MoS<sub>2</sub> from solution-phase precursors within the porous membrane of electrochemically generated Al<sub>2</sub>O<sub>3</sub>. MoS<sub>2</sub> nanotubes were obtained using Prasad, Diemann, and Muller method and characterized by high-resolution electron microscopy (HREM) and electron diffraction by Chianelli et al.<sup>[40]</sup> MoS<sub>2</sub> nanotubes were prepared using non-porous alumina templates produced by ionization of aluminum. To obtain the nanotubes, a solution-phase precursor of (NH<sub>4</sub>)<sub>2</sub>MoS<sub>4</sub> in dimethylformide (DMF) was prepared. Small pieces of alumina template were immersed into the solution for a few seconds. The templates were dried at 70°C on a hot plate until the solvent evaporated. The samples were loaded into a quartz tube, which was placed into a furnace and treated with a mixture of 10% H<sub>2</sub>/N<sub>2</sub> at 450°C. The MoS<sub>2</sub> nanotubes were then removed from the templates and characterized by high-resolution transmission electron microscopy (HRTEM). Computational calculations were carried out to study the properties of the MoS<sub>2</sub> nanotubes. A minimum diameter was determined to indicate the structural stability of the MoS<sub>2</sub> nanotubes.<sup>[40]</sup>

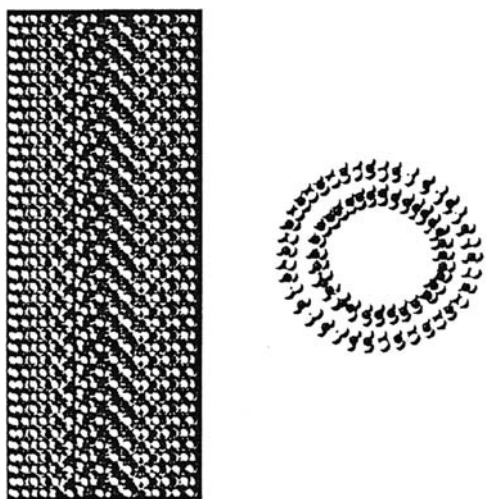

In Fig. 8A and B, two images of the Al<sub>2</sub>O<sub>3</sub> template used to produce the MoS<sub>2</sub> nanotubes are illustrated. The figure shows low-magnification and high-magnification scanning electron microscopy (SEM) pictures of the surface and the cross section of the template. The cross-section band structure illustrates pores of 25 nm in diameter in uniform distribution (Fig. 8A). The pore length was about 25 μm wide and 250 μm long, as observed in Fig. 8B. The MoS<sub>2</sub> nanotubes were grown in the pores of the templates. A characteristic high-resolution image of a nanotube is illustrated in Fig. 9. The nanotube shown is approximately 260 nm long. An interplanar average distance of about 6.25 Å and an interplanar distance of about 2.74 Å (100 plane) were determined by measuring the (002) planes of the MoS<sub>2</sub> structure at the border of the tubes using higher-magnification micrographs.<sup>[40]</sup> This value is larger than the 6.16 Å expected for crystalline MoS<sub>2</sub>. It should be noted that the (002) planes are not seen in the interior part of the tube indicating normal contrast for a tubular structure.

**Fig. 8** Scanning electron microscopy images of the surface of electrochemically produced Al<sub>2</sub>O<sub>3</sub>. (A) Low-magnification picture of the cross-section band structure. (B) High-magnification picture of the pores. *Source:* From Ref.<sup>[40]</sup>.

**Fig. 9** High-resolution transmission electron microscopy image of a section of a MoS<sub>2</sub> tube. *Source:* From Ref.<sup>[40]</sup>.

**Fig. 10** Molecular model (Cerius<sup>2</sup>) of MoS<sub>2</sub> nanotube formed by two layers. *Source:* From Ref.<sup>[40]</sup>.

A 2H-MoS<sub>2</sub> nanotube structure was determined by electron diffraction. The (002) reflection also showed an expansion to 6.22 Å of the lattice parameter as already mentioned. It was noted that the tube is not continuous, but it is split in several sections, each one with a diameter from 15 to 30 nm and a length between 150 and 500 nm. Commonly, the sections of the tube are ellipsoidal. However, in some cases, the shape is distorted as in the last section of the long tube (Fig. 9). The planes of the nanotubes are bent in a similar fashion as the bending of carbon nanotubes previously reported.<sup>[41]</sup> A computer-generated model of a MoS<sub>2</sub> nanotube including two layers built using Cerius<sup>2</sup> (molecular simulation program, ACCELRY S Corporation) is shown in Fig. 10. The MoS<sub>2</sub> in trigonal prismatic coordination was used as a starting model. As the minimum energy configurations were searched, stable configurations for cylinders of different sizes were calculated. Analyzing the Mo–S distances, two groups of measurements were reported. One group contains the interior Mo–S distances [Mo–S (int)] and the other contains the exterior Mo–S distances [Mo–S (ext)]. The mean distance for the Mo–S interior bond is 2.65 Å and the mean distance for the exterior bond is 2.75 Å. The calculation implied that MoS<sub>2</sub> nanotubes of this diameter are not stable because bending to form a tube of this diameter requires stretching of the Mo–S bonds well beyond their normal length of 2.41 Å.<sup>[40]</sup> The mean distance for six tubes between 20 and 120 Å was also calculated and plotted in Fig. 11.<sup>[40]</sup> The mean values of both the interior and the exterior Mo–S bonds approach the single crystal value of 2.41 Å. Chianelli et al. stated that below a value of approximately 120 Å, the tubes might be highly unstable because of bond strain. They have reported MoS<sub>2</sub> nanotubes

**Fig. 11** Interior and exterior distances as a function of tube diameter. *Source:* From Ref.<sup>[40]</sup>.

containing bending zones that, in the case of MoS<sub>2</sub> crystals, are often observed on the edges of the surface.<sup>[20]</sup> Hence “bent zones” are important to understanding the behavior of MoS<sub>2</sub> sheets. Fig. 12A and B presents the model of a bent sheet of MoS<sub>2</sub> comprised of four layers of MoS<sub>2</sub>. Examination of the values of the S–S and Mo–Mo distances shows a very large distortion that clearly appears in the bending zone. In comparison with the distances in the straight sections of the sheet, an increase of 20% in the distance between neighboring atoms is observed. This strongly emphasizes the instability of bent layers as the radius of curvature is reduced.

**Fig. 12** (A) Model of a bent sheet (30°) of MoS<sub>2</sub> (with four layers). (B) Atoms' position measurements for a similar sheet. *Source:* From Ref.<sup>[40]</sup>.

Synthetic nanotubes, lubricants, and catalysts all exhibit similar bending phenomena. Yacaman et al. reported that even in the case of MoS<sub>2</sub> crystals, a bending effect is often observed at the edges of the crystal surface. Their study showed that although large MoS<sub>2</sub> nanotubes can be synthesized, their minimum size is limited by the strain induced by stretched Mo–S bonds that are required to close tubes with diameters less than approximately 10 nm. Tenne et al.<sup>[42]</sup> earlier reported the synthesis of WS<sub>2</sub> nanotubes with diameters in the range of 10 nm. However, a close examination of their published micrographs reveals that the “nanotubes” become broken and discontinuous as the diameter becomes smaller, in agreement with Yacaman et al.’s study. This is in contrast to nanotubes of carbon that can exist down to very small diameters because of the change in carbon bonding, which is natural in fullerene-based materials. Layered materials such as MoS<sub>2</sub> and WS<sub>2</sub> cannot be formed into small nanotubes unless a change in Mo–S bond occurs. A change from six coordinates to a lower metal coordination might result in smaller-diameter nanotubes; however, this phenomenon has not yet been reported, but is possibly based on the known chemistry of Mo and S. Furthermore, the nanotubes made by the template method are not infinitely long but break into sections, giving the shape of a “Spanish chorizo,” a term coined by Yacaman et al. Calculations indicate that, in principle, there is no structural energetic reason for a nanotube not to grow infinitely. The total energy of the nanotube will be minimized by the distortion from the edge to the center described in “Nested Inorganic Fullerene Onion-like Structure.” Nevertheless, HRTEM images clearly show that two sections of the tube are in contact, but each one is preserving its corresponding layers. Therefore it is very likely that the sections are produced as a result of growth kinetics.

MoS<sub>2</sub> single-wall nanotubes (SWNTs) were grown by a catalyzed transport reaction involving C<sub>60</sub> as a growth promoter.<sup>[42]</sup> Remskar et al. show that the MoS<sub>2</sub> nanotubes grow in twisted chiral bundles of identically structured molecules stacked together with interstitial iodine. The nanotubes were found to vary in length but not in diameter. The chemical composition of the bundles was determined by energy-dispersive x-ray spectroscopy (EDX) and x-ray fluorescence spectrometry to be (MoS<sub>2</sub>)–I<sub>x</sub> with  $x \sim 1/3$ . However, the authors did not find C<sub>60</sub> incorporated into the structure using energy electron loss spectrometer (EELS). The bundles possess a hexagonal close-packed structure of identical nanotubes along the longitudinal direction revealed by HRTEM. The center-to-center distance between two tubes was found to be 0.961(1) nm, as seen in Fig. 13. A complex electron diffraction pattern shows a slightly distorted hexagonal symmetry, as illustrated in Fig. 14C.

**Fig. 13** The cross section of a (MoS<sub>2</sub>)–I<sub>x</sub> TEM image of (A) hexagonal structure of the tubes. (B) High-resolution view of the structure. The insert shows an image simulation for zone [001]. (C) A model structure perpendicular to the nanotube axis (gray, S; dark gray, Mo; black, I). *Source:* From Ref.<sup>[42]</sup>.

Perpendicular to the bundle axis, a period of 0.83 nm is dominant.<sup>[42]</sup> The period is equal with regard to the period 0.27 nm belonging to the hexagonal pattern. Another strong peak located close to the (030) spot is caused by a period of 0.30(1) nm. Two strong periods of 0.20(1) and 0.30(1) nm are present along the axis. The transition electron diffraction (TED) data were confirmed by x-ray diffraction where intense peaks were found corresponding to interlayer distances of 0.832(1), 0.351(1), 0.314(1), 0.308(1), 0.279(1), and 0.20(1) nm.<sup>[42]</sup> Remskar et al. proposed a model (3,3) armchair nanotube structure illustrated in Figs. 13C and 14B. The distance between sulfur and molybdenum atoms in the nanotube is nearly of the same distance in platelike MoS<sub>2</sub>. The close position of molybdenum and sulfur atoms in neighboring layers perpendicular to the nanotube axis requires at least 25% extension of the unit cell along the tube axis to avoid overlap of the covalent radii.<sup>[42]</sup> The distance

**Fig. 14** The  $(\text{MoS}_2)\text{-I}_x$  TEM image and electron diffraction in zone [101]. (A) High-resolution image with image simulation revealing ordered stacking of nanotubes; bright spots correspond to the positions of molybdenum atoms. (B) Model structure of the tubes. (C) Corresponding electron diffraction pattern indexed in accordance with the model structure. *Source:* From Ref.<sup>[42]</sup>.

between the layers was determined to be 0.20 nm by diffraction patterns. The unit cell of the hexagonal close-packed nanotubes within a bundle was found to be 0.40 nm along the bundle axis and 0.96 nm perpendicular to the bundle axis. Their van der Waals diameter corresponds approximately to the distance between the closest sulfur atoms on adjacent nanotubes [0.35(1) nm]. Iodine atoms are inserted in interstitial trigonal voids between the nanotubes, creating one-dimensional rows along the bundle axis.

The periodicity of possible sites for iodine position along the bundle is 0.40 nm, which is slightly less than the van der Waals distance for iodine (0.43 nm). The observed HRTEM images are in agreement with their simulations using the symmetry operations of group  $P6_3 (C_6)$ .<sup>[42]</sup> The authors found  $C_{60}$  to be essential in the growth process, but a detail mechanism is not clear at the moment.

## ZRSE<sub>2</sub> AND SNS<sub>2</sub> FILAMENT-LIKE NANOPARTICLES

Filament-like nanoparticles of  $\text{ZrSe}_2$  and  $\text{SnS}_2$  were obtained by microwave plasma process.<sup>[43]</sup> Synthesis is performed using microwaves with a frequency of 0.915 or 2.45 GHz.<sup>[44]</sup> The reaction takes place inside a quartz tube passing a monomode microwave cavity.<sup>[45]</sup> The precursor compounds are vaporized outside of the reaction zone and introduced to the reaction gas in front of the plasma zone, where the nanoparticles are formed. The reaction gas is preheated to avoid the precipitation of the precursor. The reaction was preformed under a pressure of 30 mbar using 0.915-GHz plasma. The reaction temperature was set at 260°C or 580°C. The flow rate of the gas was adjusted to obtain a residence time of the particles of about 8 msec in the reaction zone at a temperature of 580°C, and about 4 msec at 260°C. Further reduction of the reaction temperature is obtained by using 2.45-GHz microwaves. Vollath et al. were able to perform the reaction at a temperature as low as 160°C. Gas pressure was set to 10 mbar. The residence time of the particles in the reaction zone was about 2 msec. The reaction temperature was determined directly after the reaction zone. Because microwave plasma was a nonequilibrium system, the true temperature of the particles during the formation was different. The reaction products were collected on cooled surfaces. Sulfide synthesis used  $\text{H}_2\text{S}$  as a carrier. The metals were introduced in the form of  $\text{SnCl}_4$ . Elemental sulfur was obtained along with the nanoparticles. To evaporate the sulfur excess, the reaction product was heated up to 120–140°C in a vacuum. The selenide samples were prepared using argon 4 vol.%  $\text{H}_2$  as plasma gas. Selenium was introduced in the form of  $\text{SeCl}_4$ . Fine particles of selenides are extremely sensitive to humidity; therefore the specimens were handled under argon gas prior to electron microscopy data collection. Filament-like morphology is a characteristic example of  $\text{ZrSe}_2$  small particles, as illustrated in Fig. 15. The filaments are randomly bent and knotted together. At higher magnifications, the lattice planes clearly show the same bends and twists as the particles (Fig. 16). The fringes in the micrograph represent the  $\text{Se-Zr-Se}$  {0002} layers with a distance of 0.36 nm close to the

**Fig. 15** Filament-like zirconium selenide particles. *Source:* From Ref.<sup>[43]</sup>.

reported value of 0.3095 nm.<sup>[46]</sup> This filament-like structure is not unique for  $ZrSe_2$  and also appears in the case of  $SnS_2$  structures (Fig. 17). The distance of the lattice fringes for  $SnS_2$  is 0.56 nm, which corresponds to the  $\{0001\}$  planes (JCPDS value, 0.589 nm).<sup>[47]</sup> The reduced number of dislocation-like structures is the main difference between the  $SnS_2$  and  $ZrSe_2$  structures. In addition to these filament-like structures,  $ZrSe_2$  exhibited Onion-like crystal structures with varying distances between the lattice planes, as shown in Fig. 18. The distance between the lattice fringes was determined to be 0.34 nm. The lattice images (Figs. 17 and 19) show layered structures containing defects and varying distances between the planes.  $ZrSe_2$  tends to recrystallize in the electron microscope; therefore it cannot be completely ruled out that the particles are crystallized under the electron beam of the microscope. The electron diffraction pattern obtained from the  $SnSe_2$  samples shows a pattern similar to  $SnS_2$ <sup>[47,48]</sup> with a 1.5% expansion from 0.589 to 0.598 nm for the  $\{0001\}$  spacing, whereas the lattice parameter in the  $a$ -direction shows no expansion.

**Fig. 16** Filament-like structures of zirconium selenide particles at higher magnification. The lattice fringes distance is 0.36 nm. *Source:* From Ref.<sup>[43]</sup>.

**Fig. 17**  $SnS_2$  filaments, synthesized at 200°C. The lattice fringes distance is 0.56 nm, corresponding to the  $\{0002\}$  planes. The filaments have a length of around 30 nm and a width of 3–4 nm. *Source:* From Ref.<sup>[43]</sup>.

**Fig. 18** Onion-like zirconium selenide particle formed under electron microscope observation. *Source:* From Ref.<sup>[43]</sup>.

**Fig. 19** Zirconium selenide electron diffraction. *Source:* From Ref.<sup>[43]</sup>.

Table 1 compares the diffraction patterns for the two  $\text{SnS}_2$  phases according to JCPDS tables with experimental values. The first diffraction line of the (00*i*) type shows a maximum intensity at 0.589 nm, corresponding to the  $\beta$ - $\text{SnS}_2$  structure. However, the diffraction line observed at 0.306 nm is not allowed for  $\beta$ - $\text{SnS}_2$ . This line is allowed for the ordered polytype of the  $\beta$ -structure. Considering these observations, the authors may be tempted to conclude that the nanoparticles synthesized within this study represent a structural transition from the  $\beta$ - $\text{SnS}_2$  structure to its ordered polytype.

The  $\text{ZrSe}_2$  nanoparticle structures are not so subtle. The material has obviously a layered structure but the diffraction pattern, shown in Fig. 19, does not agree with  $\text{ZrSe}_2$  and  $\text{ZrSe}_3$  of the selenide phases with layered structures. The electron diffraction pattern indicates a broad distribution of the distances between the lattice planes. Assuming an expanded *c*-axis of 0.676 nm instead of 0.619 nm, the diffraction patterns disagree significantly with the hexagonal  $\text{ZrSe}_2$  structure.<sup>[46]</sup> The second zirconium–selenium phase with layered structure is  $\text{Zr}_2\text{Se}_3$ ,<sup>[49]</sup> given that a *c*-axis expansion from the JCPDS value of 1.251–1.351 nm has to be assumed. Furthermore, this assumed expansion in the *c*-axis still does not match the actual diffraction pattern with the published pattern. Assuming an 8% or 9% expansion in the van der Waals bond, the *c*-axis may still be reasonable. If a similar expansion is also assumed in the *a*-direction, the diffraction pattern obtained with the nanosized particles fits relatively well with the published diffraction pattern for  $\text{ZrSe}_2$  or  $\text{Zr}_2\text{Se}_3$ . Undoubtedly, this may not be a valid description of the actual structure because expanding in the *a*-direction means an elongation of the covalent bonds. Table 2 summarizes the results of measured *d*-values and shows the possible calculated indices, based on a *c*-axis and *a*-axis expansion.

### POTENTIAL USE OF LAYERED TRANSITION METAL CHALCOGENIDES AS MICROMACHINE COMPONENTS

Recently, transition metal trichalcogenides have been synthesized at high temperatures in a variety of shapes. Trichalcogenides such as  $\text{NbSe}_3$ ,  $\text{TiS}_3$ , and others have layered as well as chainlike structures.<sup>[50]</sup> These objects exhibit unusual morphologies larger than atomic scales; Fig. 20 shows an example. Morphologies observed include “wheels,” “tubes,” “rods,” and numerous other shapes. The ability to synthesize shapes such as these from materials that can be metals, magnets, semiconductors, and insulators has led to speculations regarding the construction of micromachines. For example, the “wheel,” if magnetic,

**Fig. 20** Structure of trichalcogenide– $\text{NbSe}_3$  shown. *Source:* From Ref.<sup>[50]</sup>.

might be incorporated into a microelectric motor. In another example, a microbattery might be constructed based on the intercalating abilities of the LTCM. Fabrication seems feasible, but reproducible synthesis in large uniform quantities remains a problem; however, possibilities for micromachine devices seem extensive.

### NANOPARTICULATE HETEROGENEOUS CATALYSIS

Heterogeneous catalysis used in the petroleum refining and chemical industries is an obvious example of widely applied nanoparticles. Traditionally, the industries have relied successfully on empirical methods for synthesizing these materials, but have not applied the understanding of nanoparticles to make further improvements.  $\text{MoS}_2$  may be used as an example to show how understanding of nanoparticles leads to improvements in catalytic activity and selectivity.

Catalysts based on  $\text{MoS}_2$  have been widely used in the petroleum refining industry since World War II. Usually the  $\text{MoS}_2$  is mixed with a second component such as Co or Ni to improve activity.<sup>[3]</sup> These very successful catalysts were largely discovered and developed empirically. Recently, much progress has been made in understanding their catalytic properties from a nanoparticulate point of view.<sup>[51]</sup>

Several issues have become clear and are probably applicable to other heterogeneous catalysts:

1. Commercial catalysts, because they are made at relatively low temperatures, appear in a highly folded and disordered form such as that described above. This is disadvantageous because maximum activity is obtained on catalysts that are well crystallized, and a major unrealized challenge is to cheaply make

Fig. 21 "Rim/edge" model. Source: From Ref.<sup>[51]</sup>.

nanocrystals of these commercial catalysts in large quantities in a supported form.

- In the case of  $\text{MoS}_2$ , the selectivity of the reaction is determined by the "stack height" of the crystallites, as indicated in Fig. 21. The industrially important hydrodesulfurization (HDS) reaction, indicated in Scheme 1, occurs along two pathways that take place on different parts of the crystal. The first pathway leading to cyclohexylbenzene occurs only on the "rim" sites, and the second pathway leading to biphenyl occurs on the "rim" and "edge" sites. Thus the aspect ratio of the nanoparticles must be controlled to positively affect the selectivity of the reaction, and the diameter of the crystallite must be made as small as possible to maximize the activity. All these must be accomplished with as much crystalline order as can possibly be retained.
- Working catalysts are "promoted" with a second metal such as Co or Ni. This metal usually occurs as a second component, such as  $\text{Co}_9\text{S}_8$  that interacts at the  $\text{MoS}_2$  edge plane and can form an interface with it. It is at this interface that the promotion effect occurs by

Scheme 1

Fig. 22 High resolution electron micrograph showing the interface between  $\text{Co}_9\text{S}_8$  inclusions and the  $\text{MoS}_2$  edge plane. Source: from "Hydrodesulfurization catalysts prepared by two methods analysed by transmission electron microscopy, J. Catal. Sec Ref.<sup>[52]</sup>.

setting up an interaction at the junction of the two materials. A high-resolution electron micrograph of such an interaction is shown in Fig. 22.<sup>[52]</sup> It is a further challenge to synthesize these complex nanophase materials in an optimum form in commercial quantities.

### THE STRUCTURE AND POTENTIAL ROLE OF ATMOSPHERIC NANOPARTICLES IN PHOTOCATALYTIC AND THERMAL PRODUCTION AND ATMOSPHERIC POLLUTANTS

Nanoparticles are now being recognized as playing a potentially important role in the complex physical and chemical process that occurs above heavily polluted cities.<sup>[53]</sup> Atmospheric aerosols occurring in these areas are found to be complex materials that have the potential to accelerate important ozone-forming reactions both photocatalytically and thermocatalytically. In addition, because the particles are small enough to inhale, they represent a considerable health hazard. The aerosols consist of two intermixed components: the first consists of amorphous carbonaceous materials of variable composition with "fullerene-like" materials dispersed throughout; the second is an inorganic material consisting of nanoparticles of oxides and sulfides "supported" on clay minerals. These inorganic components have all of the characteristics of an airborne photocatalyst. Nanoparticles of  $\text{Fe}_2\text{O}_3$ ,  $\text{MnO}_2$ ,

and FeS<sub>2</sub> have demonstrated catalytic properties, particularly when occurring in the nanoparticles range as they do in the subject aerosol materials. These materials have band gaps that occur in the broad solar spectrum, enhancing the photocatalytic adsorption of solar radiation beyond that of the wider band gap aluminosilicate and titanate materials that also occur in aerosols. In addition, the materials are acidic and probably are coated with moisture when suspended in air, further enhancing the catalytic ability to crack hydrocarbons and create free radicals. Although this area is still being studied, nanoparticulates appear to play an important, but as yet undetermined, environmental role.

## CONCLUSION

The layered transition metal sulfur structure encloses the significance of the fundamental and applied chemistry of molybdenum disulfide. Their properties and crucial catalytic uses of unpromoted and promoted systems are strongly dependent both on the weak van der Waals interlayer interactions and on the nature of the sites defined by its layered structure. Complete understanding of the catalytic properties of MoS<sub>2</sub> requires more information on the edge planes that terminate the anisotropic layers, which are the location of catalytically active sites. Further progress in developing this understanding will enhance the ability to improve the catalysts' effectiveness for HDS processes. The combination of chemical synthesis and physical processes provides many experimental variables that allow control of particle size and shaping distribution, and will probably be applicable to the formation of closed structures of other layered compounds. It is a further challenge to synthesize these complex nanophase materials in an optimum form in commercial quantities.

# Nanostructures Derived from Phase-Separated Polymers

Michael R. Bockstaller

Edwin L. Thomas

Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.

## INTRODUCTION

The field of polymer-based materials continues its enormous growth covering a wide range of products from disposable coffee cups to car bumpers to biomedical devices. The increased emphasis on enhancement of properties via materials with structures of components engineered on the nanoscale has opened up many new opportunities. For example, blending different polymers while retaining their individual properties in the composite is an effective way of engineering new nano- and microstructural materials from a limited palette of commodity polymers. At present five major reasons for the technological importance of polymer multicomponent systems can be identified: 1) improvements in material performance via synergistic interactions (e.g., temperature resistance, modulus, adhesion); 2) realizing desired processing conditions (e.g., melt viscosity, softening point, solvent resistance); 3) recycling industrial or municipal scrap polymers; 4) adjusting product composition to customer specifications by mixing of different batches; and 5) dilution of high-performance polymers for cost reduction.

Despite their great industrial relevance, there exists no formally accepted nomenclature for multicomponent polymer systems. A possible classification scheme is provided in [Scheme 1](#). Understanding and controlling the mechanisms of phase separation and nanostructure formation in polymer systems allows one to tailor the performance of these materials to a manifold of applications. For example, co-continuous blends of high- and low-melting point polymers where the low-melting point component is the majority component facilitate to dramatically increase thermal and mechanical properties such as toughness, stress at break, or high-temperature creep resistance while retaining ease of processability. Recent research suggests possible future applications of multicomponent polymer systems that are more far-reaching. Nanostructures based on block copolymer-homopolymer blends are currently studied as a platform for photonic materials with possible use in integrated optics or in thin films as non-lithographic route toward controlled patterning

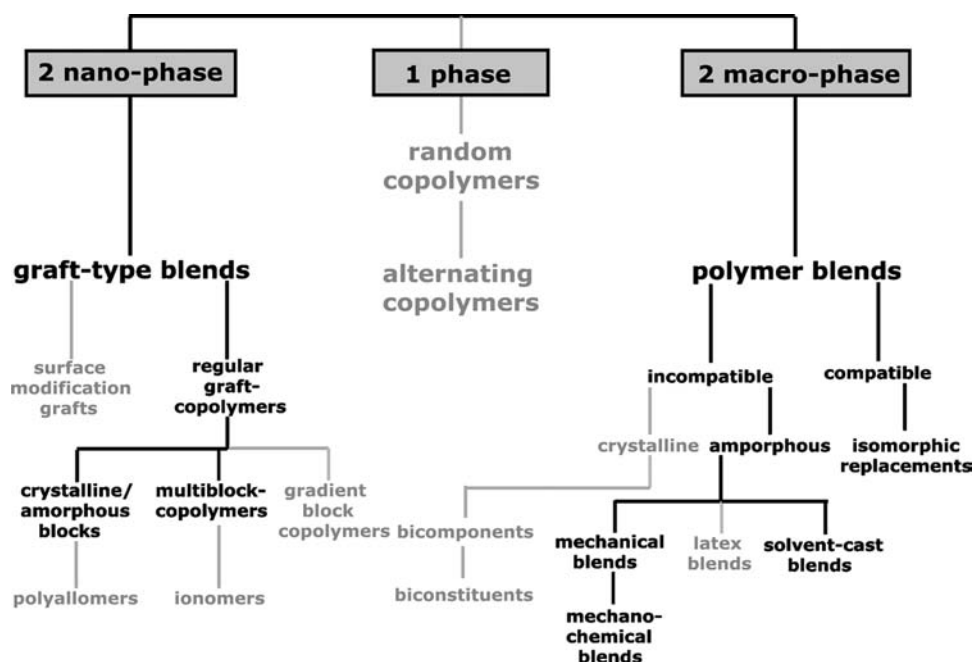

of 100-nm feature sizes. The future technological impact of the latter type of applications will crucially depend on the ability to control structure formation on multiple length scales by strategic design of chemical groups as well as integrating synthetic design with specific processing pathways that increase the likelihood of attaining a targeted structure.

This article reviews polymer phase behavior and nanostructure formation beginning with a discussion of molecular architecture, equilibrium thermodynamics, and phase separation dynamics. The second part describes recent achievements to control the structure formation processes over macroscopic dimensions. The interplay of relevant balancing forces in self-organization processes is discussed aiming to give the reader some intuition about how molecular details and processing conditions can be used in order to control structure formation. In the third part, new research areas will be presented in which polymer-based nanostructures are likely to have major technological impact. Throughout, examples will focus on synthetic polymers that either are of high industrial interest or that suitably represent characteristics of a broad range of macromolecules but leaving out the complex structure formation processes found in natural biopolymers.

## MOLECULAR ARCHITECTURE AND PHASE DIAGRAM

The term *polymer* means “many units” and designates a large molecule made up of smaller repeating units, the number of which determines the degree of polymerization  $N$ . Other basic quantities characterizing a polymer chain are the molecular weight  $M = Nm$ , with  $m$  being the molecular weight of a single repeat unit, and its radius of gyration  $R_G$  which scales as  $N^{1/2}$  for flexible chains in their melt state. As a rule of thumb, molecular weights of common-type flexible polymers of  $M \sim 10^5$  g/mol correspond to an effective size of the polymer chain of  $R_G \sim 10$  nm. The inherent length scale in the nanometer range renders polymer materials

**Scheme 1** Multicomponent polymer system classification scheme. The types of polymer systems relevant to this text are marked in black.

naturally attractive for nanoengineering purposes. Depending on the synthetic procedure, the repeating unit of a linear polymer may comprise a single identifiable precursor such as in poly(styrene) (PS) or might be composed of the residues of several smaller molecules as in poly(hexamethylene-adipamide) (Nylon-6,6). Table 1 shows the chemical structures of a small selection of polymers relevant to this article. Next to

the linear chain architecture, synthetic strategies have been developed to also obtain well-defined star- or branched molecular structures. For a detailed discussion of methods for polymer synthesis the reader is referred to Refs.<sup>[1]</sup> and<sup>[2]</sup>. A small subset of the wealth of architectures is shown in Scheme 2. Depending on molecular architecture, degree of polymerization, and temperature, the physical state of polymeric

materials can vary between viscous liquid, glassy, semi-crystalline, or liquid crystalline. Crystallization processes, which require a highly regular stereochemistry of the polymer, and the associated hierarchy of structures are beyond the scope of this article and will only be briefly mentioned.

## Homopolymer Blends

The equilibrium phase behavior of a mixture of two linear polymers A and B was first derived by Flory<sup>[3]</sup> and Huggins.<sup>[4]</sup> According to the Flory–Huggins theory, the change in free energy upon mixing  $\Delta G_m$  for a binary polymer blend is given by

$$\frac{\Delta G_m}{k_B T} = \frac{\phi_A}{N_A} \ln \phi_A + \frac{\phi_B}{N_B} \ln \phi_B + \phi_A \phi_B \chi \quad (1)$$

with  $k_B$  denoting the Boltzmann constant,  $T$  the temperature,  $N_{A/B}$  the degree of polymerization (the number of mers of A and B),  $\phi_{A/B}$  the volume fraction of polymers A and B, and  $\chi$  the Flory–Huggins segment–segment interaction parameter. As large chains assume fewer mixed configurational states, the entropic contribution (first two terms in Eq. (1)) decreases with increasing molecular weight of the polymers. The phase behavior of binary polymer blends is then largely determined by the value of  $\chi$  that is fixed by the particular choice of the repeating units of polymers A and B.  $\chi$  parameters can often be expressed as a linear function of  $1/T$ , i.e.,  $\chi(T) = \alpha + \beta/T$ ; values for  $\alpha$  and  $\beta$  have been tabulated for a variety of monomers.<sup>[5]</sup> Given a binary polymer mixture, the phase behavior can be predicted by the calculation of the spinodal and binodal that are given by the criteria of stability (Eq. (2)) and thermodynamic equilibrium (Eq. (3)), respectively.

$$\frac{\partial^2}{\partial \phi_A^2} \Delta G_m = 0 \quad (2)$$

$$\frac{\partial}{\partial \phi_A} \Delta G_m(\phi_A)^{\text{phase 1}} = \frac{\partial}{\partial \phi_A} \Delta G_m(\phi_A)^{\text{phase 2}} \quad (3)$$

The binodal and spinodal curves meet in the critical point that is given for a symmetric polymer blend with equal molecular volumes ( $N_A v_A = N_B v_B$ ,  $v_i$  denoting the volume of monomer  $i$ ) by  $\phi_c = 1/2$  and  $\chi_c = 2/N$ . A typical phase diagram for a binary mixture of symmetric linear homopolymers is shown in Fig. 1. Depending on the sign and temperature dependence of  $\chi$ , different types of phase behavior can be distinguished, the most important are referred to as: upper critical solution temperature (UCST, mixing upon heating), which is found for positive  $\chi$  and  $d\chi/d(1/T) > 0$ , as well as lower critical solution temperature (LCST, mixing upon cooling), which is found for negative  $\chi$  and  $d\chi/d(1/T) < 0$ . In a few experimental systems, closed-loop behavior has been observed, i.e., low-temperature LCST and high-temperature UCST.<sup>[6]</sup> Table 2 shows a list of some homopolymers that are frequently found in industrial applications and their mixing behavior.

## Mechanisms of phase separation in homopolymer blends

There are two major mechanisms of phase separation that have been identified and that occur in different

**Fig. 1** (A) Phase diagram of a symmetric homopolymer blend ( $N_A = N_B$ ). Shaded area indicates metastable region. (B) Schematic of the mechanism of phase separation in the metastable (nucleation and growth, NG) and unstable (spinodal decomposition, SD) region of the phase diagram.

**Table 2** Mixing behavior of selected homopolymer blends

Polymer 1	Polymer 2	Miscibility
Poly(styrene)	Poly(butadiene)	no
Poly(styrene)	Poly(methyl methacrylate)	no
Poly(styrene)	Poly(dimethyl siloxane)	no
Nylon-6,6	Poly(ethylene-propylene)	no
Poly(propylene)	Poly(ethylene)	no
Poly(styrene)	Poly(vinyl methylether)	yes
Poly(styrene)	Poly(dimethyl phenyleneoxide)	yes
Poly(ethylene oxide)	Poly(acrylic acid)	yes
Poly(vinylchloride)	Poly(butylene terephthalate)	yes
Poly(methyl methacrylate)	Poly(vinylidene fluoride)	yes

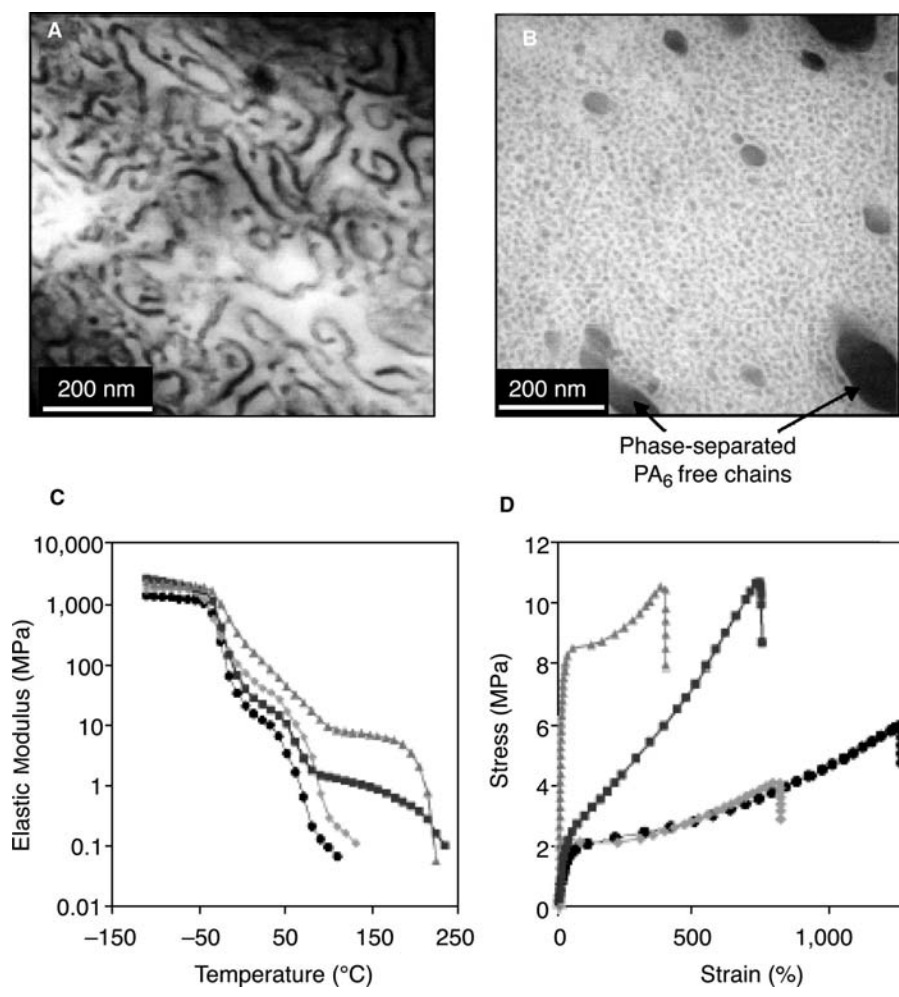

parts of the phase diagram as shown in Fig. 1: nucleation and growth (NG) and spinodal decomposition (SD). NG occurs in the metastable region of the phase diagram (the area between binodal and spinodal) and is characterized by the following steps: 1) initial formation of spherical fragments of the more stable phase (requires activation barrier); 2) growth of nuclei by first diffusion of material from the supersaturated continuum followed by droplet–droplet coalescence and Ostwald-ripening. Spinodal decomposition, which is the commonly observed mechanism for phase separation in homopolymer blends, occurs in the unstable region of the phase diagram and is characterized by initial small-amplitude composition fluctuations that increase with time and result in interconnected phase morphologies at intermediate stages of phase separation. Co-continuous polymer blends have been the subject of intense research as they generally exhibit superior mechanical properties. Co-continuous interconnected morphologies are commonly induced either by arresting SD or by mechanical mixing of polymer mixtures. Such systems often suffer the problem that they tend to move toward the equilibrium macrophase-separated structure. Blending of homopolymers in the presence of appropriately chosen graft copolymers has been shown to be a versatile alternative to mechanical mixing, facilitating the stabilization of co-continuous blends by increasing the thermodynamic stability and flexibility of the interface.<sup>[7]</sup> Figure 2 shows the microstructure of a poly(ethylene)/poly(amide) co-continuous blend

and the associated enhancement of elastic and tensile properties. Note that the elastic modulus increases by order of magnitudes in the case of the co-continuous blend with regard to its phase separated counterpart.

## Block Copolymers

Block copolymers consist of two distinct polymer chains that are covalently linked together to form a chain. The large variety of block configurations that can be constructed using modern synthetic methods can be classified based on the number of chemically distinct blocks as well as linear vs. branched connectivity of the blocks within a copolymer as indicated in Scheme 3. As structure formation processes of most of these systems are still under discussion, this article will focus on the current understanding of the simplest and most studied system—linear amorphous diblock copolymers. For excellent review articles in this field we refer the reader to Refs.<sup>[8–10]</sup>

Because block copolymers are single-component systems, they cannot macrophase separate in the melt like a pair of linear homopolymers does. Instead, block copolymers segregate on a local scale. The decrease of A–B segment contacts by local segregation is often referred to as microphase separation. The enthalpy gain obtained by the local segregation process is counterbalanced by an associated loss in system entropy that results from the localization of the block joints at the intermaterial dividing surface (IMDS) and the necessary stretching of the polymer chains away from the IMDS in order to maintain uniform density. As the entropic contribution can be shown to scale as  $N^{-1}$  with  $N = N_A + N_B$ , it is again the product  $\chi N$  that dictates the microphase-separation process. Three different limiting regimes exist for diblock copolymer melts: 1) the disordered state with unperturbed Gaussian chain statistics ( $R_G \sim N^{1/2}$ ) which is found for  $\chi N \ll 1$ ; 2) the ordered state in the weak segregation limit ( $\chi N \sim 10$ ) with sinusoidal composition fluctuations representing a periodic microstructure; and 3) the ordered state in the strong segregation limit ( $\chi N \gg 10$ ) where strong repulsive forces between segments of A and B result in sharp interfaces separating nearly pure A and B domains with pronounced stretching of the block chains ( $R_G \sim N^{2/3}$ ). Below the order–disorder transition temperature, enthalpic effects become more influential and the block copolymer microphase separates. The product  $\chi N$  and the compositional parameter  $f = N_A/(N_A + N_B)$  determine one of seven phases that represent free-energy minima for the ensemble of molecular configurations. The following sequence of phases has been observed

**Fig. 2** Transmission electron micrographs of (A) co-continuous nanostructured blend (80/20 ratio poly(ethylene)/Nylon-6,6); (B) phase separated blend. (C) and (D) show the increase of elastic modulus and stress–strain properties for co-continuous phase formation. Triangles: co-continuous (80/20), squares: micellar blend (80/20), diamonds: macrophase separated blend, circles: poly(ethylene). *Source:* From Ref.<sup>[8]</sup>. © 2002, Macmillan Publishers Ltd.

for PS–PI diblocks:  $f_{PS} < 0.17$ , body-centered cubic (BCC);  $0.17 < f_{PS} < 0.28$ , hexagonal;  $0.28 < f_{PS} < 0.34$ , bicontinuous (double gyroid);  $0.34 < f_{PS} < 0.62$ , lamellar;  $0.62 < f_{PS} < 0.66$ , inverse double gyroid;  $0.66 < f_{PS} < 0.77$  inverse hexagonal;  $f_{PS} > 0.77$ , inverse BCC. Depending on the packing frustration self-consistent field calculations also suggested the formation of a double diamond and a perforated lamellar

structure between the well-established lamellar and cylinder phases, but these microdomain geometries are considered to be only metastable and will not be discussed here. A phase diagram along with a schematic of the different periodic microstructures found as a function of  $\chi N$  and  $f$  for a typical diblock copolymer is shown in Fig. 3. Fig. 4 demonstrates the observation of the above mentioned morphologies via electron micrographs of PS–PI diblock copolymers.

**Scheme 3** Selection of di- and multiblock copolymer architectures.

### Block copolymer–homopolymer blends

A natural continuation of the research mentioned above is the study of block copolymer/homopolymer blends. Structure formation in blends of homopolymers and block copolymers is determined by the interplay of macrophase separation of the homopolymer and the microphase separation of the block copolymer. Which effect predominates depends on the relative lengths of the respective polymers and on the composition of the blend. In binary blends, low-molecular weight homopolymer is solubilized within

**Fig. 3** Phase diagram of a symmetric block copolymer ( $N_A = N_B$ ). L: lamellar phase, C: cylindrical phase, G: gyroid phase, S: spherical phase (cubic body centered). (More information about minimal surfaces: <http://www.msri.org/publications/sgp/jim/images/stills/mini/index.html>.)

a microphase-separated block copolymer structure at low concentrations. Increasing the molecular weight of the homopolymer such that it approaches that of the block copolymer leads to an increasing tendency for segregation of the homopolymer to the center of the domain. If the molecular weight of the homopolymer exceeds the one of the block copolymer, macrophase separation tends to predominate.<sup>[11]</sup>

### Binary block copolymer blends

Binary block copolymer blends offer another route toward nanoscale structures. Binary blends of triblock (ABC) and diblock (ac) copolymers, with the upper and lower case characters distinguishing the chemical composition and molecular weight of the respective blocks, were extensively studied because of their potential to microphase separate into *non-centrosymmetrical* morphologies. These nanostructures are of high technological interest, as the absence of centrosymmetry implies macroscopic polarization that is associated with many useful properties such as piezo- and pyroelectricity and second-order non-linear optical activity. Theoretical studies on the formation of non-centrosymmetric morphologies were performed for the case of lamellar structure and suggest that non-centrosymmetrical

**Fig. 4** Transmission electron micrographs of (A) lamellar; (B) hexagonal cylindrical viewing direction along cylinder axis, inset: viewing direction perpendicular to cylinder axis; (C) gyroid [view direction along (110)] and (D) BCC spherical phase of poly(styrene-*b*-isoprene) copolymer [along (100)]. For all micrographs, the isoprene block was stained with Osmiumtetroxide to enhance contrast.

morphologies require sufficient asymmetry between the Aa and Cc domains. Fig. 5 shows a schematic of possible lamellar morphologies in blends of ABC and ac block copolymers along with an excellent electron micrograph providing non-centrosymmetrical lamellar structure obtained by blending a poly(styrene-*b*-butadiene-*b*-*tert*-butylmethacrylate) triblock copolymer with poly(styrene-*b*-*tert*-butylmethacrylate) diblock copolymer.<sup>[12]</sup>

### STRATEGIES FOR CONTROLLING THE SELF-ORGANIZATION PROCESSES

Mechanical behavior can be readily tuned when, e.g., glassy mesostructures are formed in a rubbery matrix, and indeed, glassy-rubbery block copolymers are used for various applications as advanced engineering materials. However, the possible impact of block copolymer nanostructures that are envisioned is much more far-ranged. The emerging challenges that have to be resolved involve the extension of hierarchically ordered structures to larger length scales and the development of new processing technologies that allow to control the ordering process at various length scales. In the following sections, several approaches will be presented that address these challenges. 1) Strategic design of the molecular architecture, e.g., by introducing anisotropic groups that introduce configurational

**Fig. 5** (A) Diagram of the possible lamellar morphologies of ABC/ac block copolymer blends. 1: Macrophase separation, 2: random sequence, 3: centrosymmetric sequence, 4: non-centrosymmetric sequence. (B) Transmission electron micrograph of the non-centrosymmetric blend. Scale bar: 250 nm. Source: From Ref.<sup>[13]</sup>. © 1999, Macmillan Publishers Ltd.

constraints to the self-assembling process; 2) by exploiting the effect of external fields on the self-assembly process; or 3) by using surface energetics and selective polymer–substrate interactions to guide the system to the desirable global geometries.

## Techniques Involving Molecular Architecture

### Structure formation in rod–coil block copolymer systems

If one block in a coil–coil block copolymer is substituted by a polymer type that exhibits highly restricted conformational freedom, a rod–coil block copolymer is obtained. The interest in rod–coil block copolymers is fueled by the extraordinary wealth of morphologies that are found in rod–coil systems, which can result in novel functional materials with intriguing optical or electronic properties. This spectrum of domain morphologies is due to the delicate interplay between liquid crystallinity of the rod block combined with the phase separated microdomain morphologies. Rod–coil block copolymers also provide an excellent example of *designer nanoscale materials* as the rod blocks represent active sites that can be addressed by external fields (flow, electric, magnetic), providing a means to guide the system into well-defined macroscopically ordered states. A rod-like conformation of a polymer is induced either by stepwise coupling of rigid mesogenic units to form low-molecular weight oligomeric rods or in macromolecular systems by creating a rigid polymer backbone with alternating conjugation, by steric hindrance of side groups attached to each repeating unit or by the formation of helical secondary structures. The asymmetry in the rigidity of the respective rod vs. coil blocks significantly increases the Flory–interaction parameter  $\chi$ , such that rod–coil block copolymers microphase separate already at low weight fractions of the rod component. The hierarchical order from the nano- to the microscale results as a consequence of the mutual repulsion of the dissimilar blocks and the packing constraints that are imposed by the connectivity as well as the tendency toward orientational ordering of the rod block.

Currently, there exists no general theoretical framework that can account for the complex phase behavior thus observed in rod–coil copolymer systems. Three examples will be provided that represent some of the new morphologies that are encountered in rod–coil block copolymer systems. For excellent review articles of this field we refer the reader to Refs.<sup>[13]</sup> and<sup>[14]</sup>.

Stupp et al. reported the formation of large, well-organized supramolecular structures ( $10^2$  kDa) by self-assembly of rod–coil *oligomers* consisting of an elongated mesogenic rods with volume filling fractions ranging from 0.19 to 0.36 and a coil-like poly(isoprene) (PI) part.<sup>[15]</sup> Depending on the rod filling fraction, the formation of a strip morphology ( $f_{\text{rod}} = 0.36$ ) or a hexagonal superlattice structure ( $f_{\text{rod}} = 0.25$ ) was observed. Substituting the poly(isoprene) coil block by a (styrene)<sub>9</sub>-*b*-(isoprene)<sub>9</sub> oligomer was reported to result in the formation of mushroom-like assemblies

**Fig. 6** Transmission electron micrograph revealing superlattice of regularly shaped aggregates. Inset: Suggested mushroom-like morphology of the aggregate. *Source:* From Ref.<sup>[16]</sup>. © 2001, American Association for the Advancement of Science.

containing about  $N = 100$  rod-coil oligomers that self-organize into superlattice domains. A schematic of the proposed structure is given in Fig. 6.

Chen et al. investigated the structures formed in *high-molecular* rod-coil block copolymer systems consisting of poly(hexylisocyanate) with  $N = 900$  as the rod block and poly(styrene) with  $N = 300$  as the coil block.<sup>[16]</sup> Depending on the volume fraction of rod component, the formation of three different morphologies was reported. These were explained to occur as the result of microphase separation of the blocks and crystallization of the rods during solvent evaporation. For a volume filling fraction of the rod component  $f_{\text{rod}} = 0.42$ , the formation of a wavy lamellar structure was observed, in which the rod blocks are tilted

with respect to the layer normal by about  $60^\circ$ . For  $f_{\text{rod}} = 0.73$  a novel “zigzag” morphology was observed in which the rod and coil blocks are arranged in a zigzag fashion and the rod blocks are tilted with respect to the layer normal by  $45^\circ$ . For even higher rod filling fractions ( $f_{\text{rod}} > 0.96$ ) an “arrowhead-like” pattern formation was observed. Fig. 7 shows electron micrographs of the observed morphologies. The complexity of the structure formation process in rod-coil systems is indicated by the pronounced effect of solvent on the structures depicted in Fig. 7. Well-oriented zigzag patterns were observed only when toluene was used, whereas the use of chloroform as a solvent resulted in more disordered arrangement of the zigzags. The observed difference can be understood as the quality of the solvent determines the onset of microphase separation of the blocks as well as the onset of liquid crystallization of the rod blocks. As a consequence, rod-coil morphologies often do not represent equilibrium structures but rather kinetically trapped states. Park and Thomas have continued the study of microstructure formation in rod-coil block copolymers and demonstrated the formation of long-range periodic domain walls yielding a hierarchical morphology with order on multiple length scales consisting of interchain crystals of the rod blocks (1.5 nm), block copolymer microdomains (55 nm), and periodic Neel domain walls ( $\sim 1 \mu\text{m}$ ).<sup>[17]</sup> This study is remarkable for two reasons. First, the block copolymer-poly(3-(triethoxysilyl)propylisocyanate-*b*-styrene) (PIC-PS) employed in their study contains reactive groups as part of the isocyanate rod blocks. These entities allow the polymer to be covalently tethered to inorganic substrates after microstructure formation. Second, by directional solvent evaporation, the authors demonstrated unidirectional alignment of domain wall patterns on the centimeter length scale while maintaining interchain and microdomain ordering. A pair of atomic force micrographs of the observed hierarchical rod-coil structure are shown in Fig. 8.

**Fig. 7** Transmission electron micrographs of the morphologies of the PHIC-PS rod-coil block copolymer: wavy-lamellar ( $f_{\text{PHIC}} = 0.42$ ), zigzag ( $f_{\text{PHIC}} = 0.89$ ) and bilayer arrowhead ( $f_{\text{PHIC}} = 0.96$ ). ### Effect of Mechanical and Electric Fields

Polymeric materials can undergo dramatic changes in their structure in response to external fields. This provides opportunities to direct distinct alignments of polymeric nanostructures through processing. Polymer engineers have long exploited processing to increase properties (e.g., fiber production) through increase of crystallinity and chain orientation. For many envisioned applications of polymer-based nanostructures, it is of special importance to be able to produce functional macroscopic materials with uniform large-scale orientation. In general, self-assembly processes alone do not result in globally ordered structures but rather heterogeneous morphologies consisting of randomly oriented grains within which the domains have homogeneous alignment. The possibility to induce global order in block copolymer microstructures by flow field alignment was pioneered by Keller, Pendemonte, and Willmouth in extruded polymer materials and a variety of other flow methods have been developed, such as roll-casting and extensional flow.<sup>[18–20]</sup> Kornfield et al. studied the influence of oscillatory shear on the alignment of lamellar morphology forming block copolymers by in situ rheo-optical methods that allow monitoring the alignment of the lamellae as a function of applied shear rate and amplitude.<sup>[19]</sup> It was argued that with increasing shear rate three different microstructure regimes can be distinguished for layered microstructured block copolymers in which the polymer domains have dissimilar viscoelastic properties. Two characteristic frequencies that determine the effect of oscillatory shear on the alignment of lamellar samples were identified: a lower frequency limit  $\omega_d$  that is associated with the lifetime of fluctuations on a layered structure and a higher frequency limit  $\omega_c$  that reflects the dynamics of conformational distortions of single polymer chains. It was found that oscillatory strain shearing induces parallel alignment with respect to the shear direction for  $\omega < \omega_d$ , perpendicular

alignment for  $\omega_d < \omega < \omega_c$ , and parallel alignment for  $\omega_c < \omega$ .

For cylindrical microdomain forming coil-coil block copolymers subjected to steady or oscillatory shear, parallel orientation, i.e., the cylinder axes are aligned along the flow direction, was found to be the usual orientational state. However, by anchoring liquid crystalline side groups to a coil-coil block copolymer, Osuji et al. could demonstrate that the strong interaction of the mesogens with the applied flow field can force the cylindrical microdomains to align *transverse* to the flow direction.<sup>[21]</sup> In their study of the effect of oscillatory mechanical shear on the microstructure formation of a PS-PI block copolymer in which each isoprene block was functionalized with a mesogenic group, the authors concluded that the invariant homogeneous anchoring of the mesogens with respect to the IMDS results in the transverse cylindrical orientation under shear. A schematic of the proposed structural model of perpendicular smectic layers and transverse cylindrical microdomains is given in Fig. 9.

Amundson et al.<sup>[22]</sup> presented a detailed mechanistic study of the effect of electrical fields on the structure evolution in lamellar block copolymer systems. By applying electrical fields of 1.8 MV/m to a symmetric PS-PMMA diblock copolymer while heating the polymer above glass transition temperature, a significant increase in orientation of the lamellae along the electric field direction could be observed. The ordering effect of the electric field could be explained by the orientational dependence of the systems free-energy in the presence of the external field. The situation is similar to the effect of an oscillatory shear-field when  $\omega < \omega_d$ . The external field raises the free-energy associated with lamellar compression or splay and hence causes movement and annihilation of defect walls and disclination lines. A schematic of the defect movement along with electron micrographs of the films with and without electric field alignment is shown in Fig. 10. Recently, Thurn-Albrecht et al. applied a similar procedure to align cylindrical PS-PMMA block copolymers using electric field strengths of 40 MV/m.<sup>[23]</sup>

### Thin Film Morphologies

Whereas bulk morphologies of microphase-separated block copolymers are often typified by grains of ordered domains that are randomly oriented with respect to each other, thin films can sometimes exhibit highly ordered domains. This orientation can be understood as a direct result of the surface and interfacial energy minimization. The possible applications of block copolymer thin films have been widely recognized and constitute a very active current field of

**Fig. 9** Schematic structural model of the transverse alignment of cylindrical microdomains and smectic layers. Flow is along  $x$ - and vorticity is along  $y$  direction. The model represents a compromise structure in which cylinders are transverse and smectic layers are perpendicular, but the boundary condition for the mesogens are maintained homogeneous. *Source:* From Ref.<sup>[22]</sup>.

research. An excellent introduction to the field is the recent review article by Fasolka and Mayes.<sup>[24]</sup> Of the various microdomain types, the most investigated is the lamellar. Most theoretical work regarding the physics of thin film morphology was done for the case of symmetrical boundary conditions that is realized, e.g., when the film is located in between two identical substrates. It was found that for films with thickness greater than the lamellar thickness,  $t > L$ , the lamellae orient parallel to the substrate surface. As a result of the surface substrate boundary conditions the most energetically compatible block is expressed at each of the surfaces. Depending on which block wets the respective surface, one distinguishes between symmetric (same block wets each surface) and antisymmetric (different blocks wet the two surfaces) wetting. The equilibrium conditions for stability of symmetric films are then given as  $t = nL$ , with  $n$  being an integer, and  $t = (n + 1/2)L$  for antisymmetric wetting. It was proposed that the entropic penalty that is imposed on chains when surface-parallel lamellae are constrained to film thicknesses incommensurate with

integer multiples of  $L$  can induce the perpendicular lamellar orientation if the entropic penalty exceeds the enthalpic gain from preferential wetting. A summary of possible thin film morphologies is given in Fig. 11.

Although the assumption of symmetric boundary conditions simplifies the analysis, many practical thin film situations exhibit asymmetric boundary conditions, e.g., supported film systems. In supported film systems, the polymer-substrate interfacial energy of a given type of monomer can differ from its surface energy by an order of magnitude. The presence of asymmetric boundary conditions can therefore result in new morphological trends not found in the symmetric case, e.g., the formation of hybrid structures involving parallel as well as perpendicular alignment. At the time of writing no theoretical model has been developed that could accurately account for many of the experimental observations. This is in part due to the finite roughness and deformability of most surfaces on the molecular scale that represents a major problem in the application of the theoretical models mentioned above to real supported films.

### Epitaxial crystallization of block copolymer thin films

Epitaxy denotes the oriented overgrowth of one crystalline material upon the surface of another. In general, this process requires an approximate agreement in lattice spacings of the two components. Epitaxy is a traditional method of material science used to control registration and orientation. Block copolymers that contain one crystallizable block are of great interest as the crystallization provides an additional driving force for the microphase separation. The resulting morphology is the result of the interplay between segregation and crystallization process and is therefore process-path dependent, resulting in new opportunities to control the structure formation process by directing the crystallization process. Epitaxial methods were shown to be particularly interesting in controlling the orientation of microphase-separated block copolymer domains over large areas. De Rosa et al. recognized

**Fig. 11** Diblock copolymer thin film morphologies as a function of boundary conditions. A-block is gray, B-block is black.  $L_0$ : film thickness, FL: symmetric surface-parallel full lamellae, AFL: antisymmetric surface-parallel lamellae, AHY: antisymmetric hybrid structure, HL: half-lamellae, HY: symmetric hybrid structure, PL: surface-perpendicular lamellae. *Source:* From Ref.<sup>[24]</sup>. © 2001, Annual Reviews.

that because of crystallographic matching of poly(ethylene) and benzoic acid crystals, the poly(ethylene) blocks of a semicrystalline poly(ethylene-*b*-ethylene-propylene-*b*-ethylene) triblock copolymer can be epitaxially crystallized onto crystals of benzoic acid thereby directing the microphase separation process.<sup>[25]</sup> Electron micrographs depicting the microstructure of the block copolymer thin film with and without epitaxial direction are shown in Fig. 12. Epitaxial control over the microphase separation process continues to attract much attention as it opens a new dimension to the control of nanostructure formation: crystal orientation on the 1–10-nm length scale as well as microstructure orientation on the 10–100-nm length scale.

### TRENDS IN EXPLOITING POLYMER-BASED NANOSTRUCTURES

Recent advances in understanding the formation of nanostructures based on self-assembled microphase separated block copolymers and the external parameters that afford global ordering of these structures have resulted in applications that capitalize on the specific structural characteristics rather than on a volume averaged behavior. Microphase separated block copolymers have been studied extensively as an alternative approach to conventional lithographic techniques to produce highly ordered nanostructures with possible

applications such as a high-density magnetic recording device or a photonic band-gap material. In the following we present some examples of the new directions in this area of research.

### Block Copolymers as Photonic Band Gap Materials

As block copolymers self-assemble into periodic one-, two-, or three-dimensional equilibrium structures, optical effects such as photonic band gaps can be obtained when the molecular weight of the block copolymer is high enough such that the domain spacing is of the order of the wavelength of light (typically  $M \sim 10^6$  g/mol). Photonic band gaps denote frequency regions in which light of certain polarization and propagation direction cannot propagate through the material.<sup>[26]</sup> As the synthesis and processing of high molecular weight polymers is delicate, the first observation of a self-assembled polymer-based photonic material was not published until 1999.<sup>[27]</sup> Various techniques have been developed in order to solve the eminent problem of the inherently low dielectric contrast between typical polymers. Methods such as selective deposition of high index nanocrystals within the polymer scaffold<sup>[28]</sup> or selective etching of one of the

domains<sup>[29]</sup> can raise the dielectric contrast. It could be shown that even for high molecular weight copolymers the double gyroid microdomain morphology can be obtained, indicating pathways to three-dimensional photonic crystals that combine a full photonic band gap with the advantageous mechanical properties of polymeric materials and the ease of self-assembly. Fig. 13B shows a scanning electron micrograph of a double gyroid obtained from high molecular weight PS-PI after selective etching of the PI matrix using UV/ozone.<sup>[29]</sup>

### Block Copolymer Lithography

The typical length scale of microphase separation, 10–100 nm, is particularly interesting as it provides a versatile alternative to conventional photolithographic techniques for surface structuring. Possible applications for regular texturing of a surface at the 10-nm length scale are the fabrication of high-storage magnetic recording media, DNA electrophoresis membranes or microoptical elements. Of particular interest is the combination of the controlled structure formation on the nanometer length scale with the distinct chemical nature of the respective blocks. Lopes and Jaeger demonstrated the selective decoration of the

PS domains of a cylindrical microstructure forming PS-PMMA diblock copolymer by evaporation of gold on top of the spin-casted polymer thin film.<sup>[30]</sup> The dense packing of gold nanocrystals on the PS domains allowed for the formation of a regular pattern of conducting nanowires 50 nm in width which are of great interest as interconnects, gratings, or for biosensor applications. A schematic of the described structure formation process along with electron micrographs of the resulting structures is shown in Fig. 14. Block copolymer lithography has also been studied as possible alternative to conventional lithographic techniques for the fabrication of high-density magnetic storage media. For example, Cheng et al. demonstrated that single-domain ferromagnetic cobalt dots can be fabricated using self-assembled block copolymer lithography.<sup>[31]</sup> In their study, the authors took advantage from the significantly different etching rates of organic-inorganic block copolymers when exposed to a reactive ion beam, allowing the selective etching of one component from the microstructure while converting the inorganic-containing block to a ceramic. A thin film of spherical microdomain morphology forming poly(styrene-*b*-ferrocenyldimethylsilane) (PS-PFS) block

copolymer was cast on a layered cobalt-tungsten-silica substrate and the PFS domains used as a mask for subsequent reactive ion etching. A schematic of the procedure as well as a scanning electron micrograph of the obtained nanodot arrays is shown in Fig. 15.

### Inorganic-Organic Mesostructures from Block Copolymer Phases

At present, great attention is being paid to the preparation of complex inorganic-organic hybrid materials with long-range order that could find possible applications in catalysis, membrane, and separation technology. Two major synthetic approaches can be distinguished: 1) the in situ synthesis of inorganic particles within a block copolymer domain that has been loaded with a suitable precursor reagent and 2) the simultaneous self-assembly of the block copolymer in the presence

**Fig. 15** (A) Schematic of the sequential reactive ion etch process (see text for details). (B) Tilted scanning electron micrograph showing Co-nanodot arrays obtained after complete etching of the PS-PFS block copolymer. *Source:* From Ref.<sup>[31]</sup>. © 2001, Wiley Interscience.

of ex situ synthesized nanoparticles that are surface-tailored in order to allow preferential sequestration within a target domain. Whereas the first approach facilitates higher volume filling fractions of the inorganic material, the second approach allows better control of the structural characteristics of the sequestered component. Micropatterned solid particles in a block copolymer matrix were produced by Bootongkong and Cohen in a nanoreactor scheme, in which the hydrophilic domain of a poly(styrene-*b*-acrylic acid) block copolymer is pre-loaded with a metal salt that is reduced in a second reaction step.<sup>[32]</sup> The procedure is outlined in Fig. 16. The authors demonstrated that the block copolymer nanoreactor scheme might be applied to a wide variety of metal (Pd, Cu, Au, Ag) as well as semiconductor (PbS) nanocrystals. Whereas the block copolymer nanoreactor scheme results in the formation of discrete or interconnected nanocrystals dispersed within the respective block copolymer domain, Templin et al. demonstrated that by swelling of the poly(ethylene oxide) domain of a poly(ethylene oxide-*b*-isoprene) block copolymer with an inorganic

precursor followed by hydrolysis and calcination, continuous inorganic nanorelief structures can be obtained.<sup>[33]</sup> The authors also described the formation of the “plumber’s nightmare” morphology for the hybrid material, which is an uncommon bicontinuous morphology for block copolymers and which was explained by subtle differences in the phase behavior of hybrid vs. neat block copolymer structures. In contrast to the abovementioned in situ approaches, ex situ methodologies become advantageous when precise control of the structural features of the inorganic component becomes relevant to the desired function of the hybrid material or the geometrical characteristics of the inorganic component cannot be obtained through in situ synthesis. For example, Ha and Thomas studied the incorporation of “two-dimensional” clay sheets into lamellar PS-PI block copolymer microstructures.<sup>[34]</sup> The authors demonstrated that by decorating the mineral’s surface with poly(styrene),

individual clay sheets can be preferentially sequestered within the polystyrene domain of the block copolymer. The resulting nanocomposite materials exhibit highly anisotropic mechanical and permeability properties. An electron micrograph of the nanocomposite material revealing single-layer clay sheets sequestered within the poly(styrene) domains is shown in Fig. 17. The development of surface decoration techniques that allow for molecular level dispersion of the inorganic component within the polymer matrix represents a major advancement in the field as the inclusion of single-sheet (exfoliated) mineral layers permits to downscale the amount of inorganic component by an order of magnitude (only 2 wt.% inorganic is needed) while providing the advantageous material properties.

The control of the composites' architecture on the nanometer scale is of special importance for future research in this area as it facilitates to dramatically decrease the switching speed in these materials which is diffusion limited, scaling as the square of the feature size. At present, research focus is on the development of next-generation actuator materials that capitalize from both the mechanical and optical characteristics of the sequestered component as well as the rapid dynamic response to external stimulus that results from the architectural control on the molecular level.

## INTRODUCTION

We have been exploring the transport and electrochemical properties of nanotube membranes prepared by the template method,<sup>[1–3]</sup> a general approach for preparing nanomaterials. This method entails synthesis or deposition of the desired material within the cylindrical and monodisperse pores of a nanopore membrane or other solid. We have used polycarbonate filters, prepared via the “track-etch” method,<sup>[4]</sup> and nanopore aluminas, electrochemically prepared from Al foil,<sup>[5]</sup> as our template materials. Cylindrical nanostructures with monodisperse diameters and lengths are obtained, and depending on the membrane and synthetic method used, these may be solid nanowires or hollow nanotubes. We and others have used this method to prepare nanowires and tubes composed of metals,<sup>[5–12]</sup> polymers,<sup>[13–15]</sup> semiconductors,<sup>[16,17]</sup> carbons,<sup>[18,19]</sup> and Li<sup>+</sup> intercalation materials.<sup>[20–22]</sup> It is also possible to prepare composite nanostructures, both concentric tubular composites, where an outer tube of one material surrounds an inner tube of another,<sup>[23,24]</sup> and segmented composite nanowires.<sup>[25]</sup>

One application for these nanotube membranes is in electroanalytical chemistry where the membrane is used to sense analyte species.<sup>[26,27]</sup> In that work, membranes containing gold nanotubes with inside diameters that approached molecular dimensions (1–4 nm) were used.<sup>[26]</sup> The Au nanotube membrane was placed between two salt solutions and a constant transmembrane potential was applied. The resulting transmembrane current, associated with migration of ions through the nanotubes, was measured. When an analyte molecule whose diameter was comparable to the inside diameter of the nanotubes was added to one salt solution, this molecule partitioned into the nanotubes and partially occluded the pathway for ion transport. This resulted in a decrease in the transmembrane ion current, and the magnitude of the drop in current was found to be proportional to the concentration of the analyte.<sup>[26]</sup>

In the experiment discussed above, a baseline transmembrane ion current was established, and the analyte molecule, in essence, turned off this current. It occurred to us that there might be an advantage in doing the opposite, i.e., starting with an ideally zero current situation and having the analyte molecule switch on the ion current. In other words, we would like to make a synthetic membrane that mimics the function of a ligand-gated ion channel. An example is the acetylcholine-gated ion channel,<sup>[28]</sup> which is closed (“off” state) in the absence of acetylcholine but opens (and supports an ion current, “on” state) when acetylcholine binds to the channel. To accomplish this, the off state was obtained by making gold and alumina membranes hydrophobic, and the on state was obtained by introducing ions and electrolyte into the membrane.<sup>[29]</sup> Ions were introduced by either partitioning a hydrophobic ionic species (e.g., a drug or a surfactant) into the membrane.

## MEMBRANE PREPARATION AND ANALYSIS

Commercially available track-etched polycarbonate filters are used as the templates to prepare the Au nanotubes. The track-etch process<sup>[4]</sup> entails bombarding a solid material (in this case a ~10- $\mu$ m-thick polycarbonate film) with a collimated beam of high-energy nuclear fission fragments to create parallel damage tracks in the film. The damage tracks are then etched into monodisperse cylindrical pores by exposing the film to a concentrated solution of aqueous base. The diameter of the pores is determined by the etch time and the etch-solution temperature. Membranes with pore diameters ranging from as small as 10 nm to as large as ~10  $\mu$ m are commercially available. The membranes used for these studies had nominal pore diameters of 30 nm and contained  $6 \times 10^8$  pores per square centimeter of membrane surface area.

The electroless plating method is used to deposit the Au nanotubes<sup>[7,30]</sup> within the pores of these

membranes. Briefly, the template membrane is first “sensitized” by immersion into a  $\text{SnCl}_2$  solution, which results in deposition of  $\text{Sn(II)}$  onto all of the membrane’s surfaces (pore walls and membrane faces). The sensitized membrane is then immersed into a  $\text{AgNO}_3$  solution, and a surface redox reaction occurs [Eq. (1)], which yields nanoscopic metallic  $\text{Ag}$  particles on the membrane surfaces.

(The subscripts surf and aq denote species adsorbed to the membrane surfaces and species dissolved in solution, respectively.) The membrane is then immersed into a commercial gold plating solution and a second surface redox reaction occurs, which yields  $\text{Au}$  nanoparticles on the surfaces [Eq. (2)].

These surface-bound  $\text{Au}$  nanoparticles are good autocatalysts for the reduction of  $\text{Au(I)}$  to  $\text{Au(0)}$  using formaldehyde as the reducing agent. As a result,  $\text{Au}$  deposition begins at the pore walls, and  $\text{Au}$  tubes are obtained within the pores.<sup>[7,9,30,31]</sup>

### ESTIMATION OF THE NANOTUBE INSIDE DIAMETER

We used a gas-transport method to obtain an estimate of the inside diameter (i.d.) of the template-synthesized  $\text{Au}$  nanotubes.<sup>[7]</sup> Briefly, the tube-containing membrane is placed in a gas-permeation cell, and the upper and lower half-cells are evacuated. The upper half-cell is then pressurized, typically to 20 psi (138 kPa) with  $\text{H}_2$ , and the pressure–time transient associated with leakage of  $\text{H}_2$  through the nanotubes is measured using a pressure transducer in the lower half-cell. The pressure–time transient is converted to gas flux ( $Q$ ,  $\text{mol s}^{-1}$ ), which is related to the radius of the nanotubes ( $r$ , cm) via.<sup>[7]</sup>

$$Q = 4/3(2\pi/MRT)^{1/2}(nr^3\Delta P/l) \quad (3)$$

where  $\Delta P$  is the pressure difference across the membrane ( $\text{dyn cm}^{-2}$ ;  $1 \text{ dyn} = 10^{-5} \text{ N}$ ),  $M$  is the molecular weight of the gas,  $R$  is the gas constant ( $\text{erg K}^{-1} \text{ mol}^{-1}$ ;  $1 \text{ erg} = 10^{-7} \text{ J}$ ),  $n$  is the number of nanotubes in the membrane sample,  $l$  is the membrane thickness (cm), and  $T$  is the temperature (K). At long plating times, membranes containing nanotubes with i.d.’s of molecular dimensions are obtained (Fig. 1).

Fig. 1 Variation of the nanotube effective inside diameter with plating time.

### CHEMICAL SENSING WITH THE Au NANOTUBE MEMBRANES

These  $\text{Au}$  nanotube membranes have been used as sensors for the determination of ultratrace concentrations of ions and molecules.<sup>[26,27]</sup> In this case, the nanotube membrane was allowed to separate two salt solutions, a constant transmembrane potential was applied, and the resulting transmembrane current was measured. When an analyte of comparable dimensions to the inside diameter of the nanotubes was added to one of the salt solutions, a decrease in transmembrane current was observed. The magnitude of this drop in transmembrane current ( $\Delta i$ ) is proportional to the analyte concentration.

### CALIBRATION CURVES AND DETECTION LIMITS

As in the transport experiments, a U-tube cell was assembled with the nanotube membrane separating the two halves of the cell. The two half-cells were filled with the desired electrolyte and an electrode was placed into each half-cell. Three different sets of electrodes and electrolytes were used. The first set consisted of two Pt plate electrodes, and the electrolyte used in both half-cells was 0.1 M  $\text{KF}$ . The second set consisted of two  $\text{Ag/AgCl}$  wires, and the electrolyte used in both half-cells was 0.1 M  $\text{KCl}$ . The third set consisted of two  $\text{Ag/AgI}$  wires immersed in 0.1 M  $\text{KI}$ .

As noted above, the experimental protocol used with these cells was to immerse the electrodes into the appropriate electrolyte and apply a constant potential between the electrodes. The resulting transmembrane current was measured and recorded on an  $X-t$  recorder. After obtaining this baseline current, the

**Fig. 2** Chemical structures and approximate relative sizes of the three “big molecule/small molecule” pairs used in the molecular filtration experiments. Quinine, MV<sup>2+</sup>, and Ru(bpy)<sub>3</sub><sup>2+</sup> were also used as analytes in the sensor work.

anode half-cell was spiked with a known quantity of the desired analyte (Fig. 2). This resulted in a change in the transmembrane current,  $\Delta i$  (Fig. 3). A potentiostat was used to apply the potential between the electrodes and measure the transmembrane current. The transmembrane potential used was on the order of 0.5 V.<sup>[26,27]</sup>

Plots of  $\log \Delta i$  vs.  $\log[\text{analyte}]$  for the analytes Ru(bpy)<sub>3</sub><sup>2+</sup>, MV<sup>2+</sup>, and quinine (Fig. 2) were obtained using Ag/AgCl electrodes and 0.1 M KCl as the

electrolyte in both half-cells (Fig. 4). For these experiments, a membrane with 2.8-nm i.d. Au nanotubes was used. A log–log format is used for these “calibration curves” because of the large dynamic range (spanning as much as 5 orders of magnitude in analyte concentration) obtained with this cell. Analogous calibration curves were obtained for the other electrode/electrolyte systems investigated. The detection limits<sup>[26]</sup> obtained are shown in Table 1. For the divalent cationic electrolytes, the detection limits were lowest (best) in the Ag/AgI/KI cell and worst in the Pt/KF cell. The detection limit for quinine was

**Fig. 3** Nanotube membrane sensor current–time transients associated with spiking the anode half cell with the indicated concentrations of Ru(bpy)<sub>3</sub><sup>2+</sup>. Tube i.d. = 2.8 nm; Ag/AgCl/KCl cell;  $\Delta i$  determined as shown in C.

**Fig. 4** Calibrations curves for the indicated analytes. Membrane and cell are as described in Fig. 3.

**Table 1** Detection limits obtained for the three different electrode/electrolyte systems studied (nanotubule i.d.)

Cell	Analyte	Detection limit (M)
Pt/KF	Ru (bpy) <sub>3</sub> <sup>2+</sup>	10 <sup>-9</sup>
Ag/AgCl/KCl	Ru (bpy) <sub>3</sub> <sup>2+</sup>	10 <sup>-10</sup>
	Quinine	10 <sup>-8</sup>
	MV <sup>2+</sup>	10 <sup>-6</sup>
	2-naphthol	10 <sup>-6</sup>
Ag/AgI/KI	Ru (bpy) <sub>3</sub> <sup>2+</sup>	10 <sup>-11</sup>
	Quinine	10 <sup>-8</sup>
	MV <sup>2+</sup>	10 <sup>-7</sup>
	2-naphthol	10 <sup>-6</sup>

the same in both the Ag/AgI/KI and Ag/AgCl/KCl cells. In general, the detection limit decreases as the size of the analyte molecule increases (Fig. 2). Finally, the detection limits obtained (down to 10<sup>-11</sup> M) are extraordinary and compete with even the most sensitive of modern analytical methods.

The majority of the quinine in both the KCl and KI solutions is present as the monoprotonated (monocationic) form. Perhaps the reason the detection limits for Ru(bpy)<sub>3</sub><sup>2+</sup> and MV<sup>2+</sup> are lower in the Ag/AgI/KI cell while the detection limit for quinine is the same in both this cell and the Ag/AgCl/KCl cell has to do with the difference in charge of these analytes (predominantly monocationic vs. dicationic). To explore this point, the detection limits for a neutral analyte, 2-naphthol, were obtained in both the Ag/AgI/KI and Ag/AgCl/KCl cells. Like quinine, the detection limit for this neutral analyte was the same in both cells (10<sup>-6</sup> M) (Table 1).

In the membrane transport studies, it was shown that Ru(bpy)<sub>3</sub><sup>2+</sup> and MV<sup>2+</sup> come across such membranes as the ion multiples Ru(bpy)<sub>3</sub><sup>2+</sup>(X<sup>-</sup>)<sub>2</sub> and MV<sup>2+</sup>(X<sup>-</sup>)<sub>2</sub> (X<sup>-</sup> = anion).<sup>[7]</sup> In the KI cell, the ion multiple contains two larger (relative to chloride) iodide anions. Perhaps the larger size of the iodide ion multiple accounts for the lower detection limit in the KI-containing cell. If this is true, then the difference between the quinine cation paired with one I<sup>-</sup> vs. this cation paired with one Cl<sup>-</sup> is not great enough to cause the detection limit for this predominantly monovalent analyte to be significantly different in the Ag/AgI/KI vs. the Ag/AgCl/KCl cells (Table 1).

The final variable to be investigated is the effect of nanotube inside diameter on detection limit. To explore this parameter, membranes with nanotube inside diameters of approximately of 3.8, 2.8, 2.2, 1.8, and 1.4 nm were prepared and used in the Ag/AgI/KI cell.<sup>[26]</sup> Calibration curves for the analytes Ru(bpy)<sub>3</sub><sup>2+</sup>, MV<sup>2+</sup>, and quinine were generated as

before, and detection limits were obtained from these calibration curves. Fig. 5 shows plots of detection limits for these three different analytes vs. the nanotube inside diameter in the membrane used. A minimum in this plot is observed for each of the three analytes.

The nanotube membrane that produces the minimum (best) detection limit depends on the size of the analyte. These molecules decrease in size in the order Ru(bpy)<sub>3</sub><sup>2+</sup> > quinine > MV<sup>2+</sup>. The nanotube membrane that yields the lowest detection limit follows this size order; that is, the nanotube diameters that produce the lowest detection limit for Ru(bpy)<sub>3</sub><sup>2+</sup>, quinine, and MV<sup>2+</sup> are 2.8, 2.2, and 1.8 nm, respectively. For the roughly spherical analytes, the optimal tube diameter is a little over twice the diameter of the molecule.

### MOLECULAR-SIZE-BASED SELECTIVITY

The data presented above show a strong correlation between detection limit and the relative sizes of the nanotube and the analyte molecule (Fig. 5). This indicates that this device should show molecular-size-based selectivity. This is not surprising given the transport studies previously discussed. To explore size-based selectivity, a series of solutions were prepared containing decreasing concentrations of the analyte species, but containing a constant (higher) concentration of an interfering species. The interfering species was smaller than the analyte species. The response of the nanotube membrane (nanotube diameter = 2.8 nm) to these solutions was then measured starting from lowest to highest concentration of the analyte species.

The small pyridine molecule was used as the first interfering species. When present at a concentration of 10<sup>-4</sup> M, pyridine offered very little interference for any of the analytes Ru(bpy)<sub>3</sub><sup>2+</sup>, MV<sup>2+</sup>, or quinine.

**Fig. 5** Detection limits for MV<sup>2+</sup>, quinine, and Ru(bpy)<sub>3</sub><sup>2+</sup> vs. i.d. of the nanotubes used in the sensor.

The detection limits in the presence of  $10^{-4}$  M pyridine were  $10^{-10}$  M for  $\text{Ru}(\text{bpy})_3^{2+}$ ,  $10^{-6}$  M for  $\text{MV}^{2+}$ , and  $10^{-7}$  M for quinine, within an order of magnitude of the detection limit with no added interfering species (Table 1). In other words, this nanotube membrane sensor can detect  $10^{-10}$  M  $\text{Ru}(\text{bpy})_3^{2+}$  in the presence of 6 orders of magnitude higher pyridine concentration.

A second set of experiments was performed using the larger  $\text{MV}^{2+}$  as the interfering species. Now at low concentrations of analyte, there is a region where the device produces a constant response as a result of the constant concentration ( $10^{-4}$  M) of this interfering species; that is, the much higher concentration of the  $\text{MV}^{2+}$  swamps the response of the device. However, as the concentration of  $\text{Ru}(\text{bpy})_3^{2+}$  increases, there is a concentration range where the device responds to this analyte species without interference from the  $\text{MV}^{2+}$ . This concentration range begins at concentrations of  $\text{Ru}(\text{bpy})_3^{2+}$  above  $10^{-8}$  M. That is, the size-based selectivity is such that the larger analyte species,  $\text{Ru}(\text{bpy})_3^{2+}$ , can be detected down to  $10^{-8}$  M in the presence of 4 orders of magnitude higher concentration of the smaller interfering species,  $\text{MV}^{2+}$ .

## SYNTHETIC ION CHANNEL PORES

We have conducted experiments that provide proof of the basic concept that an analyte molecule can switch on an ion current in a synthetic membrane-based ion-channel mimic.<sup>[29]</sup> The membrane used for most experiments was a commercially available microporous alumina filter. The pores in this membrane were made hydrophobic by reaction with an 18-carbon ( $\text{C}_{18}$ ) alkyl silane. When placed between two salt solutions, the pores in this  $\text{C}_{18}$ -derivatized membrane are not wetted by water, yielding the off state of the membrane. When exposed to a solution containing a sufficiently high concentration of a long-chain ionic surfactant (the analyte), the surfactant molecules partition into the hydrophobic membrane, and ultimately cause the pores to flood with water and electrolyte. As a result, the membrane will now support an ion current, and the ion channel-mimetic membrane is switched to its on state. Cationic drug molecules can also switch this membrane from the off to the on state.

## MEMBRANE PREPARATION AND A.C. IMPEDANCE EXPERIMENTS WITH 1-DODECANESULFONIC ACID ANALYTE

The alumina membranes were Anopore<sup>®</sup> (Whatman Inc., Clifton, New Jersey) that had nominally

200-nm-diameter pores and were 60- $\mu\text{m}$  thick. The alumina membranes were modified with octadecyltrimethoxysilane.<sup>[29]</sup> The membrane assembly was mounted between the halves of a U-tube permeation cell, and both half-cells were filled with  $\sim 20$  mL of 0.1 M KCl. A Ag/AgCl working electrode was immersed into one half-cell solution, and a Pt counter electrode and a Ag/AgCl reference electrode were placed in the other half-cell.<sup>[32,33]</sup>

Alternating current impedance measurements proved to be a useful way to demonstrate the analyte-induced switching of the membrane between the off and on states. The uppermost curve in Fig. 6 is the Nyquist plot for a  $\text{C}_{18}$ -modified alumina membrane with 0.1 M KCl solutions, and no analyte (1-dodecanesulfonic acid, DBS) on either side of the membrane. As per prior investigations of ion-channel and ion-channel-mimetic membranes,<sup>[34,35]</sup> the impedance data were interpreted in terms of the equivalent circuit shown in the inset of Fig. 6, where  $R_s$  is the solution resistance,  $R_m$  is the membrane resistance, and  $C$  is the membrane capacitance. The dashed curve is the best fit to the experimental data, from which the  $R_m$  (Fig. 7) and  $C$  values were obtained. Also shown in Fig. 6 are impedance data after spiking the half-cell electrolyte solutions to the indicated concentrations with the analyte (DBS).

In the absence of DBS, the membrane resistance is very large,  $>50$  M $\Omega$  as opposed to  $\sim 5$   $\Omega$  for the

**Fig. 6** Nyquist plots for a  $\text{C}_{18}$ -modified alumina membrane upon exposure to increasing concentrations of DBS in 0.1 M KCl. The points are the experimental data. The lines are calculated data obtained using the equivalent circuit shown in the inset. Concentrations of DBS were as follows:  $\square$  = 0 nM;  $\blacklozenge$  = 1.4 nM;  $\triangle$  = 3 nM;  $\circ$  = 10 nM;  $\times$  = 40 nM;  $+$  = 100 nM.

**Fig. 7** Plots of log membrane resistance (left y axis) and micromoles  $\text{Ru}(\text{bpy})_3^{2+}$  transported across the membrane (right y axis) vs.  $\log[\text{DBS}]$  for a  $\text{C}_{18}$ -modified alumina membrane. The error bars represent the standard deviation of three separate experiments.

alumina membrane before modification with the  $\text{C}_{18}$  silane. Transport experiments (vide infra) show that this is because the very hydrophobic  $\text{C}_{18}$ -modified pores are not wetted by water. This is supported by contact angle measurements on the membrane surface, where a water contact angle of  $130(+8)^\circ$  was obtained for the  $\text{C}_{18}$ -treated alumina membrane as opposed to  $\sim 8(+1)^\circ$  for the untreated membrane.

While over the concentration range  $10^{-9}$  to  $10^{-7}$  M, there is some drop in membrane resistance with increasing DBS concentration (Fig. 8),  $R_m$  remains very large ( $>20$  MΩ). However, over the DBS concentration range between  $10^{-6}$  and  $10^{-5}$  M, there is a precipitous, 4-order-of-magnitude, drop in  $R_m$  (Fig. 7). This drop signals the analyte-induced switching of the membrane from the off to the on states.

**Fig. 8** Plot of membrane resistance vs. DBS concentration.

## TRANSPORT EXPERIMENTS

These were conducted by mounting the membrane between the two halves of a U-tube permeation cell and adding 0.1 M KCl to each half-cell. The feed half-cell was also  $50 \mu\text{M}$  in either  $\text{Ru}(\text{bpy})_3^{2+}$  or naphthalene disulfonate ( $\text{NDS}^{2-}$ ), the permeate ions. An increment of the analyte surfactant (for these experiments DBS) was added to both the feed and permeate half-cells and permeation was allowed to occur for 24 hr. After this time, the permeate half-cell was sampled and the UV absorbance was used to determine the moles of the permeate ion transported. The permeate solution was then returned to the permeate half-cell and a second increment of DBS was added. Permeation was again allowed to occur for 24 hr and the amount of permeate ion transport was again determined. This process was repeated for various DBS concentrations over the range from  $10^{-8}$  to  $10^{-4}$  M.

The data obtained for  $\text{Ru}(\text{bpy})_3^{2+}$  transport are shown in Fig. 7. At DBS concentrations below  $10^{-6}$  M, there is no detectable  $\text{Ru}(\text{bpy})_3^{2+}$  in the permeate solution. It is important to emphasize that each permeation data point in Fig. 7 corresponds to an additional 24 hr of permeation time. Hence by the time the DBS concentration was increased to  $9 \times 10^{-7}$  M, the total permeation time was 5 days. The inability to detect  $\text{Ru}(\text{bpy})_3^{2+}$  in the permeate solution after 5 days of permeation shows that over the DBS concentration range 0 to  $\sim 10^{-6}$  M, the pores in the  $\text{C}_{18}$  membrane are not wetted by water, making the rate of  $\text{Ru}(\text{bpy})_3^{2+}$  transport immeasurably small. These data again show that at DBS concentrations below  $10^{-6}$  M, the membrane is in the off state.

At DBS concentrations above  $10^{-6}$  M,  $\text{Ru}(\text{bpy})_3^{2+}$  transport is switched on, and flux increases with concentration of DBS for concentrations above this value. The impedance and transport data tell a consistent story about the effect of DBS on the  $\text{C}_{18}$ -derivatized membrane (Fig. 7). At low DBS concentrations ( $<10^{-6}$  M) where the membrane resistance is in the  $10^7 \Omega$  range,  $\text{Ru}(\text{bpy})_3^{2+}$  is not transported. The sudden drop in  $R_m$  at DBS concentrations above  $\sim 10^{-6}$  M is seen in the transport experiments as an abrupt switching on of  $\text{Ru}(\text{bpy})_3^{2+}$  transport across the membrane.

## X-RAY PHOTOELECTRON SPECTROSCOPY

X-ray photoelectron spectroscopy (XPS) was used to show that the prototypical analyte dodecylbenzene sulfonate (DBS) is present on the  $\text{C}_{18}$ -modified alumina surface after exposure of the membrane to DBS solution. However, the XPS cross section for S from the DBS proved too weak to obtain unambiguous evidence; furthermore, O, C, and  $\text{Na}^+$  (the counterion for the DBS) are ubiquitous, and therefore not useful as probes to prove that DBS is present on the surface. For this reason, we used a surface ion-exchange reaction to replace  $\text{Na}^+$  with  $\text{Cs}^+$  as the counterion for the surface-bound DBS. We then used XPS to look for the presence of  $\text{Cs}^+$  on the  $\text{C}_{18}$ -modified surface that had been treated with DBS, using an identical surface that was exposed to the  $\text{Cs}^+$  solution but not to DBS as the control.

Figure 9 shows XPS data for a  $\text{C}_{18}$ -modified membrane that had been exposed to an aqueous 2.0 mM solution of  $\text{Na}^+$ -DBS, rinsed, exposed to a 100 mM aqueous solution of  $\text{CsNO}_3$ , and then extensively rinsed again. The Cs 3d peaks at 724 and 738 eV are clearly evident.<sup>[36]</sup> This may be contrasted to the

**Fig. 9** X-ray photoelectron spectroscopy data for a  $\text{C}_{18}$ -modified alumina-membrane surface that was exposed to a DBS solution and then to a  $\text{Cs}^+$  solution and for an identical surface that was exposed to  $\text{Cs}^+$  but not to DBS.

control surface—a  $\text{C}_{18}$ -modified alumina membrane that was exposed to the  $\text{Cs}^+$  solution but not to DBS—where no Cs signal is seen (Fig. 9). These data show that exposure of the membrane to DBS results in partitioning of this analyte species onto the  $\text{C}_{18}$ -modified surface.

## MEASUREMENTS OF ION CURRENT

While the transport experiments show that the analyte DBS can switch on ion (e.g.,  $\text{Ru}(\text{bpy})_3^{2+}$  and  $\text{NDS}^{2-}$ ) transport across the membrane, we also wanted to obtain a direct measure of the ion current. To do this, a constant transmembrane potential of 1.5 V was applied and the resulting transmembrane ion current was measured. The current was monitored for 30 min and then the half-cell solutions were spiked with DBS to a total concentration of  $10^{-9}$  M. The current was again measured for 30 min and the half-cells were spiked again with DBS. This process was repeated for various DBS concentrations over the range from  $10^{-9}$  to  $10^{-3.5}$  M.

Figure 10 shows the measured ion current vs. time data; at the indicated times, the electrolyte solutions were spiked to the indicated concentrations with DBS. The ion-current data show the same general trend as both the impedance and transport data—at concentrations below  $\sim 10^{-6}$  M, the ion current is at a very low baseline value and at concentrations above  $\sim 10^{-6}$  M, the ion current abruptly switches on. In addition, the  $10^{-5.5}$  M datum shows that the transition from the low-current to the high-current state very abruptly occurs.

Both the impedance and ion-current data show that when the membrane is in the off state, some small baseline current does flow across the membrane. It is important to note that the resistance value for the off state obtained by the impedance and ion current measurements are essentially identical. As shown in Fig. 6, the impedance measurement yields a value of  $\sim 10^7 \Omega$ . The ion current in the off state is  $\sim 1.5 \times 10^{-7}$  A, which for a 1.5 V transmembrane potential yields a membrane resistance of  $\sim 10^7 \Omega$ . However, the issue left to resolve is—what is supporting this baseline ion current when the membrane is in the off state? At this point, we cannot say other than to suggest that this current results from some surface conduction process that occurs along the pore walls when the pores are devoid of water. In the absence of DBS, this surface conduction process may involve residual surface hydroxyl sites. The impedance data (Fig. 6) indicate that in the presence of DBS, the surfactant itself is involved in the conduction process.

**Fig. 10** Ion current through a  $C_{18}$ -modified alumina membrane vs. time. The contacting solution phases were spiked with the indicated concentrations of DBS at the indicated times. The electrolyte was 0.1 M KCl. A constant transmembrane potential of 1.5 V was applied.

## DETECTION OF DRUG MOLECULES

To explore the role of the hydrophobic effect in driving the analyte species into the  $C_{18}$ -derivatized alumina membrane, we investigated the effect of hydrophobic cationic drug molecules on the membrane resistance. The molecules and their molecular weights are amiodarone ( $645 \text{ g mol}^{-1}$ ), amitriptyline ( $278 \text{ g mol}^{-1}$ ), and bupivacaine ( $288 \text{ g mol}^{-1}$ ) (Fig. 11). Because its molecular weight is more than double those of the other drugs and because it contains very hydrophobic iodo substituents, amiodarone is by far the most hydrophobic of these molecules. If the hydrophobic effect is responsible for driving molecules into the  $C_{18}$ -derivatized membrane, then the transition from the off to the on state would occur at lowest concentrations for amiodarone, and this is what is experimentally

**Fig. 11** Plots of log membrane resistance vs. log[Drug] for the indicated drugs and a  $C_{18}$ -modified alumina membrane.

observed (Fig. 11). There is only a 3% difference in the molecular weights of amitriptyline and bupivacaine; however, bupivacaine presents two additional opportunities for hydrogen bonding with water—the lone pairs on the carbonyl group and the lone pair of the nonprotonated nitrogen. For this reason, bupivacaine is much more hydrophilic, and it would be expected to be the mostly poorly detected of the three drugs; Fig. 11 shows that this is also experimentally observed.

## CONCLUSION

We have described a highly sensitive method of electroanalysis based on Au nanotube membranes. In addition, we have also shown that synthetic micropore and nanotube membranes can mimic the function of ligand-gated ion channels; that is, they can be switched from an off state to an on state in response to the presence of a chemical stimulus. This concept of ion-channel mimetic sensing, as originally proposed by Umezawa's group,<sup>[32]</sup> has been of considerable interest in analytical chemistry.<sup>[37–40]</sup> There is also considerable appeal in using naturally occurring and genetically engineered protein channels as sensors (Ref.<sup>[41]</sup>, and references therein). Such research at the bio/nano interface is of great current interest in our group.

## INTRODUCTION

Carbon is one of the most prevalent elements in nature, and is critical to a number of important biological and geological structures. Of importance to chemistry, it can form  $sp$ -,  $sp^2$ -, and  $sp^3$ -hybridized bonds permitting the production of a wide range of geometries and hence, compounds. Graphite, albeit a key component of pencils, has one of the largest in-plane elastic moduli of any material, because of the extended sheets of  $sp^2$ -hybridized carbon arranged in a honeycomb mesh of hexagons. Diamond is the gem of choice, although it is simply a thermodynamically metastable form of carbon with the largest hardness of any material; it has the highest thermal conductivity and melting point of any solid. Fullerenes,<sup>[1–3]</sup> discovered by Kroto et al. in 1985, were produced by using laser vaporization techniques in the gas phase and were initially serendipitously detected using a molecular beam apparatus. They now have been reported to occur naturally in some forms of carbon soot<sup>[4]</sup> and have been produced by resistive heating of carbon rods in a vacuum,<sup>[5]</sup> in plasma discharges between carbon electrodes in He, and by oxidative combustion of gasoline/benzene/argon gas mixtures.<sup>[6]</sup> These molecules, essentially truncated icosahedrons, can be viewed as graphite sheets wrapped into closed carbon cages, consisting of 60 atoms shaped into a soccer ball with pentagons that can then accommodate curvature in the system.<sup>[2]</sup>

Another potentially more useful class of materials has arisen from the generation of fullerenes, that is essentially a nanometer-scale self-assembled structure of carbon. This time, however, we are not referring to cake and sandwich structures but rather to graphitic carbon, forming seamless cylindrical shells,<sup>[7]</sup> the carbon nanotubes. Of an intrinsic structural beauty,<sup>[8,9]</sup> these tubes consist of shells of  $sp^2$ -hybridized (trivalent) carbon atoms forming a hexagonal network that is itself arranged helically within the tubular motif (Fig. 1). Nanotubes are observed in two distinct

structural forms (which can be controlled by growth conditions): multiwall nanotubes (MWNTs), which are made by coaxially nesting successively larger nanotubes<sup>[10]</sup> separated roughly by the interplanar graphite spacing of  $\sim 0.34$  Å, and single-wall nanotubes (SWNTs), which consist of a single graphene sheet rolled into a seamless tube.<sup>[11–14]</sup>

## OVERVIEW

The diameter and helicity of a defect-free SWNT can be uniquely characterized by the roll-up vector,  $c_h = na + mb \equiv (n, m)$ , connecting crystallographically equivalent sites on a two-dimensional (2-D) graphene sheet, where  $a$  and  $b$  are the graphene lattice unit vectors, and  $n$  and  $m$  are integers. Each pair of integers  $(n, m)$  defines a different way of rolling up the graphene sheet to form a carbon nanotube. Electronic band structure calculations predict that the  $(n, m)$  indices will determine whether a SWNT will be a metal or a semiconductor.<sup>[11–15]</sup>

To first order,  $(n, 0)$  or zigzag SWNTs will exhibit two distinct types of behavior. The nanotubes will be metallic when  $n/3$  is an integer, but otherwise semiconducting. So as  $c_h$  rotates away from  $(n, 0)$ , chiral  $(n, m)$  SWNTs are possible with similar electronic properties to zigzag tubes. When  $(2n + m)/3$  is an integer, the tubes are metallic; otherwise, they are semiconducting. If  $c_h$  is rotated  $30^\circ$  relative to  $(n, 0)$ ,  $m = n$ . These  $(n, n)$  or armchair tubes are metallic. Zigzag and armchair tubes with wrapping angles of  $0^\circ$  or  $30^\circ$  are called achiral tubes. Single-walled nanotubes with intermediate wrapping angles are referred to as chiral tubes. Both  $(n, 0)$  and  $(n, n)$  nanotubes have especially high symmetry and exhibit a mirror symmetry plane normal to the tubule axis.<sup>[9]</sup> In other words, their structure determines their electronic behavior.

Because of their seamless cylindrical graphitic shells, carbon nanotubes<sup>[16]</sup> might be stiffer and stronger than

**Fig. 1** A single-wall carbon nanotube (SWNT) may be visualized as a sheet of graphite rolled up to form a seamless cylinder that is 1 atom in thickness. The roll-up vector or direction determines whether the tube is metallic or semi-conducting, and tubes are accordingly classified as either zigzag, armchair, or chiral. *Source:* Dr. Elton Graugnard, University of Illinois.

potentially any other known material with implications for the design of composite materials, as well as nanometer-scale devices.<sup>[17]</sup> In fact, mechanical measurements have shown that multiwalled nanotubes have a very high stiffness and, in fact, a high Young's modulus in the TPa range, at least as large if not higher than the in-plane modulus of graphite.<sup>[18]</sup> By measuring the amplitude of the intrinsic thermal vibrations of MWNTs, one group has shown that the Young's modulus of elasticity (the ratio of the force per unit area applied to the nanotube to the deformation thereby produced) is about  $1 \times 10^{12}$  Pa or  $1 \times 10^{12}$  N/m<sup>2</sup>, which is among the highest of any known material. Furthermore, bending and buckling experiments<sup>[19]</sup> indicate that MWNTs can be repeatedly bent through large angles without undergoing catastrophic failure, and that they can sustain forces that will deform a local area of the nanotube by as much as 16% without irreversible damage. Thus not only do these tubes possess extremely desirable mechanical properties of strength and flexibility,<sup>[20]</sup> but also, as has been noted, at least some are metallic in character.<sup>[21]</sup>

Indeed, the fundamental importance and uniqueness of SWNTs, relative to other types of fibrous materials such as Kevlar, arises from their molecularly "perfect" structure; there are no or relatively few imperfections within the length of the material that would cause weakness or instability. Furthermore, no surface passivation is required of these seamless cylinders. They are thought to have a host of wide-ranging, potential applications including catalyst supports in heterogeneous catalysis, field emitters, high-strength engineering fibers, sensors, actuators, tips for scanning probe microscopy, gas storage media, and as molecular wires for the next generation of electronics devices.<sup>[22–30]</sup>

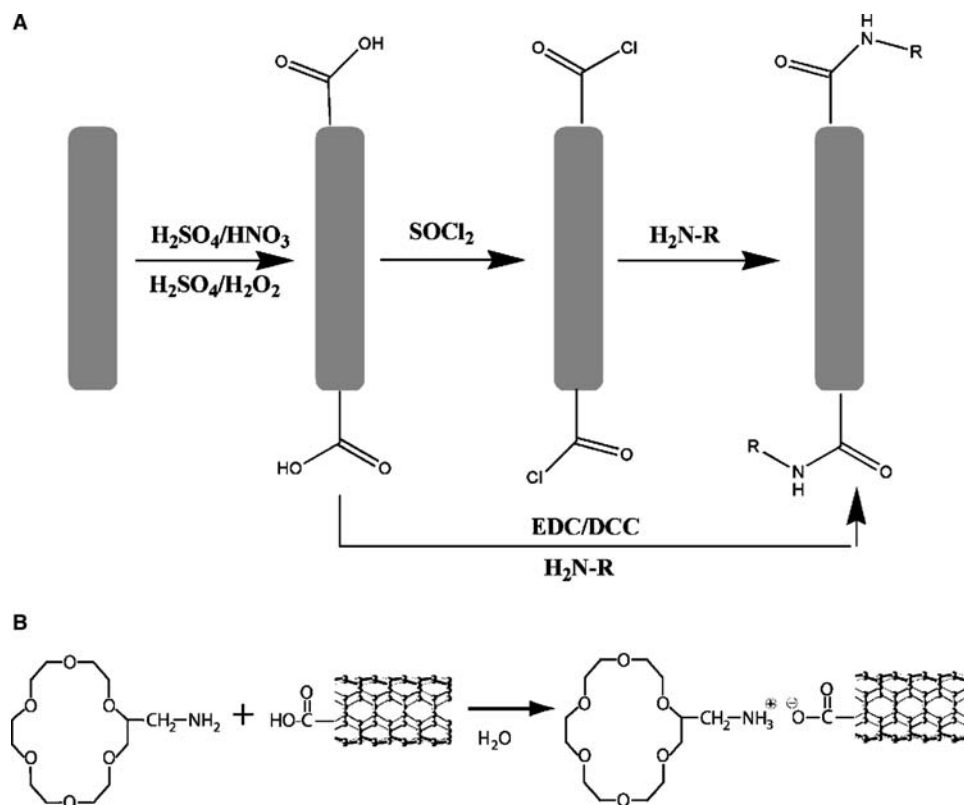

Understanding the chemistry of SWNTs thus becomes critical to rational manipulation of their properties. In fact, the ability to disperse and solubilize carbon nanotubes would open up new prospects in aligning and forming molecular devices and allow for

the development of a reproducible chemistry of these materials to take place. Nonetheless, this objective necessitates controlled chemical functionalization of tubes, a relatively unexplored area of research.

In this entry, we will explore existing strategies of nanotube functionalization, ending with recent efforts to treating nanotubes as chemical reagents (be it inorganic or organic) in their own right or in understanding chemical reactivity involving tubes from a structural perspective, which would expand the breadth and types of reactions SWNTs can undergo in solution phase. Indeed, from their inherent structure, one can view nanotubes as sterically bulky,  $\pi$ -conjugated ligands or conversely, as electron-deficient alkenes. Moreover, controllable chemical functionalization suggests that these unique electronic and mechanical properties can be tailored in a determinable manner. For instance, it has been predicted<sup>[31]</sup> that covalent chemical attachments can decrease the maximum buckling force by about 15% regardless of tubular helical structure or radius. Prevailing themes in nanotube functionalization have been involved with dissolution of tubes, enabling more precise manipulation and fractionation of these materials, as well as predictable functionalization of nanotube surfaces, at the ends (Fig. 2) as well as the sidewalls (Fig. 3). Indeed, controllable derivatization is essential for advanced functionalized material applications, as well as for the efficient generation of SWNT nanocomposites.

## SIDEWALL FUNCTIONALIZATION OF SWNTS

The sidewalls of purified SWNTs have been non-covalently functionalized<sup>[32]</sup> with a bifunctional molecule, namely 1-pyrenebutanoic acid, succinimidyl ester, which  $\pi$  stacks onto the graphene sidewalls; amide groups on proteins then react with the anchored ester to form amide bonds for protein immobilization. In an analogous fashion, ferritin, streptavidin, and

**Fig. 2** (A) Schematic of a common functionalization route, used to derivatize SWNTs at ends and defect sites. SWNTs are acid-treated to generate carboxylic acid groups at the ends and defect sites. These acidic functionalities are then linked to amines either by an initial reaction with  $\text{SOCl}_2$  and subsequently with an amine, or through carbodiimide-mediated amide bond formation with amines. An alternative route to functionalization is through zwitterionic interactions between carboxylic acid and amine groups. Panel (B) shows an example where oxidized SWNTs were linked to an amino-derivatized crown ether moiety.

biotin have been similarly localized on nanotube surfaces with high specificity and efficiency. In another approach to immobilizing proteins on the nanotube surface, SWNTs have been functionalized with bovine serum albumin (BSA) proteins via a diimide-activated amidation under ambient conditions. Based on data such as atomic force microscopy (AFM), thermal gravimetric analysis, Raman spectroscopy, and gel electrophoresis, the resultant nanotube–BSA conjugates are structurally interlinked, highly water-soluble, and bioactive, forming dark-colored aqueous solutions.<sup>[33]</sup>

It turns out that Raman spectroscopy, in particular, is notably effective at denoting the presence and extent of functionalization as well as for understanding vibrational and electronic properties of nanotubes and fullerenes. Whereas the radial breathing modes (RBM)<sup>[34,35]</sup> near  $200\text{ cm}^{-1}$  depend sensitively on tube diameter, the high-frequency tangential displacement G modes<sup>[36]</sup> near  $\sim 1590\text{ cm}^{-1}$  and the second-order G' bands<sup>[37]</sup> near  $2600\text{ cm}^{-1}$  are sensitive to the charge exchanged between nanotubes and guest atoms that have intercalated into the interstitial channels in the tube bundles. Indeed, the line shapes of the G band allow

for differentiation between semiconducting and metallic tubes. Semiconducting tubes are characterized by sharp Lorentzians while metallic tubes show Breit–Wigner–Fano line broadening. Importantly, in the context of this review, the shape and intensity of a weak disorder mode peak at  $1290\text{--}1320\text{ cm}^{-1}$  has been correlated with the extent of nanotube sidewall functionalization.<sup>[38]</sup>

Much effort has been involved with fluorinating tubes. High-temperature (over  $500^\circ\text{C}$  for several hours) reactions using pure fluorine gas destroyed nanotube structure, whereas at room temperature, transmission electron microscopy (TEM), X-ray diffraction, and Fourier transform-infrared (FT-IR) spectroscopy showed that fluorine–SWNT intercalation compounds could be formed.<sup>[39]</sup> Similarly, MWNTs<sup>[40]</sup> can be fluorinated at room temperature by using a gaseous mixture of  $\text{BrF}_3$  and  $\text{Br}_2$ . SWNTs fluorinated at temperatures ranging from  $150$  to  $325^\circ\text{C}$  survived the fluorination process. Two major diagnostic features<sup>[41]</sup> in the Raman spectra of the fluorinated tubes are 1) a decrease in intensity of the radial breathing mode near  $200\text{ cm}^{-1}$  and 2) an increase in the intensity of the disorder D band at  $\sim 1320\text{ cm}^{-1}$ , which are attributable to

Fig. 3 Schematic demonstrating various sidewall functionalization reactions of SWNTs.

the destruction of the intrinsic  $sp^2$ -hybridized structure as C–F bonds are created and sidewall carbons become  $sp^3$ -hybridized. These fluorinated tubes can also be solubilized in various alcohol solvents via ultrasonication. Scanning tunneling microscopy (STM) images (Fig. 4) of fluorinated tubes reveals a dramatic banded structure indicating broad continuous regions of fluorination terminating abruptly in bands orthogonal to the tube axis. These results suggest that the fluorine adds more favorably around the circumference of the tube, backed up by semiempirical AM1 calculations.<sup>[42]</sup> Further calculations show that the F atoms tend to bond next to each other.<sup>[43]</sup>

Sidewall-fluorinated nanotubes can be further modified by reacting them with alkyl magnesium

bromides in a Grignard synthesis or by reaction with alkyllithium precursors to yield sidewall-alkylated nanotubes, via a concerted, allylic displacement mechanism.<sup>[44]</sup> These routes render SWNTs soluble in various organic solvents such as chloroform, methylene chloride, and tetrahydrofuran. Covalent attachment to the sidewalls was confirmed by ultraviolet (UV)–visible (vis)–near IR spectroscopy, in which optical features originating from transitions between the van Hove singularities in the 1-D electron density of states of the tube disappear as the electronic structure becomes perturbed.

Oxidizing these alkylated nanotubes in air allows for recovery of pristine nanotubes. As for fluorinated tubes, it was found that hydrazine could be used to

**Fig. 4** Scanning tunneling microscopy (STM) images. (A) An image of a SWNT fluorinated at 250°C for 12 hr. The approximate carbon-to-fluorine ratio by microprobe analysis is 2:1. (B) An image of a SWNT fluorinated at 150°C for 5 hr. The corresponding carbon-to-fluorine ratio, in this case, by microprobe analysis is 3.7:1. The darker area on the left side of the image appears to be a less-fluorinated area. (C) A high-resolution image of a carbon nanotube fluorinated at 250°C for 1 hr, obtained by using a C<sub>60</sub> functionalized STM tip. *Source:* Professors Kevin Kelly and Naomi Halas, Rice University.

regenerate the unfluorinated starting material;<sup>[45]</sup> a procedure was also established to “tune” the fluorine content of the tubes by first fluorinating heterogeneously, solvating in alcohol, and then defluorinating with substoichiometric quantities of hydrazine to generate tubes with different fluorine contents.<sup>[46]</sup> Heating at 100°C in noble gases of fluorinated tubes can also lead to recovery of pristine tubes, as determined by a decrease in the IR intensity of C–F stretch bands at 1207 cm<sup>-1</sup>, reappearance of bands for the A<sub>2u</sub> mode at 867 cm<sup>-1</sup> and E<sub>1u</sub> mode at 1579 cm<sup>-1</sup>, as well as the reduced resistance of nanotubes samples.<sup>[47]</sup>

There are a number of other sidewall functionalization strategies. Single-walled nanotubes have been chemically functionalized in situ by a thermally induced reaction with diazonium compounds, generated by action of isoamyl nitrite on aniline derivatives<sup>[48]</sup> (Fig. 3). Tetra-*tert*-butylphthalocyanines have been immobilized on SWNTs through a  $\pi$ - $\pi$  interaction.<sup>[49]</sup> Direct addition to the unsaturated  $\pi$ -electron systems of SWNTs can occur through the following: 1) a [2 + 1] cycloaddition of nitrenes; 2) the addition of nucleophilic carbenes; and 3) the addition of radicals (through the photoinduced addition of perfluorinated alkyl radicals).<sup>[50]</sup> Tubes functionalized in these ways enable a large variety of functional groups to be introduced onto nanotube surfaces with implications for nanocomposite formation (Fig. 3).

Recently, our group was involved with developing<sup>[51]</sup> an ozonolysis protocol (Fig. 5) involving treatment of tubes at -78°C, followed by reaction with various reagents, in independent runs, to generate a higher proportion of carboxylic acid/ester, ketone/

aldehyde, and alcohol groups, respectively, on the nanotube surface. This “one-pot” oxidative methodology has three major consequences: first, the purification of as-prepared SWNTs to obtain a high-quality product; second, the chemical functionalization of nanotube sidewalls; and third, a systematic procedure to select for particular distributions of oxygenated functional groups in the resultant purified SWNTs.

Significantly, this work bears out the theoretical prediction that 1,3 dipolar cycloaddition to the SWNT sidewalls is experimentally achievable. In fact, these experiments indicate that a certain degree of control over the presence of particular functional groups on the surfaces of these SWNTs can be obtained by judicious choice of the appropriate cleaving agent, all of which can be achieved with minimal sample loss. More importantly, this protocol presents a nondestructive, low-temperature method of introducing oxygenated functionalities directly onto the sidewalls and not simply at the end caps of SWNTs. Thus molecular species, which can be currently tethered to the ends of the nanotubes, can now be chemically dispersed along the sidewalls as well, with implications for the design of nanotube-based optoelectronic devices and well-dispersed nanocomposites.

## INORGANIC INTERFACES TO SWNTS

While nanotubes have been treated with dichlorocarbene and Birch reduction conditions (i.e., lithium in 1, 2-diaminoethane),<sup>[52]</sup> recent efforts have been involved with generating more controllable derivatization of SWNTs, both spatially and structurally. One of the ideas pursued by our group was to derivatize SWNTs with relatively bulky inorganic complexes, which not only yields a novel metal-based molecular coordination complex but also offers the possibility of tailorable solubility in a variety of solvents, through mechanisms such as charge-mediated stabilization along the length of the tube and ligand exchange, without completely disrupting the tube’s electronic structure. In addition, these generated adducts can be used in a number of different catalytic processes, including homogeneous catalysis, upon which the expensive metal-support assembly can be readily recovered from solution. As another example of the utility of metal complexation, nanotubes, functionalized with a ruthenium complex, for example, have been utilized to create interconnects showing multiple T- and Y-junctions.<sup>[53]</sup>

Specifically, both oxidized nanotubes and raw, unfunctionalized SWNTs have been reacted with Vaska’s compound, *trans*-IrCl(CO)(PPh<sub>3</sub>)<sub>2</sub>, to form covalent nanotube–metal complexes.<sup>[54]</sup> Moreover, the complexes of oxidized SWNTs with Vaska’s

**Fig. 5** (A) Scanning electron micrograph (SEM) of ozonized tubes. Scale bar is 1  $\mu\text{m}$ . (B) Transmission electron micrograph (TEM) of as-prepared HiPco tubes. (C) TEM of ozone purified HiPco tubes. Scale bars in panels (B) and (C) are 130 and 140 nm, respectively. (D) Proposed reaction scheme for ozonation. The primary ozonide that is initially formed is cleaved to yield functional groups on the sidewalls. (E) Raman spectra show an increase of the D band upon ozonation, implying sidewall functionalization and considerable perturbation of the electronic structure.

compound are much more soluble in dimethylformamide (DMF) than raw tubes, a finding that should facilitate the chemical manipulation as well as photo-physical analyses of these materials. In fact, the solubility of oxidized tubes varied with the concentration of Vaska's complex added, suggesting that dissolution was chemically induced. The solubility of a typical adduct sample in DMF at room temperature was  $\sim 250$  mg/L, about 1 order-of-magnitude improvement over that found for unmodified tubes.<sup>[55]</sup> Analogously, the SWNT adduct with Wilkinson's complex<sup>[56]</sup> (Fig. 6) shows a relatively high degree of solubility in dimethylsulfoxide (DMSO), reproducibly  $> 150$  mg/L, and roughly 30% of that value in DMF and tetrahydrofuran (THF). Our results with oxidized nanotubes, but otherwise unmodified with any of these metal complexes, showed a solubility of  $\sim 25$  to 35 mg/L in DMF and 4–10 mg/L in THF. Conceptually, the novelty of this derivatization is that the nanotube can be considered as a primary ligand, as a functional moiety like any other, with respect to the central metal atom, Ir. Results were confirmed by  $^{31}\text{P}$  nuclear magnetic resonance (NMR) spectroscopy, FT-IR spectroscopy, electron ionization mass spectroscopy, as well as data

from transmission electron microscopy (TEM) and energy-dispersive X-ray analysis (EDX).

To summarize, Vaska's compound complexes to raw nanotubes by  $\eta^2$  coordination across the graphene double bonds. In effect, ligand binding is an associative process with the formation of a  $\pi$  complex and is expected to be similar to that observed<sup>[57,58]</sup> in (TCNE)IrBr(CO)(PPh<sub>3</sub>)<sub>2</sub> or in the fullerene adduct.<sup>[59]</sup> This type of reaction, in which the ligand acts as a weak base toward the metal complex, has been referred to as a "reductive addition" (with respect to the metal).<sup>[60]</sup> For the adduct formed with the oxidized SWNTs, coordination through the oxygen atoms seems a more likely possibility, in other words, through an oxidative addition to form a hexacoordinate structure. Oxidative additions to form 18e<sup>-</sup> "coordinatively saturated" compounds are well known for Vaska's compound and other related d<sup>8</sup> complexes and have been extensively studied.<sup>[61,62]</sup> Thus it is postulated that the oxidized nanotubes coordinate to the compound via oxidative addition to form an Ir(III) complex. These conclusions are in general agreement with theoretical predictions, based on a cluster model approach and a density functional theory study.<sup>[63]</sup>

**Fig. 6** Atomic force microscopy (AFM) height images of functionalized nanotube adducts. Scale bars are (A) 500 nm, (B) 100 nm, and (C) 200 nm. (A) A high density of tubes has been deposited from solution. Aggregates of tubes appear to be exfoliating into smaller bundles. (B) Image of a single bundle roughly 15 nm in diameter. (C) A 3-D view of exfoliating tubes. The bundles are relatively clean and free of nanoparticulate impurities. (D) Optimized geometry of  $M(PH_3)_2$  coordinated in an  $\eta^2$  fashion to SWNT sidewalls. (E) Proposed structure of SWNT–Wilkinson's adduct. Panel (D) is based on a schematic provided by Professor Antonio Sgamellotti (Universita di Perugia).

The reactivity of SWNTs toward metal complexes is substantially different from that of fullerenes, although both possess a non-planar  $sp^2$  configuration. Curvature effects and different degrees of local strain between the two structures likely account for the observed differences in behavior. Specifically, the presence of five-membered cyclopentadienyl-like rings in  $C_{60}$  substantially enhances the affinity of (6,6) bonds in coordinating metal complexes and allows for strong back donation in the resulting adducts, thereby promoting their stability. However, theoretical calculations on molecular fragments replicating SWNT surface curvature indicate that, unlike in the

case of fullerenes, five-membered rings are not present to stabilize  $\pi^*$  ligand orbitals and hence, back-bonding interactions are much weaker in these systems.<sup>[63]</sup> This would rationalize the preference for oxidative addition, when that should become a possibility.

Single-wall nanotubes have also been used as substrates for the deposition of metals by electron-beam evaporation, resulting, in the case of Au, Al, Pb, and Fe, in the formation of discrete particles on nanotubes due to a weak interaction between metals and nanotubes.<sup>[64]</sup> Acid groups on treated SWNTs can act as nucleation sites for a well-dispersed deposition of Pt

clusters.<sup>[65]</sup> With Ti, Ni, and Pd, quasi-continuous coatings are possible, resulting in the formation of nanotube-supported metal nanowire structures.<sup>[66]</sup> Zinc oxide nanowires have been grown on the surfaces of MWNTs without the presence of catalyst through a thermal treatment.<sup>[67]</sup>

Our group has been involved with the generation of nanotube heterostructures as well, involving the creation of nanotube–nanocrystal adducts. Indeed, a novel strategy of altering the electronic properties of nanotubes is to chemically functionalize them with a moiety or structure whose intrinsic properties are electronically configurable. One such structure is the family of semiconductor nanocrystals,<sup>[68]</sup> such as CdS and CdSe, alternately known as quantum dots, which exhibit strongly size-dependent optical and electrical properties. The high luminescence yield of these materials<sup>[69]</sup> as well as the potential of adjusting emission and absorption wavelengths by selecting for nanocrystal size make quantum dots attractive for constructing optoelectronic devices, for instance, with tailored properties. In fact, the electronic structure of semiconductor nanocrystallites exhibits distinctive quantum effects;<sup>[70]</sup> the bandgap of these materials increases with decreasing particle size.

We have reported<sup>[71]</sup> the synthesis and characterization of SWNTs covalently joined to CdSe and TiO<sub>2</sub> semiconductor nanocrystals by short chain organic molecule linkers (Fig. 7). In each case, purified, oxidized nanotubes were reacted with nanocrystals, derivatized with either amine or acid terminal groups in a reaction mediated by a carbodiimide reagent. By judiciously varying the nature of the organic capping groups on the nanocrystal surface and the organic bifunctional linkers, we can modulate interactions between the nanotubes and the nanocrystals, with implications for self-assembly. Such composites are expected to be useful for applications as diverse as molecular electronics, photocatalysis, solar energy conversion, and as probes for scanning force microscopy.

TEM examination (Fig. 8) showed nanocrystals linked to the oxidized SWNTs, forming discrete nanocomposites. The nanocrystals tend to be concentrated at the open caps and the “ends,” where there is the largest concentration of carboxylic groups<sup>[72,73]</sup> and thus, the highest probability of amide bond formation.<sup>[74]</sup> A commonly observed structure was a cluster of nanoparticles, especially in the case of CdSe, localized at the outer edges of the tubes (Fig. 8D). In other cases, especially with individual tubes, numbers of nanocrystals tended to disperse along the sidewalls, presumably attaching to defect sites on the oxidized nanotube surface (Fig. 8C). The TiO<sub>2</sub> system showed substantially greater coverage of the tubes with the nanoparticles (Fig. 8D). Carboxyl groups adsorb strongly onto bare titanium dioxide surfaces.<sup>[75]</sup> Hence, larger numbers of

these particles can interact with nanotubes and in effect, amide bond formation may not be required for an underivatized, uncapped TiO<sub>2</sub>–SWNT adduct to be directly produced. Indeed, we postulate that this is the reason for the enhanced coverage with TiO<sub>2</sub> particles. Energy-dispersive X-ray analysis on both nanocomposite systems was consistent with the presence of appropriately functionalized nanocrystals attached to nanotubes as proposed. These patterns of nanocrystal clustering on the nanotubes were not observed in control experiments, without the use of carbodiimide linking agents, where the tubes themselves were found to remain totally separate from the nanocrystals.

## SOLUBILIZATION OF NANOTUBES

Whereas fluorination tends to derivatize tubes and disrupt band structure of SWNTs, most experiments involving solubilization of nanotubes aim for the retention of important photophysical properties. Moreover, solubilization facilitates the placement of a huge array of functional groups onto SWNT surfaces for composite formation.

By visual inspection and quantification using UV–visible absorption spectroscopy, small-diameter SWNTs (ca. 0.7 nm), grown by a gas-phase catalytic process,<sup>[76]</sup> were found to be somewhat soluble in a number of organic solvents such as 1,2-dichlorobenzene, chloroform, 1-methylnaphthalene, dimethylformamide (DMF), and tetrahydrofuran (THF).<sup>[55]</sup> Laser-oven produced SWNTs (with diameters of about 1.2 nm) can be dissolved to some extent in DMF, *N*-methylpyrrolidinone, and hexamethylphosphoramide.<sup>[77]</sup> Many strategies aimed at improving the solubility behavior of nanotubes involve the oxidation and purification of nanotubes; reports<sup>[78,79]</sup> have placed the total percentage of acidic sites, generated by such processing, in full-length SWNTs at a range of 1–3% and defect sites in the 5% range. Examples of defects in nanotubes include pentagon/heptagon Stone–Wales-type defects, associated with a rotation of a bond in the SWNT atom network, vacancies in the nanotube lattice, the presence of adatoms or carbon dimers on the sidewalls, the occurrence of sp<sup>3</sup>-hybridized carbons, and pentagon-terminated caps.<sup>[80–82]</sup>

Indeed, metallic and semiconducting SWNTs were initially derivatized in organic solutions, such as chloroform, dichloromethane, aromatic solvents (including benzene, toluene, and chlorobenzene), and CS<sub>2</sub>, by converting acid-terminated, purified nanotubes with thionylchloride to generate acylchloride groups that could then be reacted with amines such as octadecylamine.<sup>[83]</sup> This work was later extended to amide formation from alkyl–aryl amines such as 4-dodecylaniline.<sup>[84]</sup> NMR spectra of the soluble SWNTs exhibited peaks because of the aliphatic and aromatic

**Fig. 7** Schematic of the addition of derivatized CdSe nanocrystals to oxidized SWNTs. Trioctylphosphine oxide (TOPO)-capped nanocrystals were prepared by established methods using organometallic precursors. (A) TOPO capping was substituted for a thiol ligand to form a carboxylic acid terminated CdSe nanocrystal. Substituted thiocarboxylic acids used included *p*-mercaptobenzoic acid, thioglycolic acid, and 3-mercaptopropionic acid. (B) The nanocrystals prepared in panel (A) were linked to oxidized SWNTs by an ethylenediamine linker in the presence of N-ethyl-N'-(3-dimethylaminopropyl)carbodiimide (EDC).

moieties, respectively. Raman spectroscopy indicated that nanotube structure was likely preserved. Solution-phase mid-IR analysis<sup>[85]</sup> shows that, for the reaction with octadecylamine, the weight percentage of the octadecylamino functionality is about 50%, at defect sites as well as the ends of SWNTs. Full-length dissolution<sup>[86]</sup> of purified SWNTs (containing

carboxylic acid groups) was also achieved through an acid–base reaction by forming an octadecylammonium, SWNT-carboxylate zwitterion. AFM showed that the majority of the SWNT ropes were exfoliated into small ropes (2–5 nm in diameter) and individual nanotubes with lengths of several microns during the dissolution process.

**Fig. 8** TEMs of (A) a purified single-walled carbon nanotube bundle. Scale bar denotes 30 nm. (B) Oxidized SWNT bundle circumscribed by capped  $\text{TiO}_2$  particles. Scale bar is 45 nm. (C) Oxidized tubes linked to CdSe nanocrystals capped with 4-mercaptopropionic acid. The crystallites are concentrated at the functionalized open ends, with some coverage on the sidewalls, likely on defect sites. Scale bar is 150 nm. (D) Oxidized nanotube linked to CdSe nanoparticles capped with 3-mercaptopropionic acid. Image at high magnification shows prolate nanocrystals scattered along the length of the tube. Scale bar represents 20 nm.

Single-wall nanotubes, functionalized with esters<sup>[87]</sup> at defect sites [i.e.,  $\text{SWNT-COO}(\text{CH}_2)_{17}\text{CH}_3$ ], have been prepared, as determined by Raman and IR bands, leading to improved solubilization in solvents such as THF and  $\text{CHCl}_3$ . Strong attachment of deuterium<sup>[88]</sup> to SWNTs in solution has been observed when deuterated ethanol is used as a coreactant in esterification reactions; results were obtained from  $^2\text{H}$  NMR and FT-IR measurements. Derivatization based on 1,3-dipolar cycloaddition of azomethine ylides, generated by the condensation of an  $\alpha$ -amino acid and an aldehyde, has been used to solubilize tubes in most organic solvents.<sup>[89]</sup> Evidence of functionalization was further supported by observation of fluorescence in the adducts, as was also noted in SWNT–aniline systems.<sup>[90]</sup> SWNTs have also been functionalized with derivatized pyrene, via a similar reaction, namely the esterification of nanotube-bound carboxylic acids, to create adducts soluble in chloroform, THF, and toluene.<sup>[91]</sup> Fluorescence and fluorescence excitation results suggest that the tethered pyrenes form “intramolecular” (intrananotube) excimers. The pyrene monomer and excimer excitations are quenched by the SWNTs in a mechanism whereby the nanotubes serve as

acceptors for excited-state energy transfers from the tethered pyrene moieties.

It has been proposed, for instance, that large organic groups assist in solubility by exfoliation of the bundles into individual tubes through the formation of intervening moieties that can overcome the intrinsic van der Waals forces<sup>[92]</sup> between these tubes. It is not surprising, given this improved solubility, that recent work has been performed on separating soluble SWNTs and zwitterion-functionalized shortened SWNTs by length, diameter, and chirality from THF using high-performance liquid chromatography (HPLC) and gas chromatography techniques.<sup>[93,94]</sup> In addition, this body of solubilization work in stable, organic solvents has allowed Raman and near-IR spectroscopies to be used for the detection and identification of different species (i.e., diameters and metallicity) of SWNTs based on their Raman frequencies and vis–near IR electronic transitions.<sup>[95]</sup>

In water, a stable dispersion of full-length, well-separated individual tubes has been formed upon stabilization in gum arabic,<sup>[96]</sup> a water-soluble polysaccharide; adsorption is presumed to disrupt the intertube interactions in the crystalline ropes. Aqueous solubilization

(in the range of 0.1 to 0.3 mg/mL) was also achieved by functionalizing SWNTs with glucosamine. In this case, grafting of the glucosamine to the tubes was achieved by reacting the amine with acyl chloride groups created on the SWNT surface.<sup>[97]</sup> Treatment of nanotubes with a 9:1 mixture of sulfuric acid and hydrogen peroxide for 30 min followed by sonication for varying lengths of time allows for the creation of carboxylate groups on defect sites and tube ends, which render the SWNTs water-soluble in different pH buffers. Electronic structure is maintained, as evidenced by absorption spectra, where the van Hove singularities are maintained.<sup>[28]</sup> There has also been a claim that SWNTs, sonicated and dispersed in 1% sodium dodecylsulfate buffer and glycerol, can be distributed to a certain extent by diameter and length simply by the application of an electric field, again implying that solubilization has consequences for rational manipulation of nanotubes.<sup>[98]</sup> Molecular dynamics simulations indicate that in water, polar functional groups attached to SWNTs are likely to be more energetically stable in extended configurations, whereas non-polar functional groups will prefer to remain folded.<sup>[99]</sup>

To generalize and broaden the potential of functionalization, in our group, we have also solubilized oxidized SWNTs through the attachment of organic moieties in a large number of solvents of varying polarity.<sup>[100]</sup> In this case, we grafted a functionalized organic crown ether, namely 2-aminomethyl-18-crown-6, onto our SWNTs. The resultant, synthesized adduct yielded concentrations of dissolved nanotubes on the order of  $\sim 1$  g/L in water as well as in methanol, according to optical measurements. These values are dramatic improvements over conventional dissolution behavior of unfunctionalized nanotubes. The nanotube-crown ether adduct can be readily redissolved in a number of different organic solvents, such as ethanol, 2-propanol, acetone, *o*-dichlorobenzene (ODCB), dimethylformamide (DMF), tetrahydrofuran (THF), dimethylsulfoxide (DMSO), ethyl acetate, and benzene, at substantially high concentrations. One implication of these results lies in further exploitation of the solution chemistry of these tubes for photophysical analyses in a number of previously untested solvents as well as for the generation of novel nanoscale architectures.

**Fig. 9** Molecular model of a (6,6) SWNT complex with poly(aryleneethynylene)s (PPE), showing interaction of the polymer backbone with the SWNT sidewall through  $\pi$  stacking. *Source:* Dr. Jian Chen, Zyvex Corporation.

## SWNT-POLYMER COMPOSITES

Single-wall nanotubes can also be solubilized in water by non-covalently associating them with linear polymers such as polyvinyl pyrrolidone and polystyrene sulfonate. In this case, the polymers rigidly and uniformly associate with the sides of nanotube, disrupting the hydrophobic interface with water and the intertube interactions within the tubular aggregates (Fig. 9). Nanotubes can then be “unwrapped” by changing the solvent system.<sup>[101]</sup> In another study, wrapping of polymer ropes (modified poly(*p*-phenylenevinylene) around the tube lattice occurs in a well-ordered periodic fashion, arising from a van der Waals interaction between the phenyl rings of the polymer and the hexagonal lattice of the nanotube; solutions of the polymer in toluene are thought to be able to suspend nanotubes “indefinitely.”<sup>[102]</sup> Based on Raman and absorption data, it is thought that the polymer interacts preferentially with nanotubes of certain diameters or a range of diameters. The attachment<sup>[103]</sup> of lipophilic and hydrophilic dendra, which are terminated with long alkyl chains and oligomeric poly(ethylene glycol) moieties, respectively, via amidation and esterification reactions, can render SWNTs and MWNTs soluble in common organic solvents, such as hexane and chloroform as well as water, to form colored homogeneous solutions. These functionalized tubes can be defunctionalized in homogeneous solutions under base- and acid-catalyzed hydrolysis reaction conditions.<sup>[104]</sup> These functional polymer-nanotube composites may have unique, favorable properties; for instance, SWNT-poly(metaphenylenevinylene) composites have nearly eightfold increase in electrical conductivity compared with just the polymer and have favorable photo- and electroluminescence properties as well.<sup>[105]</sup>

## ADDITIONAL CHEMICAL FUNCTIONALIZATION STRATEGIES

Single-wall nanotubes can also be modified by a number of other methodologies. Sonication of tubes in a monochlorobenzene solution of poly(methyl

methacrylate) (PMMA) created SWNTs with many defects in the sidewalls when burned in oxygen.<sup>[106]</sup> Using radio frequency glow-discharge plasma activation,<sup>[107]</sup> amino-dextran chains have been immobilized onto acetaldehyde-treated aligned SWNTs through a Schiff-base formation and reductive stabilization with sodium cyanoborohydride, while periodate-oxidized dextran-fluorescein isothiocyanate (FITC) chains have been chemically grafted onto ethylenediamine-derivatized SWNTs via the same reaction. SWNTs can also be derivatized by bombardment<sup>[108,109]</sup> with  $\text{CH}_3$  and  $\text{CF}_3$  radicals impacting with incident energies of 10, 45, and 80 eV, as was confirmed by X-ray photoelectron spectroscopy and scanning electron microscopy.

Chemical functionalization of SWNTs attached to conventional atomic force microscopy (AFM) probes was also demonstrated as a methodology yielding high-resolution, chemically sensitive images on samples containing multiple chemical domains.<sup>[10,74,110]</sup> Moreover, when these probes were derivatized with amine, carboxy, and biotin groups at their ends with domains of similarly defined functional groups localized on the surface, they could be used to measure specific and definable interactions in a variety of solvent media (Fig. 10).

## MANIPULATION OF TUBES

Although it appears that oxidized SWNTs have a tendency to stack and form larger aggregates,<sup>[111]</sup>

interesting nanoscale architectures can be created by judicious manipulation of the chemistry of these tubes. For instance, lightly etched SWNTs have been chemically reacted<sup>[112]</sup> to form rings, with an average diameter of 540 nm (Fig. 11). The same research group created a hollow spherical ring made of nested SWNTs.<sup>[113]</sup> To accomplish this geometry, SWNTs were first adsorbed onto amine-terminated silica gels in solution, a step that determined the nature of the nested network. Subsequent drying and reabsorption cycles were used to grow the nest layer-by-layer through nanotube–nanotube interactions. Ultimately, the silica gels were etched away to give hollow cages.

Carboxy-terminated SWNTs have been assembled onto amino-terminated gold surfaces via electrostatic interactions, with the aid of dicyclohexylcarbodiimide condensation agents.<sup>[114]</sup> Similar chemical strategies were employed to adsorb SWNTs onto silver surfaces.<sup>[115]</sup> Work has also been completed on depositing tubes on chemically functionalized nanolithographic patterns. Creation of these assemblies is critical because these strategies allow for precise positioning of nanotubes in specific locations and orientations; consequently, there is now the potential of creating simple nanostructures with SWNTs and of connecting these to other structures. This is crucial to the fabrication and development of simple electrical circuits with tubes and hence, provides for a means of measuring electron transport characteristics in these systems.<sup>[116]</sup> Recently, it has also been found<sup>[117]</sup> that ozonized SWNTs can be assembled onto amine-terminated self-assembled

monolayers (SAMs) as well as physically adsorbed via layer-by-layer deposition with bridging of metal cations, i.e.,  $\text{Fe}^{+3}$  on carboxylate-terminated SAMs or  $\text{Cu}^{+2}$  on thiol-terminated SAMs. A further advance has come from a report of room-temperature assembly of directional SWNT strings across polymer microchannels.<sup>[118]</sup>

## CONCLUSION

Rational nanotube functionalization provides for the potential of the manipulation of nanoscale properties in a predictive manner. In many cases, it may also render tubes soluble and stable in aqueous and organic

solution, thereby enabling further exploitation of their wet chemistry and investigation of their photophysical properties. In addition, derivatization allows for a number of site-selective nanochemistry applications such as the possibility of self-assembly of nanotubes with tailorable electronic properties, important for advances in molecular electronics. Other derivatized nanotube adducts also show the potential for novel charge transfer characteristics, the development and understanding of which have implications for photocatalysis as well as for scanning probe microscopy with functionalized tips. Finally, chemical manipulation of SWNTs is critical for hierarchical build-up of these nanomaterials into novel architectures, such

as nanocomposites and nanocircuits, with unique structural properties.

## INTRODUCTION

Fabrication of one-dimensional (1-D) fundamental nanoscale structures from molecular systems through bottom-up approach should be one of the most important steps to realize nanoscale electronic devices.<sup>[1–3]</sup> Because 1-D systems are the structures with the lowest dimension that permit efficient electron transport, the nanowires are expected to be critical to functionalize and integrate the nanoscale electronic devices. Nanowires are important units in constructing electronic circuits, particularly in electrical conducting; thus a variety of nanowires have been the focus of extensive studies aimed toward nanoscale electronic systems.<sup>[1–4]</sup> At present, a wide range of compounds from inorganic metals, semiconductors, and carbon nanotubes have been employed as nanowires (Fig. 1).<sup>a</sup> The diameter, length, and electronic structure of these nanowires varied significantly. The electronic properties of nanowires range from insulating, semiconducting, metallic, to superconducting. Electrical conduction within nanowires is dominated by the carriers at around Fermi level of the band structure, just as in bulk metals and semiconductors (Fig. 1).<sup>[5]</sup> Although the electronic density of states along the short axis of nanowire has a discrete character because of the restricted lattice translation, that along the wire direction is approximately represented as the band structure.<sup>[6]</sup> The doped polymers, single-walled carbon nanotubes (SWCNTs), semiconductor, and metal nanowires may have Fermi surfaces. On the other hand, DNAs are the insulator with large band gap. Semiconductor nanowires are more important than metal nanowires from the viewpoint of device application.<sup>[7]</sup>

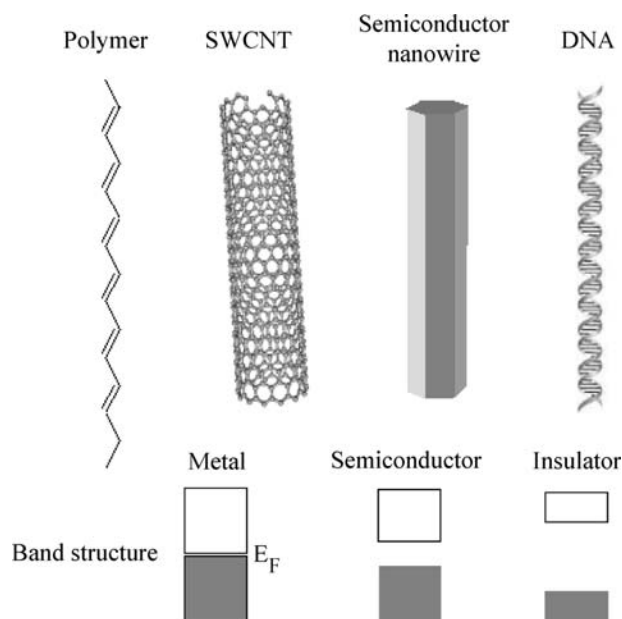

Although only a few examples are reported for the preparation of nanowires of molecular assemblies,<sup>[8–10]</sup> we consider that these molecular nanowires should have

an important role in the complete bottom-up manufacture of the molecular electronics. Such nanowires can be assembled from  $\pi$ -molecules through molecule-by-molecule  $\pi$ -stacking. The researches in the field of “molecular conductors” will offer a guiding principle in constructing electrical conducting molecular nanowires.<sup>[11–15]</sup> The anisotropic charge-transfer (CT) interaction in molecular conductors is advantageous to form the 1-D  $\pi - \pi$  stacking nanowire structure. In addition, “supramolecular chemistry” will offer powerful tools to fabricate molecular nanowires through the self-assembly process.<sup>[16–18]</sup> Appropriate design of molecule to orient and integrate the molecular-assembly nanowires on the substrate surface should be effective to realize molecular-assembly electronic devices. Furthermore, the techniques of “Langmuir–Blodgett (LB) Films” are very useful methods to fabricate nanoscale molecular-assembly structures on a variety of substrate surfaces.<sup>[19–21]</sup> To realize molecular-assembly nanoscale devices through bottom-up chemical approach, three types of scientific concepts—molecular conductor, supramolecular chemistry, and surface science—should be linked together.

## Molecular Conductors

A large number of molecular conductors, ranging from semiconductors to metals and superconductors, was prepared.<sup>[11–15]</sup> In general, a stable organic molecule has a closed-shell electronic structure without conduction carriers, thereby making molecular solids highly insulating. Conduction carriers can be generated via the intermolecular CT interaction between the highest occupied molecular orbital (HOMO) of the electron donor (D) and the lowest occupied molecular orbital (LUMO) of the electron acceptor (A) molecules. Figure 2A shows the molecular structures of typical D and A molecules utilized in the field of molecular conductors. Among them, tetrathiafulvalene (TTF) and 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) are the well-known D and A molecules, respectively, which gave the first molecular metal of (TTF<sup>+0.59</sup>)(TCNQ<sup>-0.59</sup>). The degree of CT ( $\delta$ ) in the

<sup>a</sup>Recent progress in nanowires. See special issue of nanowires in Ref.<sup>[4]</sup>.

**Fig. 1** Nanowires constructed from doped-polymer, SWCNT, semiconductor, and DNA. The electronic band structures of these are illustrated below.

binary  $(D^{+\delta})(A^{-\delta})_x$  CT complex depends on the ionization potential of D and electron affinity of A molecules. The planar  $\pi$ -conjugated D and A molecules have a tendency to form the 1-D columnar structure through the  $\pi - \pi$  stacking interaction, which also formed 1-D  $\pi$ -band structure (Fig. 2B). Because the  $\pi$ -orbitals exist orthogonal to the molecular plane, the direction of  $\pi - \pi$  interaction is highly anisotropic. Therefore, the 1-D  $\pi - \pi$  interaction in the molecular conductors is suitable for obtaining molecular nanowires.

### Langmuir–Blodgett Technique

Langmuir–Blodgett (LB) method is one of the conventional fabrication techniques of nanoscale thin-film structures utilizing the air–water interface.<sup>[19–21]</sup> Figure 3 illustrates typical procedures to obtain Langmuir monolayer at the air–water interface and the film-forming processes of LB multilayers on substrate. Amphiphilic molecules having hydrophilic and hydrophobic moieties are dissolved into conventional organic solvents, which were spread at the air–water interface. The monolayer with a thickness of molecular scale can form a variety of molecular-assembly structures such as gas-, liquid-, and solid-like short- and long-range orders through the control of surface pressure ( $F$ ,  $\text{mN m}^{-1}$ ). Increase in the  $F$  enhances the magnitude of intermolecular interactions between the molecules. The chemical designs of hydrophilicity and hydrophobicity of the component molecules are

important to obtain stable monolayer at the air–water interface.

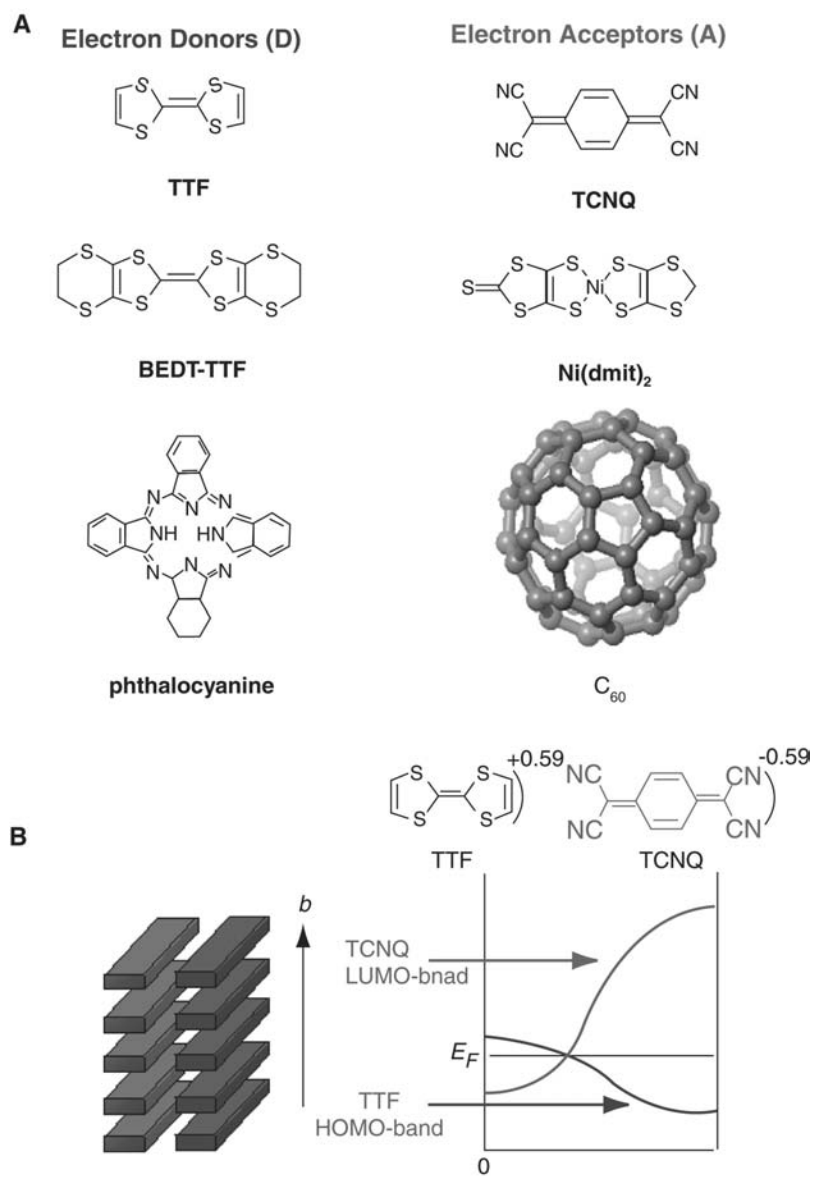

Stable monolayers at the air–water interface can be transferred onto hydrophilic or hydrophobic substrates via dipping of the substrate. Glass, quartz,  $\text{CaF}_2$ , Si, and mica are utilized as typical hydrophilic substrates. The surface wetting of these substrates largely influences the surface morphologies of the transferred LB films. Another conventional deposition technique is the horizontal-lifting method, which directly transfers the monolayer at the air–water interface onto the hydrophobic substrate.

Electrically active thin films have been fabricated by the LB techniques.<sup>[22–24]</sup> For example, metallic and semiconducting LB films have been obtained from amphiphilic molecular conductors based on TTF and TCNQ derivatives.<sup>[22–24]</sup> Although the LB films possess a periodicity along the film-forming direction, random distribution of two-dimensional crystalline domains on the substrate surface dispels bulk periodicity within the substrate surface. To realize nanoscale electronic devices through bottom–up self-assembly approach, the orientation and size control of these electrical active domains within the substrate surface are two of the important problems that need to be overcome.

### Supramolecular Chemistry

The term of supramolecular chemistry is a last key science to realize the bottom–up self-assembly approach.<sup>[16–18]</sup> Supramolecule is defined as an entity composed of several or large numbers of molecules, which are connected to each other through the non-covalent weak intermolecular interactions such as van der Waals (dipole–dipole, dipole-induced dipole and dispersion interactions), charge–transfer, hydrogen-bonding interactions, etc. The design of these intermolecular interactions is essential to obtain self-assembly molecular nanowires. Self-assembled supramolecules bearing the desired structure can be achieved by using programmed molecules that are appropriately designed. From the flexibility in supramolecular designs together with the rich physics in molecular conductors, electrical active molecular nanowires are considered as very promising candidates for constructing future nanoscale devices.

A large number of complex supramolecular assemblies have already been constructed.<sup>[16–18]</sup> A simple complex between cation and crown ether is one of the typical model systems of supramolecules<sup>[25,26]</sup> (Fig. 4). Crown ethers such as 12-crown-4, 15-crown-5, and 18-crown-6 have hydrophilic cavity to bind cation through metal–oxygen interatomic interactions. According to the size of hydrophilic cavity, cations can be selectively included into the cavity.

**Fig. 2** Molecular structures of typical (A) electron donor (D) and acceptor (A) molecules employed in molecular conductors. (B) The 1-D columnar structure through the  $\pi - \pi$  stacking interaction in crystals (left) and metallic 1-D  $\pi$ -band structure of (TTF)(TCNQ) (right).

**Fig. 3** Langmuir-Blodgett technique to fabricate nanoscale thin-film structures. (A) Langmuir monolayer at the air-water interface. Amphiphilic molecule has hydrophilic (red head) and hydrophobic tail. Surface pressure ( $F$ ,  $\text{mN m}^{-1}$ ) can be controlled by moving barriers. (B) Transfer process of Langmuir monolayer onto substrate surface.

**Fig. 4** Supramolecular complex between the cation and crown ether. Cations are complexed into the crown ether cavity through cation–oxygen interactions.

For example, 15-crown-5 and 18-crown-6 molecules show high  $\text{Na}^+$  and  $\text{K}^+$  affinity, respectively. We already introduced two design concepts of molecular conductors and LB technique to fabricate molecular-assembly nanowires. For an effective design of molecular nanowires, we further introduced the supramolecular approach to obtain nanowire orientation on the substrate surface.

## RESULTS AND DISCUSSION

### Design of Molecules for Fabricating Molecular-Assembly Nanowires

Amphiphilic bis(tetrathiafulvalene) [bis(TTF)] macrocycle **1** was designed from the concepts of molecular conductors, Langmuir–Blodgett films, and supramolecular chemistry.<sup>[27,28]</sup> The molecule has two redox-active TTF units that are linked via a [24]crown-8 macrocycle and two long hydrophobic decylthio-chains (Fig. 5). Two TTF units within the molecule **1** can act as electron donor for realizing intermolecular CT interaction with electron acceptors,

which forms electrically conducting 1-D  $\pi$ - $\pi$  stacks. The second structural point is the introduction of two hydrophobic chains ( $-\text{SC}_{10}\text{H}_{21}$ ), which were introduced into one side of the TTF unit. By introducing these hydrophobic chains, the molecule has amphiphilic character to apply the LB technique. The last designing point is carried out via the supramolecular approach—the introduction of ion-recognizing crown ether moiety into the molecule. The ion-recognizing property can be employed to fabricate oriented molecular-assembly nanowires on the substrate surface.

Compound **1** was synthesized by the cyanoethyl protected TTF building block.<sup>[29,30]</sup> Stepwise deprotection/alkylation procedure was performed by  $\text{CsOH} \cdot \text{H}_2\text{O}/2,6\text{-bis}(2\text{-iodoethoxy})\text{ethane}$ . Because a TTF molecule possesses a two-step redox process ( $\text{TTF} \rightarrow \text{TTF}^+$  and  $\text{TTF}^+ \rightarrow \text{TTF}^{2+}$ ),<sup>[11–15]</sup> donor **1** possesses a four-step redox process. The cyclic voltammetry (CV) diagram of donor **1** in 1,2-dichloroethane ( $\text{C}_2\text{H}_4\text{Cl}_2$ ) vs. SCE showed the two-step, two-electron oxidation waves at 0.56 and 0.90 V, respectively.<sup>[27,28]</sup> The two TTF units in donor **1**, linked via [24]crown-8 unit, independently exhibited redox reaction.

The CT complex between one molecule of donor **1** and two molecules of 2,3,5,6-tetrafluoro-7,7,8-tetracyano-*p*-quinodimethane ( $\text{F}_4\text{-TCNQ}$ ),  $(\text{1})(\text{F}_4\text{-TCNQ})_2$  was prepared to fabricate oriented molecular-assembly nanowires. The electronic ground state of the CT complexes can be discussed in terms of the differences between the redox potentials,  $\Delta E = E_{1/2}(\text{donor}) - E_{1/2}(\text{F}_4\text{-TCNQ})$ , for electron donor **1** and  $\text{F}_4\text{-TCNQ}$ .<sup>[31,32]</sup> Partial CT states,  $(\text{D}^{+\delta})(\text{A}^{-\delta})$  with  $0.5 < \delta < 1$ , are necessary for the formation of metallic CT complexes having a segregated-stack structure, which is achieved when  $\Delta E$  has a value between  $-0.02$  and  $0.34$  V.<sup>[31,32]</sup> Fully ionic  $(\text{D}^+)(\text{A}^-)$  and neutral  $(\text{D}^0)(\text{A}^0)$  CT complexes are typically observed when  $\Delta E < -0.02$  V

**Fig. 5** Molecular design of amphiphilic bis(tetrathiafulvalene) [bis(TTF)] macrocycle **1** from the viewpoints of molecular conductor (TTF), supramolecular chemistry (crown ether), and Langmuir–Blodgett films (hydrocarbons).

and  $\Delta E > 0.34$  V, respectively. In the case of donor **1** and F<sub>4</sub>-TCNQ ( $E_{1/2}(\mathbf{1}) = 0.73$  V), the  $\Delta E$  values of CT complex of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  was  $-0.17$  V. Because these values were far from the conditions of partial CT complexes, fully ionic ground state  $(\mathbf{1}^{2+})(\text{F}_4\text{-TCNQ}^-)_2$  was expected for the molecular nanowires.

### Monolayer of Charge–Transfer Complexes at the Air–Water Interface

The CT complex  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  was prepared in situ by mixing donor **1** and two equivalent of F<sub>4</sub>-TCNQ in CHCl<sub>3</sub>/CH<sub>3</sub>CN (9:1, v/v). Concentration of the spreading solution was fixed at 1 mM with respect to  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$ . Surface pressure ( $F$ )–area per molecule ( $A$ ) isotherms were recorded at 291.5 K with a barrier speed of 50 cm<sup>2</sup> min<sup>-1</sup>. The LB monolayers were transferred onto freshly cleaved mica surfaces by a single up-stroke drawing. Because the macrocyclic moiety may recognize ions introduced into the subphase upon the formation and deposition of the monolayers, the K<sup>+</sup> ions were introduced into the subphase for realizing ion recognition at first.

The  $F$ – $A$  isotherms of the floating monolayers of the CT complex of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  on pure water and aqueous 0.01 M KCl subphase are shown in Fig. 6. The surface areas of CT complexes extrapolated at 0 mN m<sup>-1</sup> on pure water and 0.01 M KCl subphase

**Fig. 6**  $F$ – $A$  isotherms of CT complex of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  on A) pure water and B) 0.01 M KCl subphase. The films were transferred at 10 mN m<sup>-1</sup>.

are almost consistent with each other ( $A_0 \sim 1.2$  nm<sup>2</sup>). Because these values are larger than that of neutral **1** ( $A_0 = 0.6$  nm<sup>2</sup>), the formation of CT complex causes much expansion of the surface area. The films were deposited under a controlled surface pressure of 10 mN m<sup>-1</sup>, at which point the surface areas of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  on pure water and 0.01 M KCl ( $A_{10} \sim 1.1$  nm<sup>2</sup>) were almost identical to each other.

### Molecular-Assembly Nanowires on Mica Surface

Figure 7 shows the surface morphologies of the CT complex of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  that transferred onto freshly cleaved mica by a single withdrawal from monolayer on A) pure water and B) 0.01 M KCl subphase. Although both films showed the formation of molecular-assembly nanowires, significant difference about the nanowire orientation was confirmed between them. Both nanowires had typical width of 50 nm and height of  $\sim 2.5$  nm. By introducing 0.01 M KCl into the subphase, the nanowire orientation appeared as network structure connecting the well-developed nanowires to each other. Almost all the nanowires on the mica surface formed an angle of 60° to each other.

Because the  $F$ – $A$  isotherm of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  between pure water and 0.01 M KCl subphase was almost consistent with each other, the CT complex may not recognize K<sup>+</sup> ion at the air–water interface. Therefore the orientation of nanowire should occur during the film deposition processes because the orientation direction of the nanowires was consistent with the crystal lattice of mica.<sup>[33,34]</sup> The morphology of nanowires on mica surface strongly depended on the cation species that were introduced into the subphase (Fig. 8). When we introduced Li<sup>+</sup> (ion radius  $r_i = 0.6$  Å) or Na<sup>+</sup> ( $r_i = 0.95$  Å) into the subphase, although the formation of nanowires were confirmed, the nanowire orientation completely disappeared. Much larger cation of Cs<sup>+</sup> ( $r_i = 1.69$  Å) yielded the

**Fig. 7** Surface morphology of transferred nanowires of  $(\mathbf{1})(\text{F}_4\text{-TCNQ})_2$  from A) pure water and B) 0.01 M KCl. The scales of AFM images are  $10 \times 10 \mu\text{m}^2$ .

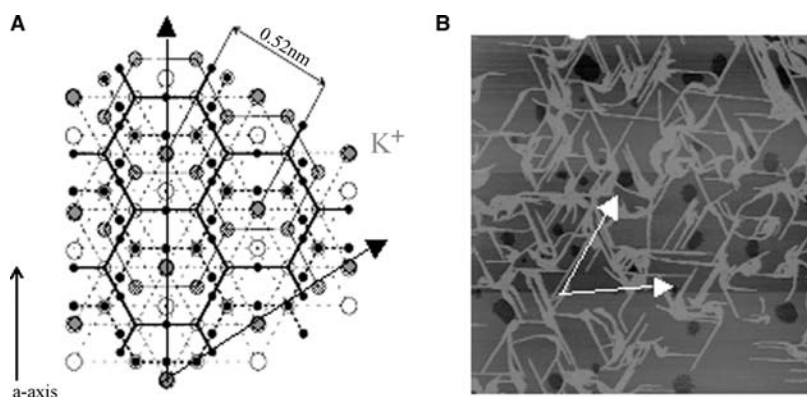

**Fig. 8** Surface morphology of transferred nanowires of (1)(F<sub>4</sub>-TCNQ)<sub>2</sub> on mica from A) LiCl, B) NaCl, C) KCl, D) RbCl, E) CsCl, and F) BaCl<sub>2</sub> containing subphase. The concentration of ions in the subphase was fixed at 0.01 M. The scales of AFM images are 10 × 10 μm<sup>2</sup>.

ill-developed molecular nanowires with maximum length of less than ~1 μm. In the case of Rb<sup>+</sup> ( $r_i = 1.48 \text{ \AA}$ ), well-developed oriented nanowires were observed at a typical length of above 2 μm. The most densely developed oriented nanowires were confirmed by the introduction of K<sup>+</sup> ( $r_i = 1.33 \text{ \AA}$ ) into the subphase, which resulted in a typical nanowire dimension of  $2.5 \times 50 \times \sim 2000 \text{ nm}^3$ . Although Ba<sup>2+</sup> ( $r_i = 1.35 \text{ \AA}$ ) has almost similar ionic radius to that of K<sup>+</sup>, the nanowire orientation completely disappeared on the mica surface.

The difference of the nanowire orientation according to the ions is related with the surface property of mica rather than the ion radius. Mica has a typical composition of KAl<sub>3</sub>Si<sub>3</sub>O<sub>10</sub>(OH)<sub>2</sub>, and vacant potassium sites of sixfold symmetry appear by the cleavage (Fig. 9).<sup>[33,34]</sup> These K<sup>+</sup> sites should be negatively charged and attract cations when the mica substrates are immersed in the K<sup>+</sup>-containing subphase. The

nanowire orientation may occur by matching of the surface potential of mica surface and that of the nanowires, rather than by ion recognition of individual molecules. The anionic species of F<sub>4</sub>-TCNQ anion radical should be embedded on K<sup>+</sup>, and nanowires may orient in an epitaxial way through the lattice matching between mica and nanowires. Such recognition mechanism is the most probable explanation for the nanowire orientation. Although the dimension of nanowires is much larger than the unit cell of hexagonal array of K<sup>+</sup> on mica surface, the nanowire orientation was affected by the K<sup>+</sup> array on mica surface.

Figure 10 shows selected AFM images (1 × 1 μm<sup>2</sup>) of oriented molecular-assembly nanowires on mica. As previously mentioned, the nanowires oriented 60° to each other, which provided interesting nanoscale structures such as nanowire tree and triangles. The six-folded connecting modes of each nanowire form novel nanoscale junction structures, which can

**Fig. 9** (A) Crystal structure of mica surface. Hexagonal arrays of K<sup>+</sup> sites are indicated by red closed circles. (B) Atomic force microscopy (AFM) image of oriented nanowires on mica surface deposited from 0.01 M KCl subphase. The white arrows correspond to hexagonal lattice of K<sup>+</sup> site on mica, showing the relation between the nanowire orientation and K<sup>+</sup> array.

apply for constructing the integrated nanoscale electronic circuits.

### Molecular-Assembly Structures within Nanowire

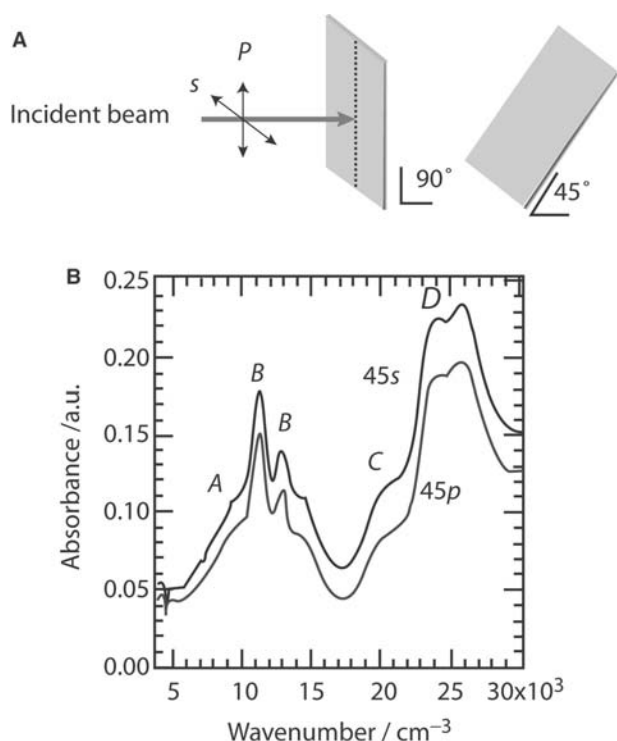

The single crystal of  $(2)(\text{F}_4\text{-TCNQ})_2$  were obtained, and here donor **2** is the four-alkyl chain derivative of compound **1**. Assuming a similar molecular packing structure of CT complex between  $(2)(\text{F}_4\text{-TCNQ})_2$  and  $(1)(\text{F}_4\text{-TCNQ})_2$ , we can discuss the molecular-assembly structure in the nanowires based on the crystal structure of  $(2)(\text{F}_4\text{-TCNQ})_2$ .<sup>[35]</sup> Figure 11 shows the unit cell of  $(2)(\text{F}_4\text{-TCNQ})_2$  viewed along the  $b$  axis. Donor **2** formed an intramolecular  $\pi$ - $\pi$  dimer through folding of the flexible 24-crown-8 moiety, in which the  $\pi$ -planes of the two TTF units overlapped at their inner  $\text{C}_3\text{S}_5$  rings. Along the  $c$  axis, the D-A layers are separated by the hydrophobic decylthio chains; moreover, the hydrophilic and hydrophobic layers are alternately arranged. The crystal structure suggests that the direction normal to the substrate surface in the LB film is consistent with the  $c$  axis ( $c = 1.72 \text{ nm}$ ). As indicated in Fig. 11, which shows the  $\pi$ - $\pi$  stacking structure within the  $ab$  plane, the  $\pi$ - $\pi$  dimer structure of

$\text{F}_4\text{-TCNQ}$  stacked alternately with the intramolecular TTF dimer along the  $-a+b$  axis. The  $\pi$ - $\pi$  stacking sequence between donor **2** and  $\text{F}_4\text{-TCNQ}$  was  $-\text{D}-\text{A}-\text{A}-\text{D}-$ , forming a 1-D mixed-stack structure.

The molecular orientation within the LB films was evaluated by using the polarized ultraviolet-visible-near infrared (UV-vis-NIR) spectra.<sup>[19-21]</sup> The polarized UV-vis-NIR spectra of the LB film of  $(1)(\text{F}_4\text{-TCNQ})_2$  did not indicate any in-plane anisotropy with the normal incidence, indicating the isotropic distribution of molecular orientation within the substrate surface. Two sharp absorptions (B bands) were assigned to the intramolecular transition of the  $\text{F}_4\text{-TCNQ}^-$  anion radical,<sup>[36]</sup> while the C and D bands were assigned to the intramolecular transitions of  $\text{TTF}^+$  and  $\text{F}_4\text{-TCNQ}^-$ , respectively.<sup>[37]</sup> The broad A bands were assigned to the intramolecular transition of bis(TTF)-macrocycles,<sup>[38-40]</sup> which overlapped with the B bands. With  $45^\circ$  incidences (Fig. 12A), the absorption intensity for the s-polarization was larger than that for the p-polarization. Because the intramolecular transition moments of donor **1** and  $\text{F}_4\text{-TCNQ}$  lie along the long axes of TTF and  $\text{F}_4\text{-TCNQ}$  molecules, the long axes of donor **1** and  $\text{F}_4\text{-TCNQ}$  were relatively parallel to the substrate surface.

**Fig. 11** Crystal structure of CT complex  $(2)(\text{F}_4\text{-TCNQ})_2$ . (A) Unit cell viewed along the  $b$  axis. (B) Alternate  $\pi$ - $\pi$  stacking structure between donor **2** and  $\text{F}_4\text{-TCNQ}$  dimer along the  $-a+b$  axis. Alkyl chains are omitted.

**Fig. 12** Polarized UV-vis-NIR spectra of the LB film of  $(1)(F_4\text{-TCNQ})_3$ . A) Optical arrangements of the substrates to measure the polarized UV-vis-NIR spectra at  $90^\circ$  and  $45^\circ$  incidence. B) Polarized UV-vis-NIR spectra of  $45^\circ$  incidence with p- and s-polarization.

From the results of X-ray structural analysis and polarized UV-vis-NIR spectra, we constructed the schematic molecular packing model within the nanowire (Fig. 13).<sup>[27,28]</sup> The nanowires transferred from  $K^+$  containing subphase had typical dimensions of  $2.5 \times 50 \times \sim 1000 \text{ nm}^3$ . Considering the molecular size of donor **1**, the nanowire should be composed of 1–2 molecular layers in the height direction and 20–30 molecules in the width direction. Assuming that the nanowire has a local structure similar to that of crystal structure of  $(2)(F_4\text{-TCNQ})_2$ , the longitudinal direction of the nanowire should correspond to the  $\pi$ - $\pi$  stacking direction of TTF units and/or  $F_4\text{-TCNQ}$  molecules. Therefore, a few thousand molecules are

necessary to form over 1- $\mu\text{m}$ -long nanowire, taking into account that the standard  $\pi$ - $\pi$  stacking distance is around 0.35 nm.

### Electrical Conductivity and Magnetic Properties

To estimate the electrical conductivity of nanowires, the temperature-dependent electrical conductivity and paramagnetic susceptibility were measured in the form of the LB film. Figure 14 shows the temperature-dependent electrical conductivity (right scale) and paramagnetic susceptibility (left scale) of LB film of  $(1)(F_4\text{-TCNQ})_2$ . The room-temperature electrical conductivity ( $\sigma_{RT}$ ) was  $1.5 \times 10^{-3} \text{ S cm}^{-1}$  with an activation energy of 0.17 eV. The semiconducting temperature dependence was consistent with that of the mixed-stack arrangement of donor and  $F_4\text{-TCNQ}$  dimer. Although the accumulated film should be composed of piles of nanowires and monolayers of  $(1)(F_4\text{-TCNQ})_2$ , each nanowire may have the same order of electrical conductivity.

The temperature-dependent paramagnetic susceptibility ( $\chi$ ) of the LB films of  $(1)(F_4\text{-TCNQ})_2$  was measured via electron spin resonance (ESR). As shown in Fig. 14,  $\chi$  increased monotonically with decreasing temperatures, which followed the Curie-Weiss law. The line-shape of the ESR signals could be fitted using Lorentzian. Line width around 0.5 mT did not show anomaly within the measured temperature range. Because  $g$ -values for  $\text{BEDT-TTF}^+$  cation and  $F_4\text{-TCNQ}^-$  anion radicals have been typically observed at 2.0074 and 2.0025, respectively,<sup>[11–15]</sup> the  $g$ -values ( $\sim 2.004$ ) of the LB films for  $(1)(F_4\text{-TCNQ})_2$  were observed in the intermediate range between  $\text{BEDT-TTF}$  and  $F_4\text{-TCNQ}$ , which indicated that both the cation and the anion radical species contribute to the paramagnetic susceptibility of the LB films.

### CONCLUSION

We constructed oriented molecular-assembly nanowires, which are important parts for the fabrication

**Fig. 13** Possible molecular arrangements within a nanowire.

Fig. 14 Temperature-dependent electrical conductivity (right scale) and paramagnetic susceptibility (left scale) of the LB film of (1)(F<sub>4</sub>-TCNQ)<sub>2</sub>.

of nanoscale electronic devices. Molecular-assembly nanowires have a potential to fabricate nanoscale electronics in all self-assembly chemical processes. Amphiphilic bis(TTF) macrocycle derivative is one such example, forming self-assembly nanowires oriented on mica surface. This molecule was designed from the viewpoints of: 1) molecular conductor; 2) Langmuir–Blodgett films; and 3) supramolecular chemistry. Designs from the concepts of molecular conductor and Langmuir–Blodgett film are necessary to construct nanoscale electrical conducting, one-dimensional structure. Furthermore, the design of weak intermolecular interactions (ion recognition) from the supramolecular approach should be a key methodology to construct oriented molecular-assembly nanowires. Control of electronic structures of the nanowires may be achieved through careful design of the charge–transfer interactions (electronic dimensionality, bandwidth, carrier concentration, etc.), while a variety of nanoscale structures such as zero-dimensional nanodots and nanowires should be obtainable from the designs of supramolecular chemistry.

# Nanowires and Nanobelts: Mechanical Properties

Zhong Lin Wang

Center for Nanoscience and Nanotechnology, Georgia Institute of Technology,  
Atlanta, Georgia, U.S.A.

## INTRODUCTION

Because of the high size and structure selectivity of nanomaterials, their physical properties could be quite diverse, depending on their atomic-scale structure, size, and chemistry.<sup>[1]</sup> To maintain and utilize the basic and technological advantages offered by the size specificity and selectivity of the nanomaterials, there are three key challenges that we need to overcome for the future technological applications of nanomaterials. First, synthesis of size, morphology and structurally controlled nanomaterials, which are likely to have the precisely designed and controlled properties. Secondly, novel techniques for characterizing the properties of individual nanostructures and their collective properties.<sup>[2]</sup> This is essential for understanding the characteristics of the nanostructures. Finally, integration of nanomaterials with the existing technology is the most important step for their applications, especially in nanoscale electronics and optoelectronics.

Characterizing the mechanical properties of individual nanotubes/nanowires/nanobelt [called one-dimensional (1-D) nanostructure] is a challenge to many existing testing and measuring techniques because of the following constraints. First, the size (diameter and length) is rather small, prohibiting the applications of the well-established testing techniques. Tensile and creep testing require that the size of the sample be sufficiently large to be clamped rigidly by the sample holder without sliding. This is impossible for 1-D nanomaterials using conventional means. Secondly, the small size of the nanostructure makes their manipulation rather difficult, and specialized techniques are needed for picking up and installing individual nanostructure. Therefore new methods and methodologies must be developed to quantify the properties of individual nanostructure. The objective of this entry is to introduce the theory and techniques that have developed for characterizing the mechanical properties of individual nanotubes/nanowires/nanobelt using in situ transmission electron microscopy (TEM).

## DYNAMIC BENDING MODULUS BY ELECTRIC FIELD-INDUCED MECHANICAL RESONANCE

The main challenge for characterizing the mechanical behavior of a single nanostructure is its ultrasmall size that prohibits the application of conventional techniques. We first have to see the nanostructure and then measure its properties. TEM is a powerful tool for characterizing the atomic-scale structures of solid materials. A modern TEM is a versatile machine that not only can provide a real space resolution better than 0.2 nm but also can give a quantitative chemical and electronic analysis from a region as small as 1 nm. It is feasible to receive a full structure characterization from TEM. A powerful and unique approach could be developed if we can integrate the structural information of a nanostructure provided by TEM with the properties measured in situ from the same nanostructure.<sup>[3–5]</sup> This is a powerful technique that not only can provide the properties of an individual nanotube but also can give the structure of the nanotube through electron imaging and diffraction, providing an ideal technique for understanding the property–structure relationship. The objective of this section is to introduce this technique and its applications.

## Experimental Method

To carry out the property measurement of a 1-D nanostructure, a specimen holder for a TEM was built for applying a voltage across a 1-D nanostructure and its counter electrode (Fig. 1).<sup>[4,6]</sup> In the area that is loading specimen in conventional TEM, an electromechanical system is built that allows not only the lateral movement of the tip, but also applying a voltage across the 1-D nanostructure with the counter electrode. This setup is similar to the integration of scanning probe technique with TEM. The static and dynamic properties of the 1-D nanostructures can be obtained by applying a controllable static and alternating electric field. The microstructure of the measured object can be fully characterized by electron imaging, diffraction, and chemical analysis techniques.

**Fig. 1** A transmission electron microscope and a schematic diagram of a specimen holder for in situ measurements.

The 1-D nanostructure to be used for property measurements is directly imaged under TEM (Fig. 2), and electron diffraction patterns and images can be recorded from the 1-D nanostructure. The information provided by TEM directly reveals both the surface and the intrinsic structure of the 1-D nanostructure. This is a unique advantage over the SPM techniques. The distance from the 1-D nanostructure to the counter electrode is controllable. The typical dimensions of

the 1-D nanostructures are 5–100 nm in diameter/width and lengths of 1–20  $\mu\text{m}$ . The counter electrode is typically an Au ball of diameter  $\sim 0.25$  mm.

### The Fundamental Resonance Frequency and Non-linear Effect

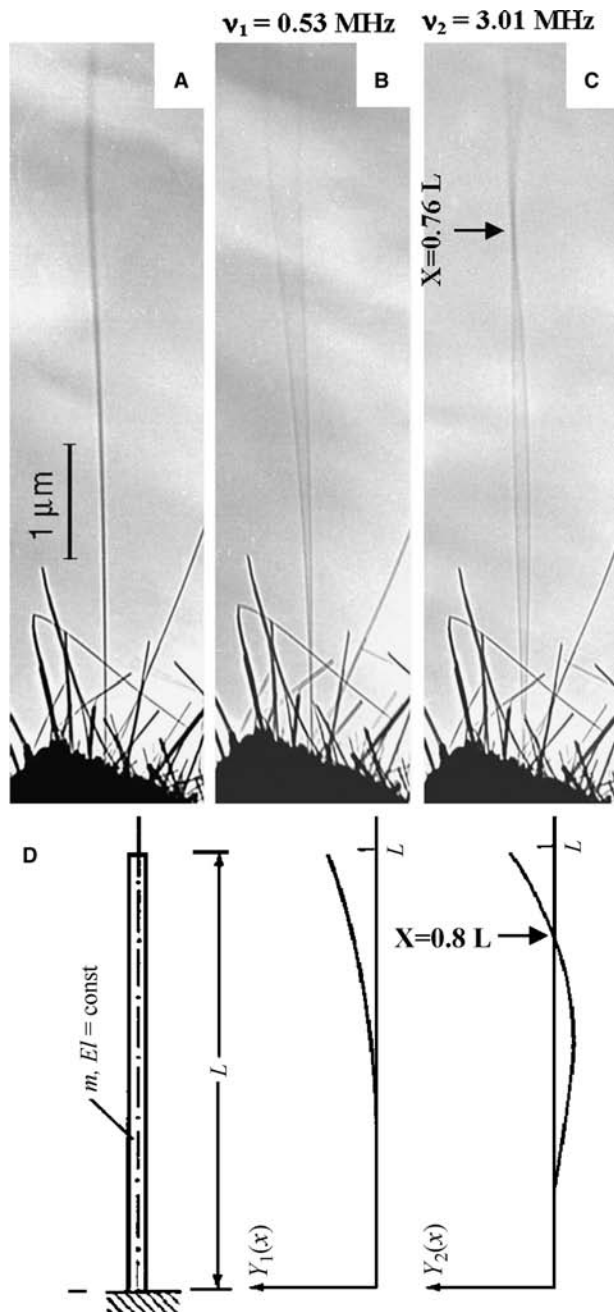

Our first measurements were carried out for multi-walled carbon nanotubes produced by an arc-discharge technique. Because of the sharp needle shape of a carbon nanotube, it can be charged by an externally applied voltage; the induced charge is distributed mostly at the tip of the carbon nanotube and the electrostatic force results in the deflection of the nanotube. Alternatively, if an applied voltage is an alternating voltage, the charge on the tip of the nanotube is also oscillating, so is the force. If the applied frequency matches the natural resonance frequency of the nanotube, mechanical resonance is induced. By tuning the applied frequency, the first and the second harmonic resonances can be observed (Fig. 3). The analysis of the information provided by the resonance experiments relies on the theoretical model for the system. The most established theory for modeling mechanical systems is the continuous elasticity theory, which is valid for large-size objects. For atomic scale mechanics, we may have to rely on molecular dynamics. The diameter of the nanotube is between the continuous model and the atomistic model; thus we need to examine the validity of applying the classical elasticity theory for the data analysis.

We have compared the following three characteristics between the results predicted by the elasticity theory and the experimental results shown in Fig. 3. First, the theoretical node for the second harmonic resonance occurs at  $0.8L$ , and the experiment showed  $\sim 0.76L$ . Secondly, the frequency ratio between the second to the first mode is  $\nu_2/\nu_1 = 6.27$  theoretically, while

**Fig. 2** TEM image showing one-dimensional nanostructures at the end of the electrode and the other counter electrode. A constant or alternating voltage can be applied to the two electrodes to induce electrostatic deflection or mechanical resonance.

**Fig. 3** A selected carbon nanotube at (A) stationary, (B) the first harmonic resonance ( $\nu_1 = 1.21$  MHz), and (C) the second harmonic resonance ( $\nu_2 = 5.06$  MHz). (D) The traces of a uniform one-end fixed elastic beam at the first two resonance modes, as predicted by the continuous elasticity theory.

the observed one is  $\nu_2/\nu_1 = 5.7$ . The agreement is reasonably well if one looks into the assumptions made in the theoretical model: the nanotube is a uniform and homogeneous beam, and the root of the clamping side is rigid. The latter, however, may not be realistic in practical experiment. Finally, the shape of the nanotube during resonance has been compared quantitatively with the shape calculated by the elasticity theory, and the

agreement is excellent. Therefore we can still use the elasticity theory for the data analysis.

If the nanotube is approximated as a uniform solid bar with one end fixed on a substrate, from classical elasticity theory, the resonance frequency is given by<sup>[7]</sup>

$$\nu_i = \frac{\beta_i^2}{8\pi} \frac{1}{L^2} \sqrt{\frac{(D^2 + D_i^2)E_b}{\rho}} \quad (1)$$

where  $D$  is the tube outer diameter,  $D_i$  the inner diameter,  $L$  the length,  $\rho$  the density, and  $E_b$  the bending modulus. It must be pointed out that the bending modulus is different from Young's modulus, because bending modulus depends on the geometrical shape of the object. The resonance frequency is nanotube selective and it is a specific value of a nanotube.

The correlation between the applied frequency and the resonance frequency of the nanotube is not trivial. From Fig. 2 we know that there are some electrostatic charges built on the tip of the carbon nanotube. With consideration of the difference between the surface work functions between the carbon nanotube and the counter electrode (Au), a static charge exists even when the applied voltage is withdrawn. Therefore under an applied field the induced charge on the carbon nanotube can be represented by  $Q = Q_0 + \alpha V_0 \cos \omega t$ , where  $Q_0$  represents the charge on the tip to balance the difference in surface work functions,  $\alpha$  is a geometrical factor, and  $V_0$  is the amplitude of the applied voltage. The force acting on the carbon nanotube is

$$\begin{aligned} F &= \beta(Q_0 + \alpha V_0 \cos \omega t)V_0 \cos \omega t \\ &= \alpha\beta V_0^2/2 + \beta Q_0 V_0 \cos \omega t + \alpha\beta V_0^2/2 \cos 2\omega t \end{aligned} \quad (2)$$

where  $\beta$  is a proportional constant. Thus resonance can be induced at  $\omega$  and  $2\omega$  at vibration amplitudes proportional to  $V_0$  and  $V_0^2$ , respectively. The former is a linear term in which the resonance frequency equals to the applied frequency, while the latter is a non-linear term and the resonance frequency is twice of the applied frequency. In practical experiments, the linear and non-linear terms can be distinguished by observing the dependence of the vibration amplitude on the magnitude of the voltage  $V_0$ . This is an important process to ensure the detection of the linear term.

Another factor that one needs to consider is to identify the true fundamental resonance frequency. From Eq. (1), the frequency ratio between the first two modes is 6.27. In practice, if resonance occurs at  $\omega$ , resonance could occur also at  $2\omega$ , which is the double harmonic. To identify the fundamental frequency, one needs to examine the resonance at a frequency that is half or close to half of the observed resonance frequency; if no resonance occurs, the observed frequency is the true fundamental frequency.

The diameters of the tube can be directly determined from TEM images at a high accuracy. The determination of length has to consider the 2-D projection effect of the tube. It is essential to tilt the tube and to catch its maximum length in TEM, which is likely to be the true length. This requires a TEM that gives a tilting angle as large as  $\pm 60^\circ$ . Also, the operation voltage of the TEM is important to minimize radiation damage. The 100-kV TEM used in our experiments showed almost no detectable damage to a carbon nanotube, while a 200-kV electron could quickly damage a nanotube. The threshold for radiation damage of carbon nanotubes is  $\sim 150$  kV.

To trace the sensitivity of resonance frequency on beam illumination and radiation damage at 100 kV, a carbon nanotube was resonanced for more than 30 min. The resonance frequency showed an increase of  $\sim 1.4\%$  over the entire period of experiment, but no dependence on the electron dose was found. The FWHM for the resonance peak was measured to be  $\Delta\nu/\nu = 0.6\%$  in a vacuum of  $10^{-4}$ – $10^{-5}$  Torr. A slight increase in the resonance frequency could be related to the change of carbon structure under the electron beam, but such an effect has a negligible effect on the measurement of the bending modulus.

The Young's modulus is a quantity that is defined to characterize the interatomic interaction force, and it is the double differential of the bonding energy curve between the two atoms. The ideal case is that it is an intrinsic property at the atomic level and is independent of the sample geometry. For the nanotube case, the bending of a nanotube is determined not only by the Young's modulus, but also by the geometrical shape of the nanotube, such as the wall thickness and tube diameter. What we have measured by the in situ

**Fig. 4** Bending modulus of the multiwalled carbon nanotube produced by arc-discharge as a function of the outer diameter of the nanotube. The inner diameter of the nanotubes is  $\sim 5$  nm, independent of the outer diameter. The FWHM of the resonance peak is inserted.

TEM experiments is the bending modulus. Fig. 4 shows a group of experimentally measured bending modulus of multiwalled carbon nanotubes. It is apparent that the smaller-size nanotubes have a bending modulus approaching the Young's modulus, while the modulus for the larger-size ones is much smaller. This size-dependent property is related to the elastic deformation of the carbon nanotubes.

To explore the intrinsic meaning of the measured  $\Delta\nu/\nu_1$  value, we consider a 1-D harmonic oscillator with an intrinsic resonance frequency  $\nu_1$ . If a viscosity (or friction) force is acting on the particle and the force is proportional to the instantaneous speed of the particle, the damping of the vibration amplitude is given by  $\exp(-t/\tau_0)$ , where  $\tau_0$  is the life decay constant of the oscillator. This decay constant is related to  $\Delta\nu/\nu_1$  by  $\Delta\nu/\nu_1 \ll 1$  by

$$\tau_0 = [(\Delta\nu/\nu_1)\pi\nu_1/1.732]^{-1} \quad (3)$$

For  $\Delta\nu/\nu_1 = 0.65\%$ ,  $\nu_1 = 1.0$  MHz, the lifetime is  $\tau_0 = 85$   $\mu$ sec. From the definition of  $\tau_0$ , the viscosity/friction coefficient  $\eta = 2M/\tau_0$ , where  $M$  is the mass of the particle; thus the time decay constant depends mainly on the viscosity coefficient of the nanotube in vacuum ( $10^{-4}$  Torr) under which the measurement was made, and it is almost independent of the intrinsic structure of the carbon nanotube. This agrees with our experimental observation and Eq. (1) can also be used to explain the larger value of  $\Delta\nu/\nu_1$  obtained in air than that in vacuum given that the atmosphere should have a higher viscosity (friction) coefficient.

Theoretical investigation by Liu, Zheng, and Jiang<sup>[8]</sup> suggests that the Eq. (1) used for the analysis is based on the linear analysis, which is valid for a small amplitude of vibration; for large vibration amplitude, the nonlinear analysis may have to be used. Based on the nonlinear elasticity theory, they have successfully explained the rippling effect observed experimentally by Wang, Poncharal, and de Heer.<sup>[4]</sup> In practical experiments, the resonance frequency shows no drift as the vibration increases to as large as  $30^\circ$ , suggesting that the frequency measured can still be quantified using the linear analysis.

## BENDING MODULUS OF COMPOSITE NANOWIRES

The technique demonstrated for carbon nanotubes applies to any nanowire shape object regardless of its conductivity.<sup>[9]</sup> Here we use composite silicon carbide–silica nanowires synthesized by a solid–vapor process as an example. The as-synthesized materials are grouped into three basic nanowire structures: pure  $\text{SiO}_x$  nanowires, coaxially  $\text{SiO}_x$  sheathed  $\beta$ -SiC

**Fig. 5** (A,B) TEM images of the coaxial and biaxial structured SiC-SiO<sub>x</sub> nanowires, and (C,D) the cross-sectional TEM images, respectively.

nanowires, and biaxial  $\beta$ -SiC-SiO<sub>x</sub> nanowires. Fig. 5 depicts the TEM images of the nanowires and their cross-section images, showing the coaxial and biaxial structures. The nanowires are uniform with a diameter of 50–80 nm, and a length that can be as long as 100  $\mu$ m. The coaxial SiC-SiO<sub>x</sub> nanowires have been extensively studied and have a  $\langle 111 \rangle$  growth direction with a high density of twins and stacking faults perpendicular to the growth direction.

For a beam with one end hinged and the other free, the resonance frequency is given by:<sup>[7]</sup>

$$\nu_0 = (\beta^2/2\pi)(EI/m)^{1/2}/L^2 \quad (4)$$

where  $\nu_0$  is the fundamental resonance frequency,  $\beta = 1.875$ ,  $EI$  is the flexural rigidity (or bending stiffness),  $E$  is the Young's modulus,  $I$  is the moment of inertia about a particular axis of the rod,  $L$  is the length of the beam, and  $m$  is its mass per unit length. For a uniform solid beam with a coaxial cable structured nanowire whose core material density is  $\rho_c$  and diameter is  $D_c$  and a sheath material density that is  $\rho_s$  with outer diameter  $D_s$ , the average density of the nanowire is given by

$$\rho_e = \rho_c(D_c^2/D_s^2) + \rho_s(1 - D_c^2/D_s^2) \quad (5)$$

The effective Young's modulus of the composite nanowire,  $E_{\text{eff}}$ , is

$$E_{\text{eff}} = \rho_e[8\pi f_0 L^2/\beta^2 D_s]^2 \quad (6)$$

The bending modulus for the coaxial cable structured SiC-SiO<sub>x</sub> nanowires results in combination from SiC and SiO<sub>x</sub>, where the contribution from the sheath layer of SiO<sub>x</sub> is more than that from the SiC core because of its larger flexural rigidity (or bending stiffness). The bending modulus increases as the diameter of the nanowire increases (Table 1), consistent with the theoretically expected values of  $E_{\text{eff}} = \alpha E_{\text{SiC}} + (1 - \alpha)E_{\text{SiO}_x}$ , where  $\alpha = (D_c/D_s)^4$ . The data match well to the calculated values for larger diameter nanowires.

From the cross-sectional TEM image of a biaxially structured nanowire, the outermost contour of the cross section of the nanowire can be approximated to be elliptical. Thus the effective Young's modulus of the nanowire can be calculated using Eq. (6) with the introduction of an effective moment of inertia and density. For an elliptical cross section of half long-axis  $a$  and half short-axis  $b$ , the moments of inertia are  $I_x = \pi ab^3/4$ , and  $I_y = \pi ba^3/4$ , where  $a$  and  $b$  can be calculated from the widths of the composite nanowire. With consideration of the equal probability of resonance with respect to the  $x$  and  $y$  axes, the effective moment of inertia introduced in the calculation is

**Table 1** Measured Young's modulus of coaxial cable structured SiC-SiO<sub>x</sub> nanowires (SiC is the core, and silica is the sheath) ( $\rho_{\text{Silica}} = 2.2 \times 10^3 \text{ kg/m}^3$ ;  $\rho_{\text{SiC}} = 3.2 \times 10^3 \text{ kg/m}^3$ ). The Young's moduli of the bulk materials are  $E_{\text{SiC}} = 466 \text{ GPa}$  and  $E_{\text{SiO}_2} = 73 \text{ GPa}$

$D_s$ (nm) ( $\pm 2$ nm)	$D_c$ (nm) ( $\pm 1$ nm)	$L$ ( $\mu$ m) ( $\pm 0.2$ $\mu$ m)	$f_0$ (MHz)	$E_{\text{eff}}$ (GPa) experimental	$E_{\text{eff}}$ (GPa) theoretical
51	12.5	6.8	0.693	46 $\pm$ 9.0	73
74	26	7.3	0.953	56 $\pm$ 9.2	78
83	33	7.2	1.044	52 $\pm$ 8.2	82
132	48	13.5	0.588	78 $\pm$ 7.0	79
190	105	19.0	0.419	81 $\pm$ 5.1	109

**Table 2** Measured Young's modulus of biaxially structured SiC–SiO<sub>x</sub> nanowires.  $D_{\text{wire}}$  and  $D_{\text{SiC}}$  are the widths across the entire nanowire and across the SiC subnanowire, respectively

$D_{\text{wire}}$ (nm) (±2 nm)	$D_{\text{SiC}}$ (nm) (±1 nm)	$L$ (μm) (±0.2 μm)	$f_o$ (MHz)	$E_{\text{eff}}$ (GPa) experimental
58	24	4.3	1.833	54 ± 24.1
70	36	7.9	0.629	53 ± 8.4
83	41	4.3	2.707	61 ± 13.8
92	47	5.7	1.750	64 ± 14.3

taken to be approximately  $I = (I_x + I_y)/2$ , and the density per unit length is  $m_{\text{eff}} = A_{\text{SiC}}\rho_{\text{SiC}} + A_{\text{Silica}}\rho_{\text{Silica}}$ , where  $A_{\text{SiC}}$  and  $A_{\text{Silica}}$  are the cross sectional areas of the SiC and SiO<sub>x</sub> sides, respectively. The experimentally measured Young's modulus is given in Table 2.

## BENDING MODULUS OF OXIDE NANOBELTS

### Nanobelts—Structurally Controlled Nanowires

In the literature, there are a few names being used for describing 1-D elongated structures, such as nanorod, nanowire, nanoribbon, nanofiber, and nanobelts. When we named the nanostructures to be “nanobelts”,<sup>[10]</sup> we mean that the nanostructure has specific growth direction, the top/bottom surfaces and side surfaces are well-defined crystallographic facets. The requirements for nanowires are less restrictive than for nanobelts because a wire has a specific growth direction, but its side surfaces may not be well defined, and its cross section may not be uniform nor have a specific shape. Therefore, *we believe that nanobelts are more structurally controlled objects than nanowires, or simply a nanobelt is a nanowire that has well-defined side surfaces.* It is well known that the physical property of a carbon nanotube is determined by the helical angle at which the graphite layer was rolled up. It is expected that, for thin nanobelts and nanowires, their physical

and chemical properties will depend on the nature of the side surfaces.

The most typical nanobelt is ZnO (Fig. 6A), which has a distinct cross section from the nanotubes or nanowires.<sup>[10]</sup> Each nanobelt has a uniform width along its entire length, and the typical widths of the nanobelts are in the range of 50 to 300 nm. A ripple-like contrast appearing in the TEM image is due to the strain resulting from the bending of the belt. High-resolution TEM (HRTEM) and electron diffraction studies show that the ZnO nanobelts are structurally uniform, single crystalline, and dislocation free (Fig. 6B).

There are a few kinds of nanobelts that have been reported in the literature. Table 3 summarizes the nanobelt structures of function oxides.<sup>[10–14]</sup> Each type of nanobelts is defined by its crystallographic structure, the growth direction, top surfaces, and side surfaces. Some of the materials can grow along two directions, but they can be controlled experimentally. Although these materials belong to different crystallographic families, they do have a common faceted structure, which is the nanobelt structure. In addition, nanobelts of Cu(OH)<sub>2</sub>,<sup>[15]</sup> MoO<sub>3</sub>,<sup>[16,17]</sup> MgO,<sup>[18,19]</sup> and CuO.<sup>[20]</sup>

### Dual-Mode Resonance of Nanobelts

Because of the mirror symmetry and rectangular cross section of the nanobelt (Fig. 7A), there are two distinct fundamental resonance frequencies corresponding to the vibration in the thickness and width directions, which are given from the classical elasticity theory as.<sup>[21]</sup>

$$\nu_x = \frac{\beta_1^2 T}{4\pi L^2} \sqrt{\frac{E_x}{3\rho}} \quad (7)$$

$$\nu_y = \frac{\beta_1^2 W}{4\pi L^2} \sqrt{\frac{E_y}{3\rho}} \quad (8)$$

**Fig. 6** (A) TEM image of ZnO nanobelts synthesized by a solid–vapor phase technique. (B) High-resolution TEM image of a ZnO nanobelt with incident electron beam direction along  $[2\bar{1}\bar{1}0]$ . The nanobelt grows along  $[0001]$ , with top/bottom surfaces  $(2\bar{1}\bar{1}0)$  and side surfaces  $(01\bar{1}0)$ .

**Table 3** Crystallographic geometry of functional oxide nanobelts

Nanobelt	Crystal structure	Growth direction	Top surface	Side surface
ZnO	Wurtzite	[0001] or [01 $\bar{1}$ 0]	$\pm(2\bar{1}\bar{1}0)$ or $\pm(2\bar{1}\bar{1}0)$	$\pm(01\bar{1}0)$ or $\pm(0001)$
Ga <sub>2</sub> O <sub>3</sub>	Monoclinic	[001] or [010]	$\pm(100)$ or $\pm(100)$	$\pm(010)$ or $\pm(10\bar{1})$
<i>t</i> -SnO <sub>2</sub>	Rutile	[101]	$\pm(10\bar{1})$	$\pm(010)$
<i>o</i> -SnO <sub>2</sub> wire	Orthorhombic	[010]	$\pm(100)$	$\pm(001)$
In <sub>2</sub> O <sub>3</sub>	C-Rare earth	[001]	$\pm(100)$	$\pm(010)$
CdO	NaCl	[001]	$\pm(100)$	$\pm(010)$
PbO <sub>2</sub>	Rutile	[010]	$\pm(201)$	$\pm(10\bar{1})$

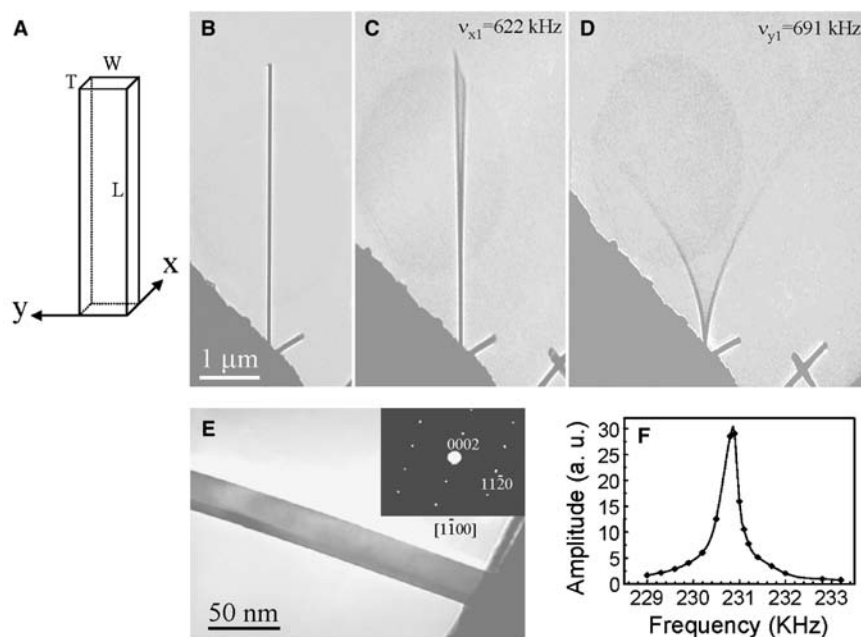

where  $\beta_1 = 1.875$ ;  $E_x$  and  $E_y$  are the bending modulus if the vibration is along the  $x$  axis (thickness direction) and  $y$  direction (width direction), respectively;  $\rho$  is the density,  $L$  is the length,  $W$  is the width, and  $T$  is the thickness of the nanobelt. The two modes are decoupled and they can be observed separately in experiments.

Changing the frequency of the applied voltage, we found two fundamental frequencies in two orthogonal directions transverse to the nanobelt.<sup>[21]</sup> Fig. 7C and D shows the harmonic resonance with the vibration planes nearly perpendicular and parallel to the viewing direction, respectively. For calculating the bending modulus, it is critical to accurately measure the fundamental resonance frequency ( $\nu_1$ ) and the dimensional sizes ( $L$ , and  $T$  and  $W$ ) of the investigated ZnO nanobelts. To determine  $\nu_1$ , we have checked the stability of the resonance frequency to ensure that one end of the nanobelt is tightly fixed, and the resonant excitation has been carefully checked around the half value of the resonance frequency.

ZnO nanobelts can be used as a force sensor. Fig. 8A shows a selected ZnO nanobelt with a hooked end, which is equivalent to a cantilever with an integrated tip. Because of the two transverse vibration modes of the nanobelt, resonance along two orthogonal directions has been observed (Fig. 8B and C). The two resonance modes just correspond to the two modes of the tip operation when the nanobelt-base cantilever is used as a force sensor: one is the tapping mode and the other is the noncontact mode. Thus the force sensor fabricated using the ZnO nanobelts is versatile for applications on hard and soft surfaces.

### Bending Modulus of Nanobelt

The geometrical parameters are the key for derivation of the mechanical property from the measured resonance frequencies. The specimen holder is rotated about its axis so that the nanobelt is aligned perpendicular to the electron beam; thus the real length ( $L$ ) of the

**Fig. 7** A selected ZnO nanobelt at (A,B) stationary, (C) the first harmonic resonance in the  $x$  direction,  $\nu_{x1} = 622$  kHz, and (D) the first harmonic resonance in the  $y$  direction,  $\nu_{y1} = 691$  kHz. (E) An enlarged image of the nanobelt and its electron diffraction pattern (inset). The projected shape of the nanobelt is apparent. (F) The FWHM of the resonance peak measured from another ZnO nanobelt. The resonance occurs at 230.9 kHz.

**Fig. 8** A selected ZnO nanobelt with a hooked end at (A) stationary, (B) resonance at 731 kHz in the plane almost parallel to the viewing direction, and (C) resonance at 474 kHz in the plane closely perpendicular to the viewing direction.

nanobelt can be obtained. The normal direction of the wide facet of the nanobelt could be firstly determined by electron diffraction pattern, which was  $[2\bar{1}\bar{1}0]$  for the ZnO nanobelt. Then the nanobelt was tilted from its normal direction by rotating the specimen holder, and the tilting direction and angle were determined by the corresponding electron diffraction pattern. As shown in the inset of Fig. 7E, the electron beam direction is  $[1\bar{1}00]$ . The angle between  $[1\bar{1}00]$  and  $[2\bar{1}\bar{1}0]$  is  $30^\circ$ , i.e., the normal direction of the wide facet of this nanobelt is  $30^\circ$  tilted from the direction of the electron beam. Using the projected dimension measured from the TEM image (Fig. 7E), the geometrical parameters of this nanobelt are determined to be  $W = 28$  nm and  $T = 19$  nm. Based on the experimentally measured data, the bending modulus of the ZnO nanobelts is calculated using Eqs. (7) and (8). The experimental results are summarized in Table 4.<sup>[21]</sup> The bending modulus of the ZnO nanobelts was  $\sim 52$  GPa. This value represents the modulus that includes the scaling effect and geometrical shape, and it cannot be directly compared to the Young's modulus of ZnO ( $c_{33} = 210$  GPa,  $c_{13} = 104$  GPa),<sup>[22]</sup> because

the shape of the nanobelt and the anisotropic structure of ZnO are convoluted in the measurement. The bending modulus measured by the resonance technique, however, has excellent agreement with the elastic modulus measured by nanoindentation for the same type of nanobelts.<sup>[23]</sup>

Although nanobelts of different sizes may have a slight difference in bending modulus, there is no obvious difference if the calculation was done using either Eq. (7) or Eq. (8). The ratio of two fundamental frequencies  $\nu_{y1}/\nu_{x1}$  is consistent with the aspect ratio  $W/T$ , as expected from Eqs. (7) and (8), because there is no significant difference between  $E_x$  and  $E_y$ .

The resonance technique demonstrated here is very sensitive to the structure of a nanowire. Fig. 9A and B shows a silicon nanowire that has a Au tip, but the Au particle is off the symmetric axis of the nanowire. This asymmetric structure results in two distinct resonance along two perpendicular directions (Fig. 9C and D). The difference between the two resonance frequencies is related to the mass of the Au particle.

## THE HARDNESS OF A NANOBELT BY NANOINDENTATION

Nanoscale mechanical properties of individual zinc oxide nanobelts were characterized by Nanoscope IIIa atomic force microscope (AFM) (Fig. 10A) and Hysitron TriboScope with homemade side-view CCD camera.<sup>[23]</sup> The prepared nanobelt sample was investigated by two means: one is by tapping mode of Nanoscope IIIa, using a diamond indenter tip with a radius of  $<25$  nm. The other is by STM mode of Hysitron TriboScope, an add-on force transducer from Hysitron Inc., using a diamond cubic corner tip with a radius of  $<40$  nm. In either case, individual nanobelts were imaged, and then nanoindentations were made on the nanobelt using varied loads (Fig. 10B and C). After indentation, the indent was imaged in situ using the image mode of the AFM. For nanoindentations, the hardness is normally defined as the maximum load divided by the projected area of the indenter in contact

**Table 4** Bending modulus of the ZnO nanobelts.  $E_x$  and  $E_y$  represents the bending modulus corresponding to the resonance along the thickness and width directions, respectively

Nanobelt	Length $L$ ( $\mu\text{m}$ ) ( $\pm 0.05$ )	Width $W$ (nm) ( $\pm 1$ )	Thickness $T$ (nm) ( $\pm 1$ )	Fundamental frequency (kHz)			Bending modulus (GPa)		
				$W/T$	$\nu_{x1}$	$\nu_{y1}$	$\nu_{y1}/\nu_{x1}$	$E_x$	$E_y$
1	8.25	55	33	1.7	232	373	1.6	$46.6 \pm 0.6$	$50.1 \pm 0.6$
2	4.73	28	19	1.5	396	576	1.4	$44.3 \pm 1.3$	$45.5 \pm 2.9$
3	4.07	31	20	1.6	662	958	1.4	$56.3 \pm 0.9$	$64.6 \pm 2.3$
4	8.90	44	39	1.1	210	231	1.1	$37.9 \pm 0.6$	$39.9 \pm 1.2$

**Fig. 9** (A) A silicon nanowire with a gold particle at the tip, showing (B,C) two independent resonance along two perpendicular directions.

with the sample at the maximum load. Thus,

$$H = \frac{P_{MAX}}{A_C} \quad (9)$$

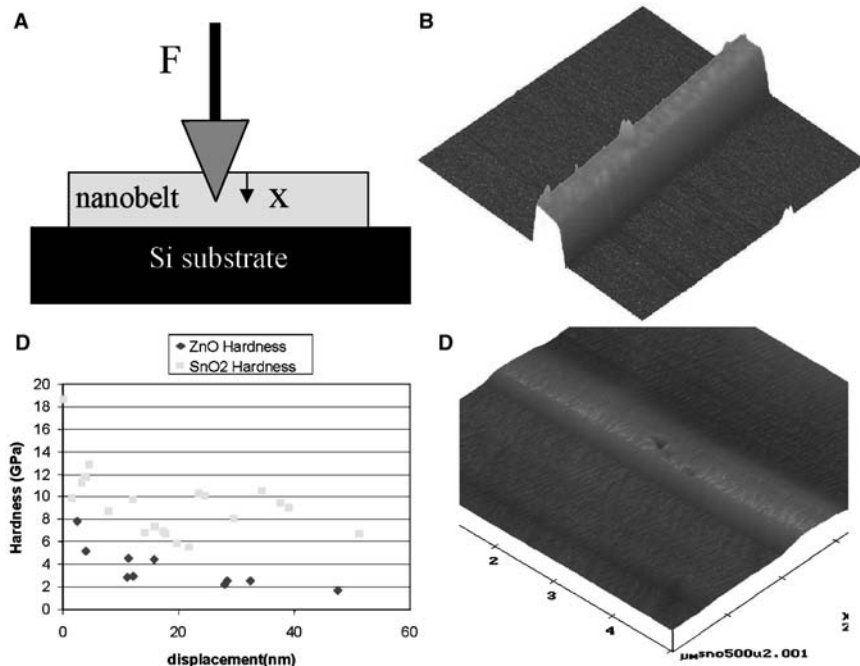

where  $H$ ,  $P_{MAX}$ , and  $A_C$  are the hardness, maximum applied load, and projected contact area at the maximum applied load, respectively. Because the indenter tip is not rigid during indentation, the elastic modulus cannot be directly determined from the load vs. the displacement curve. However, the reduced elastic modulus can be determined from the unloading

portion of the curve by the relation:

$$E_r = \frac{\sqrt{\pi}}{2} \cdot \frac{dP}{dh} \cdot \frac{1}{\sqrt{A_c}} \quad (10)$$

where  $E_r$  and  $dP/dh$  are the reduced modulus and experimentally measured stiffness, respectively.

Based on Eq. (9), using load vs. deflection curves during nanoindentation, the hardness of ZnO and SnO<sub>2</sub> nanobelts was calculated as a function of indentation penetration, and the result is summarized in Fig. 10D. The hardness of ZnO is lower than that in the SnO<sub>2</sub>

**Fig. 10** (A) Schematic of nanoindentation on ZnO by AFM tip. (B,C) AFM image of a nanobelt before and after being indented, showing plastic deformation on the surfaces. (D) Hardness of ZnO and SnO<sub>2</sub> nanobelts as a function of penetration during nanoindentation.

nanobelt. Also, it can be seen that the lower the penetration of the nanoindentation, the higher the hardness of the nanobelt, which is attributed to the strain gradient effect (size effect) during nanoindentation for most materials.<sup>[24]</sup> The effective elastic modulus can also be derived from the force–displacement curve and the result is  $E = 45$  GPa for ZnO, in good agreement with that from the resonance technique.<sup>[21]</sup>

## NANOBELTS AS NANOCANTILEVERS

The cantilever-based scanning probe microscopy (SPM) technique is one of the most powerful approaches in imaging, manipulating, and measuring nanoscale properties and phenomena. The most conventional cantilever used for SPM is based on silicon,  $\text{Si}_3\text{N}_4$  or SiC, which is fabricated by e-beam or optical lithography technique and typically has a dimension of thickness of  $\sim 100$  nm, width of  $\sim 5$   $\mu\text{m}$ , and length of  $\sim 50$   $\mu\text{m}$ . Utilization of nanowire- and nanotube-based cantilevers can have several advantages for SPM. Carbon nanotubes can be grown on the tip of a conventional cantilever and be used for imaging surfaces with a large degree of abrupt variation in surface morphology.<sup>[25,26]</sup> We demonstrate here the manipulation of nanobelts by AFM and its potential as nanocantilevers.<sup>[27]</sup>

**Fig. 11** A series of shape of a ZnO nanobelt created by manipulation using an AFM tip, showing deformation and break-up. *Source:* Image courtesy of M.S. Arnold, Ph. Avouris.

Manipulation of nanobelts is important for integrating this structurally controlled nanomaterial with microelectrical mechanical system (MEMS). Using an AFM tip, a nanobelt can be manipulated into different shapes (Fig. 11). A ZnO nanobelt of 56 nm in width can be bent for over  $60^\circ$  without breaking, demonstrating extremely high mechanical flexibility. Further bending bent the nanobelt into two segments. This is a technique for cutting a nanobelt into specific length.

Combining MEMS technology with self-assembled nanobelts, we are able to produce cost-effective cantilevers with much heightened sensitivity for a range of devices and applications. Force, pressure, mass, thermal, biological, and chemical sensors are all prospective devices. Semiconducting nanobelts are ideal candidates for cantilever applications. Structurally, they are defect-free single crystals, providing excellent mechanical properties. The reduced dimensions of nanobelt cantilevers offer a significant increase in cantilever sensitivity. The cantilevers under consideration are simple in design and practice. Using a Dimension 3000 SPM in tapping mode, we have successfully lifted ZnO nanobelts from a silicon substrate. Capillary forces are responsible for the adhesion strength between the AFM probe and the ZnO nanobelts. Combining the aforementioned techniques with micromanipulation has led to the alignment of individual ZnO nanobelts onto silicon chips (Fig. 12). The aligned ZnO cantilevers were manipulated to have a range of lengths. This exemplifies our ability to tune the resonance frequency of each cantilever and thus modify cantilevers for different applications such as tapping and contact mode AFM. The nanobelt-based nanocantilever is  $\sim 50$ – $1000$  times smaller than the conventional cantilever. Decreased size in microoptical mechanical devices corresponds to increased sensitivity. Combining the aforementioned techniques with micromanipulation has led to the horizontal alignment of individual ZnO nanobelts onto silicon chips (Fig. 12). This exemplifies our ability to tune the resonance frequency of each cantilever and thus modify cantilevers for different applications such as contact, noncontact, and tapping mode AFM.

## THE WORK FUNCTION AT THE TIP OF A NANOBELT BY RESONANCE TECHNIQUE

The field-emission property for well-aligned ZnO nanowire arrays has been reported,<sup>[28]</sup> demonstrating a promising application of semiconductor nanowires as field emitters for flat panel display. Following the Fowler–Nordheim (F–N) theory,<sup>[29]</sup> an important physical quantity in electron field emission is the surface work function, which is well documented for elemental materials. For the emitters such as ZnO

**Fig. 12** Site-specific placement and alignment of ZnO nanobelts onto a silicon chip, forming nanocantilever arrays. The inset is an enlarged SEM image of the third nanocantilever showing its shape; the width of the cantilever was measured to be 525 nm.

nanowire arrays, most of the electrons are emitted from tips of the nanowires, and it is the local work function that matters to the properties of the field emission. However, the work function measured based on the F-N theory is an average over the large scale of emitting materials. So it is necessary to measure the local work function at the tip of an individual emitter. Gao, Pan, and Wang<sup>[30]</sup> have measured the work function at the tips of carbon nanotubes by an in situ TEM technique. The measurement relies on the mechanical resonance of the carbon nanotube induced by an externally applied oscillating voltage with tunable frequency.

The measurement of the work function at the tip of a single ZnO nanobelt was carried out in situ at 200 kV in a Hitachi HF-2000 FEG TEM. A specimen holder was built for applying a voltage across a nanobelt

**Fig. 13** Experimental set-up for measuring the work function at the tip of a ZnO nanobelt.

and its counter gold electrode. The nanobelts to be used for measurements are directly imaged under TEM. Fig. 13 is a setup for work function measurement. One end of the nanobelt was electrically attached to a gold wire, and the other end faces directly against the gold ball. Because of the difference in the surface work function between the ZnO nanobelt and the counter Au ball, a static charge  $Q_0$  exists at the tip of the nanobelt to balance this potential difference.<sup>[31]</sup> The magnitude of  $Q_0$  is proportional to the difference between the work function of the nanobelt tip (NBT) and the Au electrode,  $Q_0 = \alpha (\phi_{Au} - \phi_{NBT})$ , where  $\alpha$  is related to the geometry and distance between the nanobelt and the electrode.

The measurement is based on the mechanical resonance of the nanobelt induced by an externally alternative electric field. Experimentally, a constant voltage  $V_{d.c.}$  and an oscillating voltage  $V_{a.c.} \cos 2\pi ft$  are applied onto the nanobelt (Fig. 13A), where  $f$  is the frequency and  $V_{a.c.}$  is the amplitude. Thus the total induced charge on the nanobelt is

$$Q = Q_0 + \alpha e(V_{d.c.} + V_{a.c.} \cos 2\pi ft) \quad (11)$$

The force acting on the nanobelt is proportional to the square of the total charge on the nanobelt

$$\begin{aligned} F &= \beta [Q_0 + \alpha e(V_{d.c.} + V_{a.c.} \cos 2\pi ft)]^2 \\ &= \alpha^2 \beta \{ (\phi_{Au} - \phi_{NBT} + eV_{d.c.})^2 + e^2 V_{a.c.}^2 / 2 \\ &\quad + 2eV_{a.c.} (\phi_{Au} - \phi_{NBT} + eV_{d.c.}) \\ &\quad \times \cos 2\pi ft + e^2 V_{a.c.}^2 / 2 \cos 4\pi ft \} \end{aligned} \quad (12)$$

where  $\beta$  is a proportional constant. In Eq. (12), the first term is constant and it causes a static deflection of the ZnO nanobelt. The second term is a linear term,

**Fig. 14** A plot of vibration amplitude of a ZnO nanobelt as a function of the applied direct current voltage, from which the offset voltage  $V_{dc0} = 0.12$  V.

and the resonance occurs if the applied frequency  $f$  is tuned to the intrinsic mechanical resonance frequency  $f_0$  of the ZnO nanobelt. The most important result of Eq. (12) is that, for the linear term, the resonance amplitude  $A$  of the nanobelt is proportional to  $V_{a.c.}(\phi_{Au} - \phi_{NBT} + eV_{d.c.})$ .

The principle of the measurement is as follows. We first set  $V_{d.c.} = 0$  and tune the frequency  $f$  to get the mechanical resonance induced by the applied oscillating field. Second, under the resonance condition of keeping  $f = f_0$  and  $V_{a.c.}$  constant, slowly change the magnitude of  $V_{d.c.}$  from zero to a value  $V_{d.c.0}$  that satisfies  $\phi_{Au} - \phi_{NBT} + eV_{d.c.0} = 0$ . At this moment, the resonance amplitude  $A$  becomes zero although the external a.c. voltage is still in effect. Therefore the work function at the tip of the ZnO nanobelt is  $\phi_{NBT} = \phi_{Au} + eV_{d.c.0}$ , while  $\phi_{Au} = 5.1$  eV. Fig. 14 is a plot of the vibration amplitude  $A$  of the nanobelt as a function of the applied direct current voltage  $V_{d.c.}$ , from which the value for  $V_{d.c.0}$  is determined. The work function of the ZnO nanobelts is  $\sim 5.2$  eV.<sup>[32]</sup>

## CONCLUSION

The property characterization of nanomaterials is challenged by their small-size structures because of the difficulties in manipulation. A typical example is the mechanical properties of individual 1-D nanostructures, such as nanotubes, nanowires, and nanobelts. This entry reviews the experimental methods for measuring the mechanical properties of 1-D nanostructures using a resonance technique in TEM. The static and dynamic properties of the 1-D nanostructures can be obtained by applying controllable static and alternating electric fields. The resonance of carbon nanotubes

can be induced by tuning the frequency of the applied voltage. The technique is powerful in such a way that it can directly correlate the atomic-scale microstructure of the carbon nanotube with its physical properties, providing a one-to-one correspondence in structure-property characterization.

Because of the rectangular cross section of the nanobelt, two fundamental resonance modes have been observed corresponding to two orthogonal transverse vibration directions, showing the versatile applications of nanobelts as nanocantilevers and nanoresonators. The bending modulus of the ZnO nanobelts was measured to be  $\sim 52$  GPa. Nanobelts have also been demonstrated as ultrasmall nanocantilevers for sensor and possibly imaging applications in AFM.

## INTRODUCTION

While force interactions are most commonly employed for probing, manipulation, and addressing of nanoscale features, dielectric contrast mechanisms are also potentially useful means of probing nanostructures. Optical absorption or emission, dielectric contrast in the infrared (IR), far-infrared (FIR), or microwave regime are all part of a rich pool of phenomena observable with electromagnetic interactions, with applications in nanoelectronics, spintronics, and biotechnology being developed. To attain the highest resolution, it is necessary to confine the area in which the probing field interacts with the sample to subwavelength dimensions. This is accomplished by fabricating probes with subwavelength-sized features and scanning such near-field probes very close to the sample. This article summarizes such near-field techniques in the visible, IR, and microwave regime and relates them to current and future applications.

## HISTORICAL OVERVIEW

Doing microscopy with electromagnetic waves usually implies using visible light. This is because Abbe's<sup>[1]</sup> much-cited criterion limits resolving power to  $\sim \lambda/2$  (where  $\lambda$  is the wavelength), so using millimeter wave and infrared frequencies would result in unattractively low resolution. While this criterion is correct for far-field microscopy, it is not limiting when near-field interactions are taken into account. Theoretical considerations were first published by Synge<sup>[2]</sup> in 1928 and Bethe<sup>[3]</sup> in 1944. The first practical implementation of near-field microscopy was developed for radio frequency applications by Frait<sup>[4]</sup> (1959) and Soohoo<sup>[5]</sup> (1962). Further important milestones were the first use of a coaxial waveguiding probe to localize microwave fields for measuring material properties by Bryant and Gunn<sup>[6]</sup> in 1965 and  $\lambda/60$  wavelength-relative resolution

achieved by Ash and Nichols<sup>[7]</sup> in 1972 using a subwavelength aperture. The advent of scanning tunneling microscopy (STM)<sup>[8]</sup> and subsequent scanning probe techniques provided a means by which accurate nanoscale tip-sample distance control became possible for the first optical near-field microscopes.<sup>[9,10]</sup> Finally, the advent of scanning force microscopy (SFM) in 1986<sup>[11]</sup> allowed for near-field scanning optical microscopy (NSOM or SNOM) instruments relying on (shear-) force feedback<sup>[12]</sup> in 1992. From that point, near-field microscopy has spread through a wealth of techniques and applications to form a diverse and very active field of research.

## SCANNING NEAR-FIELD OPTICAL MICROSCOPY

### Fiber Probes

For visible wavelengths, the most common probe type today uses tapered optical fibers that are coated with an opaque metal layer except at the apex where a small opening defines the optical output (Fig. 1). The shear-force feedback signal is commonly electronically detected using tuning fork feedback.<sup>[14]</sup> In comparison to SFM probes, straight SNOM fibers are much stiffer and more fragile, leading to slower scan speeds and difficulties in establishing reliable feedback, particularly on soft samples. Another major concern for optical near-field microscopy is the low-power throughput of NSOM fibers because they act as cutoff waveguides for light near the apex. To improve transmission over that of the common technique of pulling heated fibers, meniscus etching<sup>[15]</sup> and double-tapered probes have been used.<sup>[16]</sup> Tube etching, a technique where the polymer coating of the fiber is not removed prior to etching, has been introduced.<sup>[17]</sup> Typical applications for fiber-NSOM instruments are found in chemistry, biology, material science, and integrated optics, e.g.,

**Fig. 1** A scanning electron micrograph of a typical tapered aluminum-coated optical fiber tip. *Source:* From Ref.<sup>[13]</sup>. © 1995 American Institute of Physics.

single molecule spectroscopy,<sup>[18]</sup> cell membrane structure<sup>[19]</sup> analysis, and optical waveguide mapping<sup>[20]</sup> (Fig. 2). Another field of activity is to use NSOM as a means for high-density optical data storage.<sup>[21]</sup> Further information regarding aperture NSOM can be found in two review articles by Hecht et al.<sup>[22]</sup> and Dunn.<sup>[23]</sup>

### Apertureless Probes

Apertureless SNOM is the complement to aperture SNOM. Apertureless SNOM includes a wide variety of related approaches, including the use of surface plasmons and scattering-type SNOM (s-SNOM). While the use of plasmon-guiding effects to localize light is still in its infancy, considerable interest in this field exists<sup>[24]</sup> because light throughput might be increased by orders of magnitude, e.g., through the use of a tetrahedral tip with an integrated surface-plasmon guide as a scanning probe.<sup>[25]</sup>

The s-SNOM technique is a prime example of apertureless SNOM.<sup>[26]</sup> Here a sharp probe, typically an STM or SFM probe, is scanned over an illuminated surface (Fig. 3). The optical contrast of s-SNOM arises from the dipole-dipole interaction between the sharp tip and the sample, leading to characteristic local scattering [more about the theory can be found in the section about infrared (IR) near-field microscopy]. The main advantage of s-SNOM is that the resolution is not limited by an aperture or the skin depth of metal, but rather by the sharpness of the probing tip, potentially leading to better resolution. This advantage has been used to localize polymerization of commercial photoresists in an effort to push the resolution of optical lithography. Resolutions down to 70 nm were recently reported using this technique.<sup>[28]</sup> An s-SNOM setup was also used to simultaneously record optical amplitude and phase contrast on a subwavelength scale.<sup>[29]</sup>

## Integrated Probes

Finally, researchers have been microfabricating SNOM probes that could be applied in the same fashion as cantilevered SFM probes, with minor instrumental changes. Some of the proposed concepts are passive, such as metal-coated probes with circular<sup>[30]</sup> apertures and solid immersion lenses on cantilevers<sup>[31]</sup> (strictly speaking a far-field technique). Initial efforts have been made to fabricate active devices in GaAs that include integrated light sources.<sup>[32]</sup> Considerably more research has been performed to produce photodetectors integrated close to the probe<sup>[33,34]</sup> or right at the apex of the sharp tip,<sup>[35]</sup> preferably integrated with the cantilever and chip body.<sup>[36]</sup>

## SCANNING NEAR-FIELD INFRARED AND FAR-INFRARED MICROSCOPY

Because of the wealth of chemical information available through vibrational band spectroscopy, many traditional infrared techniques such as Fourier-transform infrared spectroscopy (FTIR), thermal probing, and Raman scattering have become cornerstones of chemical characterization. In recent years, characterization of optoelectronic devices in the IR also gained importance for probing integrated-circuit lasers. Proximal probes offer a way to combine IR imaging with subwavelength resolution. Fiber-based aperture scanning near-field infrared microscopy (SNIM) setups, similar to optical fiber NSOM instruments, have been developed, based on special infrared transmissive fibers and etching techniques.<sup>[37]</sup>

The far-infrared (FIR) spectrum ( $10 \mu\text{m} < \lambda < 1 \text{mm}$ ) is of particular interest because it is part of the molecular fingerprint regime. Here characteristic molecular rotational or vibrational absorption spectra offer the promise of chemical microscopy. Biological membrane absorption and conductive or dielectric properties of materials, e.g., superconductors and quantum dots, offer additional applications for FIR near-field microscopy. Little work has been performed in this frequency regime, mostly because high-power FIR sources and sensitive FIR detection are not yet readily available.

### Aperture Techniques

One practical FIR technique is to use a three-dimensional funnel or tapered cylindrical waveguide to confine radiation in an aperture approach. This geometry was employed<sup>[38]</sup> to overcome the imperfect focusing capabilities of traditional FIR optics. Power transmittance in the

**Fig. 4** The relative transmittance at a wavelength of  $\lambda = 392 \mu\text{m}$  of focusing cones with different output apertures is investigated. Adding a central, coaxial wire prevents cutoff reflection at  $d < \lambda/2$ . Source: From Ref.<sup>[39]</sup>. © 1995 Elsevier Science.

cutoff region is

$$T = e^{-4\pi\sqrt{f_c^2 - f^2}t}$$

where  $t$  is the penetration depth into the cutoff region, and  $f$  and  $f_c$  are the frequency of the radiation and the cutoff frequency, respectively. In practice, a sharp cutoff in transmitted intensity was found at an aperture size of about  $\lambda/2$ . This setup was then applied for far-infrared near-field spectroscopy of two-dimensional electron systems.<sup>[38]</sup> Aperture confinement of FIR radiation has been one of the leading techniques to date<sup>[39,40]</sup> because of its straightforward implementation. Keilmann et al. showed that by introducing a center conductor into the tapered hollow guide and creating an in situ coaxial waveguide, the aperture size can be decreased by almost an order of magnitude without losing transmitted power (Fig. 4). It was also found that the transmitted power varies with a period of  $\lambda/2$  as the length of wire protruding from the aperture is extended because it acts as a resonant antenna.

### Apertureless Techniques

Using apertureless (scattering) SNIM (Fig. 3) in the IR and FIR has even better prospects than in the visible regime. For one, because the resolution depends on the scattering tip, not the wavelength, the wavelength-specific resolution is far better. Far-infrared microscopy with nanometer resolution is possible and has been demonstrated.<sup>[41,42]</sup> Furthermore, because the wavelength is much longer than the occasional

**Fig. 5** (A) Infrared s-SNOM image of a flat Si sample with subsurface doping (bright), taken at  $\lambda = 10.59 \mu\text{m}$ . (B) Line scans taken across doping stripes, measured at four different wavelengths, demonstrating 30-nm spatial resolution and a contrast reversal when the infrared wavelength tunes through the induced plasmon resonance, here at about  $\lambda = 10 \mu\text{m}$ . Source: From Ref.<sup>[27]</sup>. © 2000 American Institute of Physics.

distance variations between tip and sample, optical interference effects play less of a role, reducing the risk of topographical artifacts in the optical data. In scattering-type instruments, it is also possible to eliminate topography contrast and record pure optical contrast.<sup>[42,43]</sup> Here when applying noncontact SFM, the nonlinear dipole–dipole interaction between the tip and sample leads to (purely optical) higher modulation harmonics in the scattered signal, which can be used for lock-in detection. Following one argument,<sup>[42]</sup> image contrast arises from the interaction between the polarizable probe (modeled as a sphere with polarizability  $\alpha$  and radius  $a$ ) and the dielectric or metallic sample with complex dielectric number  $\epsilon$ . This results in an effective polarizability of the coupled system

$$\alpha_{\perp}^{\text{eff}} = \frac{\alpha(1 + \beta)}{1 - \frac{\alpha\beta}{16\pi(z+a)^3}}$$

where  $\beta = (\epsilon - 1)/(\epsilon + 1)$ . This formula shows both strong enhancement at short probe–sample separation  $z$  and the existence of amplitude and phase effects because  $\alpha$  and  $\beta$  are complex. Thus the scattered far field  $E_{\text{sca}} = \alpha^{\text{eff}}E$  reports the phase and amplitude of the complex near-field interaction. With this technique, Knoll and Keilmann<sup>[27]</sup> have mapped conductivity of a silicon sample with nanometer resolution using a scattering-type near-field microscope and 10.6- $\mu\text{m}$  radiation as shown in Fig. 5. The same researchers<sup>[44]</sup> reported contrast between polystyrene (PS) and polymethylmethacrylate (PMMA) on the nanometer scale using the same instrument and two wavelengths around 10  $\mu\text{m}$  (Fig. 6). Hillenbrand et al.<sup>[45]</sup> applied this instrument to probe the local interaction with an

SiC sample and found phonon-enhanced near-field coupling that is extremely sensitive to the chemical and structural composition of polar materials.

### Additional Techniques

Another promising approach is to use antenna structures as near-field sources.<sup>[46,47]</sup> While any coaxial open-ended waveguide can be considered an antenna, guiding radiation at visible or infrared wavelengths is

**Fig. 6** Simultaneously acquired topography (left) and infrared images (right) of PS embedded in PMMA using an s-SNOM. The upper row is recorded with an illumination wavelength of  $\lambda = 9.68 \mu\text{m}$ , where PS has an absorption maximum. The lower row shows the same spot, illuminated at the PMMA absorption maximum wavelength of  $\lambda = 10.17 \mu\text{m}$ . The field of view is  $3.5 \times 2.5 \mu\text{m}$ . Source: From Ref.<sup>[44]</sup>. © 1999 Nature.

not yet technologically feasible. However, by using antennas that collect far-field radiation and channel it to near-field tips for exciting the sample, antenna concepts can be very effective. Other approaches for FIR near-field microscopy include THz time domain spectroscopy (TDS) using photoconductive THz emitters<sup>[40]</sup> pumped by femtosecond optical lasers and all-electronic generation of THz radiation with nonlinear transmission lines (NLTL).<sup>[48]</sup>

Aperture probes, scattering probes, and coaxial tips form the main body of research on near-field microscopy as it is applied in NSOM. An entirely different approach to infrared microscopy lies in the use of photothermal signals for near-field spectroscopy.

Here a thermal probe in temperature-sensing mode directly measures absorption of incident IR radiation by sensing the induced heating of the sample. This heating can either be directly measured for each wavelength in the dispersive approach<sup>[49]</sup> or a Fourier-transform absorption spectrum can be acquired when using intensity-modulated illumination.<sup>[50]</sup> Many other thermal techniques exist, e.g., scanning thermal microscopy (SThM) where the tip is used to heat the sample and sense heat flow out of the probe. More about localized thermal imaging can be found in a review by Kölzer et al.<sup>[51]</sup> Reviews of near-field infrared microscopy and near-field vibrational spectroscopy have been written by Dragnea and Leone<sup>[52]</sup> and by Pollock and Smith.<sup>[53]</sup>

## SCANNING NEAR-FIELD MICROWAVE MICROSCOPY

Unlike in the visible or infrared regime, metals are good conductors for microwave frequencies. Metal waveguides are an efficient means of transmitting

microwave power and can be subwavelength sized in cross section. Microwave near-field probes are either broadband or resonant, which can make them more sensitive, but also more limited in the frequency range in which they can be operated.

## Coaxial Waveguides

An advantageous waveguide design is to use tapered coaxial waveguide probes that increase resolution and provide high throughput. For the highest resolution, a sharpened center helps concentrate the fringing fields emanating from the probe apex (lightning rod effect) and thus confines the interaction area between the probe and sample. Proof-of-principle experiments with a sample between two such sharpened coaxial transmission line tips by Keilmann et al.<sup>[54]</sup> resulted in  $\lambda/10^6$  wavelength-relative resolution. Integrating coaxial structures with cantilevered SFMs enables microscale probing of passive or active samples in reflection or transmission mode, respectively. Initial probes by van der Weide et al.<sup>[55]</sup> were made by coating a commercial silicon SFM probe with photoresist and gold, then opening the coaxial structure by gently rubbing the tip on a substrate while in feedback. These probes allowed for local measurements of waveforms on fast integrated circuits. Microfabricated probes (Fig. 7)<sup>[36]</sup> have various advantages, among them higher resolution and batch fabrication. Probes made from GaAs report superior signal transfer.<sup>[57]</sup>

## Scanning Tunneling Microscopy-Based Microwave Microscopy

Just as with SFM, STM can offer a tip-sample distance feedback system for microwave near-field

**Fig. 7** (A) Scanning electron micrograph of a nanometer-scale Schottky diode at the apex of an SFM tip. (B) This SNOM detector is integrated on a cantilever and chip body that contains waveguides for straightforward connection to macroscopic instrumentation. *Source:* From Ref.<sup>[56]</sup>. © 2002 American Institute of Physics.

microscopy while providing a sharp conducting tip to localize high-frequency electromagnetic interaction. One such system was developed by Kramer et al.<sup>[58]</sup> Here higher harmonic signals are generated because of tunnel junction nonlinearities. Because the higher-harmonic generation strongly depends on the electronic properties of the surface, it is possible to differentiate different chemical species. McCarty and Weiss<sup>[59]</sup> and Michel et al.<sup>[60]</sup> have explored this possibility in a number of publications. These instruments have been applied from d.c. to 20 GHz, recording linear or nonlinear (higher-harmonic)<sup>[61]</sup> microwave spectra. Usually, topography has been controlled using conventional STM while simultaneously recording millimeter wave amplitude in transmission or reflection mode.

### Apertureless Approaches

Scattering of incident far-field microwave radiation from a conducting tip in close proximity to a sample is analogous to s-SNOM in the visible, IR, or FIR regions. Thus numerical and theoretical treatments of s-SNOM can be applied to the microwave regime if certain material constants, such as indices of refraction, are revised. Surprisingly, although the resolution of such a microscope is defined by the sharpness of the tip and can lie in the nanometer range, little research has been carried out in this field. Keilmann et al.<sup>[62]</sup> described the coaxial setup specified above<sup>[58]</sup> as essentially equivalent to an s-SNOM setup for the microwave regime. Instead of using far-field optics to focus the radiation, they use coaxial cables to direct the fields, which is much more convenient for microwave frequencies. They point out that the resolution achieved is already an order of magnitude higher than the microwave penetration depth of the tip material, indicating that no intrinsic physical mechanism seems to exist that would limit the resolution achievable.

### Ultrafast Scanning Tunneling Microscopy

Ultrafast scanning tunneling microscopy (USTM) was independently invented by Weiss et al.<sup>[63]</sup> and Nunes and Freeman<sup>[64]</sup> in 1993. Both techniques rely on pump and probe experiments for highest temporal resolution. Using femtosecond lasers that repetitively illuminate photoconductive (PC) switches ensures high temporal resolution, while using a sharp tip gives the additional benefit of high spatial resolution. The nonlinear current vs. voltage tunneling characteristics are employed to measure the picosecond cross-correlation. In the setup of Nunes, pump and probe travel along one transmission line while Weiss employs the more common setup of pumping the sample and probing the tunneling tip as shown in Fig. 8.

**Fig. 8** Localized pump and probe setup that uses photoconductive switches to trigger a pulse on the DUT and to probe the instantaneous voltage on the DUT through the tip. *Source:* (From Ref.<sup>[65]</sup>. © 1996 American Institute of Physics.

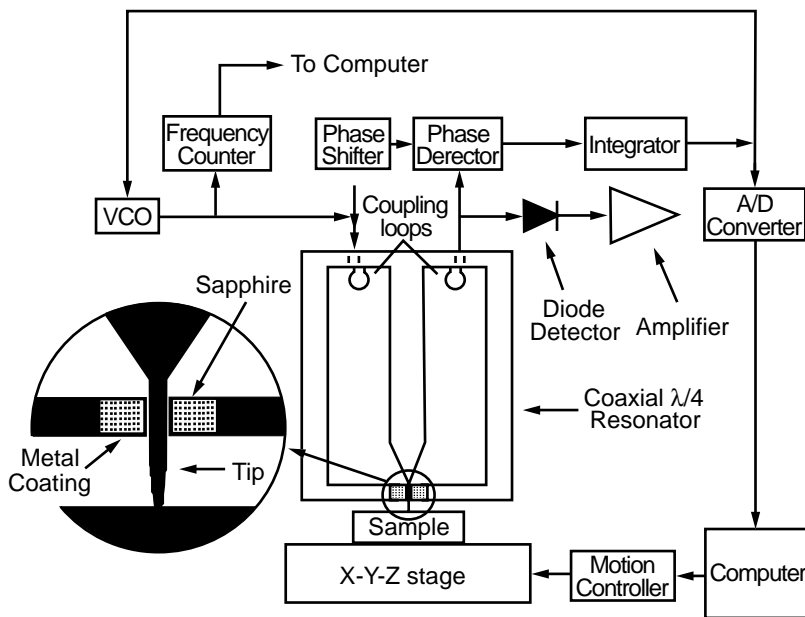

A related pump-probe technique was introduced by Kim et al.<sup>[66]</sup> that relies on direct conduction through a tip. They brought a probe with Ti tip, PC switch, and electric lead into contact with a transmission line. The convolution between pump pulse and probe pulse could be mapped out by probing the instantaneous electric field at the tip position by opening the PC switch and collecting the signal transmitted through the tip. Takeuchi and Mizuhara<sup>[67]</sup> improved on this concept by using an LT-GaAs tip and employing SFM feedback. A propagating pulse on a metal strip was mapped in 2-D and observed in sequential images with 0.8-psec time intervals.

Oesterschulze et al.<sup>[68]</sup> have also reported on an SFM setup with Lt-GaAs probe and PC switches. Here contact and noncontact images of a voltage pulse on a coplanar stripline were presented with picosecond temporal resolution.

### Resonant Probes

Resonant structures are superior in that they allow localization of high field areas and are often more sensitive. However, most resonant techniques do not allow for resolution on the single micrometer scale or below. Among those larger-scale probes are narrow resonant slots in a rectangular hollow waveguide<sup>[69,70]</sup> and open resonant coaxial resonators.<sup>[71]</sup>

For higher resolution, Tabib-Azar et al.<sup>[72]</sup> have used a tapered stripline resonator for near-field microwave microscopy in a series of publications. The resonator is designed by capacitively coupling to the stripline, and a sharpened stainless steel wire was used as a probe tip. Because the strong distance

**Fig. 9** Resonant SNMM setup using a coaxial cavity. *Source:* From Ref.<sup>[73]</sup>. © 1997 American Institute of Physics.

dependence of the reflected signal is also present in this resonant setup, an independent distance control was employed. The researchers used a reflectance-compensated fiber optic distance sensor next to the tip and maintained the probe-sample separation with an accuracy of  $0.4\ \mu\text{m}$ . The researchers claim  $0.4\ \mu\text{m}$  spatial resolution at 1 GHz for this instrument.

High-resolution microwave near-field probes incorporating  $\lambda/4$  coaxial resonators have been produced by the group of Xiang<sup>[73]</sup> using an STM-like tip as a point-like field emitter, protruding from a small aperture (Fig. 9). The sharp tip results from tapering the center conductor of the coaxial cavity. The instrument achieves a spatial resolution of 100 nm and was used to image dielectric-constant profiles and ferroelectric domains.<sup>[74]</sup> Ferroelectric domains can be imaged using microwave fields by taking advantage of the nonlinear components in the dielectric constant for these materials. The contrast mechanism is based on a low-frequency oscillating voltage between sample and substrate that modulates the effective dielectric constant of the sample. The slight shift of the resonance frequency in the coaxial resonator probe could be related to this variation in dielectric constant, allowing for quantitative mapping of the third-order dielectric constant in a ferroelectric domain structure as seen in Fig. 10. To decrease tip damage resulting from excessive forces on the tip, and to be able to image unprepared conducting samples, Duewer et al.<sup>[75]</sup> introduced a tip-sample feedback scheme based on regulating the resonance frequency of the cavity to maintain a constant separation. In this experiment, conductivity was simultaneously measured via the amplitude of the cavity resonance. The principle for resistivity microscopy is

**Fig. 10** Linear dielectric constant image (A) and nonlinear third-order dielectric constant image (B) of the same area of a  $\text{LiNbO}_3$  single crystal with periodically polarized ferroelectric domains, recorded using a coaxial resonator SNMM. *Source:* From Ref.<sup>[74]</sup>. © 1998 American Institute of Physics.

based on the fact that the reflection of electromagnetic waves from conducting surfaces is determined by their resistivity. Therefore measuring the reflected amplitude and phase of a near-field probe yields a resistivity map. The reflection coefficient of a plane wave from a conducting surface is

$$\Gamma = \left( \frac{Z_s - Z_0}{Z_s + Z_0} \right)$$

where  $Z_0$  is the characteristic impedance of the line and  $Z_s$  is the surface impedance, which is directly connected to the conductivity:

$$Z_s = \sqrt{\frac{i\omega\mu_0}{\sigma + i\omega\epsilon}}$$

where  $\omega$  is the radial frequency,  $\mu_0$  is the permeability of free space, and  $\epsilon$  is the dielectric constant. For thick conducting layers, much thicker than the skin depth, surface impedance is measured while thin layers yield sheet resistance. Another important application of evanescent microwave probing is to measure spatially resolved surface impedance of high-temperature superconductor films. By finding superconducting and normally conducting features on superconducting thin films, it is possible to localize defects and evaluate film quality. The contrast mechanism is based on variations in microwave absorption when keeping the sample close to the critical temperature.<sup>[76]</sup> Others employ room temperature normal-state measurements<sup>[77]</sup> and relate them to the film's superconducting properties.

Tabib-Azar et al.<sup>[78]</sup> have used evanescent microwave probes for several nontraditional probing applications. These include transient and steady state thermography on semiconducting materials with 0.01 K thermal and 1  $\mu$ s temporal resolution. We recently published a review of near-field microscopy in the microwave and infrared regime.<sup>[56]</sup>

## CONCLUSION

We have summarized recent and current trends in optical, infrared, and microwave near-field microscopy incorporating surface force feedback. In the visible regime, the most common techniques are fiber-based aperture microscopes and scattering-type setups using AFM tips. On the other side of the spectrum in the microwave regime, metallic waveguide geometries play a dominant role. Future developments will enable combined probing of topography and field at the nanometer scale. The development of tools and instruments for mechanical manipulation of structures at nanometer length scales has driven progress in

nanoscale science and technology. At these scales, the doors to new worlds in biology, chemistry, and physics begin to open, enabling new applications such as real-time protein structure identification, molecular electronics, and quantum computation. However, to approach these ambitious applications, a great instrumental challenge must be surmounted: Tools must not only be able to touch, hold, and move molecular-scale objects, but must also be able to identify and control molecules and molecular-scale objects such as nanowires based on their chemical species or function. Near-field probes that combine access to dielectric contrast mechanisms at the nanometer scale hold out this promise.

Chico, California, U.S.A.*

## INTRODUCTION

Near-field Raman Spectroscopy (NFRS) combines the chemical-information-gathering power of Raman spectroscopy with the spatial resolution of the atomic force microscope (AFM). In addition, it allows the researcher to correlate topographic and optical data in ways impossible via other techniques. This entry presents an overview of the methods used in NFRS, a brief history of the field, and a tour of some recent achievements in this rapidly evolving field. As with any other field at this stage of development, there are still unanswered questions in NFRS; some of these will be addressed as well.

## NEAR-FIELD SCANNING OPTICAL MICROSCOPY

Microscopy is one of the most powerful tools available in modern science. Much of our basic understanding of the world comes from our ability to see the details of how things operate. Until recently, however, the available resolution for optical microscopes has been limited by diffraction effects arising from the wave nature of light. Near-field scanning optical microscopy (NSOM) provides a means of surpassing those limits, thus bringing to the researcher a variety of research tools available in visible-light optics at resolutions previously unattainable at those wavelengths. Because near-field Raman microscopy (NSRM) obtains both its resolution and its enhancement effects from the characteristics of light in the near field, it is necessary to begin any discussion of NSRM with an overview of NSOM.

### Resolution Limits to Conventional Microscopy

The fundamental limit to resolution of conventional optical microscopes arises from the nature of light. Because light is a wave, it diffracts on interaction with the sample being studied. The diffraction angle depends on the light frequency and the spatial frequency of the features on the sample. In order to resolve an object, it is necessary to collect not only

the central zeroth-order diffracted light, but some of the higher orders as well.<sup>[1]</sup> These higher-order diffraction maxima contain the spatial information.

As an example, consider a one-dimensional sample with some contrast mechanism having two distinct spatial frequencies (Fig. 1). Here, the contrast is represented as height; it could be contrast in color, refractive index, reflectivity, optical density, fluorescence, or anything else observable with light. The lens shown in Fig. 1 has sufficient numeric aperture (NA) to capture the light diffracted from the larger features, but light diffracted from the smaller features is not collected. Thus, the image formed does not include the components with higher spatial frequency. A lens with a higher NA could collect the light from these smaller features, but there is a practical limit to how far this sort of improvement can go. The highest NA obtainable with oil-immersion lenses is just over 1.4, resulting in a minimum resolution of roughly 250 nm for visible light.

### How to Avoid Resolution Limits

NSOM allows higher resolution than would be allowed by the Abbe limit. It does this by utilizing the continuity of the fields near an aperture or sharpened conductor. The illumination pattern cannot change instantaneously from subwavelength source spot to broad far-field spot. In the far field, defined as distances greater than a few tip radii from the source, light is diffracted at extremely high angles and illuminates a broad region. At the tip, the light is constrained to a region near the tip.<sup>[2]</sup> Close to the tip, in the near field, the light is still limited to a relatively small region, on the order of the tip radius. By holding the sample within this near-field region, the illuminated area on the sample is kept small—smaller than would be allowed by the Abbe limit. Light interacting with the sample can be collected in the far field with conventional optics. Although the collection optics are incapable of resolving that illuminated region, the light collected is known to have originated from a well-defined small spot; by scanning the aperture over the sample one can form a rasterized image with optical resolution approximately equal to that spot size.

**Fig. 1** The origin of the resolution limit in conventional microscopy. Object (A) has a contrast profile (B) with two distinct spatial frequencies. Light from the sample is diffracted by the larger features at angle (C), and by the smaller features at angle (D). The lens (E) collects only the light diffracted by the larger features, so the resulting image (F) contains information about only the larger features (G). Increasing the magnification would create a larger image of (G), with no increase in information content.

In the region near the tip, often called the near-field enhancement region, the electric field decreases exponentially with distance. This is of particular importance in Raman applications, where the enhanced electric field in the near field can result in significantly increased Raman signal and may be responsible for other effects as well.

The earliest NSOM systems used a sharpened optical fiber as a tip. This was prepared by either heating and pulling or boundary-layer chemical etching<sup>[3]</sup> and then was coated with metal to constrain the electric field to the interior of the tip. An aperture at the end of this tip is formed by focused ion-beam machining or, more commonly, by holding the tip at an angle during the metal-coating process so that the end was shadowed and not coated. This subwavelength aperture is held close to the sample and acts as a light source or detector, or both, depending on the experimental configuration. More recent systems have used a sharpened metallic tip or metal-coated AFM tip as a scattering source. This “apertureless” tip is held near the sample as before, and then illuminated externally.

### Behavior of Light Near a Tip

The problem of diffraction through a subwavelength aperture was first solved by Bethe<sup>[4]</sup> and later improved

by Bouwkamp.<sup>[5]</sup> Their solution assumes a circular aperture in an infinitely thin, flat, perfect conductor. Other work has been done, e.g., with numeric calculations of the field components near a two-dimensional tip (a slit) with a more realistic tip profile made of real materials<sup>[6]</sup> and apertureless NSOM.<sup>[7–9]</sup> All of these calculations show the same basic characteristics in the resulting fields: very strong distance dependence, evanescent fields near the tip, and dependence on polarization.

The square of the electric field for light emerging from a tip aperture with the original polarization (Bethe–Bouwkamp model) is shown in Fig. 2. Here the aperture radius is one-fifth the wavelength of the light, and the electric field magnitude is calculated at a distance of one-tenth the aperture radius. Some light emerging from the aperture is polarized at 90° to the incident light; this profile (with the same tip parameters) is shown in Fig. 3. There is also a relatively strong component of the emerging light that is polarized in the direction of propagation, which is shown in Fig. 4. All of these fields, with the exception of the central component of the first, die out rapidly with increasing distance from the tip. Fig. 5 shows the field profile at increasing distance from the tip for the first case, corresponding to Fig. 2.

For apertureless tips, there is a similar enhancement region near the tip. Typically, the tip is modeled as a conical metal probe with a spherical apex. The enhancement region extends over a region approximately the size of the diameter of the tip apex, and only the component of the light polarized in the direction of the tip axis is strongly enhanced. This enhancement occurs for both metallic and dielectric probes, but for metallic probes there is additional enhancement because of surface plasmon–polaritons at the apex of the tip.<sup>[9]</sup> One significant advantage to apertureless tips

**Fig. 2** Near-field enhancement. Graph height represents the intensity of the light emerging from a circular subwavelength aperture with the incident ( $x$ ) polarization, with an aperture size  $a$  equal to one-fifth the wavelength, at a distance of one-tenth  $a$ .

**Fig. 3** Near-field enhancement, showing the component of the light intensity polarized at  $90^\circ$  ( $y$ ) to the incident light. The aperture parameters are the same as in Fig. 2.

is that the incident light intensity is not subject to the limitations<sup>[10]</sup> imposed by the threat of thermal breakdown of the reflective coating on a fiber optic tip. Ordinary lenses are used to focus the light on the tip, either from the side or through the sample from below with a high-NA lens.<sup>[11]</sup> The illuminated region is much larger than the tip; but the signal from the enhancement region at the tip is by far the dominant component of the collected signal.

### Tip–Sample Distance Regulation

For either aperture or apertureless NSOM and NSRM, it is necessary to hold the tip at a close and well-regulated distance from the sample. The feedback mechanism responsible for maintaining this near-field distance is central to any microscope head design and depends on the type of tip used. Frequently, tips are formed by coating commercial cantilever AFM tips

**Fig. 4** Near-field enhancement, showing the component of the light intensity polarized in the direction of the incident light ( $z$ ). The aperture parameters are the same as in Fig. 2.

**Fig. 5** Line cuts showing distance dependence of near-field enhancement. The line at  $0.1a$  is a cut through the center of Fig. 2; the others show how that enhancement changes with distance.

with metal. If this is the case, it is simplest to use standard AFM feedback methods, described elsewhere. If the tips used are formed from optical fibers or etched metal wires, or if it is desirable to control the tip–sample distance more precisely than is possible with relatively flexible cantilever AFM tips, then shear-force feedback must be used. In shear-force feedback, the tip is shaken, at or near its resonance, in a plane perpendicular to the plane of the sample. Some measurement of the tip oscillation amplitude is made, and as the tip approaches the sample this amplitude decreases. The feedback electronics keep the tip positioned via piezoelectric actuators so that the amplitude remains at some intermediate value between its free-oscillation value and zero. By recording the adjustment necessary to maintain a constant tip–sample distance, it is possible to map the topographic features of the sample. This topographic detail can then be correlated to the optical information for a better understanding of the phenomena being observed.

The earliest method of shear-force tip–sample distance control was optical feedback. In an optical feedback system, a laser beam is focused on the oscillating fiber near the tip. The diffraction pattern “shadow” of the tip falls on an edge-masked detector. The signal from this detector serves as a measurement of the tip oscillation amplitude, and thus provides a shear-force feedback signal.

In recent years, optical feedback has been largely superseded by tuning-fork feedback.<sup>[12]</sup> In the tuning-fork method for distance regulation, the optical fiber or wire, with the subwavelength aperture or tip at the end, is glued to the side of a small quartz tuning fork. The fork/tip assembly is shaken at or near its

resonance, and the piezoelectric tuning fork provides an electric signal proportional to the amplitude of oscillation of the tip. The tuning-fork method offers considerable advantages over the optical feedback method. It eliminates the difficulty of aligning and focusing the feedback laser with the fiber and edge mask. With optical feedback, any drift in feedback laser power or alignment of the feedback optics can be misinterpreted as a change in feedback level, causing problems in low-light experiments requiring long integration times. Tuning-fork feedback provides a feedback signal that is much more stable on long scans. Finally, tuning-fork feedback does not require a second laser beam, thus eliminating one more source of noise in spectroscopic or fluorescence applications.

## RAMAN SPECTROSCOPY

Raman spectroscopy, discovered in 1928 by Chandrasekhara Venkata Raman, is the spectroscopy of vibrational transitions measured by the inelastic scattering of light. The energy of vibrational levels typically corresponds to wave numbers of  $10^2$  to  $10^4 \text{ cm}^{-1}$ , compared with the  $10^4$  to  $10^6 \text{ cm}^{-1}$  of valence electron transitions seen with visible and UV spectroscopy. The light wavelength required for absorption spectroscopy in this energy range is in the infrared to far-infrared range. This range of wavelengths is inconvenient to work with: appropriate optical materials for this entire range of wavelengths are scarce or non-existent, requiring different gratings and detectors for different portions of the region, entirely reflective optics, and relatively large sample volumes. By measuring these transitions with inelastic scattering, it is possible to cover the entire vibrational spectrum with a single recording using easily managed visible light. In addition, the selection rules for IR spectroscopy and for Raman spectroscopy are markedly different. Some vibrations are strongly IR active but weak or non-existent in Raman; others are strongly Raman active but weak in IR. The two tools should be regarded as complementary: For a complete understanding of the vibrational levels of the material, it is often necessary to study both IR and Raman spectra.

Raman spectroscopy has advantages over IR spectroscopy. The primary advantage is the ability to do the spectroscopy with visible light. The benefits of using conventional optics, readily available light sources, and visible-light alignment are not to be underestimated. Another advantage is the ability to work with small sample volumes. Micro-Raman systems typically can work with a sample region of about 1- $\mu\text{m}$  diameter on a surface, whereas IR spectroscopy,

as an absorptive phenomenon, requires a larger volume of material to have a significant effect. Water is a strong absorber of IR light, so it is difficult to do IR spectroscopy of compounds in aqueous solution, but water is a weak Raman scatterer, making it ideal for the study of biological materials in solution.

In the classical one-dimensional derivation of the Raman effect,<sup>[13]</sup> the polarization  $P$  of the material depends on the polarizability  $\alpha$  of the material and on the incident electric field  $E$ , which is provided by the incident light at frequency  $\nu_o$ :

$$P = \alpha E_o \cos(2\pi\nu_o t) \quad (1)$$

The electric field magnitude  $E_o$  is presumed to be constant over the dimensions of the oscillation. This is an excellent approximation for visible light in the far field. Charges in the material may oscillate at some frequency  $\nu_m$  about their equilibrium positions:

$$q = q_o \cos(2\pi\nu_m t) \quad (2)$$

This oscillation may induce a change in the polarizability of the material, which can be approximated by a Taylor expansion of  $\alpha$ :

$$\alpha \approx \alpha_o + \left(\frac{\partial\alpha}{\partial q}\right) q_o + \dots \quad (3)$$

Combining these and simplifying gives, to first order in  $q$ :

$$P \approx \alpha_o E_o \cos(2\pi\nu_o t) + \frac{1}{2} q_o \left(\frac{\partial\alpha}{\partial q}\right)_o E_o [\cos\{2\pi(\nu_o - \nu_m)t\} + \cos\{2\pi(\nu_o + \nu_m)t\}] + \dots \quad (4)$$

The first of these terms is the Rayleigh scattering, which is unshifted in frequency. The second is the Raman scattering, at the characteristic Stokes (–) and anti-Stokes (+) frequencies. The existence of Raman-scattered light depends on the Raman activity,  $\partial\alpha/\partial q$ : if there is no change in the polarizability for a given vibrational transition,  $\partial\alpha/\partial q = 0$  and the transition is not Raman active.

In three dimensions, the equations become tensorial, but other than that the derivation is essentially unchanged. Change in the polarizability tensor  $\alpha$ , which is symmetric for conventional Raman scattering, still determines the activity, but now the vibration is Raman active if any one of the polarizability tensor components is changed during the vibration. Additionally, the three-dimensional form of the derivation brings to light the polarization dependence of the

Raman activity. It is possible, in crystalline materials, e.g., to have normal modes of vibration that are excited only by certain polarization states of the incident light. This is a great advantage in solid-state studies, because it allows investigation of anisotropic bonds for a more complete understanding of the material.

The primary experimental difficulty with Raman spectroscopy is signal-to-noise ratio. The quantum efficiency of Raman spectroscopy is typically on the order of  $10^{-6}$ : for every million photons that strike the sample, one might be Raman shifted. This low signal level is exacerbated by the close proximity, spectrally, of the Rayleigh-scattered light. The spectrometer must be designed to minimize internal scattering of this unshifted light, as even slight scattering will overwhelm the small Raman signal. A double spectrometer has long been the accepted minimum for Raman work, and triple spectrometers are not unusual. These cut the amount of light that reaches the detector, but they cut the amount of scattered light that reaches the detector even more. In recent years, the development of holographic notch filters has allowed researchers to block the unshifted light before it reaches the spectrometer.<sup>[14–16]</sup> This allows use of single spectrometers and lessens the signal losses associated with double and triple spectrometers. Use of a holographic notch filter and single spectrometer also allows one to collect the final signal with a charge-coupled device (CCD). This permits collection of an entire spectrum at once, rather than one point at a time, which is a great advantage when—as in NSRM—long integration times are necessary.

## NEAR-FIELD RAMAN SPECTROSCOPY

The primary difficulty with Raman spectroscopy is also the primary weakness of near-field scanning optical microscopy: low signal levels. The amount of light that can be sent through a subwavelength probe aperture is severely limited by the shape and material of the probe.<sup>[17]</sup> The combination of this low excitation power and the low cross section for Raman scattering necessitates long integration times. In order to image the sample, this long integration time must be applied at each point in the scan.

The first NSOM image successfully taken on a Raman line was achieved in 1995.<sup>[18]</sup> The image, a  $4\text{-}\mu\text{m}^2$  square area on a sample of Rb-doped potassium titanyl phosphate (KTP), used the difference in Raman spectra between the pure and the doped regions as a contrast mechanism. It used a tapered fiber probe, had a resolution of approximately 250 nm, and took over 10 hr to complete.

Apertureless probes offer much higher illumination power, and may offer greater near-field enhancement

as well.<sup>a</sup> The resolution of an NSOM image is dependent on the size of the probe, so the smaller tip size for an apertureless probe also offers a resolution advantage. The highest-resolution NSRM images published to date, with spatial resolution of less than 25 nm, have been produced using silver apertureless probes<sup>[19]</sup> (Fig. 6). The data represented by Fig. 6 took approximately 40 min to collect.

The significant decrease in the time it takes to obtain an NSRM image with apertureless probes has resulted in their almost universal adoption. It has also sparked a surge in research applications. Recent uses of NSRM include measurement of residual stress in a damaged silicon wafer,<sup>[20]</sup> imaging of organic molecules,<sup>[21]</sup> and measurement of variation in Raman spectra along single-walled nanotubes<sup>[19]</sup> as well as many others.

## Differences Between NSRM and Micro-Raman

It is tempting to view NSOM-Raman spectroscopy as merely the next resolution increase in a well-understood chain of improvements. Micro-Raman spectroscopy increased the spatial resolution of Raman studies far beyond that of ordinary Raman work,<sup>[22]</sup> and on a superficial level, NSOM-Raman is seen as the next step in resolution enhancement. This is not entirely the case: there are aspects of NSRM that are fundamentally different from micro-Raman.

The differences between NSRM and other Raman spectroscopies originate with the nature of light in the near field. As discussed above, the electric field components near an NSOM tip are not uniform in either space or polarization. For an apertured tip, with  $x$ -polarized incident light, the transmitted light has  $x$ ,  $y$ , and  $z$  components. With apertureless tips, there is a similarly strong enhancement of the polarization component along the tip axis. The total intensity of the radiation varies strongly with distance from the tip. This variation is due to the presence, in the near field, of evanescent (non-propagating) modes, which exist for each of the three polarization states.

The first of the effects in near-field Raman spectroscopy is due to the overall enhancement of the light intensity near the probe aperture. This enhancement does not extend to the far field, and thus does not contribute to measurements of the total radiation emitted from the probe. Because this total intensity near the probe tip includes the evanescent modes, which do not contribute to any far-field intensity measurements, there is actually more light available for Raman

<sup>a</sup>The magnitude of the enhancement is inversely related to the radius of curvature of the probe. Apertureless probes are typically much sharper than tapered fiber probes, although the geometry of the two is different enough that a direct comparison is difficult.

**Fig. 6** Raman image of carbon nanotubes (A) together with simultaneously acquired topography (B). Line scans (C) and (D) are taken along the dotted lines in (A) and (B), and have vertical scales of kcts/sec and nm, respectively. *Source:* Courtesy of Achim Hartschuh, Physikalische Chemie, Universität Siegen.

excitation in the near field than one would expect. This effect has proven useful in measuring the Raman spectra of extremely thin films: in the far field, there is no observed Raman signal from the film, but when a tip is in the near field there is a strong signal from the film.<sup>[23]</sup> The same effect may be useful for measurements of surface states on solids.

The  $z$  polarization component of the light near the probe also leads to unusual near-field Raman effects.<sup>[24]</sup> In conventional Raman spectroscopy, vibrational modes with  $x$  or  $y$  components are excited by the incident light, which is necessarily polarized in the  $xy$  plane. Modes with purely  $z$  components require an electric field in the  $z$  direction for excitation. In liquid- or gas-phase Raman work, this is not a limitation, likewise in amorphous materials or polycrystalline materials with domain size less than the minimum spot size. In single-crystal work, the  $z$  modes are usually measured by reorienting the crystal so that the incident light has a polarization component along the desired axis. In near-field Raman, there is a  $z$  component of the field that provides excitation of these modes without reorientation of the crystal. This effect can be effectively “turned off” by moving the tip out of the near field. Comparison of near-field and far-field spectra allows the researcher to determine the polarization dependence of the material.

The third of the effects possible in NSRM is due to the strong gradient in the near-field electric fields.<sup>[25]</sup> In the standard derivation of the Raman effect (Eqs. (1)–(4)) it is assumed that the electric field

magnitude remains constant over the entire extent of the oscillation. For conventional Raman techniques, this is true. Even for confocal Raman spectroscopy, this is an excellent approximation; the intensity of the traveling wave is not going to change measurably over molecular distances. With NSRM, however, the approximation no longer holds. The traveling-wave component of the transmitted radiation is only part of the oscillating field present in NSOM: the evanescent modes also contribute to the total electric field and to the Raman excitation.

The effect of the field gradient can be explored by taking a Taylor expansion of the electric field.

$$E \approx E_0 + \left( \frac{\partial E}{\partial q} \right)_0 q + \dots \quad (5)$$

Inserting that expansion in place of  $E_0$  in the derivation given in Eqs. (1)–(4) gives:

$$\begin{aligned} P \approx & \alpha_0 E_0 \cos(2\pi\nu_0 t) \\ & + \frac{1}{2} q_0 \left( \frac{\partial \alpha}{\partial q} \right)_0 E_0 [\cos\{2\pi(\nu_0 - \nu_m)t\} \\ & + \cos\{2\pi(\nu_0 + \nu_m)t\}] \\ & + \frac{1}{2} q_0 \left( \frac{\partial E}{\partial q} \right)_0 \alpha_0 [\cos\{2\pi(\nu_0 - \nu_m)t\} \\ & + \cos\{2\pi(\nu_0 + \nu_m)t\}] + \dots \quad (6) \end{aligned}$$

The first two terms of Eq. (6) are the same as before. The third describes a scattering with the same Stokes

and anti-Stokes frequency shifts as the Raman lines, but no dependence on the Raman activity  $\partial\alpha/\partial q$ . Instead, this scattering term is dependent on the field gradient and the polarizability. Selection rules for this term depend on the characteristics of  $\alpha$ , and so would have activity similar to IR absorption spectroscopy. The net result would be the observation of transitions that are normally seen in IR absorption spectroscopy but are not Raman active.

The effect of a strong electric field gradient on Raman spectra has been discussed previously as a mechanism for some of the observed spectral lines in surface-enhanced Raman spectroscopy (SERS).<sup>[26]</sup> Because there is no good, controllable method of regulating distance or field gradient in SERS, NFRS offers the first opportunity to test the distance dependence of this effect. The effect was also predicted as an effect in the Raman spectra of microparticles suspended in laser traps.<sup>[27]</sup> This prediction was tested at the time, but for the gradients available in that experimental configuration the strength of the effect was calculated to be four orders of magnitude lower than the Raman effect and no lines were observed. There has been at least one possible sighting of this field-gradient effect in NFRS<sup>[28]</sup> although some other researchers who have looked for it have not seen it.<sup>[19]</sup>

## CONCLUSION

Near-field Raman spectroscopy allows researchers to make measurements of chemical bonds and vibrational transitions with spatial resolution unavailable via conventional optical methods. These high-resolution spectroscopic data come with corresponding topographic information, allowing better understanding of how nanoscale features affect the nanoscale spectroscopic data. The enhancement region near the tip falls off very rapidly, so NSRM can be used for Raman measurements of thin films and surface effects that would otherwise be either too small to observe or washed out by the bulk signal.

The primary difficulties in NSRM are low signal level and correspondingly long integration times. The development and use of apertureless tips has greatly increased the signal strength available, decreased the time required for image collection, and increased the resolution as well. These improvements have brought NSRM to the point where it is possible to obtain detailed high-resolution images, with separate topographic and Raman data, in well under an hour.

NSRM is not simply the next resolution step beyond micro-Raman. The presence of the metallic probe near the sample causes changes in intensity and polarization of the incident light, resulting in effects similar to surface-enhanced Raman spectroscopy. It is also

possible, although not yet entirely certain, that the strong field gradients created by the tip may make visible some lines that are not normally Raman active.

## INTRODUCTION

Optical microscopy is a well-established technology of microanalysis for material science, biology, pathological diagnostics, industry, and so on. However, the smallest analyzing dimension of the sample resolvable with a conventional optical microscope is a half wavelength of light or several hundreds of nanometers in visible region because of the nature of the light wave. This is a so-called diffraction limit of light, which is not small enough to observe the structures of interest in the current advanced sciences and technologies, including protein molecules, quantum nanodevices, and self-assembled molecules. Near-field optical microscopy is a tool to overcome the barrier of wavelength by confining photons in nanoscale volume.

A combination of the state-of-the-art near-field technology with the conventional optical measurements enables us to explore the nanoworld with visible light.<sup>[1,2]</sup> Especially, near-field Raman spectroscopy makes it possible to assign molecules, to analyze chemical behavior of molecules, and to observe molecular dynamics at nanometric or molecular scale.<sup>[3,4]</sup> Lasers and detectors of visible region are available in Raman spectroscopy, and quenching phenomenon<sup>[5]</sup> and photobleaching could be avoided; hence near-field Raman spectroscopy is suitable for molecular sensing with a nanometric spatial resolution. Because the cross section of Raman scattering is much smaller than fluorescence and infrared absorption cross section, it is necessary to enhance Raman cross section for its accurate measurement. This can be performed by using a metallic tip that also works as one of a near-field probe for detection. In this article, we present how the metallic tip works as a near-field probe at first and then show the current progress in near-field Raman spectroscopy using a metallic tip.

## LOCAL FIELD ENHANCEMENT AT A METALLIC TIP

A small metallic structure with size smaller than the probing wavelength scatters light field and enhances the electric field intensely because of the strong interaction between the light field and the metal structure when the light is incident on such a structure. The reason for such an enhancement of the light field is that collective oscillation of free electrons in the metal resonates with the light field. This phenomenon is known as localized surface plasmon polaritons (SPPs). The electric field, which is coupled with the localized SPPs at the metallic structure, comprises evanescent field. Because the evanescent field is localized around the structure, the superresolving capability is attained by detecting the field for observation, measurement, and so on. Such a scheme of near-field scanning optical microscopy (NSOM) with a metallic probe of which the tip enhances electric field locally and strongly was first proposed in 1994.<sup>[6]</sup> The NSOM is called as an apertureless NSOM,<sup>[7,8]</sup> and the resolution is determined by the radius of the tip.

An apex of a metallic probe, such as a tip of a scanning tunneling microscopy (STM), works as a scatterer for enhancing electric field locally.<sup>[9]</sup> Fig. 1A shows intensity distribution of the light field scattered at the tip that is obtained using a numerical analysis.<sup>[1]</sup> Fig. 1B shows a schematic model for calculation. In this model, it is considered that a silver metallic tip with radius 20 nm is placed in contact on a glass substrate (refractive index: 1.5). The silver tip is illuminated with plane wave traveling in the substrate. Wavelength of the incident field is 488 nm, and its polarization is TM mode (i.e., p-polarization). Incident angle is 45°. Evanescent field is generated over surface of the glass substrate because the incident angle meets the

**Fig. 1** Field enhancement effect induced by a metallic tip. (A) Intensity distribution of electric field locally enhanced at a silver probe tip calculated by the FDTD method. (B) Schematic of the calculation model for the analysis.

condition of total internal reflection. Finite-difference time-domain (FDTD) method was used in the calculation.<sup>[10,11]</sup> Localized and enhanced field spot is observed in the proximity of the tip apex of Fig. 1A. The size of the small spot is around 30 nm, while approximately corresponds to the radius of the tip. Maximum intensity of the small spot was calculated to be 80 times as large as intensity of the incident field. Considering the tip to be a glass probe having the same tip radius of 20 nm, enhancement factor of the glass tip was calculated to be 7 when illuminating with TM mode. No enhancement of electric field was estimated at the metallic tip when TE mode (i.e., s-polarization) is used for illumination light in the calculation. These analyses show that strong enhancement of the localized field requires the use of a metallic tip and TM mode illumination in an apertureless probe, and that the small light field spot strongly enhanced at the tip is caused by excitation of the localized SPPs.

## NEAR-FIELD RAMAN SPECTROSCOPY AND MICROSCOPY

Fig. 2 shows illustrations of (a) near-field excitation of Raman scattering and (b) conventional Raman

**Fig. 2** Schematic illustration of illumination for (A) near-field Raman spectroscopy using a locally enhanced field, (B) conventional micro-Raman spectroscopy.

microspectroscopy (far-field detection). For near-field Raman spectroscopy, a metallic tip is placed in the vicinity of the specimen and local electric field is generated at the tip apex. Raman scattering of molecules, which are just below the enhanced electric field at the metallic tip, is selectively enhanced and detected with a sufficiently high spatial resolution.

An optical setup of near-field Raman microscopy is shown in Fig. 3.<sup>[3,4,12,13]</sup> An expanded and collimated light field from a laser enters into the epi-illumination inverted microscope. A circular mask is inserted in the optical path of the illumination light and located at the conjugate plane of the pupil of the objective lens with numerical aperture (NA) equal to 1.4. Because the mask rejects part of the beam corresponding to focusing angles that are less than  $\text{NA} = 1.0$ , the transmitted light forms a focused spot that produces an evanescent field on the sample surface.<sup>[14]</sup> As the metallic tip approaches to the focused spot, a locally enhanced electric field is observed to be generated at the tip apex. Fig. 4 shows CCD images of the scattering of the evanescent field at the metallic tip that were observed from the side of the tip. In Fig. 4A, the tip

**Fig. 3** Optical setup of near-field Raman spectroscopy using a metallic tip.

**Fig. 4** (A) Photograph of a metallized cantilever tip shining in the focused evanescent field. (B) Photograph of a metallized tip which is retracted 500 nm from the sample.

is in contact with the sample surface placed on the focused spot, which corresponds to Fig. 2A. Strong Rayleigh scattering of the evanescent field at the tip apex is seen in the figure. In Fig. 4A and 4, the tip is 0 and 500 nm away from the sample surface, respectively. No scattering of the evanescent field is observed because the tip is out of the skin depth of the evanescent field, while only very weak Rayleigh scattering light at the focused spot is observed because of the sample roughness. The electric field enhanced locally at the tip is scattered inelastically by Raman active molecules, which corresponds to near-field Raman scattering. Raman scattering is collected by the same objective lens and is directed to the spectrophotometer (focal length = 300 mm, 1200 lines/mm) that is equipped with a liquid-nitrogen-cooled CCD camera ( $1340 \times 400$  channels) for Raman spectra measurement and with an avalanche photodiode (APD) for Raman imaging. The APD is located after the exit slit of the spectrophotometer so that a specific Stokes-shifted line can be detected. Excitation light or Rayleigh scattering is sufficiently rejected by a notch filter. The metallic tip is a silicon cantilever that is coated with a 40-nm-thick silver film by a thermal evaporation process. The evaporation is performed at a relatively slow rate of  $0.3 \text{ \AA}$  per second to avoid undesirable bending of the silicon lever. Fig. 5 shows a scanning electron micrograph of a metallized tip. Diameter of the silver-coated tip apex is around

40 nm. The distance between the sample and the cantilever is regulated in contact-mode AFM operation, and the sample is scanned with piezoelectric transducers (PZT) in the  $X$ - $Y$  plane. Near-field Raman images are reconstructed by detecting near-field Raman signal at a specific Stokes-shifted line with the APD while scanning the PZT stage on the sample.

Raman spectra of Rhodamine 6G obtained with the near-field Raman microscope are shown in Fig. 6. Spectrum (A) is obtained with a silver-coated cantilever, and spectrum (B) is obtained without it. Intensity of spectrum (A) is higher than that of (B) because of the local field enhancement at the silver tip. Several Stokes-shifted Raman lines are observed in the spectrum. Acquisition time of the spectrum was 5 sec, and no accumulation was performed. The sample was made by casting the solution of Rhodamine 6G ( $6.0 \times 10^{-4}$  wt) onto the 8-nm silver island-coated coverslip and depositing Rhodamine 6G because of evaporation of the solution. Raman scattering is hence doubly enhanced because of surface-enhanced Raman scattering (SERS) both with the metallized tip and silver island film coated on substrate.

The Raman spectrum of Fig. 6A includes not only near-field component, but also far-field component. Near-field spectrum is obtained by subtracting the far-field spectrum of Fig. 6 obtained without the tip from the spectrum shown in Fig. 6A. Fig. 7 shows

**Fig. 5** Scanning electron microscopy images of the metallized cantilever tip. (A) Whole image of the tip. (B) Expanded image of the apex.

the result of subtraction of a near-field Raman spectrum of Rhodamine 6G. Each of Stokes-shifted peaks can be assigned to vibrational mode, such as peaks at 1359, 1503, 1570, and 1647  $\text{cm}^{-1}$  which correspond to the aromatic C–C stretching vibrational modes, a peak at 1269  $\text{cm}^{-1}$  which corresponds to the asymmetric vibrational mode of C–O–C bonding, a peak at 1120  $\text{cm}^{-1}$  which corresponds to the in-plane bending mode of C–H bonding, and a peak at 766  $\text{cm}^{-1}$  which corresponds to the out-of-plane bending mode of C–H bonding. Assignment of all Stokes-shifted peaks observed in Fig. 7 is shown in Table 1. When a silicon cantilever was used for near-field Raman detection, no enhancement is observed.<sup>[4]</sup>

Fig. 8 shows the Raman spectra of crystal violet molecules. Spectra (A) and (B) have been obtained with and without the metallic tip, respectively. The peaks at 1383, 1537, 1586, and 1617  $\text{cm}^{-1}$  are assigned to the C–C stretching vibrational mode of the aromatic ring; the peak at 1363  $\text{cm}^{-1}$  is assigned to the *N*-phenyl vibrational mode; the peak at 1172  $\text{cm}^{-1}$  is assigned to the C–H in-plane bending vibrational mode; the peaks

assigned to the phenyl–C–phenyl vibrational mode. These peaks are in good agreement with the results of other authors.<sup>[15–17]</sup> The peak at  $2050\text{ cm}^{-1}$  is a ghost line, which arises from the laser diode that was used as feedback in AFM operation. The exposure time of the liquid-nitrogen-cooled CCD camera was 1 sec with  $230\text{-}\mu\text{W}$  laser power at the entrance of the inverted microscope. Fig. 8C shows near-field Raman spectrum of crystal violet which is obtained by subtracting the spectrum of Fig. 8B from that of Fig. 8A. Assignment of all Stokes-shifted peaks observed in Fig. 8 is shown in Table 2.

## NEAR-FIELD RAMAN IMAGING

Molecular identification at nanometric scale is possible in two dimensions by detecting near-field Raman signal at a specific Stokes line with a monochromator and a point detector while scanning the sample laterally. A metallic tip reduces measurement time for Raman imaging drastically because of the amplification of near-field Raman scattering with locally enhanced field. Consequently, spatial distribution of molecules can be

imaged at nanometric scale during reasonable acquisition time.<sup>[13]</sup> Near-field Raman imaging enables us to attain direct and sensitive observation of many kinds of molecules and their local distributions as well as biological cells without labeling with dye.

In this section, we show such an example of molecular imaging. Mixed aggregates of Rhodamine 6G and crystal violet molecules are used as samples for near-field Raman imaging. The sample is prepared by casting ethanol solution of Rhodamine 6G and crystal violet on a coverslip coated with an 8-nm-thick silver film and drying the solution. The distribution of molecules for

**Fig. 9** Near-field Raman images obtained at (A)  $607\text{ cm}^{-1}$ ; C–C–C in-plane bending mode of Rhodamine 6G and (B)  $908\text{ cm}^{-1}$ ; C–H out-of-plane bending mode of crystal violet; (C) the corresponding topographic image of the scanned area. It took 10 min to obtain one image where  $1 \times 1\text{ }\mu\text{m}$  scanning area consisted of  $64 \times 64$  pixels.

**Fig. 10** Typical Raman spectra of the aggregated sample used in Fig. 9, (A) with and (B) without a metallic tip. Stokes-shifted-lines of Rhodamine 6G and crystal violet are observed. Arrows indicate the Stokes-shifted-lines used for near-field Raman imaging in Fig. 9.

both samples is fairly inhomogeneous and is set to have a 1-nm average thickness of the layer of molecules.

Fig. 9A–C shows near-field Raman images from the same area of the sample, where the concentrations of Rhodamine 6G and crystal violet are  $1.25 \times 10^{-3}$  and  $1.25 \times 10^{-2}$  wt.%, respectively. These concentrations resulted in a comparable Raman scattering intensity from Rhodamine 6G and crystal violet because Rhodamine 6G yields higher scattering cross section than that of crystal violet molecules. Fig. 9A shows an image corresponding to the peak at  $607 \text{ cm}^{-1}$ , which comes from the Stokes-shifted C–C–C in-plane bending vibrational mode of Rhodamine 6G. Fig. 9B is obtained at  $908 \text{ cm}^{-1}$  of which peak corresponds to the Stokes-shifted line of the C–H out-of-plane bending vibrational mode of crystal violet. Fig. 9C shows a corresponding topographic image obtained simultaneously with Fig. 9A in AFM operation. The dimension of all the images comprising  $64 \times 64$  pixels

was  $1 \times 1 \mu\text{m}$ . The scanning rate used for each line was 0.1 Hz. At this rate, a single image can be achieved in only 10 min. Fig. 10 shows the Raman spectra of the mixed sample, which exhibits the Stokes-shifted lines of both Rhodamine 6G and crystal violet molecules. The arrows depicted in Fig. 10 point to the Stokes-shifted lines used for the near-field Raman imaging in Fig. 9. We can selectively obtain the distributions of each vibrational mode that we cannot distinguish in the topographic image. The distributions of each vibrational mode are quite different and show complicated structures corresponding to the inhomogeneous distributions of both molecules. According to Fig. 9A, Rhodamine 6G molecules are mainly localized at the lower right position of the figure; on the other hand, Fig. 9B shows that crystal violet molecules are randomly dispersed in the scanned area. In Fig. 9C, the island structures of the silver film are observed in the topographic image because the average thickness of the aggregated molecular layer is estimated to be 1 nm which is much thinner than the silver film (average thickness: 8 nm). Accordingly, the distributions of both molecules are not clearly seen in the topographic image that reflects the pancake structure of the silver grains (30–50 nm in diameter and 8 nm in thickness). Note that without a metallic tip (far-field detection), we could not obtain such high-resolution images because the far-field signal is averaged out within the focused spot [Fig. 2B]. Fig. 9 shows that the near-field Raman images attain the molecular vibrational distributions with a high sensitivity, even if the thickness of the molecular layer is 1 nm. In the experiment, organic dye molecules adsorbed on silver films were used. While the silver films are required for dye molecules to quench the strong fluorescence, near-field Raman spectroscopy and imaging by an apertureless metallic probe scanning optical microscope are applicable not only to organic, but also to inorganic sample even without the support of the silver films. Single molecule detection can be performed after optimizing

**Fig. 11** Near-field Raman spectra mapping at several positions.

**Fig. 12** Some features in the near-field region can be seen and the remarkable near-field characteristic Raman spectra -e, -f, -g in Fig. 11 are plotted. For comparison, spectrum -a and -h are also shown. The numbers correspond to the same assignments as shown in Fig. 7 and remarkable features are pointed out by arrows with capital alphabets (A ~ R).

the tip material, shape,<sup>[18]</sup> and illumination method<sup>[19]</sup> because the enhancement factor is very sensitive to the tip and the polarization of the light.

### SPECTRAL CHANGE OF NEAR-FIELD RAMAN SPECTRUM

Because near-field Raman spectroscopy using a metallic tip realizes surface-enhanced Raman scattering singly on its apex, chemical enhancement of Raman scattering can be expected besides physically electromagnetic enhancement as mentioned above. Fig. 11 shows a one-dimensional near-field image of the Rhodamine 6G distribution at spatial steps of 30 nm. At each position, the near-field Raman spectrum is detected. The spectra in Fig. 11 are all enhanced by the tip apex, while some of them, e.g., spectra -e, -f, and -g, exhibit remarkable features which are quite different from others or from far-field spectrum.

The distinguishable near-field features in those spectra replotted in Fig. 12 are marked with capital alphabetic letters, and the numbers in different spectra correspond to the same assignments as in Fig. 7. Some peaks are slightly shifted and their relative intensities are quite different from those of the far-field spectrum. Furthermore, some additional peaks, which are not observed in the far-field, appear.

For the aromatic C–C stretching vibrational mode, the peaks between 1350 and 1650  $\text{cm}^{-1}$  are heavily modified. New shifted peaks, e.g., A: 1457  $\text{cm}^{-1}$  in spectrum -e, G: 1483  $\text{cm}^{-1}$  in spectrum -f, appeared. For the C–H out-of-plane bending vibrational mode (number 13), peak intensities are constant throughout the scanning, while for the in-plane bending (number 11), weak peaks are strongly enhanced and slightly shifted (see, e.g., J: 1112  $\text{cm}^{-1}$ ). For the C–O–C bending vibrational mode, the new Stokes-shifted peaks appear and those are largely enhanced (see peaks, e.g., B: 1278  $\text{cm}^{-1}$ , H: 1286  $\text{cm}^{-1}$ , and M: 1275  $\text{cm}^{-1}$ ). Furthermore, other new peaks which have not been assigned yet also appear in the spectra (see, e.g., C: 1054  $\text{cm}^{-1}$ , D: 1027  $\text{cm}^{-1}$ , E: 946  $\text{cm}^{-1}$ , F: 902  $\text{cm}^{-1}$ , K: 1040  $\text{cm}^{-1}$ , L: 705  $\text{cm}^{-1}$ , O: 1057  $\text{cm}^{-1}$ , P: 1027  $\text{cm}^{-1}$ , Q, 700  $\text{cm}^{-1}$ , and R: 425  $\text{cm}^{-1}$ ). Some of the peaks can be identified as the same vibrational modes (e.g., C, K, and O; D and P; L and Q). While some of Stokes-shifted peaks are strongly enhanced, the fluorescence intensity is constant throughout the positions. This can be explained by the chemical mechanism of surface-enhanced Raman scattering because of the charge transfer excitation between molecules and metal.<sup>[20]</sup>

### CONCLUSION

Application of near-field optics to Raman spectroscopy brings microanalysis of most of materials to their nano-identifications. For example, molecules can be assigned, observed, and detected directly at the nanometric or molecular scale by using this technique without the need for staining a specimen with a dye. Low cross section of Raman scattering is amplified to detectable level by the locally enhanced field at a metallic tip. Near-field Raman signal is also enhanced by the chemical interaction between molecules and metallic tip. The nanoscale chemical phenomenon has a potential for determination of molecular orientation. Raman spectroscopy coupled with locally enhanced electromagnetic field, which may contribute to nonlinear spectroscopy such as multiphoton processes, second harmonic generation, and coherent anti-Stokes Raman scattering, will be one of the main topics of microspectroscopic or nanospectroscopic research in the next decade.

Bloomington, Indiana, U.S.A.*

## INTRODUCTION

Chemical near-field microscopy is a promising optical technique, which transcends the diffraction limit of classical optical microscopy while maintaining its spectroscopic capabilities and sharing the benefit of topographic contrast from proximal probe microscopies. Several techniques and sources of chemical contrast are discussed, from the time-resolved mapping of electric field-induced molecular reorientation in polymer films to the vibrational Raman spectrum of single-carbon nanotubes with 28 nm spatial resolution in the optical image.

## BEYOND THE DIFFRACTION LIMIT

With the advent of scanning probe microscopies, the past 20 years or so have witnessed an explosion of analytical tools to explore materials at a nanometer scale. Advances in the understanding of physical and chemical phenomena at these length scales are expected to have a strong impact on microbiology, materials science, and microelectronics. At present, modified viruses are explored as nanobeakers for controlled chemical reactions in confined environments.<sup>[1]</sup> New materials having exotic optical and electronic properties have been synthesized.<sup>[2,3]</sup> Novel polymeric resists for sub-100 nm photolithography<sup>[4]</sup> and alternative schemes for electronic component integration are intensely explored.<sup>[5]</sup> As a general feature, systems representative of these domains often possess a complex hierarchical organization, which requires the ability to map chemical phenomena on a certain range of length scales.<sup>[6]</sup> Such studies, more often than not, involve some type of direct imaging technique, which is non-intrusive, has chemical specificity, and has adequate space and time resolution.

Vibrational spectroscopy, encompassing infrared (IR), near-IR, Raman, inelastic neutron scattering, electron energy loss, and cavity ring-down spectroscopy, has exquisite chemical specificity. The positions and intensities of vibrational absorption bands

can be used to confirm or identify the presence of a particular group, whereas spectral correlations can be used to access structural and environmental information on selected groups.<sup>[7]</sup> IR and Raman spectroscopies are particularly non-intrusive, require a small amount of sample, and can be easily coupled with microscopy to provide for spatial resolution.<sup>[8,9]</sup> The importance of these qualities is reflected in the available range of commercial Raman and Fourier transform infrared (FTIR) microscopes, and in the multitude of applications ranging from materials science to forensics and identification of cultural artifacts. For basic research applications (usually concerning molecular relaxation phenomena), pulsed lasers and fast detectors provide for temporal resolution down to a few femtoseconds.

Classical microscopes achieve a maximum spatial resolution of about 10–20  $\mu\text{m}$  in mid-IR (for wavelengths between 2 and 10  $\mu\text{m}$ ), whereas Raman microscopes approach the 1- $\mu\text{m}$  limit. The current spatial resolution limitation in mid-IR is because of the lack of suitable dielectrics to build aberration-corrected lenses.<sup>[10]</sup> Even if perfect materials were available, there is still a fundamental limitation of imaging instruments based on spherical lenses or mirrors. This fundamental spatial resolution limit is known as the Abbe diffraction limit.<sup>[11]</sup> Following Abbe's explanation, every object behaves as a superposition of diffraction gratings. In any classical imaging instrument, the front lens is placed, for practical reasons, at least several wavelengths from the object from which the scattered light is collected. The smaller the details of the object are, the higher are the diffraction orders or spatial frequencies of the scattered light. Not all the spatial frequencies will make their way into the lens; there is a cutoff spatial frequency necessarily connected to the geometry of the collection optics. Moreover, the highest spatial frequencies decay exponentially along the object normal.<sup>[12]</sup> Thus the geometry of the lens and the distance to the sample limit the achievable spatial resolution at:  $\Delta x = \lambda / (2\pi\text{NA})$ , where  $\lambda$  is the wavelength and NA is the numerical aperture of the lens.

Many problems studied by vibrational microspectroscopy would gain from better spatial resolution. Some of these problems are reviewed later in the section “Applications of Optical Near-Field Microscopy in Chemistry” of this entry. Although the Abbe resolution limit of classical microscopes continues to be pushed in small steps, especially for visible wavelengths, by using special geometries of illumination<sup>[13]</sup> or non-linear optical effects,<sup>[14,15]</sup> two other conceptually different approaches currently hold the promise of a major breakthrough in ultramicroscopy. The first is the near-field approach, an idea credited to Synge,<sup>[16]</sup> who proposed the use of a subwavelength source of light such as a tiny hole in a metal screen illuminated by bright light or a gold particle, scattering light from a location very close to the sample surface in a dark-field illumination configuration (Fig. 1). A key element of Synge’s approach is the location of the light source very close to the sample surface. As a consequence of the probe proximity, sampling of the evanescent waves bound to the surface occurs. Because in modern instruments based on Synge’s idea, the subwavelength light source is scanned across the sample surface by maintaining a constant gap between the surface and the probe to sequentially map the near-field optical interaction, such a microscope is called a near-field scanning optical microscope (NSOM or SNOM),<sup>[17]</sup> as opposed to far-field instruments, which deal with propagating waves only. The second approach is the negative refraction concept upon which Pendry<sup>[18]</sup> built his idea of a superlens. Such a lens may overcome the evanescent wave decay and therefore should focus light to considerably smaller areas than that allowed by the Abbe diffraction limit. Although numerous experimental realizations of Synge’s proposal have broken the diffraction limit barrier by more than one order of magnitude, the more recent solution based on the Pendry superlens remains in the stage of theoretical concept.

**Fig. 1** Synge’s proposal for an ultrahigh resolution optical microscope to overcome the diffraction limit. The subwavelength source of light may be (A) a microscopic aperture defined in a metal screen, at the tip of a sharp dielectric cone, and (B) a nanoparticle with large optical polarizability. The proximity of the probe to the surface is an essential element in near-field microscopy.

We are concerned here with those techniques and applications of the NSOM principles that have been applied to chemical problems. A number of alternative non-optical techniques, capable of nanoscale mapping with chemical specificity, will be also mentioned with the goal of situating the near-field optical microspectroscopy within the broader context of chemical mapping methodologies.

## APERTURE, APERTURELESS, AND TIPLESS NSOM

Three approaches have been used to date to generate near-field optical images with spatial resolution superior to the diffraction limit. The first approach, and the most often utilized at present, is the one based on a subwavelength optical aperture at the apex of a tapered transparent optical fiber, which has been metal-coated<sup>[19]</sup> (Fig. 1). The spatial resolution is limited by the size of the aperture and the electromagnetic skin depth of the metal coating. The second method is based on an apertureless sharp tip, usually metallic, which is acting as a scattering probe, converting surface sample-bound evanescent waves into propagating waves (Fig. 2). The spatial resolution attainable with this method is determined by the tip radius, rather than the electromagnetic skin depth of the metal.<sup>[20]</sup> The third proposal does not use a tip. The probe in this case can be a nanoparticle, which is manipulated by optical tweezers to scan the sample surface.<sup>[21]</sup> The theory of this microscope, including the excitation of particle eigenmodes, has been worked out by Lester, Arias-Gonzalez, and Niefo-Vesperinas<sup>[22]</sup> Tischer et al. have demonstrated a related nanoparticle-based technique that is able to provide topological three-dimensional (3-D) images of nanoscopic cavities

**Fig. 2** Schematic of the optical probe region in an apertureless NSOM with grazing illumination.

accessible to the particle with 20-nm spatial resolution normal to the immersed surfaces and  $\sim 200$ -nm lateral resolution. The accessible volumes are reconstructed from the histogram of thermal position fluctuations of the particle, hence the name of the technique—3-D thermal noise imaging.<sup>[23]</sup> The 3-D thermal noise imaging has not been used yet in conjunction with near-field measurements. Palanker et al.<sup>[24]</sup> have used a localized non-equilibrium plasma concentration on a semiconductor surface photoinduced by a tightly focused laser beam operating at visible wavelengths as a scanning local probe for near-field IR reflectivity measurements.

Among the three near-field optical schemes, only the optical fiber NSOM and the apertureless NSOM have been applied to the spatial mapping of chemical properties. Nevertheless, the nanoparticle approach holds a special appeal because of intrinsic field enhancements at the particle surface,<sup>[25]</sup> which may provide for 3-D surface-enhanced Raman or IR microspectroscopy of fluid-immersed interfaces in the future.<sup>[26]</sup> Several comprehensive reviews on the theory and applications of the optical fiber NSOM and the apertureless NSOM, especially in the visible range of the spectrum, have been published to date.<sup>[27–30]</sup> Particularities and chemical applications of the mid-IR NSOM have been reviewed by Dragnea and Leone<sup>[31]</sup> and Keilman.<sup>[32]</sup> The far-IR and the microwave region have been covered by Rosner and van der Weide.<sup>[33]</sup>

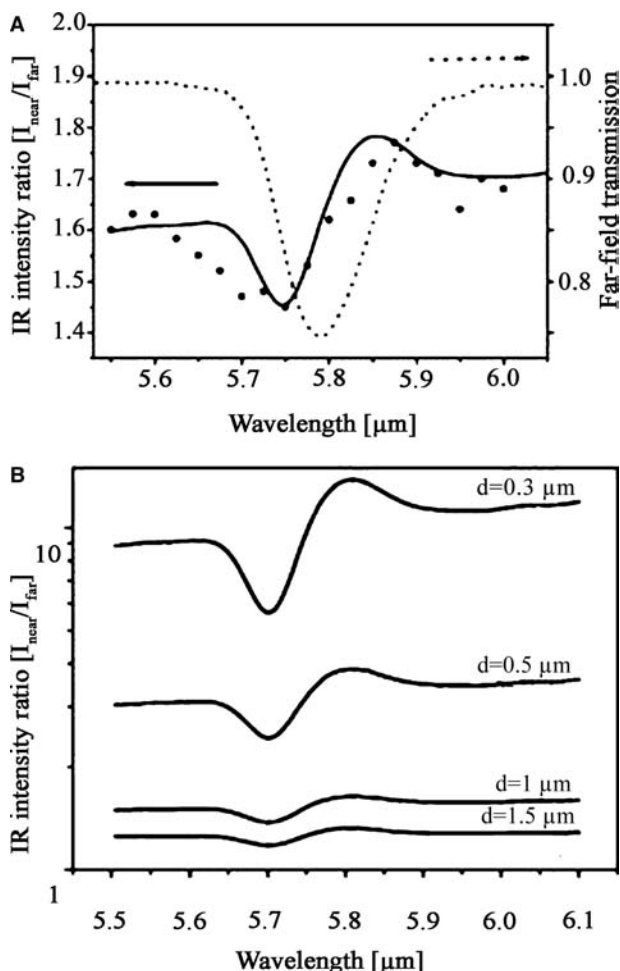

Choosing an apertureless or a fiber optic aperture NSOM for chemical characterization depends on the type of application. The fiber-based instrument is closer to a scanning confocal microscope, which, instead of the NSOM aperture, would use the real image of a pinhole formed through a lens system. Therefore contrast formation is arguably more intuitive. An important advantage of the aperture scheme is negligible background. For a perfect metal coating, the only light comes from the subwavelength aperture. As a consequence, sensitive detection schemes such as photon counting can be used. Bringing the light close to the sample through a fiber may represent a very important feature, which makes the aperture NSOM unique for certain applications dealing with samples immersed in an absorbing fluid. For example, Hong et al.<sup>[34]</sup> have succeeded to image living cells in water using an IR near-field microscope. Such studies are not possible in far field or with an apertureless NSOM because of the strong attenuation of the incident beam caused by water absorption bands associated with H–O–H bending, which overlap with the protein amide bands at  $\sim 1650\text{ cm}^{-1}$ . However, in aperture NSOM, because the gap between the fiber probe aperture and the cell membrane (sample surface) is of a few nanometers, most of the signal comes from absorption by the cellular protein and not by the water layers

between the probe and the sample surface. A disadvantage of the optical fiber approach is low transmission ( $10^{-4}$ – $10^{-6}$ , depending on the wavelength and on the fiber taper profile), combined with a limit on the incident light power dictated by the damage threshold of the metal coating ( $\sim 10\text{ mW}$  for Al-coated fibers). The throughput problem is a challenge in particular at longer wavelengths because the cutoff diameter for guided propagation occurs earlier along the taper than for shorter wavelengths, and the light has to propagate evanescently over longer distances until it reaches the aperture. At IR wavelengths, one usually has to reach a compromise between spatial resolution, determined by the aperture diameter, and sensitivity. The fiber probe fabrication remains, at present, the main challenge and a key element for further improvements of the aperture NSOM, at least at IR wavelengths.

The apertureless NSOM has four advantages on its side, with respect to the aperture NSOM. 1) The attainable optical resolution exceeds that of the aperture-based microscopes. This is because of the fact that, for a suitable incident field polarization, field enhancement occurs in a very localized area of the size of the tip radius.<sup>[35]</sup> 2) The problem of the strong attenuation in the fiber taper is alleviated in the apertureless scheme because the light is focused from the far field directly on the tip, without loss. This is why the apertureless NSOM has, until now, dominated microspectroscopy applications in the mid-IR and far-IR ranges, where the losses within the fiber taper are the largest. 3) The tip fabrication step can be avoided altogether because a large selection of commercial atomic force microscopy (AFM) tips is available. Apertureless tips are more robust and their fabrication is more reproducible than that of coated optical fiber tips. 4) The range of usable wavelengths is not limited, such as in the case of fiber-based NSOMs by material properties. The main disadvantage of the apertureless NSOM comes from strong scattered light in areas of the tip shaft, far from the sample, which creates a strong background for the detector. Furthermore, the background usually varies during scanning because of the  $z$ -motion of the tip in constant force scanning mode, hence the strong possibility of topographic artifacts. Great care has to be taken to decouple the topographic artifacts, which often adds complexity to the experimental setup. However, several strategies have been found to eliminate this problem from apertureless NSOM images.<sup>[20,36]</sup>

Whether an apertureless or a fiber optic aperture NSOM is chosen, two issues have to be considered while interpreting the data: one is the mechanism of contrast generation; the other is scanning probe imaging artifacts.<sup>[37]</sup> The electromagnetic field distribution around a nanoscopic object is extremely sensitive to both physical characteristics of the object and

the illumination mode. A rigorous description of the interaction optical between the probe and the field close to the surface is necessary to properly describe the image formation. Numerous simulation schemes for numerically solving Maxwell's equations have been used. The practical difference between these schemes lies in how the challenge of sharp corners and edges, much smaller than the wavelength, is handled.<sup>[38]</sup> Palanker et al.<sup>[39]</sup> have provided an approximate phenomenological model for contrast formation in aperture IR-NSOM. The model relies on a photon tunneling picture in which the size of the barrier representing the tip/gap/surface system is determined experimentally from tip-surface approach curves. The model correctly reproduces the observed differences between near-field and far-field IR absorption spectra

**Fig. 3** (A) Differences between experimental infrared near-field (symbols) and far-field (dashed line) spectra. The continuous line represents a fit generated from a phenomenological model based on the photon tunneling picture. (B) Calculated spectra for tip diameters ranging from 0.3 to 1.5 μm. The amplitude of the near-field modulation is inversely proportional to the aperture diameter. *Source:* From Ref.<sup>[39]</sup>, with permission.

obtained experimentally (Fig. 3). An analytical approximation for the scattered field in the apertureless case has been proposed by Hillenbrand, Knoll, and Keilmann.<sup>[36]</sup>

To avoid *z*-motion crosstalk in the optical images, the safest way is to turn off the force feedback on the *z*-piezo and scan at constant height. However, if constant gap scanning is required to be certain that the near-field optical images are not merely topographic artifacts, according Hecht et al.,<sup>[37]</sup> at least one of the following conditions should be satisfied:

- Near-field images and topographic images are uncorrelated. This means that often the best way to use a near-field microscope is on samples that are flat, but have heterogeneities with strong optical contrast.
- When correlations between the topographic image and the optical image are apparent, they should be displaced by a constant amount.
- The spatial resolution of the optical image is different from that of the topographic image.

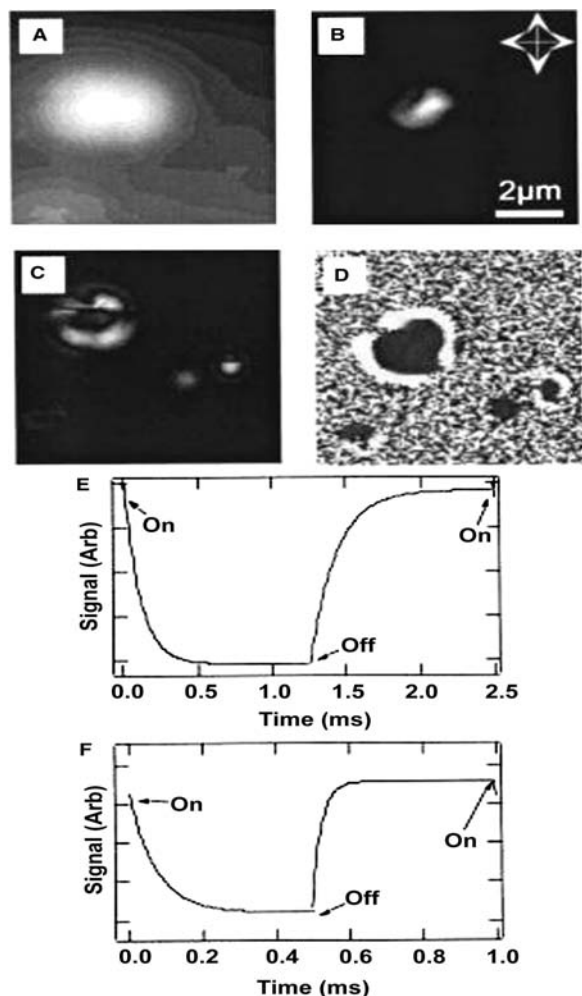

## APPLICATIONS OF OPTICAL NEAR-FIELD MICROSCOPY IN CHEMISTRY

In a few NSOM applications, which take advantage of the presence of narrow absorption bands of the sample and tunable light sources, such as in the case of vibrational microspectroscopy or the fluorescence emission properties of the sample, the near-field image contrast formation can be at least qualitatively understood in a more straightforward way than by numerically solving the Maxwell equations. A few examples from this category are described below.

### Fluorescence NSOM

In fluorescence NSOM, the chemical contrast is achieved by measuring the local fluorescence spectroscopy of the sample. Because the fluorescence wavelengths of many organic materials lie in the visible range, this method has been extensively applied to organic materials. The visible wavelength range has the benefit of sensitive detectors, optimized optics, and powerful and relatively low-cost laser sources. These features, plus the fact that the strong excitation background can be easily filtered out, made fluorescence NSOM reach single-molecule sensitivity at room temperature.<sup>[40]</sup> Fluorescence NSOM has been used to directly identify molecular aggregations in amorphous conjugated polymer films of approximately 100 nm, which were detrimental to the photoluminescent and

electronic properties of the film.<sup>[41]</sup> Such studies have clearly shown that the NSOM technique can contribute to a better understanding of the technologically important thin organic films. Barbara, Adams, and O'Connor<sup>[42]</sup> have reviewed the characterization of complex organic thin film materials by time-resolved and wavelength-resolved near-field microspectroscopy. In organic materials for electronic devices, the device fabrication processes induce morphological changes at length scales for which NSOM became the method

**Fig. 4** Measuring the local field-induced reorientation in molecular films. A sinusoidal electric bias is applied between the Al coating of the fiber probe and the transparent support electrode on which a polymer-dispersed liquid crystal film is deposited. Frame (A) represents the shear-force topographic image acquired simultaneously with near-field optical images (B–D). Frames represent the modulated optical signal as a function of the applied voltage. (D) A map of the phase lag of the optical modulation signal with respect to the applied bias. Frames (E) and (F) represent time-dependent variations in the transmitted optical signal from central and edge probe locations. The relaxation rate is faster in the edge region. Source: From Ref.<sup>[42]</sup>.

of choice. More recently, fluorescence NSOM investigations have proven instrumental in the direct observation of the influence of device operating conditions on local organic material morphology.<sup>[43]</sup> Fig. 4 is an illustration of how the dynamics of field-induced local reorientation of polymer-dispersed liquid crystal films can be measured using fluorescence NSOM.

## Raman Near-Field Microscopy

When chemical identification is required, few methods can be as specific as vibrational spectroscopy. In vibrational Raman spectroscopy, the chemical contrast comes from a non-linear effect: the molecule polarizability is modulated, depending on the molecular symmetry, by vibrational interactions. Because of its non-linear origin, the Raman scattering has a much smaller molecular cross section ( $10^{-31}$ – $10^{-29}$  cm<sup>2</sup>) when compared with typical IR absorption cross sections ( $10^{-17}$ – $10^{-16}$  cm<sup>2</sup>). However, when a molecule is placed in close vicinity to a rough metal surface, the Raman scattering may be enhanced by an average factor of  $10^6$ . The surface enhancement is thought to be of both chemical and electromagnetic origin; however, the separation of contributions from these two effects continues to be elusive.<sup>[25]</sup> An additional enhancement for surface-enhanced Raman scattering (SERS) of approximately  $10^5$  occurs when there is resonance between the pump wavelength and a molecular electronic transition. Even when combining these enhancements, the resulting cross section seems to be too small to be used to generate aperture NSOM contrast, if one takes into consideration the limit imposed by fiber damage threshold on the pump power,  $\sim 10$  mW. However, Emory and Nie<sup>[44]</sup> and Kneipp et al.<sup>[45]</sup> showed that the aforementioned enhancements represent only ensemble-averaged values, and that selected silver colloidal particles may exhibit individual Raman enhancement factors of  $10^{14}$ – $10^{15}$ , or effective molecular cross sections for Raman scattering comparable with linear IR absorption. The discovery boosted the interest in the possibility of using the surface enhancement to build near-field Raman scattering probes. The apertureless NSOM approach has been the method of choice in this endeavor. In this case, the nanostructure generating SERS enhancement is the tip itself. To establish a strong electromagnetic local enhancement, the electric field polarization of the pump laser beam has to be oriented along the tip axis.<sup>[35]</sup> Two experimental apertureless schemes have been implemented, different in respect to the way in which this condition is accomplished (Fig. 5). The first approach has been to use the side illumination of the tip.<sup>[46]</sup> Its advantage is that opaque samples can be

**Fig. 5** Apertureless Raman NSOM approaches. (A) On-axis illumination. The contour lines in the center of the focused beam represent schematically the distribution of regions of equal intensity. (B) Grazing incidence illumination.

imaged. The disadvantage is that long working distance Raman objectives have to be used, which limits the collection efficiency. An alternative illumination technique is to use on-axis illumination by strongly focused light, with the tip displaced from the center of the beam in the direction of polarization in one of the side lobes of the focal region.<sup>[47]</sup> An impressive optical 25-nm spatial resolution and a photon rate of a few thousands of photons per second have been obtained on isolated single-walled carbon nanotubes using this approach by Hartschuh, Anderson, and Novotny. Because of the large Raman signal, acquisition of simultaneous near-field Raman and topographic images is possible. In this work, local variations in the Raman spectrum along a carbon nanotube have been found (Fig. 6). A clear proof of the near-field origin of the Raman enhancement has been made through tip-sample distance measurements.<sup>[47]</sup> The Raman spectrum local variations reflect changes in the molecular structure, which can be caused by defects, the presence of catalyst particles, or variations in the tube lattice, clearly demonstrating the promise that SERS-NSOM hold for experimental investigations of individual nanostructures, perhaps down to the single macromolecule level.

### Infrared Near-Field Microscopy

The impressive chemical sensitivity and spatial resolution of the Raman NSOM are based on the local enhancement of the field very close to the tip. The decrease in enhancement is predicted to vary as  $(a + H)^{-12}$ , with the distance  $H$  from the tip, where  $a$  is the radius of the tip.<sup>[25]</sup> This means that apertureless Raman SERS is essentially a surface technique, which probes a 1- to 2-nm-thick layer. In the case of aperture NSOM, the axial length of the probing region roughly corresponds to the diameter of the aperture. For a 100-nm aperture, one may probe a  $\sim$ 100-nm film without loss in lateral resolution. However, the

**Fig. 6** (A) Topographic image of a single-wall nanotube on glass. (B) Near-field Raman spectra detected at the marked positions 1–4 in (A). The three bumps in the topographic image are probably metal catalyst nanoparticles. *Source:* From Ref.<sup>[47]</sup>.

aperture scheme has not made the same progress as the apertureless NSOM in Raman microscopy because of the absence of surface enhancement. An alternative is IR near-field microscopy.

Mapping the chemical composition of thin films by transmission IR-NSOM has proven particularly useful in the characterization of polymeric resists for deep ultraviolet (DUV) nanolithography.<sup>[48]</sup> In this example, IR absorption near-field spectroscopy has been employed by taking advantage of the “fingerprint” region of the molecular spectra of different compounds resulting from the DUV-patterned exposure of the resist. The goal of this work was the characterization of the latent image formation during the technological steps of proximity mask-assisted DUV patterning and postexposure bake. Two polymeric species were present: poly(methacrylic acid) in the exposed regions and poly(*tert*-butylmethacrylate) in the unexposed regions, which is a photoresist from the acrylate family showing promise for DUV lithography. The most prominent differences in the IR spectra of the two polymers reside in the 2500–3500  $\text{cm}^{-1}$  region, because of the hydroxyl absorption of the poly(methacrylic acid), and in the 800–1500  $\text{cm}^{-1}$  region, because of the loss of the *t*-butoxy group (Fig. 7A). Tuning the wavelength of the color center laser source on and off, the OH stretch absorption

**Fig. 7** (A) Infrared spectra of as-coated (left) and irradiated and postexposure baked polymeric resist films (right). The horizontal double arrow represents the tunable wavelength range of the IR color center laser. (B) IR-NSOM mapping of 8  $\mu\text{m}/8 \mu\text{m}$  line/space pattern latent images written by DUV exposure on a 1- $\mu\text{m}$ -thick chemically amplified photoresist film. The images are taken at wavelengths outside (2.80  $\mu\text{m}$ ) and within (2.94  $\mu\text{m}$ ) the OH stretch absorption band of the exposed polymer, in constant height mode (shear-force coupling with the sample disabled).

band resulted in generating chemical contrast in near-field images of the latent pattern (Fig. 7B). The attained optical resolution was approximately 280 nm for a 3- $\mu\text{m}$  wavelength. McDonough et al.<sup>[49]</sup> have extended this work in a promising direction by measuring the water vapor uptake in photolithographic polymers in a controlled environment.

Although the IR fingerprint region offers a very convenient way for chemical identification, there are three main experimental challenges to consider when working with IR-NSOM. The first is the limited availability of tunable laser sources in IR. The closest to the ideal source from the point of view of spectral brightness, tunability, and collimation is the free electron laser,<sup>[50]</sup> which has the best chances at present to support the realization of an IR near-field microspectroscopic instrument that would surpass the spatial resolution of an FTIR microscope, while covering the same spectral range. Another possible approach is to use a tabletop ultrafast broadband laser source. By difference frequency mixing, the signal and the idler beams in a nonlinear crystal tunable IR radiation

between 2.5 and 12  $\mu\text{m}$  can be obtained at reasonable average powers (around 10 mW).<sup>[51]</sup> Another popular choice, especially for apertureless IR-NSOMs, are CO<sub>2</sub> lasers. Knoll and Keilmann<sup>[52]</sup> used a tunable CO<sub>2</sub> laser coupled with such a microscope to demonstrate vibrational band contrast around  $\lambda = 10 \mu\text{m}$  on polystyrene particles embedded in polymethyl methacrylate. On the biological applications side, Akhremitchev et al. reported on monolayer-sensitive imaging of DNA hexadecanethiol stripes, using a similar instrument. In this case, chemical contrast was achieved because of absorption by phosphate stretching band of DNA.<sup>[53]</sup> Interestingly, the measured infrared contrast, free of topographic artifacts, was significantly greater than the calculated one in both examples. This result was interpreted as evidence for surface-enhanced IR absorption.<sup>[54]</sup>

Besides the light source challenge, other experimental issues to be aware of when dealing with IR-NSOM are: probe optimization, to increase coupling with the near-field; and improved detection, because the detectivity of available detectors for IR is approximately four orders of magnitude less than in the visible. Moreover, vibrational absorptions in IR are a few orders of magnitude weaker than the average electronic absorptions in the visible. These aspects have been considered in detail by Dragnea and Leone<sup>[31]</sup> in their review of submicron infrared vibrational band chemical imaging.

### Nonlinear Near-Field Spectroscopy

The various field enhancements present in the near field make possible the observation and use of coherent non-linear effects for near-field imaging. Non-linear techniques are appealing because: 1) the signal wavelength is shifted with respect to the pump wavelength. As a consequence, these techniques have low background and, sometimes, the signal wavelength is situated in a spectral region where detectors have higher sensitivity (such as in the IR-visible sum frequency generation, a vibrational spectroscopy where the measurements are done in the visible although molecular vibrational bands are probed). 2) Based on same principles as SERS, resonant enhancements may boost the non-linear optical response by orders of magnitude. It follows that in certain situations, the non-linear optical contrast will be significantly enhanced with respect to linear absorption microspectroscopy. 3) Within the dipole approximation, depending on the symmetry of the sample and the order of the non-linear effect in use, interfacial or bulk selectivity can be obtained. Techniques and applications of non-linear chemical imaging microspectroscopy have been reviewed by Schaller et al.<sup>[55]</sup>

## OTHER TECHNIQUES OF CHEMICAL MICROSCOPY

The resolution range of near-field optical microscopy covers length scales between a single molecule and a few microns. At the smallest scales, it overlaps with scanning tunneling microscopy (STM), from the same family of scanning probe techniques. The single-molecule chemistry, imaging, and manipulation by STM have been described in detail in a recent review by Ho.<sup>[56]</sup> An alternative scanning probe technique with chemical specificity is chemical force microscopy (CFM), a variant of AFM.<sup>[57]</sup> CFM overcomes the chemical non-specificity of AFM by covering the tips with well-defined layers of molecular groups having specific interactions with the surface species to be studied.<sup>[57]</sup> CFM is a complementary technique to chemical NSOM in several respects: first, it is a surface technique, which probes only the topmost atomic layers of the sample; second, chemical identification of unknown compounds is not possible—a priori knowledge of the sample is necessary; third, transient species cannot be studied by CFM, which is essentially a static method; and, fourth, the contrast mechanism arises from different molecular forces between the tip and the surface, whereas in optical microscopy, chemical information is usually gathered using molecular vibrational or electronic transitions.

## CONCLUSION

Instrumental advances in chemical near-field optical microscopy have been the focus of the majority of articles published in the past decade in this area. However, at present, the field starts to emerge from the stage of method development. The selected examples mentioned above have been chosen to provide an illustration of notable concepts, which already have begun to shape the research areas where they have been applied, rather than to faithfully illustrate the breath of this rapidly emerging field. At present, these applications mostly span topics in molecular materials, where interesting property variations occur at submicron length scales. Although the potential of the chemical near-field microscopy for biological sciences has been demonstrated with high-resolution Raman, IR near-field, and non-linear optical spectroscopy, significant contributions to solving problems in this area are still to come.

# Noble Metal Nanoparticles on Carbon Fibers

Dmitri A. Bulushev

Igor Yuranov

Swiss Federal Institute of Technology,  
Lausanne, Switzerland

## INTRODUCTION

Today, noble metal nanoparticles find many applications in different fields of human activity. To increase the stability of nanoparticles, a deposition over another material (support) is often performed. The surface chemistry of the support determines the size and structure of the formed metal particles. Among different types of materials used as supports, carbons attract great interest due to their specific characteristics: 1) chemical resistance to acids and bases; 2) opportunity to tailor both physical and chemical surface properties; and 3) easy recovery of precious metals by support burning.<sup>[1–4]</sup> Being in the form of microfibers, carbonaceous materials offer a number of additional advantages.<sup>[5]</sup> Carbon fibers (CFs) are flexible and exhibit the highest specific strength of all reinforcing fibers.<sup>[6]</sup> They have good electrical and thermal conductivity, and low linear coefficient of thermal expansion and abrasion.<sup>[1]</sup> The fibers are also favored, because of the ease in handling when they are used in felt or woven forms.<sup>[7,8]</sup> Activated carbon fibers (ACFs), which are usually utilized as metal nanoparticle supports, assure better reactant transport properties as compared with granular or powdered activated carbons (AC). The unique physical and chemical properties of novel forms of fibrous carbon–carbon nanofibers (CNFs) and carbon nanotubes (CNTs) offer also impressive opportunities for supporting metal nanoparticles.<sup>[9–13]</sup>

The scope of this entry is to review the current status of research of noble metal nanoparticles supported on carbon micro- and nanofibrous materials. Special attention is given to the role of the support surface chemistry and morphology in the formation and properties of metal nanoparticles. Application fields for these promising nanostructured materials are considered.

## ACTIVATED CARBON FIBERS

Activated carbon fibers are produced from polymeric microfibers through processes of carbonization and activation. They exhibit a superhigh specific surface area, normally in the range of 1500–3000 m<sup>2</sup>/g. This originates from uniform split-shaped micropores (<2 nm) that are believed to open directly to the outer fiber surface.<sup>[8]</sup> The chemical reactivity of carbon surface is primarily due to the existence of unsaturated valences (active sites) at the edges of graphitelike hexagonal crystallites (graphene layers). Heteroatoms (mainly oxygen, hydrogen, and nitrogen) form functional groups on these active sites (Fig. 1). In high surface area carbons, surface oxygen may be responsible for more than 20% of their mass. The polar functional groups make the carbon surface more accessible to the metal precursor during impregnation from aqueous solutions. Acidic properties of a carbon material are caused by the presence of carboxylic, phenolic, lactone, and lactol groups. Carbons treated with liquid oxidants (H<sub>2</sub>O<sub>2</sub>, HNO<sub>3</sub>, KMnO<sub>4</sub>, etc.) usually contain more carboxylic groups than O<sub>2</sub>-oxidized samples.<sup>[2,14]</sup> Upon heat treatment, carboxylic groups evolve CO<sub>2</sub> at relatively low temperatures (below 573 K); however, other groups are thermally more stable. At elevated temperatures, less acidic groups provide an interaction of metal precursors or nanoparticles with the support and thus minimize the metal sintering.<sup>[4]</sup> Pyrones are considered to be the most important basic functionalities at the edges of graphene layers.<sup>[14,15]</sup> Nitrogen-containing groups and inorganic impurities can also play a non-negligible role.

Depending on pH, either negatively or positively charged functional groups may exist on a carbon surface in aqueous solutions. A net overall surface charge is zero at the isoelectric point (pH<sub>IEP</sub>). The surface attracts cations at pH > pH<sub>IEP</sub>, and anions

Fig. 1 Functional groups on carbon surface.

at  $\text{pH} < \text{pH}_{\text{IEP}}$ .<sup>[2]</sup> When preparing metal nanoparticles, the support surface should have a suitable charge. Otherwise, electrostatic repulsion forces may be stronger than nonspecific dispersion forces of attraction, and upon drying, the benefits of having a large support surface would be lost with subsequent loss of metal dispersion.

## CARBON NANOFIBERS AND NANOTUBES

Since their discovery,<sup>[9]</sup> CNFs (nanotubes) have captured attention of researchers worldwide.<sup>[10–13,16]</sup> Potentially, CNFs have unique properties for use as a support: with diameters in the range of 1–100 nm and lengths of 0.1–1000  $\mu\text{m}$ , they have a high specific surface area of 10–500  $\text{m}^2/\text{g}$ , being free of micropores and impurities. The materials exhibit an outstanding mechanical stability. Carbon nanofibers are conductive or semiconductive along fibrils and quantized cross-fibrils. This offers opportunities of novel applications that are dependent on the electron conductivities in terms of nanofiber diameters and surface properties.

The manufacturing processes of CNFs now include different methods of graphite vaporization and thermal or plasma-enhanced chemical vapor deposition (CVD).<sup>[17]</sup> Catalytic growth of CNFs by CVD has a great potential for scaled-up material synthesis. Depending on the synthesis conditions and catalyst used, the fibers of different morphologies (tubular, fishbone, platelet, ribbon types, etc.) can be produced (Fig. 2). The tubular type fibers (CNTs) have a hollow core. The fiber surface exposes only basal planes of graphite, while only graphite plane edges are exposed on the surface of the fishbone and platelet type fibers. Another strategy of CNF fabrication involves a template synthesis using anodic nanoporous alumina and ordered mesoporous silicas.<sup>[18–23]</sup>

Due to the peculiar structure, as-produced CNTs [multiwalled (MWNTs) and single-walled (SWNTs)] do not possess a high amount of functional groups on the surface (basal planes of graphite), and mainly surface defects can be considered as anchoring sites for metals. Special pretreatment procedures are needed in this case to achieve optimal interaction between the support and metal precursor. At the same time, CNFs

Fig. 2 Types of carbon nanofibers.

can be used as a support without any pretreatment. Fishbone and platelet structures present potentially reactive groups on the graphene platelet edges. The nature and concentration of the groups are modified by chemical or thermal treatments. Nitric acid treatment is effective for the creation of oxygen-containing groups on the fiber surface. An estimation of the amount of carboxylic/phenolic groups formed on CNTs after  $\text{HNO}_3$  treatment gave  $\sim 10^{21}$  sites per gram.<sup>[24]</sup> Similar value was obtained for the  $\text{HNO}_3$ -treated ACFs.<sup>[25]</sup>

## SUPPORTED METAL NANOPARTICLES

It is well known that mechanical, physical, and chemical properties of nanoparticles may differ considerably from those of bulk substances. Physical properties of unsupported nanoparticles are thoroughly reviewed.<sup>[26]</sup> The deposition over support often endows particles with novel or improved properties. These changes are provided by the change of electronic and structural properties, strong interaction with the support, and increase of the particle/support interface length taking place with metal dispersion. These factors are closely interrelated and determine, for example, the number of catalytically active sites and adsorption energies during catalytic reactions. Thus, the dispersion of a supported metal can be extremely high, making almost every metal atom accessible to reactants. Advantages of metal dispersing over support widely used for catalytic applications are also applicable for different fields of nanotechnology.

Among the noble metals, the most fascinating example of the change of catalytic properties, because of the metal dispersion change, is gold. Noble properties of bulk gold are known for centuries. However, when decreasing the Au particle size up to 3–10 nm, gold becomes a very active catalyst for low-temperature CO oxidation, water gas-shift reaction, NO reduction, diol oxidation, and other reactions.<sup>[27]</sup> An analysis of the activity of gold catalysts in CO oxidation allowed to conclude that the most important reason of the improved activity of finely dispersed gold is the increase of the concentration of low co-ordinated surface Au atoms.<sup>[28]</sup> The effects of the support nature may contribute, but to a lower extent.<sup>[28]</sup>

## NOBLE METAL NANOPARTICLES SUPPORTED ON CARBON FIBERS

Different methods such as incipient-wetness impregnation, ion exchange, organometallic grafting, electron beam evaporation, and deposition/precipitation

followed by reduction are used to prepare noble metal nanoparticles supported on carbon fibrous materials. In all cases, a delicate optimization of carbon surface chemistry is needed to achieve optimal interaction between the support and metal precursor.

## Noble Metals on Carbon Microfibers

The effectiveness of gold and silver adsorption by AC and ACFs from solutions is dependent on the type of the metal precursor, conditions and properties of the carbon surface.<sup>[29–31]</sup> It was found that up to 3 g of metallic gold could be collected on 1 g of ACFs from an  $\text{Au}^{3+}$ -containing solution.<sup>[32]</sup> A decrease of the surface carboxylic groups content was observed after gold adsorption/reduction.<sup>[25]</sup> The reduction capacity was larger than the amount of carbon dioxide released, but approximately equal to the amount of protons produced.<sup>[33]</sup> At the same time, Jia et al.<sup>[34]</sup> report that the oxygen functionality on AC does not have an effect on adsorption of Au and Ag cyanide anionic forms  $[\text{M}(\text{CN})_2]^{n-}$ , while total pore volume is important. They indicated that the graphene layers on carbon are the main adsorption sites of cyanide anions.

Bulushev et al.<sup>[25]</sup> tried to apply aqueous  $\text{HAuCl}_4$  to obtain gold nanoparticles on ACFs. However, utilization of this Au precursor resulted in fast metallization of the external fiber surface independent of the support pretreatment. The obtained material was almost not active in CO oxidation at room temperature, confirming that only big particles of gold are formed on the ACF surface. In contrast, adsorption of ethylenediamine (en) complex  $[\text{Au}(\text{en})_2]\text{Cl}_3$  led to nanosized gold deposition. Interaction took place via ion exchange of  $[\text{Au}(\text{en})_2]^{3+}$  with the surface carboxylic and phenolic groups.  $\text{Au}^{3+}$  exchanged with protons of phenolic groups could be reduced to metallic state by hydrogen (573–773 K) forming nanoparticles of 3–5 nm size, which are extremely active in CO oxidation at room temperature. Ion exchange of the precursor with carboxylic groups was accompanied by spontaneous reduction of  $\text{Au}^{3+}$  to metallic gold nanoparticles of  $\sim 2$  nm size, which served as nucleation sites of bigger particle ( $>9$  nm) formation during  $\text{H}_2$  reduction. Such particles were less active in CO oxidation. The regulation of the carboxylic/phenolic group ratio performed by thermal treatment of ACFs in inert atmosphere allowed controlling the Au particle size. Thus, the treatment at 973 K led to the removal of carboxylic groups, while phenolic groups were still stable. The Au nanoparticles prepared on such a support exhibited the highest activity in CO oxidation. The complete removal of oxygen-containing surface groups at 1273 K resulted in a carbon support, which did not interact with  $[\text{Au}(\text{en})_2]^{3+}$ . It was also found that prior

precipitation–deposition of iron hydroxide on the ACF surface removed mainly carboxylic groups, keeping the phenolic groups intact. This led to the formation of very active Au nanoparticles (3–5 nm) non-contacting with Fe<sub>2</sub>O<sub>3</sub> nanoparticles (Fig. 3).

The importance of the phenolic groups for the interaction of Au nanoparticles with the support was claimed for the Au/AC catalysts prepared using metal sols.<sup>[35]</sup> Among the catalysts with the same average Au particle size (~12 nm), the catalysts based on AC with higher concentration of phenolic groups were more active in liquid phase oxidation of ethylene glycol.<sup>[35]</sup>

Interaction of copper precursors with the carbon surface was also shown<sup>[36,37]</sup> to be dependent on the presence of oxygen-containing surface groups. It was noted that pretreatment of carbon materials in HNO<sub>3</sub> significantly increased copper adsorption. This gives evidence that the following reaction may play an important role for copper adsorption:

Nitrogen-containing groups (pyridinic surface groups) incorporated by ammonia treatment at high temperature may also act as surface co-ordination sites adsorbing Cu<sup>2+</sup> ions from the solution.<sup>[38]</sup>

Baker and coworkers<sup>[39,40]</sup> deposited Cu nanoparticles on different allotropic forms of carbon: AC, diamond, and graphitized microfibers. Activated carbon contains small domains of disordered graphitic

**Fig. 3** Gold nanoparticles on activated carbon microfibers: HRTEM image of the 1.3 wt.% Au/4.5 wt.% FeO<sub>x</sub>/ACFs (elementary filament cut). *Source:* From Ref.<sup>[25]</sup>. © Elsevier, 2004.

structures and has lower electronic and thermal conductivities. Graphite is the most stable form of carbon and possesses excellent thermal and electronic properties. Diamond is an electrical insulator, but it exhibits excellent thermal conductivity. Weakly acidic and non-acidic groups were presented on graphitized CFs and diamond, contrary to AC treated in HNO<sub>3</sub>, which contained strongly and weakly acidic groups. Reduction of Cu<sup>2+</sup> to metallic copper by H<sub>2</sub> was found to be dependent on the nature of carbon support. It was proposed that epitaxial interaction existed between copper and diamond surfaces, which facilitated the copper reduction on that material. The most difficult was the reduction of Cu<sup>2+</sup> on AC, since the strongly acidic carboxylic groups formed copper-carboxylate species on the surface. A higher Cu dispersion was obtained via wet impregnation on diamond as compared with graphitized CFs. It was assigned to stabilization of copper through “dangling” bonds on the diamond surface. Cu dispersed by ion exchange was stabilized on graphitized CFs in aggregates of globular particles deposited on top of graphitic basal planes and smaller crystallites at the edges of defects within these planes. Such distribution of copper affected its reducibility. The shape of supported Cu particles was also found to depend on the carbon support. Thus, following the reduction in H<sub>2</sub> at 373 K, Cu particles on AC and graphitized fibers adopted a toroidal (or “donut”) geometry. For diamond-supported copper, a hexagonal-shaped form was found. The latter geometry was predominant for all supports when the reduction temperature was increased to 573 K. After 24 hr of reduction, the following mean size of the Cu particles was obtained on AC, graphitized fibers, and diamond: 11–20, 8–12, and 7–15 nm, respectively.<sup>[39,40]</sup>

Highly dispersed palladium (3–6 nm)<sup>[41,42]</sup> and platinum<sup>[43]</sup> were supported on ACFs via impregnation followed by reduction. It was mentioned that a large amount of surface functional groups on ACFs made the reduction of platinum precursor to metallic state difficult.<sup>[43]</sup>

### Noble Metals on Carbon Nanofibers and Nanotubes

Due to their unique nature, CNTs and nanofibers are considered as exciting supports for noble metal nanoparticles. Indeed, hollow nanotube cavities can be used to control a particle size and shape. High metal dispersion was obtained on CNTs even if the specific surface area of the support was only 25 m<sup>2</sup>/g.<sup>[44]</sup> Nanotubes can be filled by metals during the arc-discharge synthesis in the presence of metals or through opening and filling the tubes by a metal precursor followed by reduction. It is also possible to remove unwanted metal

particles from outside surface of CNTs. An example of Pd nanoparticles inside the CNTs is shown in Fig. 4.<sup>[45]</sup>

Bera et al.<sup>[46]</sup> deposited Pd nanoparticles (3 nm) inside the CNTs during one-step synthesis using an arc-discharge in solution. The process took place via reduction of  $[\text{PdCl}_4]^{2-}$  anions and simultaneous encapsulation of Pd nanoparticles in CNTs during rolling of graphene sheets from the anode.

Satishkumar et al.<sup>[47]</sup> managed to fill CNTs by Au, Ag, Pd, and Pt nanoparticles. They opened the ends of nanotubes using a variety of oxidants, treated nanotubes with acid solutions containing noble metal ions, reduced the samples in liquid phase, and closed the ends of the filled CNTs by heating in a benzene/hydrogen gas mixture. Encapsulated metal particles of 1–17 nm size were obtained.

An example of Pt nanoparticles located on the external surface of CNTs is shown in Fig. 5.<sup>[48]</sup> The sample was prepared through the treatment of CNTs in an ethylene glycol solution of  $\text{H}_2\text{PtCl}_6 \cdot \text{aq}$  at 313 K followed by washing with diluted  $\text{HNO}_3$ .

Xue et al.<sup>[49]</sup> synthesized Au, Ag, Pd, and Pt particles with the average size of 8, 17, 7, and 8 nm, respectively, on the outer surface of CNTs by impregnation from a metal salt solution, evaporation of the solvent, and reduction in  $\text{H}_2$  at 973 K. It was noticed that the

particle size corresponded to the size of nanotubes used as a support. By comparison, much bigger particles of Pd were obtained on graphite and AC using the same preparation method. The adhesion of nanoparticles to CNTs was not strong. However, stabilization of the particles using different coupling compounds could be achieved.<sup>[50–52]</sup> Thus, alkanethiolate-capped Au nanoparticles (2 and 5 nm) were assembled on the surface of  $\text{HNO}_3$ -treated MWNTs in the presence of bifunctional linking agents.<sup>[52]</sup> The chemistry involved in the assembly is a combination of the hydrophobic interaction between the alkyl chains of the capping molecules and the hydrophobic backbones of nanotubes as well as of the hydrogen-bonding interaction between carboxylic groups of linking molecules and the functional groups of the nanotubes' surface. The organic shells could be removed by thermal treatment. The morphology and packing density for the nanoparticle assembly depended on the relative concentrations of nanoparticles, linking molecules and nanotubes.

It is important to note that Au,<sup>[50]</sup> Pd,<sup>[50,53,54]</sup> and Rh<sup>[55]</sup> could not be attached to CNTs and CNFs without functionalization of the support. However, Au, Pt, and Ag nanoparticles with size of 1–7 nm were successfully obtained on  $\text{HNO}_3$ -pretreated CNTs.<sup>[24]</sup>

**Fig. 4** HRTEM image of Pd nanoparticles inside carbon nanotubes. *Source:* From Ref.<sup>[45]</sup>. © Elsevier, 2003.

**Fig. 5** HRTEM image of Pt nanoparticles on the external surface of carbon nanotubes. *Source:* From Ref.<sup>[48]</sup>. © Elsevier, 2004.

Ye, Lin, and Wai<sup>[56]</sup> decorated MWNTs with Pd particles by reduction of Pd  $\beta$ -diketone precursor in supercritical CO<sub>2</sub>. The authors obtained well-dispersed particles of 5–10 nm size anchored to the external walls of the support.

Hoogenraad et al.<sup>[53,54]</sup> used tubular and fishbone type CNFs as supports for Pd nanoparticles. Pd was deposited from the ammine complex [Pd(NH<sub>3</sub>)<sub>4</sub>]Cl<sub>2</sub>. It was essential to keep air-free conditions during drying of impregnated material in order to escape big Pd particle formation. The hemispherical Pd particles with the size of 1.5–4 nm were observed by HRTEM (high-resolution transmission electron microscopy) after reduction.

Chesnokov et al.<sup>[57]</sup> used three types of CNFs for Pd deposition from PdCl<sub>2</sub>. They showed that Pd nanoparticles exhibited a strong interaction with the butt ends of graphite (0 0 2) layers. This interaction probably resulted in electron transfer from the metal to the support and stabilization of nanoparticles.

Ma et al.<sup>[58]</sup> studied Cu particles supported on different (fishbone, platelet, ribbon, and tubular) types of CNFs. Copper was deposited from aqueous salt solutions. If Cu nanoparticles were located on the edge sites of nanofibers, they adopted a thin faceted morphology indicating a strong metal–support interaction. The particles formed in such a way were very stable with respect to sintering. However, the particles tended to acquire a globular geometry if the copper was supported on AC or the basal planes of graphite, showing a very weak interaction with the support. Thus, the fishbone and platelet CNFs were the best supports to provide small particles with a narrow size distribution. A precursor salt and carbon surface functionality turned out to also affect the particle size distribution and stability.

Supported Cu nanoparticles (<10 nm) were prepared using CNFs with a diameter ranging from 100 nm.<sup>[59]</sup> Carbon nanofibers were impregnated with a copper salt solution, dried and treated by H<sub>2</sub> (773 K). The electronic properties of the nanoparticles differed considerably from those of bulk copper. It was noticed that the size of Cu particles was dependent on the size of CNFs: the smaller the fiber diameter, the smaller the Cu nanoparticle size obtained. However, the nanoparticles were not strongly attached to the support and could be detached by ultrasonic treatment.

Up to 10 wt.% of platinum loading on SWNTs was achieved by Lordi, Yao, and Wei<sup>[60]</sup> using K<sub>2</sub>PtCl<sub>4</sub> as a metal precursor and reduction by ethylene glycol. The average size of supported Pt nanoparticles was 1–2 nm. These particles were located on bundles of CNTs but never on isolated tubes. The authors pointed out that a strong agitation could remove weakly bound Pt particles from the support. Therefore, the nanotubes were

pretreated in diluted HNO<sub>3</sub> in order to create surface functional groups able to stabilize Pt nanoparticles. Similarly, it was noted that functional groups may provide not only effective interaction of the Rh precursor with carbon, but also stabilization of the resulting Rh nanoparticles.<sup>[61]</sup>

Extremely small stable Pt nanoparticles were synthesized on the nanostructured carbon by incipient-wetness impregnation from an H<sub>2</sub>PtCl<sub>6</sub>/acetone solution followed by drying and H<sub>2</sub> reduction.<sup>[22]</sup> In this case the carbon structure was composed of ordered nanotubes, which were originally formed inside the cylindrical nanochannels of the SBA-15 template. Even after the template had been removed, the nanotubes were rigidly interconnected into a hexagonal array by carbon spacers, which were formed inside the complementary micropores between the SBA-15 nanochannels. When the Pt loading was 2 wt.%, the Pt nanoparticles were less than 1.3 nm in diameter. A narrow particle size distribution (~2.5 nm) was observed at 50 wt.% Pt loading.

## APPLICATIONS OF NOBLE METAL NANOPARTICLES SUPPORTED ON CARBON FIBROUS MATERIALS

Decoration of CFs by metal nanoparticles endows the materials with new valuable properties. Up to now, noble metal nanoparticles supported on carbon fibrous materials have been mostly applied as heterogeneous catalysts. However, other applications are intensively developing.

### Catalytic Applications of Noble Metals on Carbon Microfibers

Gold nanoparticles on ACFs possess the catalytic activity in room-temperature CO oxidation comparable with the best reported catalysts (Au/TiO<sub>2</sub>, Au/Fe<sub>2</sub>O<sub>3</sub>).<sup>[62]</sup> The activity increases in the presence of water vapor and hydrogen. Application fields of Au nanoparticles on CFs could be extended to other catalytic reactions, since Au on the conventional activated carbon is shown to be an effective catalyst, for example, for liquid phase selective oxidation of alcohols and aldehydes.<sup>[35,63,64]</sup>

Copper catalysts supported on AC, graphitized carbon microfibers, and diamond powder were studied in crotonaldehyde hydrogenation.<sup>[65]</sup> Copper deposited on graphitized microfibers demonstrated lower activity and higher selectivity toward crotyl alcohol as compared to other catalysts. This was attributed to small Cu nanoparticles preferentially stabilized along the edges of the graphitic basal planes. However, no effect

of carbon support was found for hydrogenation of furfural.<sup>[66]</sup> The Cu catalysts based on graphitized CF and diamond suffered from deactivation contrary to the catalyst supported on AC.

Ma et al.<sup>[67]</sup> studied Cu nanoparticles based on different allotropic forms of carbon including graphitized carbon microfibers for N<sub>2</sub>O decomposition. The catalytic activity was found to be directly related to the copper dispersion.

Copper in combination with ZnO supported on AC, black carbon, and ACFs was used in hydrogen production during partial methanol oxidation.<sup>[68]</sup> It was concluded that a deposition of the active phase on a microporous structure leads to a lower initial activity, but a better stability with respect to Cu sintering.

A linear dependence of the activity in nitrobenzene hydrogenation on Pt dispersion was found for the catalysts based on ACFs.<sup>[43]</sup>

Activated carbon fibers were applied as a structured support for deposition of palladium nanoparticles active in hydrogenation of unsaturated hydrocarbons<sup>[41]</sup> and nitrite.<sup>[42,69]</sup> The catalysts with average Pd particle size of 3–6 nm on ACFs showed a better activity than the ones prepared on glass fibers.

### Catalytic Applications of Noble Metals on Carbon Nanofibers and Nanotubes

It was mentioned<sup>[44]</sup> that opportunities for using single-walled CNTs are rather limited, while multiwalled CNTs and CNFs seem to be more perspective.

Pd nanoparticles supported on CNFs exhibited a comparable activity in hydrogenation of nitrobenzene to aniline<sup>[53]</sup> and increased activity in hydrogenation of C=C bond of cinnamaldehyde<sup>[70]</sup> with respect to the commercial Pd catalyst based on AC. An important advantage of the CNF support is that surface area, size of fibrils, as well as mechanical strength can be controlled and mass transfer limitation can be decreased, because of the absence of micropores. A change of electronic properties of Pd particles provided by interaction with CNFs resulted in a change of their catalytic properties in 1,3-butadiene hydrogenation to butanes.<sup>[57]</sup> An increase of the Pd<sup>2+</sup> fraction in the catalysts decreased the activity and selectivity.

The following trend of specific activity was found for gas phase phenol hydrogenation over Pd catalysts: Pd/AC ~ Pd/ribbon CNFs < Pd/fishbone CNFs < Pd/SiO<sub>2</sub> ~ Pd/graphite < Pd/Ta<sub>2</sub>O<sub>5</sub>.<sup>[71]</sup> The size of the particles was in the range 6–17 nm. The authors concluded that the stronger was the Pd particles-support interaction, the higher was the reaction rate. The selectivity toward cyclohexanone and cyclohexanol was assumed to be dependent on the crystallographic orientation of Pd nanoparticles.

Pd particles (5–10 nm) supported on MWNTs showed high activity in hydrogenation of olefins in supercritical CO<sub>2</sub> and in oxygen electrocatalytic reduction.<sup>[56]</sup>

Some specific properties of Pt on the platelet type nanofibers with respect to Pt on silica in *n*-hexane isomerization were reported by Baker et al.<sup>[72]</sup> The former catalyst produced more isomers at lower temperature and higher H<sub>2</sub> partial pressure. This was assigned to the presence of a larger amount of hydrogen on the CNFs support.

Lordi, Yao, and Wei<sup>[60]</sup> applied Pt nanoparticles supported on SWNTs to hydrogenate 3-methyl-2-butenol to 3-methyl-2-butenol with high selectivity.

Ros et al.<sup>[55]</sup> used the fishbone type CNFs as a support for Rh nanoparticles (1–2 nm) applied in hydrogenation of cyclohexene. No significant effect of the size of nanoparticles on the catalytic activity was found.

Rh nanoparticles supported on graphite nanofibers were used as a catalyst in ethylene hydroformylation.<sup>[73]</sup> Their activity was compared with the activity of Rh/SiO<sub>2</sub>. They were found similar, but the selectivity toward propaldehyde was higher for Rh on nanofibers. Rh on the ribbon type nanofibers gave the highest selectivity. The morphological factor was accepted to be more important than the particle size. For the most selective catalyst, the (1 1 1) face of Rh was preferentially exposed to the gas phase.

Rh supported on MWNTs was used for hydrogenation of cinnamaldehyde and hydroformylation of hexane in liquid phase.<sup>[74]</sup> In both cases, the catalyst was found to be selective toward C=C bond hydrogenation and aldehyde production, respectively. The functionalization of nanotubes by the HNO<sub>3</sub> treatment before the Rh deposition from [Rh<sub>2</sub>Cl<sub>2</sub>(CO)<sub>4</sub>] was necessary to get an active catalyst. Otherwise, the Rh dispersion and catalyst activity were low.

Luo et al.<sup>[75]</sup> showed that Rh nanoparticles (~10 nm) supported on CNTs can decompose NO at temperatures lower than 573 K more effectively than Rh nanoparticles supported on γ-Al<sub>2</sub>O<sub>3</sub>. The Rh/CNTs catalyst was found to be more capable in keeping rhodium in metallic state indicating a strong Rh-support interaction.

The catalytic properties of Ir (30 wt.%) supported on a CNFs/carbon felt composite and alumina were compared in hydrazine decomposition.<sup>[45,76]</sup> The advantages of the former catalyst with the average metal particle size of 2 nm were the mechanical resistance, stability, low weight, and high thermal conductivity.

### Miscellaneous Applications

Antibacterial properties of Ag and Cu are well known. Activated carbon fibers demonstrate higher sorption

characteristics than granular AC. Combination of these properties in one material [Ag(Cu) nanoparticles/ACFs] is reported to be promising for water cleaning.<sup>[77]</sup>

Cu nanoparticles obtained by chemical methods were active in production of regularly coiled fishbone type CNFs by decomposition of acetylene, while nanoparticles produced from H<sub>2</sub> arc plasma revealed the ribbonlike nanofibers only.<sup>[78]</sup>

Cu filled CNTs were proposed as interconnect material for integrated circuits.<sup>[79]</sup>

Javey et al.<sup>[80]</sup> fabricated a high-performance nanotube field-effect transistor with almost zero Schottky barrier using Pd-SWNT junctions. Palladium greatly reduces the barriers for electron transport through the valence band of nanotubes.

SWNTs decorated with Pd nanoparticles were found to exhibit a significant electrical conductance modulation upon exposure to small concentrations of H<sub>2</sub> in air. The Pd nanoparticles/CNTs-based H<sub>2</sub> sensors showed high sensitivity, fast response, and reversibility at room temperature.<sup>[81]</sup>

Pd supported on the fishbone type CNFs<sup>[82]</sup> and CNTs<sup>[83,84]</sup> was studied in hydrogen storage. The hydrogen loading of 1.5 wt.% was reached at 10 MPa of H<sub>2</sub> pressure for nanofibers with specific surface area of 400 m<sup>2</sup>/g and Pd:C mole ratio close to 1. Hydrogen of 3.1 wt.% stored was reported for the 4.1 wt.% Pd/MWNT material. However, all these values are well below the 6.5 wt.% benchmark set by the U.S. Department of Energy for such kind of materials.

Development of fuel cells based on CNTs or mesoporous carbon coated by metal nanoparticles as electrodes for mobile and laptop applications was reported by some leading electronics companies.<sup>[85,86]</sup> Using CNTs with platinum nanoparticles for fuel cell purposes was discussed in a number of publications.<sup>[87-89]</sup> Higher catalytic activity and better cell performance as compared to the catalysts supported on commercial carbons were found. The current density during methanol oxidation at the Pt (~7 nm)/CNT membrane electrode was ~20 times higher than at the bulk Pt electrode. This enhancement was due to both high surface area and high electrocatalytic activity of Pt nanoparticles dispersed inside the CNTs.

The high Pt dispersion (<3 nm) on the ordered array of CNFs prepared by using mesoporous SBA-15 silica as a template also gave rise to a promising activity for O<sub>2</sub> electrocatalytic reduction.<sup>[22]</sup>

## CONCLUSIONS

Carbon micro- and nanofibers provide impressive opportunities for supporting highly dispersed noble metals. Resulting functional materials combine specific properties of metal nanoparticles and fibrous supports.

Carbon surface chemistry allows controlling metal particle size and stabilizing nanoparticles on the support. On the other hand, carbon fibrous supports represent the materials with the advantages of structured materials such as mechanical stability, improved hydrodynamic and transport properties, etc. Nanocarbons, due to their dimensions, bring new unique opportunities to control the size and morphology of supported metal nanoparticles. Today, noble metal nanoparticles supported on carbon fibrous material are already used extensively in electro- and heterogeneous catalysis. Undoubtedly, tomorrow, they will find a wide application in other fields of nanotechnology.

## INTRODUCTION

Second-order non-linear optical (NLO) materials possess non-centrosymmetric structures in which there is a net orientation of an NLO-active constituent. Materials that exhibit second-order NLO properties are the active components in optoelectronic devices such as electro-optic modulators and frequency doubling devices.<sup>[1–3]</sup> Non-linear optics refers to the optical response of a material that relates the polarization vector  $P$  to an applied electric field  $E$  according to:

$$P = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \dots \quad (1)$$

where  $\chi^{(n)}$  is the  $n$ th-order susceptibility. The susceptibilities for the non-linear terms characterize the non-linear optical response of a material. Consider the interaction of an optical electric field at frequency  $\omega$  and amplitude  $E_\omega$

$$E_\omega(t) = E_\omega(e^{+i\omega t} + e^{-i\omega t})/2 \quad (2)$$

When a static electric field  $E_0$  is also present in a medium with a nonzero  $\chi^{(2)}$ , the second-order

polarization term becomes

$$\begin{aligned} P^{(2)}(t) &= \chi^{(2)}E^2(t) \\ &= \chi^{(2)}[E_\omega^2(e^{+2i\omega t} + e^{-2i\omega t})/4 \\ &\quad + E_\omega E_0(e^{+i\omega t} + e^{-i\omega t}) \\ &\quad + (E_\omega^2/2 + E_0^2)] \end{aligned} \quad (3)$$

The first term in Eq. (3) oscillates at frequency  $2\omega$  and depends only on the optical electric field and not the static field. This effect is referred to as second harmonic generation (SHG) and is the NLO effect directly probed in this work. The second term oscillates at frequency  $\omega$  and causes a variation in the refractive index  $n$  in the medium that is linearly proportional to  $E_0$ . This effect is known as the linear electro-optic effect and forms the basis for electro-optic modulator devices. The third term is time-independent and is referred to as optical rectification, the conversion of an oscillating electric field to a static d.c. field in the NLO material. For all three effects, the magnitude of  $\chi^{(2)}$  governs their contribution to  $P^{(2)}(t)$ . To possess nonzero even-order non-linear optical susceptibilities, a material must lack a center of inversion at the macroscopic level.<sup>[2,3]</sup> Because these second-order  $\chi^{(2)}$  nonlinear

optical effects are quadratic in the applied fields, symmetry considerations require that a material must be non-centrosymmetric to possess a non-zero  $\chi^{(2)}$ .

## OVERVIEW

The most common high  $\chi^{(2)}$  materials are ferroelectric, inorganic crystals such as lithium niobate, potassium dihydrogen phosphate, and beta-barium borate.<sup>[2,3]</sup> Growth of high-quality crystals, however, is difficult, time consuming, and expensive. However, organic NLO materials offer several performance advantages such as enhanced non-linear susceptibilities, faster modulation rates, and potentially lower device fabrication costs.<sup>[4]</sup> For organic thin films containing NLO-active chromophores,  $\chi^{(2)}$  is related to the NLO chromophore hyperpolarizability ( $\beta$ ), chromophore density ( $N$ ), orientation angle ( $\theta$ ) relative to the film normal vector, and a local field factor effect ( $F$ ) by

$$\chi^{(2)} = NF\beta\langle\cos^3\theta\rangle \quad (4)$$

For effective electro-optic modulators,  $\chi^{(2)}$  should be as large as possible. Rational design of an organic film thus involves choosing a chromophore with a suitably high  $\beta$  and incorporating it into a film with high density  $N$  and low orientation angle  $\theta$ . For effective optical waveguide performance, the film thickness should be in the range 1–10  $\mu\text{m}$ .

The objective of this work was to demonstrate that organic, low molecular weight, nonsymmetric chromophores can be integrated into films by a facile, layer-by-layer deposition process using a combination of electrostatic and covalent bonding.<sup>[5]</sup> This deposition process results in noncentrosymmetric films that exhibit significant SHG intensities where the square root of the SHG intensity scales linearly with bilayer number, indicating that deposition results in a reproducible orientation of the chromophore molecules from bilayer to bilayer up to high bilayer numbers. The effect of pH is shown to be critical in controlling both the electrostatic and covalent coupling steps.

## OVERVIEW OF ORGANIC, HIGH $\chi^{(2)}$ FILMS

In previous work, organic films exhibiting non-zero  $\chi^{(2)}$  have been made using various techniques including corona poling, Langmuir–Blodgett (LB) methods, covalent self-assembly, and, more recently, ionically self-assembled monolayers involving polyelectrolytes. Poled polymer materials are fabricated by doping a host matrix with chromophore molecules, which are then oriented by an applied electric field while the

matrix is above its glass transition ( $T_g$ ) temperature. The temperature of the matrix is then brought below the  $T_g$ , which locks in the orientation.<sup>[6]</sup> While poled polymer systems are capable of high second-order NLO activity and are easy to fabricate, the orientation of the chromophore molecules in the host is usually lost over time. The randomization of the dipole orientation in poled polymer devices occurs more quickly at elevated temperatures, and this severely limits the operating lifetime of these materials.<sup>[7]</sup> Langmuir–Blodgett films have been made with noncentrosymmetric Z- and X-type structures that exhibit relatively high values for  $\chi^{(2)}$ , but their relatively poor mechanical properties have limited their application in devices.<sup>[8]</sup>

Layer-by-layer (LBL) film deposition techniques that use intermolecular interactions such as covalent bonds, electrostatic attractions, or hydrogen bonding to drive self-assembly are particularly interesting for fabricating wholly organic and organic–inorganic hybrid films that exhibit SHG. There is a large, growing body of literature on the use of LBL methods for fabricating nanostructured films for a number of applications, including organic light emitting diodes,<sup>[9]</sup> humidity sensors,<sup>[10]</sup> biosensors,<sup>[11]</sup> photovoltaics,<sup>[12]</sup> electrochromics,<sup>[13]</sup> and non-linear optic (NLO) materials.<sup>[14]</sup> The LBL technique relying on purely electrostatic interactions, referred to hereafter in this paper as the ionically self-assembled monolayer (ISAM) process, was first developed by Iler<sup>[15]</sup> and elaborated upon by Decher, Lvov, and Schmitt<sup>[16]</sup> This process involves the sequential immersion of a charged substrate into solutions of polyelectrolytes of opposite charge.<sup>[16]</sup> A monolayer of polymer adsorbs onto the surface, resulting in charge reversal. The substrate is then removed from the solution, thoroughly rinsed to remove non-adsorbed polymer, and immersed in a solution of polyelectrolyte with a charge opposite to that of the adsorbed layer. A monolayer of polymer adsorbs, forming a bilayer with the first polymer, and the immersion process is repeated, building up a multilayer film. Reviews by Decher<sup>[17]</sup> and Hammond<sup>[18]</sup> describe many studies of films made with a variety of organic polyelectrolytes and nanoparticles.

With the ISAM method, NLO-active chromophores are oriented by the non-covalent interactions between soluble and deposited species to form multilayered films with compositions controlled at the nanometer length scale. Hefin et al.<sup>[19]</sup> and Lindsay et al.<sup>[20]</sup> demonstrated that the ISAM process can be used to create films exhibiting SHG by incorporating an NLO-active polymer as one of the constituents in a film and that these ISAM films have greater stability than poled polymer systems. Herman and Roberts<sup>[21]</sup> studied chromophore orientation in ISAM films and found that the orientation of the chromophore in the first layer can be influenced by hydrophobic interactions

between the chromophore molecule and the substrates. Furthermore, they concluded that orientation in subsequent layers is influenced by the orientation of this first layer. DeWitt and Hammond<sup>[22]</sup> showed that the average tilt angle of the charged chromophoric group in a film and the film thickness depend strongly on the solution pH values. Lee et al. showed linear growth of absorbance and thickness for films made by deposition of a polycation and a polymeric dye precursor. These films were then functionalized with the dye moiety. These films showed the expected quadratic relationship between the SHG intensity and the number of bilayers, meaning that chromophore orientation is consistent from one bilayer to the next.<sup>[23]</sup> Deposition of ordered films using reactive silane compounds has been demonstrated, but the deposition processes required organic solvents and high temperatures.<sup>[24,25]</sup>

Because of the nature of the formation of ISAM films utilizing two polymers, the NLO-active polyelectrolyte necessarily has chromophores oriented in opposite directions to provide binding to the preceding and following oppositely charged layers (Fig. 1). The opposing dipole orientations cancel one another and lead to an overall reduction in the  $\chi^{(2)}$  of the film. Thus polyelectrolyte-based ISAM films suffer from lack of orientation of chromophores within the "bulk" of a monolayer and partial cancellation of the preferentially oriented chromophores at the lower interface by chromophores at the upper interface.

A related approach that could be employed to fabricate NLO materials involves the use of low molecular weight, ionic dye molecules and polyelectrolytes as film constituents. Yamada et al.<sup>[26]</sup> fabricated films of poly(diallyldimethylammonium chloride) and Eriochrome Black T and observed linear growth of the film during the non-covalent deposition process. These films exhibited a SHG intensity that increased only for the first five bilayers and then reached a plateau. This plateau after five bilayers was attributed to the chromophore molecules in upper layers not having

**Fig. 1** Schematic illustration of an ISAM film containing a polar non-linear optical polymer.

**Fig. 2** Structure of Procion Red MX-5B.

the same orientation as they did in lower layers; however, the addition of layers did not perturb the orientation of previous layers. Yet to be demonstrated is a combination of low molecular weight chromophore molecules and polyelectrolytes that can be used to construct stable NLO-active films with high bilayer numbers needed for electro-optic device fabrication.

## NON-LINEAR OPTICAL FILM FABRICATION BY COVALENT/IONIC SELF-ASSEMBLY

This present work shows that low molecular weight, non-symmetric chromophores can be stably integrated into films by a facile, layer-by-layer deposition process using both electrostatic and covalent bonding.<sup>[5]</sup> Additionally, it is shown that this deposition process results in non-centrosymmetric films that exhibit significant SHG intensities where the square root of the SHG intensity scaled linearly with bilayer number, indicating that deposition results in a reproducible orientation of the chromophore molecules from bilayer to bilayer up to high bilayer numbers. The model chromophore used is Procion Red MX-5B (Fig. 2), a reactive dye that contains a triazine ring and two sulfonic acid groups. Poly(allylamine hydrochloride) (PAH, Fig. 3) was used to provide both the nucleophilic primary amine groups for reaction with the triazine ring and the protonated amine groups for electrostatic interaction with the sulfonic acid groups of PR (Fig. 4). Koetse, Laschewsky, and Verbiest<sup>[27]</sup> earlier demonstrated that Procion Red and a reactive primary amine that was not PAH could form layer-by-layer

**Fig. 3** Structure of poly(allylamine hydrochloride) (PAH),  $pK_a = 8.7$ .

Fig. 4 Reaction between PR molecule and a previously adsorbed monolayer of PAH.

films, but no polar ordering was observed, unlike the present work.

The pH of the PR and PAH solutions was found to be a key processing variable for achieving reproducible films with a high degree of polar ordering of the PR molecules. Conditions favoring incorporation of PR by covalent bonds resulted in films with high SHG intensity. The deposition steps involve only aqueous solutions at ambient conditions, and immersion times can be as low as 2 min/monolayer.

Details of film fabrication can be found elsewhere and so only a summary is presented here.<sup>[5]</sup> The anionic/reactive Procion Red MX-5B chromophore was commercially available. The absorbance spectrum of this chromophore in deionized water solution is shown in Fig. 5. The characteristic peak for this molecule is 538 nm, which was used for all absorbance measurements.

The NLO-inactive polycation used in this study was poly(allylamine hydrochloride) (PAH; MW

~70,000 g/mol), which was also commercially available. Poly(allylamine hydrochloride) solutions at a concentration of 0.01 M on a monomer basis were used in all experiments, while the concentration of all PR solutions was 5 mg/ml. Dynamic light scattering (DLS) was used to measure the diffusion coefficient of the PAH as a function of pH to characterize the polymer solubility.<sup>[28]</sup> Deionized (DI) water with a specific resistivity above 17 M $\Omega$  cm was used in all of the experiments.

Glass microscope slides were used as the substrates on which films were deposited after the slides were rigorously cleaned.<sup>[29]</sup> The glass slide immersion time in PAH was 5 min, with the exception of the first layer which was 10 min. The immersion time in PR was 10 min. Between immersions, the substrates were vigorously agitated and rinsed with deionized water. Thorough rinsing is critical for obtaining films with good optical homogeneity. Slides were dried every 10 dips (which gives five bilayers on each side of the slide) using N<sub>2</sub> gas.

## NON-LINEAR OPTICAL FILM CHARACTERIZATION

Absorbance measurements were made at a wavelength of 538 nm, and film thicknesses were measured using a variable angle spectroscopic ellipsometer.<sup>[30]</sup> Second harmonic generation measurements were performed using a 10-nsec pulse width, Q-switched Nd:YAG laser with a fundamental wavelength of 1064 nm.<sup>[31]</sup> Because the film was deposited on both sides of the substrate and the incidence angle  $\alpha$  was varied, the path length through the film on both sides varied with  $\alpha$ . This led to interference fringes of the SHG intensity. The  $\chi^{(2)}$  value was determined from the peak of the interference fringe in the vicinity of  $\alpha \sim 45^\circ$ . By comparison to

**Fig. 6** Representative plots of the absorbance at 538 nm as a function of the number of bilayers deposited.

Maker fringes in a quartz crystal wedge,  $\chi^{(2)}$  of a film was obtained from

$$\frac{\chi_{\text{film}}^{(2)}}{\chi_{\text{q}}^{(2)}} = \frac{2l_{\text{c,q}}}{\pi l_{\text{film}}} \sqrt{\frac{I_{\text{film}}^{2\omega}}{I_{\text{q}}^{2\omega}}} \quad (5)$$

where  $l_{\text{film}}$  is the total path length through the film, the coherence length of quartz,  $l_{\text{c,q}} = \lambda/[4(n^{2\omega} - n^{\omega})]$ , is 22.4  $\mu\text{m}$ , and  $\chi^{(2)}$  of quartz is  $1.92 \times 10^{-9}$  esu.

This study focused on the effect of the pH of the PR and PAH solutions on the film properties. Successful film growth was characterized by homogeneity and a linear increase in the absorbance and thickness with the number of bilayers deposited. Absorbance data for successfully deposited films are shown in Fig. 6 and Table 1. The slope characterizes the amount of dye deposited per bilayer; the standard deviation of this slope describes the reproducibility of the film deposition among replicates for a given set of experimental conditions; the correlation coefficient characterizes the reproducibility of PR deposition from bilayer to bilayer. These films displayed a linear increase in the absorbance as a function of the bilayer number.

When the pH of the PAH solutions was held constant, the amount of PR deposited per bilayer

**Fig. 7** Dynamic light scattering results for the translational diffusion coefficient of PAH in solution as a function of pH at two polymer concentrations (molarity of repeat unit) with no added salt.

increased as the pH of the PR solution was increased (compare experiments A vs. B and C vs. D, Table 1). This trend was observed until the pH of the PR solution was raised to 12.0, at which point deposition of PR failed. The best PR deposition was observed when the PR solution was at a pH of 10.5. At this optimal PR deposition condition, as the pH of the PAH solution was increased from 4.5 to 7.0 (compare experiments B vs. D), a small but statistically insignificant increase in the film thickness per bilayer ( $p > 0.05$ ) and a significant increase in the amount of PR deposited per bilayer ( $p < 0.05$ ) were observed.

Poor film formation was observed for PAH solutions deposited at  $\text{pH} \geq 8.5$ . This is likely a result of incipient aggregation and insolubility of the PAH as the pH increased. The dramatic decrease in diffusion coefficient for  $\text{pH} > 7$  (Fig. 7) is consistent with the reduction in charge density of the PAH given its  $\text{p}K_{\text{a}}$  (8.7). The reduced charge density leads to reduced solubility and the formation of aggregates consisting of multiple PAH chains. Such aggregates hinder the formation of uniform, homogeneous monolayers of adsorbed PAH chains that lead to poor layer-by-layer film formation, especially when the other constituent is not a polyelectrolyte.

When the film thickness is much less than the coherence length of the material, the SHG intensity should

**Table 1** Summary of the slopes of the absorbance vs. number of bilayers and ellipsometric thicknesses for deposition of PR (0.025 m) and PR (0.025 mM)

Experiment	PAH pH	PR pH	Slope (Abs/bilayer) (correlation coefficient)	Bilayer thickness (nm)	$\chi^{(2)}$ ( $10^{-9}$ esu)
A	4.5	7.0	$8.9 \times 10^{-4} \pm 1.0 \times 10^{-5}$ (0.998)	N/A <sup>a</sup>	N/A
B	4.5	10.5	$2.0 \times 10^{-3} \pm 1.0 \times 10^{-4}$ (0.992)	$0.34 \pm 0.02$	11.2
C	7.0	7.0	$2.3 \times 10^{-3} \pm 4.0 \times 10^{-4}$ (0.999)	$0.55 \pm 0.05$	1.2

exhibit a quadratic dependence on the film thickness or, correspondingly, number of bilayers. Fig. 8 shows the square root of the peak second harmonic intensity as a function of the number of bilayers for the sets of films fabricated with different PAH and PR solution pH values. The linear dependence of the square root of the SHG intensity on the number of bilayers for the films fabricated with a PR solution at pH 10.5 (Fig. 8, experiments B and D) demonstrates that the SHG signal is due to polar ordering in each successive bilayer of the film. If the degree of ordering decreased in successive bilayers or if the SHG signal was a result of interface effects, the SHG intensity would have a subquadratic dependence on the number of bilayers. For the films fabricated with a PR pH of 7.0, there is a much weaker dependence of the SHG intensity on the number of bilayers, indicating a lesser degree of ordering.

The growth of the self-assembled films in real time was monitored using in situ second harmonic generation. In this case, a glass substrate coated with an adsorbed layer of PAH was immersed in a cuvette filled with PR dye solution. The substrate was held fixed in

the laser beam throughout the procedure. Because the glass cuvettes, the immersion solutions, and the glass substrate are all centrosymmetric, the SHG signal is due to the polar film as it grows on the substrate along with a small background signal from the air-glass and glass-liquid interfaces. The substrate was first immersed in PAH solution at pH 7.0 to produce a cationic surface. Figure 9 shows the SHG intensity as a function of time as the substrate was then immersed in a PR pH 10.5 solution. The covalent deposition of Procion Red on PAH was essentially complete in 2 min. The simplicity and potential scalability of this alternating ionic/covalent deposition process are illustrated by the in situ SHG signal that is obtained as the reactive dye is incorporated into the film. A single bilayer film is saturated with dye within about 2 min at pH 10.5. Thus multilayer films with thicknesses required for optoelectronic devices can be made just as quickly with reactive dyes as with polymeric dyes in the ISAM process. After accounting for the non-zero intercept, which is a result of the inherent non-centrosymmetry of the substrate/solvent interface effects, simple Langmuir kinetics can be used to model the dye deposition process.

## CHROMOPHORE DEPOSITION AND ORIENTATION—EFFECT OF PH

Ionic interactions alone are not sufficient for constructing LBL films with low molecular weight chromophores that exhibit polar order.<sup>[32]</sup> However, by alternating the mechanism of the deposition of each monolayer between covalent and electrostatic coupling and decoupling the chromophore orientation from the steric constraints of a polymer chain, the PR chromophore was deposited with a non-centrosymmetric orientation that is required for the film to display NLO properties such as SHG.

**Fig. 9** In situ measurement of the SHG intensity as Procion Red is deposited in the film.

The effects of polymer type, pH, salt concentration, and other processing variables on film deposition by physisorption of charged polymers have been studied by Decher and Schmitt,<sup>[33]</sup> Lvov et al.,<sup>[34]</sup> Rubner et al., and others.<sup>[35–42]</sup> Shiratori and Rubner<sup>[43]</sup> found that the thickness of ISAM bilayers made with weak polyelectrolytes can be varied by over an order of magnitude simply by varying the pH and ionic strength. This is particularly relevant to the present work in that it suggests a method for controlling the conformation and thickness of the adsorbed polymer layers which is critical for controlling the orientation of deposited NLO-active chromophores.

The pH determines the ionization state of the amine side groups on PAH, which affects both the conformation of the polymer upon adsorption and its subsequent reactivity with Procion Red. Efficient electrostatic deposition of PAH requires that the pH of the PAH dipping solution is maintained near or below the amino group  $pK_a$  (8.7), where the majority of the side groups will be protonated and available for interaction with the negative charges on the substrate or the sulfonate groups on the dye.<sup>[44]</sup> For cases A–D described in Table 1, the amino groups on the PAH chain were essentially fully protonated when the chains were deposited. With no additional salts in these solutions, these PAH solutions were at low ionic strengths, typically 0.003 M, so there was relatively little shielding of charged groups. Under these conditions, the fixed positive charges on the polymer chain strongly repelled each other and were strongly attracted to the negatively charged surface. These two effects led to the deposition of PAH in flat, train-like layers where the bilayer thickness was less than 1 nm/bilayer.

The PR solution pH also plays an important role in the film deposition process. The PR solution pH directly affects the degree of protonation of the previously deposited PAH layers, and thus affects the subsequent reaction kinetics for PR incorporation. At a pH above the  $pK_a$  of the side chain amines of PAH, the majority of the amines will be unprotonated and thus able to react with the triazine ring of PR. Additionally, the reactivity of the triazine ring on PR increases with increasing pH.<sup>[45]</sup> These two effects result in reactive deposition being favored as the pH is increased. The clearest example of the effect of PR

solution pH on deposition can be seen in Fig. 6 and Table 1, when the PAH pH was held constant at either pH 4.5 or 7.0, and the PR solution pH was increased from 7.0 to 10.5. The amount of dye deposited per bilayer increased as the PR solution pH was increased from 7.0 to 10.5. In fact, when the PAH pH was 4.5 and the PR pH was 7.0, very little PR was deposited at all. In addition to a fairly low reactivity of the triazine rings at pH 7.0, the PAH layers deposited at pH 4.5 did not have a sufficiently high surface concentration to allow PR deposition to occur.

Importantly, the pH of the deposition solutions affects the SHG intensities and the degree of polar ordering of the PR molecules in the film. Table 2 presents the data of Table 1 normalized to the PAH pH 4.5/PR pH 10.5 case. In addition to the absorbance/bilayer and thickness data, Table 2 also contains the normalized square root of the SHG intensity  $[(I_{2\omega})^{1/2}]$  per bilayer.

The effect of PAH solution pH on the films can be seen by comparing experiments B vs. D, where the PR solution pH is held constant at 10.5. Increasing the PAH solution pH from 4.5 to 7.0 results in increases in the absorbance per bilayer. The  $(I_{2\omega})^{1/2}$  per bilayer increases by the same relative amount (~55–60%) as the absorbance. Within this pH range, the PAH is deposited as thin, flat layers. Thus as the pH of the PAH solution is increased,  $(I_{2\omega})^{1/2}$  scales proportionally with small changes in amount of PR per bilayer, and the increase in  $(I_{2\omega})^{1/2}$  is interpreted to be a result of simply incorporating more PR into the film.

Experiments C and D keep the PAH solution pH constant at 7.0 while varying the PR solution pH from 7.0 to 10.5. In these experiments, the bilayer thickness is similar, but the absorbance per bilayer and  $(I_{2\omega})^{1/2}$  per bilayer both increase as the PR pH is increased from 7.0 to 10.5. While 42% more PR is incorporated per bilayer, the value of  $(I_{2\omega})^{1/2}$  per bilayer increases by over 800%. Thus the pH of the PR solution has a dramatic effect on the orientation of the PR molecules that are incorporated in the films. At pH 7, the reactivity of the PAH amine groups with the triazine ring of the PR is lower, and PR may be incorporated by a combination of electrostatic, hydrogen bond, and covalent interactions. Thus at conditions favoring covalent reaction between PR and PAH, a high degree of PR ordering was obtained, while at conditions not

**Table 2** Relative values of the absorbance per bilayer and  $(I_{2\omega})^{1/2}$  per bilayer, both normalized to the values for PAH at pH 4.5 and procion red at pH 10.5 as a function of deposition pH

Experiment	PAH pH	PR pH	Absorbance/bilayer	Bilayer thickness	$(I_{2\omega})^{1/2}$ /bilayer
B	4.5	10.5	1.0	1.0	1.0
C	7.0	7.0	1.15	1.61	0.17
D	7.0	10.5	1.63	1.53	1.55

favoring covalent reaction between PR and PAH, the PR deposited within the films has a more random orientation. The  $\chi^{(2)}$  values obtained for deposition of PR at pH 10.5 are  $11.2 \times 10^{-9}$  and  $11.3 \times 10^{-9}$  esu (Table 1), which are sixfold greater than quartz.

The larger SHG observed in the PR pH 10.5 case serves as confirmation of the hypothesis that alternating the mechanism of deposition in these films and decoupling of the chromophore from steric constraints of a polymer backbone can provide a route to successful deposition and orientation of a low molecular weight chromophore. In earlier studies with NLO-active polymeric dyes such as PS119<sup>[46]</sup> which consists of a poly(vinylamine) backbone with an ionic azo dye chromophore, and poly{1-4-(3-carboxy-4-hydroxyphenylazo)-benzenesulfonamido-1,2-ethanediyl, sodium salt} (PCBS), films were made under deposition conditions leading to relatively thin bilayers ( $\sim 0.2$  nm/bilayer). In both PS119 and PCBS, the NLO-active chromophores are charged side groups on the polymer chain. As observed using in situ SHG intensity measurements, polar ordering of an adsorbed chromophore layer is reduced by subsequent adsorption of the next polyelectrolyte monolayer.<sup>[47]</sup> By decoupling the NLO-active chromophore from a polymer chain, the steric constraints to achieving ordered films that are present when using a large chromophore side group were reduced. Additionally, by using a heterobifunctional chromophore in which the mechanism for chromophore deposition (i.e., covalent bonding) differs from the deposition of the polymeric component (electrostatic interactions), the competing intermolecular interactions that prevent the achievement of a high net polar ordering of the chromophore within the film can be minimized.

Finally, the structure of the polycation plays a role in chromophore orientation. Koetse, Laschewsky, and Verbiest<sup>[27]</sup> previously reported on the fabrication of films using PR and the polycation poly[*N*-(3-aminopropyl)-*N*-(4-vinylbenzyl)-*N,N*-dimethylammonium chloride] (PAVDMA). The structure of this polycation is shown in Fig. 10 and consists of a quaternary

**Fig. 10** Structure of the polycation poly(*N*-(3-aminopropyl)-*N*-(4-vinylbenzyl)-*N,N*-dimethylammonium chloride) (PAVDMA).

ammonium group in addition to a primary amine. While layer-by-layer deposition of the PR chromophore was observed at pH  $\sim 9$ – $10$ , conditions that should favor covalent coupling of the PR to the primary amine, SHG results for this system showed that there was a lack of bulk polar order. The precise structural differences between PAVDMA and PAH that result in ordering of the PR when PAH is used are not known at present.

## CONCLUSION

A hybrid covalent/electrostatic deposition scheme has been demonstrated that can be used to obtain self-assembled, organic films in which there is long-range, polar ordering of a chromophore. The ordering is believed to arise from alternating the mechanism of deposition from monolayer to monolayer and decoupling the chromophore from the steric constraints of a polymer backbone. Using Procion Red MX-5B as a model reactive/anionic monomeric NLO chromophore and PAH as the cationic polyelectrolyte, films with  $\chi^{(2)}$  values  $\sim 11 \times 10^{-9}$  esu were constructed. This deposition process is highly sensitive to the pH values of both the PAH and PR solutions. In this work, we focused on the effect of pH on the film properties, and we found an operating window for optimal deposition and orientation. The PR solution pH should be high enough to favor covalent deposition. The PAH solution pH should also be as high as possible while still obtaining layer-by-layer growth of homogeneous films. While initial  $\chi^{(2)}$  values are significant, these values are far from optimized because the Procion Red chromophore is far from an ideal NLO chromophore. This methodology appears suitable for making thick films ( $1$ – $10$   $\mu\text{m}$ ) necessary for electro-optic modulator devices.

## INTRODUCTION

This entry summarizes the design and synthesis of conjugates resulting from the combination of nucleic acid base derivatives, particularly nucleosides and nucleotides, with oligopyrrole macrocycles. In addition to detailing the methods of preparation and fundamental chemical properties, the vision behind such projects and the various applications targeted for use by these conjugates are also described. These systems combine into one chemical entity two of the more important biological building blocks found in Nature, namely, nucleic acid bases (nucleobases) and porphyrins, and this leads to new constructs with rather unique chemical features as well as novel molecular recognition properties. Although the focus of the present chapter will be on systems containing natural nucleobase components, it is important to appreciate that the porphyrin portion of these constructs can include a range of synthetic oligopyrrole macrocycles that have no biological equivalent. This gives rise to products with unexpected supramolecular properties, including those associated with anion recognition.

## BACKGROUND

Nucleotides and nucleic acids play key roles in many biological processes ranging from information processing to energy storage and transduction. In addition, a number of nucleotide and nucleoside analogues exhibit antiviral activity. As a consequence, considerable study is devoted to simple, monomeric nucleic acid bases (“nucleobases”; NBs), both in terms of understanding their fundamental properties and in terms of developing potential new drug leads. Activity is also high in the areas of synthesis (e.g., new methods development) and sensing (i.e., finding ways to detect specific nucleic

acid derivatives selectively). The NBs also inspired supramolecular chemists as a result of their ability to undergo complementary Watson–Crick-type base pairing. This, of course, represents the most ubiquitous and fundamental kind of hydrogen bond-based molecular recognition. It thus provided an incentive to construct new, rationally designed conjugates, including covalent combinations of nucleobase with oligopyrrolic macrocycles (OPMC). These latter systems, which are the focus of this review, possess unique photophysical and molecular recognition properties that are specifically defined by the nature of the constituent NB and OPMC components, as well as the extent of “chemical communication” between two parts of what may be considered a complex, multifunctional receptor molecule. In this entry the chemistry and properties of NB–OPMC conjugates will be reviewed with a focus on the specific choice of NB, OPMC, and/or covalent linkage. However, to keep the discussion within reasonable limits, only naturally occurring purine and pyrimidine NB component(s) will be considered. By contrast, our coverage of known systems containing various linking spacer (SP) subunits and OPMCs attempts to be more comprehensive. Of the latter, which run the gamut from biomimetic to wholly synthetic, porphyrins have received the greatest attention. Thus we start our discussion with NB–SP–OPMC conjugate systems that are based on this biologically all-important chromophore.

## Nucleobase–Porphyrin Derivatives

The first porphyrin nucleoside conjugates, represented by structures **1**, were synthesized by Kus and coworkers in 1990.<sup>[1]</sup> Unfortunately, these systems proved essentially insoluble in water,<sup>[2]</sup> a feature that diminished their biomedical significance and limited their

utility in terms of various targeted therapeutic applications. To overcome this problem, the *meso*-(1-methylpyridinium-4-yl)<sub>n</sub>porphyrin core was chosen as the key OPMC subunit. This choice was dictated by solubility considerations and by the recognition that *N*-methylated pyridyl porphyrins and related systems bind strongly to DNA with a preference of G–C base pair regions<sup>[3]</sup> and that certain methylated derivatives can be photoactivated to generate active species, such as single oxygen, that are known to cleave oligonucleotides.<sup>[4]</sup> The remaining *meso* positions were then used to attach the nucleoside parts. In this way, the first water soluble porphyrinyl nucleosides **2** were prepared, specifically via the condensation of *meso*-(pyridin-4-yl)<sub>n</sub>-(*p*-hydroxyphenyl)<sub>4-n</sub>porphyrins ( $n = 1-3$ ) with 5'-*O*-tosylate of 2',3'-*O*-isopropylideneuridine and subsequently subjecting the pyridine cores to

methylation.<sup>[2,5]</sup> The same synthetic strategy was used to prepare analogues containing other porphyrinyl-nucleosides, in particular the thymidine derivatives, **3**,<sup>[6]</sup> the fluorinated thymidine (**4a**, **4b**),<sup>[7]</sup> and guanosine (**4c**) porphyrinyl derivatives.<sup>[7]</sup> The biological properties of the porphyrinyl-nucleoside conjugates **2a** and **3** and their porphyrin-centered Co(II) complexes were then studied in terms of growth suppression of malignant melanoma cells.<sup>[6]</sup> Significant suppression was achieved using the Co(II) complex of porphyrinyl-dithymidine **3b**. In this instance, the extent of inhibition reached 95%. By contrast, in the case of the corresponding Co(II) complex of **3a**, containing one thymidine unit, only a low level of suppression was observed<sup>[6]</sup> (Scheme 1).

A strategy analogous to that described above was also used to prepare the two adenine-containing

Scheme 1

Scheme 2

porphyrinyl–NB derivatives<sup>[8]</sup> **5a** and **5b**. The synthesis was modified, however, such that:

- i. The *N*-methylation step was carried out prior to forming the hybrid molecule.
- ii. The bromo derivative of the nucleobase-functionalized alkyl spacer was used instead of the tosylate employed in the case of more tightly coupled conjugates **1–4**. Unfortunately, this procedure failed to provide a more loosely linked thymidine analogue of **3a** (e.g., **6**). Thus an alternative approach was developed. It involved the treatment of 5,10,15-tris(1-methylpyridinium-4-yl)-20-(pyridin-4-yl)porphyrin with a 6-carbon bromoalkyl derivative of thymidine; this gave target **6** in almost quantitative yield.<sup>[8]</sup>

Once in hand, the interactions of **5** and **6** with nucleosides and polynucleotides were studied via UV–VIS and fluorescence-based spectroscopic titration methods. The calculated  $K_s$  values (1:1) for all combination of **5** and **6** with simple nucleosides were the same within the error of the method (ca  $1.6 \times 10^4 \text{ M}^{-1}$ ). In other words, no preference was observed between the porphyrin–nucleobase conjugates and the corresponding complementary Watson–Crick nucleotides. The absence of any significant Watson–Crick-type hydrogen bonding selectivity was interpreted as reflecting the dominance of intermolecular stacking interactions, as opposed to base-pairing ones. In the case of polynucleotide, two binding processes were inferred from the fluorimetric titration experiments. First, a set of spectroscopic changes at  $r > 0.1$  ( $r$  = ratio porphyrin/polynucleotide) were attributed to an intermolecular association of the porphyrin portion of the conjugate with the polynucleotide

polyanion. Second, a set of different emission features were observed when the intercalation binding sites were present in large excess ( $r < 0.1$ ) that were explained in terms of the porphyrin subunits intercalating into the polynucleotide backbone. Interestingly, some selectivities<sup>[8]</sup> were observed in the case of titrations carried out with polyU, with different results being seen for conjugates **5** containing complementary bases than for the corresponding noncomplementary conjugate **6**<sup>[8]</sup> (Scheme 2).

With a different focus, Masiero et al. constructed the alkyl-tethered porphyrin-guanosinyl derivative **7**. The propensity of guanosine derivatives to self-assemble into so-called G-quartets was then used to prepare a novel circular porphyrin array.<sup>[9]</sup> In terms of specifics, these researchers showed that system **7** self-assembles in chloroform solution in the presence of potassium picrate to form a supramolecular complex that consists of eight units of **7** arranged in the form of two G-quartets, as evidenced by UV–VIS, CD, and <sup>1</sup>H NMR spectroscopic studies. In the context of this work, complexation of the cation has a dramatic effect on the CD spectrum. In particular, the addition of  $\text{K}^+$  leads to the appearance of excitation couplets in both the guanine absorption and porphyrin Soret spectral regions. The couplet observed in the Soret region was deemed particularly significant inasmuch as it indicates an intermolecular electronic interaction between the porphyrin chromophores.<sup>[9]</sup> This, in turn, supports the conclusion that the porphyrins are arrayed unsymmetrically around the central  $[\text{G}]_8\text{K}^+$  “core” (Scheme 3).

Nucleobase–porphyrin constructs containing nucleosides with free ribofuranose hydroxyl groups have also been prepared. For instance, Li and Czuchajowski prepared the porphyrin nucleoside analogues (**8**) that

7

Scheme 3

are attractive as a potential building block for porphyrin–oligonucleotide/DNA systems wherein the number and position of the porphyrin subunits can, at least in principle, be controlled.<sup>[10]</sup> This system (**8**) was generated from (+)-6-iodo-2'-deoxyuridine and the 5,10,15-tri(4-pyridyl)-20-(*p*-acrylamidophenyl)porphyrin using a Heck reaction. Its interactions with the 20-mer oligonucleotide duplexes (dG)<sub>20</sub>–(dC)<sub>20</sub> and (dA)<sub>20</sub>–(dT)<sub>20</sub> were then studied by UV–VIS spectroscopy, as were those with the DNA plasmid-pRIT6. Comparisons with the methylated starting 5,10,15-tri(4-pyridyl)-20-(*p*-acrylamidophenyl)porphyrin revealed that, in every case, the porphyrin Soret band was red-shifted by 6–14 nm. Hypochromicity in the range of 10–54% was also observed. Interestingly, derivative **8** gave rise to a greater degree of

bathochromic shift and a lower level of induced hypochromicity than the corresponding 5,10,15-tri(1-methylpyridinium-4-yl)-20-(*p*-acrylamidophenyl)porphyrin “control.”<sup>[10]</sup>

In all of the above examples, the nucleosides were covalently attached to the porphyrin subunit via functionalization of a *meso* aryl substituent. This is not, however, the only way to link these two kinds of components, a point that was elegantly underscored by Goh and Czuchajowski. These researchers bound two nucleosides to the axial positions of phosphorus(V) porphyrins through the ribofuranose 3'-hydroxyl and 5'-hydroxyl substituents<sup>[11]</sup> The resulting products, potentially a mixture of three *O*-P(V) coordination isomers (vide infra), contain free 3'-hydroxyl and the 5'-hydroxyl groups (cf. structure **9**) and can thus be used,

Scheme 4

Scheme 5

at least in principle, to prepare oligo-porphyrin DNA analogues linked through a positively charged phosphorus(V) porphyrin “backbone.” They were prepared by subjecting a dichlorophosphorus(V) tetraphenylporphyrin to nucleophilic substitution using a non-protected nucleoside as the nucleophile. The least polar and least sterically hindered 5',5'-*O*-isomer was formed with the highest yield from the three possible (and observed) products (i.e., the 3',3'-, 3',5'-, and 5',5'-*O*-isomers). However, this isomer proved less stable than the corresponding 3',3'- and 3',5'-isomers and was found to undergo rapid hydrolysis to the corresponding dihydroxyl phosphorus(V) porphyrin unless protected from light and moisture (Scheme 4).

A different kind of linked system was described by Cornia et al. These workers prepared porphyrin–uridine derivatives wherein the uridine subunits are anchored to the porphyrin macrocycle by means of robust carbon–carbon bonds (i.e., systems **10** and **11**).<sup>[12]</sup> The synthesis of these systems, which contain direct meso-ribofuranose bonds, began with the coupling of two equiv. of pyrrole to one equiv. of 2',3'-*O*-isopropylidene-5'-oxo-5'-deoxy-uridine under conditions of acid catalysis (SnCl<sub>4</sub>). The intermediate dipyrrolyl–uridyl methane was then subject to macrocyclization (BF<sub>3</sub> etherate) in the presence of 2',3'-*O*-isopropylidene-5'-oxo-5'-deoxy-uridine or 4-fluorobenzaldehyde, followed by DDQ-mediated oxidation to produce the corresponding 2',3'-*O*-isopropylidene-protected porphyrins, 5,10,15,20-tetrakisuridinylporphyrin **10a**, and 5,15-bisuridyl-10,20-(*p*-fluorophenyl)porphyrin **11a**, respectively.<sup>[12]</sup> Deprotection with aqueous trifluoroacetic acid at ambient temperature followed by neutralization with ammonia then yielded the free hydroxyl products **10b** and **11b** in nearly quantitative yield (Scheme 5).

Yet another approach to generating nucleobase–porphyrin conjugates was pursued by Hisatome et al. These workers targeted the connection of a nucleobase moiety to a porphyrin via amide linkages, relying in particular on the reaction of an aminophenylporphyrin

with an activated form of a nucleobase-bearing alkanic acid.<sup>[13,14]</sup> Unfortunately, initial efforts to affect the coupling of *anti* 5,15-bis(2-aminophenyl)porphyrin derivatives with nucleobase–alkanoic acids using standard coupling agents such as *N,N'*-dicyclohexylcarbodiimide and *N,N'*-carbonyldiimidazole under a variety of conditions gave only small amounts of the expected amide or no product at all. On the other hand, very good results were obtained in the presence of ethoxycarbonyl chloride. However, in this case, only the corresponding singly functionalized, mixed monoamide monocarbonate derivatives **12** could be separated from the reaction mixture. In light of this finding, a decision was made to protect one of the two amino groups present in the starting bis-aminophenyl porphyrin with a benzyloxycarbonyl group.<sup>[13]</sup> Subsequent coupling with a nucleobase alkanic acid afforded monofunctionalized compounds of general structure **13**.<sup>[13,14]</sup> The adenine and thymine derivatives **14** bearing free amino group were then prepared by removing the carbobenzyloxy groups from the corresponding precursors **13**. Coupling of thymine butanoic acid to **14a-A** then led to the *anti* adenine–thymine derivative **15**. The corresponding *syn* atropoisomer **18** was also prepared<sup>[13]</sup> using the same synthetic strategy, although in this instance the “intermediates” consisted of **16** and **17**, rather than **13** and **14** (Scheme 6).

As implied above, one of the prime motivations for generating porphyrinyl nucleoside, nucleotides, and oligonucleosides conjugates stemmed from a desire to produce water soluble, site-specific DNA binding and modifying systems.<sup>[15]</sup> While systems involving species containing oligonucleotides lie outside the scope of this review, it is worth noting that the covalent attachment of a photosensitizing porphyrin unit to an antisense oligonucleotide produced a system that allowed for the sequence-specific photomodification of target DNA after activation of the porphyrin subunit by photoillumination.<sup>[16]</sup>

Scheme 6

### NB-Substituted porphyrins as a model for electron transfer system

One of the more intriguing questions in the area of electron- and energy-transfer chemistry involves how covalent pathways differ from non-covalent ones in terms of mediating both short- and long-range transfer processes. Motivated by a desire to understand these issues, as well as to develop cytosine and guanine systems as new biomimetic modules for use in supramolecular ensemble construction, Sessler and coworkers prepared a series of noncovalent electron- and energy-transfer systems that contained porphyrinyl-nucleosides as key components.<sup>[17–20]</sup> These systems, which can be considered as containing a hydrogen-bonded assembled photon antenna, relied on Watson–Crick nucleobase pairing interactions between donors

and acceptors attached to functionalized guanosine and cytosine subunits.

In one early system, guanosine- and cytosine-bearing methaleted (ZnP) and nonmethaleted (H<sub>2</sub>P) porphyrins were used to construct an ensemble where photoexcitation led to energy transfer from the metalloporphyrin (characterized by a higher energy excited state) to a free-base porphyrin moiety (characterized by a lower energy excited state) in accord with Fig. 1. In this case, the requisite porphyrin–nucleobase conjugates **20** and **21** were prepared by alkylation of a nucleobase derivative bearing an amine “tail” with an electrophilic porphyrin. This provided the protected intermediates **19**. Subsequent deprotection afforded the free-base porphyrins **20** (H<sub>2</sub>P), whose metalation gave the Zn(II) porphyrin analogues **21** (ZnP)<sup>[17,21]</sup> (Scheme 7).

Fig. 1 Schematic representation of the hydrogen-bonded dimers **20–21** and subsequent energy transfer from ZnP **20** to H<sub>2</sub>P **21**.

Scheme 7

The photophysical characteristics of the porphyrin-nucleobase conjugates **20** and **21** and the supramolecular dimers formed as a result of their undergoing Watson-Crick-type association (Fig. 1) were then determined by studying their spectroscopic properties in ethanol-free  $CHCl_3$ . Here, both standard static fluorescence and time-resolved methods were used. The latter proved particularly revealing. For instance, when solutions containing roughly equimolar concentrations of both  $H_2P$  **20** and  $ZnP^*$  **21** were subject to laser excitation at 570 nm, the excited  $ZnP$  singlet state ( $ZnP^*$ ) was formed as the dominant product (ca. 85%). Emission from this species, essentially free of fluorescence signals arising from the corresponding free-base excited singlet,  $H_2P^*$ , could be monitored at 600 nm. Thus, varying the concentration of  $H_2P$  and studying the emission behavior of the whole system allowed the monitoring of the dimeric ensemble formation and energy transfer dynamics within it as well. At low concentrations of  $H_2P$  relative to  $ZnP$ , the fluorescence (as monitored at 600 nm) decayed with a lifetime  $\tau_1$  of  $\sim 1.5$  nsec, a value that corresponds to the singlet state lifetime of a simple, monomeric (i.e., non-complexed) photoexcited zinc(II) porphyrin (i.e.,  $ZnP^*$ ). As the

relative concentration of  $H_2P$  increased, however, the decay profiles became increasingly dual exponential in character because of the appearance of a faster decaying component that was observed in addition to the longer ca. 1.5-nsec lifetime seen in the absence of  $H_2P$ . This shorter lifetime,  $\tau_2$  (ca. 0.6–0.8 nsec), was assigned to a  $Zn$  subunit held within a base-tethered dimer that was undergoing deactivation as a result of the intra-ensemble energy transfer occurring between  $ZnP^*$  and  $H_2P$ . Energy transfer was observed also from the triplet excited state of the  $ZnP$  subunit, providing an ancillary set of data that could confirm the formation of the Watson-Crick associated ensemble. In fact, the extent of association could be calculated in quantitative terms from the observed singlet and triplet lifetimes. The resulting values, given in Table 1, confirmed the expected impression that the extent of nucleobase-nucleobase association increases in the order guanine-guanine < cytosine-cytosine < cytosine-guanine.<sup>[17]</sup>

In an effort to produce a model for electron-, as opposed to energy-, transfer, an ensemble involving the  $ZnP$ -guanosine derivative **21a** and the quinone cytosine derivative **22** was constructed via non-covalent self-assembly (Fig. 2). In  $CH_2Cl_2$ , fluorescence from the porphyrin subunit in **21a** was increasingly quenched upon the addition of concentrations of **22** (to a limit of ca. 35% total quenching at the highest concentrations used). By contrast, no fluorescence changes were observed when similar experiments were carried out in the presence of methanol or when the exocyclic amine groups of **21a** were blocked. Time-resolved fluorescence studies of an equimolar mixture of porphyrinyl-guanosine **21a** and quinone cytosine **22** displayed a biphasic profile that was almost identical to that displayed by the self-assembled dimer of **20** and **21** (Table 1).<sup>[18]</sup> Such an observation was consistent with rapid intra-ensemble electron transfer in

**Table 1** Rate constants for energy transfer ( $k_{ss}$ ) within the nucleic acid base dimers and association constants ( $K_a$ )

Porphyrins	$\tau_1$ (nsec)	$\tau_2$ (nsec)	$k_{ss}/10^8$ ( $sec^{-1}$ )	$K_a$ ( $M^{-1}$ )	Reference

**Fig. 2** Schematic representation of the porphyrin-guanosine and quinone-cytosine ensembles and subsequent energy transfer from porphyrin to quinone parts.

the case of the porphyrin–quinone pseudodimer formed from **21a** and **22**.

While important in terms of demonstrating the utility of Watson–Crick base pairing as a means of constructing noncovalent electron transfer model systems, the above first-generation system suffered from considerable conformation flexibility. Such flexibility was thought to limit the extent to which quenching could be achieved within the self-assembled pseudodimer formed from **21a** and **22** and, as such, complicated interpretation of the observed electron transfer process. For instance, quenching arising from inter- or intracomplex diffusional encounters between the donor and acceptor, rather than through a hydrogen bond process, could be invoked to account for the observed quenching and presumed electron transfer

events. Thus more rigid, second-generation, model systems (Fig. 3) were developed.<sup>[19,20]</sup> In particular, new porphyrin–nucleobase monomers were prepared from *O*- and *N*-protected guanosine- and cytidine-substituted benzaldehyde intermediates using the MacDonald–Chang porphyrin synthesis.<sup>[22]</sup> Subsequent deprotection and selective protection of the condensation products gave rise to the guanosine (**23**) and cytidine (**24**) porphyrins. Derivative **23** was then converted into its corresponding zinc porphyrin **25** (Scheme 8).

The non-covalent donor–acceptor systems derived from porphyrin **25** and either quinone-cytidine **26** (Fig. 2) or porphyrin-cytidine **24** (Fig. 3) were then subject to analysis via time-resolved fluorescence spectroscopy. In accord with the earlier, first-generation

**Fig. 3** Porphyrinic array wherein two ZnP **25** and one H<sub>2</sub>P **24a** are held together in a trimeric conformation.

Scheme 8

systems described above, addition of **24** or **26** to a chloroform solution of **25** caused a primarily monoexponential fluorescence decay profile to become biphasic. The resulting decay profiles were then analyzed in terms of two exponential profiles, corresponding to two excited state components (Table 1). The fractional amplitude of the shorter-lived component, considered to reflect an intra-ensemble quenching process, increased as the concentration of the acceptor component, either **24** or **26**, was increased. The corresponding association constants,  $K_a$ , were significantly higher than those derived for the more flexible aggregate<sup>[18]</sup> formed between **21a** and **22** ( $K_a = 8990 \pm 600 M^{-1}$  for the complex formed between **25** and **26** vs.  $1290 \pm 230 M^{-1}$ ).<sup>[19]</sup>

### NB-Sapphyrin Derivative

Very different kinds of nucleobase-oligopyrrole conjugates may, in principle, be obtained when chromophores other than porphyrins are used. This is because other oligopyrrolic macrocycles are often characterized by properties that are very different than those of porphyrin. While a large number of porphyrin-like oligopyrrolic macrocycles now exist, the fact remains that, with the exception of porphyrin itself, most work in the NB-OPMC area has been largely limited to the use of sapphyrin. Sapphyrins are a class of pentapyrrolic expanded porphyrin that were first reported by Woodward (for a review, see Ref.<sup>[23]</sup>). Characterized by two relatively basic "pyridine-like" pyrrolic centers, sapphyrins are readily protonated and, in marked contradistinction to porphyrins, form complexes with a wide variety of anions, including in particular phosphates.<sup>[24,25]</sup> In fact, sapphyrin derivatives have been used to effect both nucleoside<sup>[26]</sup> and nucleotide<sup>[27]</sup> recognition. Furthermore, a silica-bound sapphyrin proved useful as a solid support for the HPLC separation of monomeric and short oligomeric nucleotides<sup>[28]</sup> at pH 7, while certain water-soluble

sapphyrins were found to bind DNA in aqueous solution at physiological pH.<sup>[29]</sup> A variety of spectroscopic studies as well as X-ray diffraction analysis established that phosphate-type species are bound to the protonated sapphyrin core via a "helicopter-like" set of hydrogen bonding interactions between the phosphate oxyanion and the pyrrolic hydrogens of the protonated macrocycle.<sup>[24]</sup>

Although unique, the phosphate binding capability of the sapphyrins is rather nonselective. For instance, the use of sapphyrin to affect the transport of nucleotide monophosphate through a model membrane (Fig. 4) consisting of an initial aqueous phase (Aq. I), an organic barrier, and a second, receiving phase (Aq. II) revealed that it is a very efficient but non-selective carrier at pH < 4 (where it exists in its diprotonated form).<sup>[30]</sup> Such findings provided an incentive for Sessler and coworkers to develop more selective systems through the construction of NB-sapphyrin conjugates. These workers considered it likely that the combination of a NB (to recognize the complementary Watson-Crick nucleobase) and a sapphyrin (to effect phosphate binding) would lead to receptors with a unique ability to bind and transport nucleotides selectively. To the extent such species could be generated and might have an important application

**Fig. 4** Schematic representation of GMP transport effected under synport conditions using sapphyrin as the hydrophobic phosphate-binding carrier.

Scheme 9

in the area of drug delivery; they could help affect the into-cell transport of nucleotide-based antiviral agents or, even in the limit, various antisense oligonucleotides. Important, however, as are these potential end-use applications, the initial goal was less ambitious; it was to find a saphyrin-based nucleotide carrier that would work at physiological pH. Here, it was hoped that the “extra” recognition “power” derived by linking a nucleobase recognition subunit to a saphyrin core would suffice to allow nucleotide transport at or near neutral pH.

In light of the above design considerations, systems **28** and **30** were chosen as initial targets. They were prepared by coupling protected derivatives of 2-aminoethylcytosine and 2-aminoethylcytosine with

activated forms of either a saphyrin carboxylic acid or saphyrin diacid. Following deprotection<sup>[31]</sup> of the resulting intermediates, compounds **27** and **29**, the nucleobase functionalized saphyrins **28** and **30** were obtained in good yield (Scheme 9).

As hoped, the cytosine-bearing carriers **28a** and **30a** exhibited selective transport of guanosine monophosphate through a model membrane at near-neutral pH. Interestingly, in all cases, receptor **28a** displayed a higher selectivity for GMP than its congener **30a** (Table 2). Control experiments were performed using 3, 8, 12, 13, 17, 22-hexaethyl-2, 7, 18, 23-tetramethylsaphyrin (saphyrin).<sup>[32]</sup>

The regioselectivity of carrier **28a** for the phosphate group in isomeric GMPs was also studied (Fig. 5). Here,

Table 2 Initial nucleotide-5'-monophosphate transport rates for the carriers **28a** and **30a**

Carrier	Aq. I (pH)	Aq. II	$k_T$ 5'-GMP ( $10^{-8}$ mol/cm <sup>2</sup> hr)	$k_{5'-GMP}/k_{5'-CMP}$	$k_{5'-GMP}/k_{5'-AMP}$
<b>28a</b>	6.15	H <sub>2</sub> O	1.201	101.7	7.66
<b>28a</b>	6.70	H <sub>2</sub> O	0.287	42.9	8.87
<b>28a</b>	7.05	H <sub>2</sub> O	0.001	20.1	9.49
<b>28a</b>	6.15	10 mM NaOH	1.423	26.3	2.73
<b>28a</b>	6.70	10 mM NaOH	1.228	40.8	4.36
<b>28a</b>	7.05	10 mM NaOH	0.708	43.3	9.60

Saphyrin	7.00	10 mM NaOH	<10 <sup>-5</sup>		

**Fig. 5** Proposed structure for the complex formed between the monoprotonated form of carrier **28a** and monobasic 5'-GMP or 2'-GMP, respectively.

the 2'-isomer of GMP was transported roughly 10 and 6 times faster than its 5'- and 3'-substituted congeners, respectively (Table 3). The association constants,  $K_a$ , of complex **31** and **32** were determined to be  $8 \times 10^3$  and  $2.2 \times 10^4 \text{ M}^{-1}$ , respectively, in methanol as judged from UV-VIS spectroscopic titrations.<sup>[31]</sup>

In the case of the guanine-bearing sapphyrins **28b** and **30b**, transport selectivity for cytosine monophosphate was observed. Compared to **28b**, the relative rates of carrier-induced, through-membrane transport were found to be smaller for the monosubstituted system, **28b**, than for doubly functionalized analogue, **30b** (Table 4).<sup>[31]</sup>

To build on the above success, a new solid phase was prepared. It was produced by attaching a cytosine-substituted sapphyrin containing a carboxylic group to aminopropyl silica gel via an amide bound (Fig. 6). An HPLC column, generated by packing this stationary phase, separated guanosine 5'-mono-, di-, and triphosphate effectively from a mixture of the mono-, di-, and triphosphates of cytidine, uridine,

adenosine, and guanosine under isocratic condition at pH 7. In addition, by using this column, it was found that all nucleotides monophosphate could be separated from one another readily under similar separation conditions.<sup>[33]</sup> Control experiments, affected using a column packed with a nucleoside-free sapphyrin-substituted silica gel,<sup>[28]</sup> allowed for the separation between mono-, di-, and triphosphates. However, no selectivity was observed. In other words, separation between the different mono-, di-, and trinucleotides present was not affected.<sup>[33]</sup>

### NB-Phthalocyanine Derivatives

Although not expanded porphyrins, phthalocyanines represent a different kind of tetrapyrrole and one of the few aromatic chromophores, other than porphyrin and sapphyrin, to be conjugated to a nucleobase. While in principle the rich chemistry of the phthalocyanines would lead one to consider that a variety of

nucleobase-containing conjugates would have been prepared to date, in fact, only the adenine-containing zinc(II) phthalocyanines **33** have so far been reported in the literature. These conjugates were prepared using a procedure analogous to that used to prepare the porphyrin–nucleobase systems **5** and **7**. Specifically, treatment of tetrahydroxyphthalocyanine with an excess of 9-(2-bromoethyl) adenine and K<sub>2</sub>CO<sub>3</sub> gave the adenine–phthalocyanine conjugate **33a**. The unsymmetrical analogues **33b** and **33c** were prepared by using only one equiv. of the appropriate 9-(bromoalkyl)-adenine, followed by the addition of excess 1-bromopentane<sup>[34]</sup> (Scheme 10).

The base-pairing effects of **33a** were studied by carrying out a fluorescence-type spectroscopic titration that consisted of adding a thymine-modified 9,10-anthraquinone and monitoring the resulting decrease in emission intensity. Interestingly, in DMF/THF (9:1), the fluorescence quenching of **33b** and **33c** was modest with the extent of quenching being almost the same as was observed in experiments involving the use of 9,10-anthraquinone as a control.<sup>[34]</sup> While not constituting an absolute proof, such findings argue against the adenine-substituted conjugates **33** being able to interact strongly with species containing their Watson–Crick complement, thymine, and, as a consequence, an inability to form hydrogen bond-tethered self-assembled ensembles. If this conclusion is correct, it underscores the benefit of using cytosine–guanine interactions as supramolecular motifs as originally put forward by Sessler and coworkers.

## NB–Calix[4]pyrrole Derivatives

While traditionally the term “oligopyrrole macrocycles” refers to aromatic systems, such as porphyrin, phthalocyanine, and expanded porphyrins, in recent years increasing attention has been devoted to the development and study of non-conjugated oligopyrrolic macrocycles.<sup>[35–38]</sup> One of the best studied of such systems is calix[4]pyrrole,<sup>[35,36,39]</sup> a non-aromatic tetrapyrrolic product produced by the condensation of pyrrole with acetone. This system, whose synthetic origins can be traced back to Baeyer,<sup>[40]</sup> was “rediscovered” as a neutral anion-binding agent by Gale and coworkers in 1996.<sup>[39]</sup> This rediscovery led, inter alia, to considerations that calix[4]pyrroles could provide the basis for easier-to-make analogues of the sapphyrin-based nucleotide binding and transporting agents described above.<sup>[41]</sup> Toward this end, receptors **34** and **35** were prepared by condensing the corresponding calix[4]pyrrolecarboxylic acid with 2-aminoethylcytosine.<sup>[42]</sup> Again, the question was whether the combination of an anion binding subunit with a nucleobase binding site would allow for selective nucleotide recognition and transport, with the added wrinkle being what would be the effect of using a weaker anion binding site (Scheme 11). (As they are neutral receptors, calix[4]pyrroles show much weaker phosphate anion binding affinities than do the protonated, and correspondingly charged, sapphyrins.<sup>[41]</sup>)

In order to test the efficacy and selectivity of the calix[4]pyrrole-derived systems **34** and **35**, they

**Fig. 6** Cytosine–sapphyrin derivative immobilized on 3-aminopropyl-modified silica.

Scheme 10

were studied as nucleotide carriers, in analogy to what was done with the sapphyrin systems (vide supra), and as the key components in membrane-based ion selective electrodes (ISEs) (see Tables 5–7 and ensuing discussion).

### Ion-Selective Electrode Studies

An important motivation for studying systems **34** and **35** as carrier-based ion-selective electrodes (ISE) is that analysis of such systems provides another means of testing whether a given receptor displays selectivity for a targeted analyte.<sup>[27,43–48]</sup> As true for bulk membrane transport studies (cf. Fig. 4), this method can provide insight into recognition events that take place at an aqueous–organic interface. However, it does not directly monitor binding (and/or release) per se. Rather, what is studied is the change in membrane potential observed on exposure of a liquid/polymer membrane electrode to solutions of various putative analytes. Read-out parameters thus include response (total emf change engendered by a given concentration of analyte), sensitivity (change in emf as a function of analyte concentration), and selectivity, often expressed in relative terms as a selectivity coefficient  $K_{I/J}^{Pot}$  or

selectivity factor  $k_{I/J}^{Psel}$ , where I and J represent the two competing analytes in question, and the linear range over which the response, Nernstian or otherwise, is seen.

The original benchmark for nucleotide sensors was an electrode for 5'-adenosine monophosphate (5'-AMP) that was produced by Papastathopoulos and Rechnitz.<sup>[49]</sup> This electrode consisted of a layer of suspended 5'-adenylic acid deaminase (AMP deaminase) in conjunction with an ammonia gas-sensing membrane electrode. The substrate was selectively deaminated by this enzyme to produce inosine 5'-monophosphate (5'-IMP) and  $NH_3$  in stoichiometric quantities. Monitoring the ammonia thus indirectly measured the 5'-AMP concentration present in the sample.

Because the above method represents an indirect determination, efforts have been devoted in recent years to developing more biomimetic approaches. Complementary base pairing, directed multisite hydrogen bonding interactions, specific ( $\pi$ - $\pi$ ) stacking effects, and generalized electrostatic interactions, individually or in concert, are thought to contribute to the exquisitely sensitive nucleotide recognition observed in the biological systems. Incorporating one or more of these recognition motifs into appropriately designed synthetic receptors could culminate in the

Scheme 11

**Table 5** Results of transport experiments carried out with  $\beta$ -(**34**) and *Meso*-(**35**) cytosine-functionalized calix[4]pyrroles

Carrier	$k_T$ 5'-GMP ( $10^{-11}$ mol/ cm <sup>2</sup> hr)	$k_{5'-GMP}/k_{5'-CMP}$	$k_{5'-GMP}/k_{5'-AMP}$
<b>34</b>	9.8	0.2	1.8
<b>35</b>	93	7.8	1.9

These transport studies were carried out using the set-up shown in Fig. 4 and in analogy to those discussed previously in the case of the sapphyrin-derived systems. The concentration of the carriers in the organic phase was 0.1 mM, the pH of the initial and receiving aqueous phases were 6.0 and 12.5, respectively, and the concentration of tetrabutylammonium perchlorate, added as a charge neutralizing cocarrier to the organic phase, was 0.1 mM.

production of highly specific ISEs more suited for use in various “real world” bioanalytical applications. Whether this goal will be fully realized remains to be seen. However, its pursuit has stimulated the evolutionary development of several elegant nucleotide-targeting ISEs in recent years, including (as will be discussed below) those based on calix[4]pyrrole–nucleobase conjugates.

An electrode derived from a cytosine-pendant triamine was the first ISE system to affect the potentiometric discrimination between guanine and adenine nucleotides by using complementary base-pairing and phosphate–ammonium electrostatic binding interactions within the electrode.<sup>[47]</sup> However, the multiple protonation equilibria that were a consequence of using polyamines as the electrostatic binding motif likely complicated the response mechanism and were also most probably responsible for the non-Nernstian emf slopes observed in these systems (5'-GMP:  $-10$  mV/decade;  $5 \times 10^{-4}$ – $10^{-2}$  M).

Recognizing the design limitations, it was thought that better phosphate recognition motifs would lead to improved sensors. In a previous portion of this review, it was demonstrated how this approach led to successful sapphyrin-based nucleotide carriers (e.g., systems **27a** and **28a**)<sup>[31,32,50]</sup> and, as implied above,

efforts were made to generalize this success by using calix[4]pyrroles as the anion binding cores. Thus because they were of inherent interest in their own right and because they would provide important controls for the newer calix[4]pyrrole-based systems, ISEs containing nucleobase-functionalized sapphyrins were prepared. Specifically, the guanine-bearing sapphyrins (**28b** and **30b**) were incorporated into poly(vinyl chloride) (PVC) membranes plasticized by *o*-nitrophenyl octyl ether (*o*-NPOE), and the potential response as a function of nucleotide concentration was measured using a standard Hg|Hg<sub>2</sub>Cl<sub>2</sub>|3 M KCl||0.1 M HEPES–NaOH, pH 6.6||sample|modified PVC membrane|0.1 M M KCl|AgCl|Ag cell assembly. Similar studies were carried out using the cytosine-substituted calix[4]-pyrrole conjugates **34** and **35**.

### Guanine-substituted sapphyrins

The ditopic receptor **28b** was designed to allow for specific cytosine-base recognition as well as for more general phosphate binding recognition. Its bis-(guanine)-bearing analogue, sapphyrin **30b**, a potential tritopic receptor, was thought to allow for the formation of complex-derived “triple helix” such as G–C–G motifs, wherein the bound nucleobase C-subunit would be the beneficiary of two kinds of hydrogen bonding interactions, involving both Watson–Crick and Hoogsteen recognition patterns.

At pH 6.6, sapphyrin exists as a monoprotonated, singly charged entity, whereas nucleotide monophosphates are largely dianionic. The sensitivity expected for experimental electrodes at neutral pH should thus be equal to  $-29$  mV/decade (theoretical Nernstian value for a divalent anion). The results obtained with systems **28b** and **30b** (Table 6) revealed that the doubly functionalized guanine derivative, **30b**, provided a more effective electrode system than its mono-substituted analogue. It should be noted that the sensitivity of the PVC-membranes derived from the bisguanine receptor **30b** was dependent on the time

**Table 6** Potentiometric characteristics of PVC membranes based on mono-(**28b**) and bisguanine-substituted (**30b**) sapphyrins toward nucleotides

Nucleotide	<b>28b</b>		<b>30b<sup>a</sup></b>		<b>30b<sup>b</sup></b>	
	Sensitivity (mV/decade)	Linear range (M)	Sensitivity (mV/decade)	Linear range (M)	Sensitivity (mV/decade)	Linear range (M)

<sup>c</sup>No response.

of contact between the membrane and the nucleotide (analyte) solution, as well as the nature of the measured nucleotide (Table 6).

### Cytosine-substituted calix[4]pyrroles

In predicative work involving unfunctionalized calix[4]pyrroles,<sup>[45]</sup> it was demonstrated that simple, substituent-free calix[4]pyrroles display potentiometric selectivity to a range of anionic analytes, including phosphates, when incorporated into PVC-(*o*-NPOE) membranes and tested as ISEs. The question then became whether appending a cytosine “tail” onto the calixpyrrole skeleton would lead to the generation of nucleotide-specific ISEs and, to the extent this proved true, whether or not the choice of linkage (*meso*- vs.  $\beta$ -pyrrolic) would effect the response selectivity.<sup>[42]</sup>

Before analyzing the “tailed” systems **34** and **35**, their unfunctionalized analogues, i.e., octamethyl and cyclohexyl-substituted systems, were tested as ISE sensor elements. In neither case was evidence of pH-dependent behavior seen, at least at or near neutral pH. On the other hand, an inherent selectivity for 5'-AMP < 5'-GMP  $\approx$  5'-CMP < 5'-UMP  $\approx$  5'-TMP was observed at pH 6.6 (a value chosen to ensure a significant concentration of the dianionic forms of the nucleotides under investigation) for both systems, as judged from the extent of the anionic (negative) potentiometric response. By contrast, a slight selectivity for 5'-GMP and 5'-CMP was seen in the case of “control” electrodes made up from the hydrophobic cation, tridodecylmethylammonium chloride (TDDMACl); here, 5'-AMP (0.00) < 5'-UMP (0.07) < 5'-CMP (0.24) < 5'-GMP (0.76), where the values in parentheses refer to the selectivity coefficients ( $\log K_{5'-AMP/5-XMP}^{pot}$ ).

Taken together, these findings are consistent with the conclusion that unfunctionalized calixpyrroles mediate their observed ISE response for nucleotides by acting more as specific, nucleobase-dependent molecular recognition elements than as pure anion extractants, as is known to be true for membranes made up from TDDMACl. Support for this conclusion comes from the observation that a greater response is observed in the case of the more hydrophobic cyclohexyl-substituted system than in the octamethyl

system and that the selectivity pattern correlates with the number of accessible hydrogen bond acceptor elements (i.e., carbonyl groups) present in the nucleobase portion of the mononucleotides being studied [i.e., 5'-UMP  $\approx$  5'-TMP (two carbonyls) > 5'-GMP  $\approx$  5'-CMP (one carbonyl) > 5'-AMP (no carbonyls)]. This latter observation also rules out a response process that is dominated by direct phosphate-calixpyrrole “anion chelation”; rather, it supports the conclusion that, under the interfacial conditions of the ISE experiment, the strength and specificity of the nucleobase-calix[4]pyrrole NH interactions dominate the selectivity, even if it is the presence of the negatively charged phosphate groups that leads to the actual observation of an anionic potentiometric response.

Transport experiment demonstrated that the *meso*-substituted cytosine calix[4]pyrrole conjugate, but not its  $\beta$ -pyrrole linked congener, is capable of acting as a ditopic receptor, binding concurrently both the phosphate anion and nucleobase portions of 5'-GMP to the calixpyrrole core and cytosine “tails” of the molecule, respectively. These findings were rationalized in terms only the former is capable of binding concurrently both the phosphate and nucleobase portions and provided a backdrop against which the corresponding ISE studies could be considered. In particular, the availability of two cytosine-substituted calix[4]pyrroles, bearing the appended cytosine on either a  $\beta$ -pyrrolic (**34**) or *meso* (**35**) position, respectively, would allow the potential importance that ditopic binding interactions might play in terms of regulating a selective electrode response.

In the case of the transport studies, it proved necessary to add tetrabutylammonium perchlorate to neutralize the negative charge present in the calix[4]pyrrole-nucleotide complex that arises as a result of binding a phosphate-containing entity within a neutral receptor (cf. Table 5 and Ref.<sup>[42]</sup>). Thus a lipophilic electrically charged additive, such as TDDMACl, was also employed in the case of the PVC membranes derived from **33** and **35**. Addition of this additive served to highlight the effects of base-pairing, which proved more discernable in the case of **35** than **34**. Specifically, adding 50 mol% TDDMACl to the PVC membranes containing these two potentially

**Table 7** Effect of pH on the potentiometric selectivity of PVC membranes based on  $\beta$ - and *meso*-substituted cytosine-functionalized calix[4]pyrroles **34** ( $\log k_{5'-UMP/5-XMP}^{sel}$ ) and **35** ( $\log k_{5'-UMP/5-XMP}^{sel}$ ). These membranes additionally contained 50 mol% TDDMACl

pH	<b>34</b>			<b>35</b>		
	5'-AMP	5'-CMP	5'-GMP	5'-AMP	5'-CMP	5'-GMP
6.6	-0.07	+0.97	+0.89	+1.53	0.00	+2.23
8.5	-0.20	+0.58	+0.10	-0.68	0.00	-1.23

ditopic receptors resulted in selectivity sequences that approximated those seen in the transport experiments (Table 7; pH 6.6). Unfortunately, the inherent selectivity for 5'-GMP seen in membranes containing just TDDMACI (vide supra) complicates analysis. Thus it is not possible at present to quantify in energetic terms the specific effect of the proposed cytosine-guanosine Watson-Crick binding interactions on the experimentally determined for-analyte selectivities. Nonetheless, there is little doubt that the effect is real, and in ISEs based on suitably designed receptors, can be quite substantial.

Model membrane transport studies provide a useful potential complement to ISE studies in terms of analyzing the specificity and mode of action of a particular receptor. The fact that the transport selectivity may be influenced strongly by the rate of receptor-substrate complex formation and dissociation, and hence the pH of both aqueous phases, made it important to compare the potentiometric selectivity of the PVC-membrane electrodes based on **34** and **35** when the contacting aqueous phase was held at pH 6.6 and at 8.5. The chosen pH should approximate the conditions of potentiometric measurement to transport model when the monitored nucleotides "enter in" and "release from" bulk membrane interface. As can be seen from Table 7, the selectivity sequence for the *meso*-linked conjugate **35** is more influenced by pH than its  $\beta$ -linked congener **34**. In fact, the potentiometric selectivity of the *meso*-substituted receptor, **35**, could be reversed by changing the pH from 6.6 to 8.5, as is evident upon inspection of the following sequences:

The sensitivity to pH is as would be expected for a system where ditopic interactions are thought to be playing an important role. For instance, under conditions of high pH, where the nucleotide species would exist as a dianion, rather than a monoanion, and the nucleobase itself could bear negative charge, the ancillary benefit that would accrue from the proposed Watson-Crick base pairing interactions would be reduced if not altogether eliminated. On the other hand, the potentiometric data at high pH could help explain the relative lack of for-GMP selectivity observed in the case of the transport experiments involving receptor **34**, where the receiving phase is also held at high pH; what is observed might simply reflect the inherent preference for cytosine binding that apparently pertains at high pH. To the extent this conclusion is correct, it underscores the benefit that

can come from studying nucleobase-oligopyrrole conjugates under two rather different kinds of experimental conditions and via the use of two very different techniques. It is thus hoped that such comparisons will be carried out with other systems in the near future.

## CONCLUSION

Nucleobase-macrocylic oligopyrrole conjugates represent a new class of potential ditopic receptor. With the ability to bind the Watson-Crick complementary nucleoside or nucleotide via specific hydrogen bonding interactions and elicit some key, useful functional feature through the appended oligopyrrole, a range of chemical processes become possible that are without precedent in the case of simple, single-motif systems. These include the ability to affect selective recognition of appropriate oligonucleotide fragments, facilitate long-range energy- and electron-transfer processes, affect the specific transport and electrochemical sensing of individual nucleotides. Improvements in synthetic methodologies, coupled with an ever-increasing lexicon of available oligopyrrolic macrocycles, lead to the prediction that many new nucleobase-oligopyrrole conjugates will be constructed in the near future and that these systems will demonstrate utilities that range well beyond those that have already been described.

# Oil-Filled Nanocapsules

Royale S. Underhill

Emerging Materials Section, Defence Research and Development Canada–Atlantic,  
Dartmouth, Nova Scotia, Canada

## INTRODUCTION

Feynman<sup>[1]</sup> was correct when he predicted “There’s Plenty of Room at the Bottom.” Since Feynman’s talk, given at Caltech in 1959, there has been an explosion of research in the ever-shrinking areas of nanoscience. A nanometer (nano—Greek for *dwarf*) is one billionth of a meter, or ten times the size of an individual hydrogen atom. Since the mid-1980s, there has been a substantial increase in interest over the creation and use of nanocapsules,<sup>[2]</sup> a subset of nanoparticles. Nanocapsules have a number of potential applications, some of which include dye dispersants, nanoreaction vessels, and encapsulation media for fragrances, flavors, or drugs. This entry will discuss the specific case of oil-filled nanocapsules. Such structures readily encapsulate lipophilic/hydrophobic and oil-soluble compounds, allowing them to be dispersed and transported through aqueous media.

## DEFINING OIL-FILLED NANOCAPSULES

Nanoparticles have their largest dimension in the 1–200 nm range. Nanoparticles can be made of a wide range of materials: inorganic, organic, and biological. Nanoparticles are of interest in materials science for a number of reasons. Because chemical characteristics such as optical, magnetic, electrical, adsorptive, and catalytic are size-dependent, a nanoparticle may exhibit useful properties not seen in the larger bulk sample.<sup>[3]</sup> The surface area-to-volume ratio can be very high, which can increase the performance of catalysts.<sup>[3]</sup> For these reasons, material scientists are investigating a wide number of nanostructures, hoping to find new applications. One possible application is the encapsulation of guest moieties, which would be possible with hollow or filled nanoparticles. Nanocapsules are superior to nanospheres and other nanoparticles for these applications because of their high loading capacity.

The general definition of a nanocapsule is a spherical, hollow structure with a diameter less than 200 nm. The cavity can be empty or filled with a solvent, either polar or non-polar (Fig. 1). Nanocapsules can be distinguished from other nanoparticles because they have a well-defined core and shell, whereas the latter

do not. Although this definition includes coated nanoparticles, the term *nanocapsule* as referred to here is a submicrometer colloidal particle with a cavity surrounded by a shell. When made from polymers, nanocapsules have also been referred to as “hollow polymer nanostructures,” “polymer/oil composite particles”,<sup>[4]</sup> and “colloidosomes.”<sup>[5,6]</sup> Nanocapsules have been made for many years, following the example of nature, using phospholipids, which are amphiphilic. Phospholipids will self-assemble in aqueous environments to form vesicles, which have a water core and a bilayer of the phospholipid forming the shell. This is the basis of cells. In a similar manner, a single layer of phospholipid can stabilize oil droplets, resulting in liposomes (Fig. 2).

Micro-Pak, Inc. has produced lipid vesicles that can be tailored to have either aqueous or oil-filled central cavities.<sup>[7]</sup> This central cavity can be filled wholly or in part with oil such that it can be used to encapsulate hydrophobic molecules.<sup>[7]</sup> The core of these vesicles is large and unstructured, which makes it ideal as a transport vehicle. Phospholipid vesicles have two major drawbacks.<sup>[7]</sup> First, phospholipids can be degraded by a number of enzymes, thus causing problems in biomedical applications. Second, the most common phospholipids contain polyunsaturated acyl chains, which are prone to peroxidation, resulting in a fracture of the vesicle. Liposomes are generally unstable.<sup>[8]</sup> Although similar to liposomes, polymeric capsules are held together through covalent bonding in the shell, making them more robust. Thus polymeric oil-filled nanocapsules are just robust, man-made mimics of naturally occurring liposomes.

The remainder of this review is divided into three major sections. The first deals with the characterization techniques used when making nanocapsules. The second deals with research published to date, and the third briefly describes some of the possible applications for oil-filled nanocapsules.

## CHARACTERIZATION TECHNIQUES

Because of the small size and often complex formulations, a detailed characterization of nanocapsules is difficult. Some of the techniques used include quasi-elastic light scattering [QELS; also known as photon correlation

Fig. 1 Schematic of an oil-filled nanocapsule.

spectroscopy (PCS)], gel permeation chromatography (GPC), transmission electron microscopy (TEM), scanning force microscopy (SFM), and scanning electron microscopy (SEM). To date, none of these techniques has provided a clear picture of the nanocapsule shell.<sup>[9]</sup> It remains unknown as to whether the shell is a continuous or a porous network. The synthetic route used to attain the nanocapsules may also affect the nature of the shell. The characteristics of interest are morphology, size and size distribution, density, and zeta potential.

### Morphology

Morphology refers to the structural shape of the nanocapsule. This can be determined using a number of microscopy techniques. The most commonly used is TEM, with either positive staining using a heavy atom such as osmium, or negative staining where the medium surrounding the nanocapsule is stained (typically with phosphotungstate or uranyl acetate). Another technique, which has proven effective, is freeze-fracture TEM, where the polymer shell, inner core, and wall thickness are all observed. Quintanar-Guerrero et al.<sup>[10]</sup> have already used SFM for oil-filled nanocapsules. Cryoelectron microscopy and SFM have

a promising future for determining nanocapsule morphology and surface properties.<sup>[9]</sup> Scanning electron microscopy has also shown some applicability for examining the morphology of nanocapsules. It is limited by its magnification ability, but when combined with x-ray analysis, it is a powerful tool to identify nanocapsules with specific atoms. For example, it would be possible to characterize nanocapsules incorporating the iodine-containing oil, Lipiodol<sup>®</sup>.<sup>[9]</sup>

### Size and Size Distribution

For many applications, nanocapsules of specific, uniform size are desirable. Microscopy techniques are capable of giving information about size and size distribution, but have some limitations. First, the typical sample size in microscopy is very small, thus one has to make the assumption that it is representative of the whole. Second, the sample is usually dried, which may adversely affect the morphology. To obtain data on the whole population, QELS or PCS is typically used. Nanoparticles dispersed in a fluid are in constant Brownian motion. The speed of the particles is inversely proportional to their size. Photon correlation spectroscopy analyzes the frequency of shifts in the light intensity that results from the particles moving into and out of the lightpath. Time dependence provides the information needed to determine the diffusion coefficient of the nanocapsules in solutions. Once the diffusion coefficient ( $\langle D \rangle_z$ ) is determined, it can be related to the hydrodynamic radius ( $R_h$ ) of the nanocapsule using the Stokes–Einstein law:

$$R_h = \frac{kT}{6\pi\eta\langle D \rangle_z} \quad (1)$$

where  $\eta$  is viscosity and  $kT$  is the Boltzmann coefficient multiplied by temperature. The distribution of the frequency shifts in light intensity also provides the size distribution of the sample.

It is important to note that the size determined in this method is  $R_h$ , which includes a sphere of solvation

Fig. 2 Two-dimensional schematic of a 3-D phospholipid vesicle (A) and a liposome (B). The phospholipids shown actually form a shell around a 3-D sphere in each case.

around the nanocapsule. As a result, the size may appear larger than that observed in microscopy images.

Gel permeation chromatography can be performed to determine the molecular weight and polydispersity of the prepolymer.

## Density

Chouinard, Buczkowski, and Lenaerts<sup>[11]</sup> showed that nanocapsule density could be determined by isopycnic centrifugation. This technique can be performed using either a classical or analytical centrifuge. Isopycno-graphy (or equilibrium density gradient centrifugation) is a separation technique based on the differing intrinsic densities of the particles. The nanocapsules migrate through the centrifuge tube until they reach a point where they are surrounded by a solvent of equivalent density. The solvent used for nanocapsule analysis is Percoll<sup>®</sup>. The particle density can be backcalculated by comparing with a calibration curve obtained from density-calibrated particles, by collecting the zone of the gradient in which the particles accumulated, and by measuring its density.<sup>[11]</sup>

Comparing densities is a good method to determine whether the nanoparticles observed by microscopy are solid nanospheres, hollow nanocapsules, or oil-filled nanocapsules. The density of nanocapsules tends to be intermediate between that of the polymer matrix and the oil.<sup>[9]</sup> Solid nanospheres have a density equal to that of the polymer matrix. By comparing the density achieved via isopycno-graphy with the densities of the starting materials, one can determine whether nanospheres or nanocapsules are present.<sup>[11]</sup> The density can also be used to yield the nanocapsule oil/polymer composition:<sup>[9]</sup>

$$1/\rho_{\text{NC}} = X_{\text{poly}}(1/\rho_{\text{poly}}) + X_{\text{oil}}(1/\rho_{\text{oil}}) \quad (2)$$

$$X_{\text{poly}} + X_{\text{oil}} = 1 \quad (3)$$

where  $X_{\text{poly}}$  and  $X_{\text{oil}}$  are the mass fractions of the polymer and oil in the nanocapsules, respectively, and represent unknowns.  $\rho_{\text{NC}}$ ,  $\rho_{\text{poly}}$ , and  $\rho_{\text{oil}}$  are the densities of the nanocapsules, polymers, and oils, respectively.

## Zeta Potential

Zeta potential is a surface characterization technique that can be used to investigate whether a guest molecule is truly encapsulated or simply adsorbed onto the surface of a nanocapsule.<sup>[9]</sup>

Particles, when dispersed in water, have a charge because of surface-solvent interactions. For example, silica particles lose a surface proton from silanol

(Si-OH) groups to the aqueous solvent. The charged particle surface attracts a layer of counterions from the bulk solvent, leading to a double layer, whose thickness is dependent on the surface charge density. A large charge stops particles from getting close to each other because of electrostatic repulsion. Conversely, a small surface charge results in a smaller double layer, leading to flocculation.

Zeta potential is a measure (in millivolts) of the energy needed to shear the particle and its inner layer of counterions away from the bulk solvent. The higher the zeta potential is, the larger is the double layer and the more stable the nanocapsule is in the solution. Changes in zeta potential can indicate the adsorption of moieties to the surface of the nanoparticle, which have affected its double layer.

## SYNTHETIC ROUTES

Two main techniques are used to synthesize nanocapsules: the first is interfacial polymerization around a droplet, and the second is deposition of a preformed polymer at the interface of a droplet. Both techniques utilize self-assembly.

### Interfacial Polymerization

In this method, either a monomer or an amphiphilic polymer with a cross-linkable group is used and polymerization is induced at the surface of an oil droplet. This technique requires a system that can polymerize on a faster time scale than the fluctuation in the droplet geometry. The advantage of this technique is that the polymeric shell is formed *in situ*, allowing it to follow the contours of the droplet.<sup>[9]</sup> The drawback is that the cross-linking or polymerization reaction may have side reactions with other species present in the system. For example, if the nanocapsule is being used to encapsulate a drug, the monomer or cross-linkable group may have reactivity toward the drug. At the least, this would result in a reduced availability of the drug and, at its worst, this could result in toxic by-products.

Thurmond, Kowalewski, and Wooley<sup>[12]</sup> of the Washington University, St. Louis have prepared nanocapsules containing a hydrophilic shell and hydrophobic core properties. Thurmond et al. rely on self-assembly to form micelles, which are then stabilized through covalent bonding of the outer shell (Fig. 3). The result is a surface cross-linked "Knedel" (SCK).<sup>[12]</sup> The shell cross-linking provides two functions; first, it stabilizes the micelles; second, it offers the ability to control the permeability of the shell.<sup>[13]</sup> Thurmond et al.'s work was one of the first examples of chemically cross-linked nanosphere surfaces. Lowe,

**Fig. 3** Two-dimensional schematic of a 3-D SCK. *Source:* Adapted from Ref. [12].

Billingham, and Arms<sup>[14]</sup> and Bütün et al.<sup>[15,16]</sup> have also created SCK structures. In this case, the core could be reversibly hydrated or dehydrated depending on the solution temperature resulting in a hydrophilic or hydrophobic core, respectively.

Although SCKs have core-shell structures, they are not oil-filled. They are made from unswollen micelles, thus the core is composed of the hydrophobic, alkyl chain ends of the block copolymers used to make the shell.<sup>[17]</sup> Despite this, depending on the properties of the core polymer chains (glassy, fluidlike, or crystalline), the SCKs can have a variety of core properties, including the fluidlike properties found in oil-filled nanocapsules.<sup>[18]</sup> These last properties can be achieved by using a block copolymer that has a degradable core. Huan et al.<sup>[19]</sup> and Zhang, Remsen, and Wooley<sup>[20]</sup> showed the utility of this approach by hydrolyzing the poly- $\epsilon$ -caprolactone core of SCKs. The hydrolysis products resulted in a polar core, but it is conceivable that a similar process could be used with different polymers to yield nonpolar, oil-like cores.

The synthesis of oil-filled nanocapsules using amphiphilic surfactants follows a route similar to that used to make liposomes. Oil-filled nanocapsules are created when an oil-in-water microemulsion is used as the template for the interfacial polymer layer (Fig. 4). Micrometer-sized capsules have already been proven possible<sup>[21]</sup> from regular emulsions, and the chemistry can be extended to the formation of nanocapsules from microemulsions. Such nanocapsules are water-soluble, but coating the nanocapsules with additional layers of polymers, proteins, or other materials can change solubility. Surface materials are chosen for their specific properties, such as chemical and biological resistance, adhesion, and reactivity.

Water-in-oil emulsions have been used to make nanocapsules with aqueous cores.<sup>[22]</sup> The emulsions were stirred while a shell was polymerized at the oil-water interface. Similar techniques have been used to make nanocapsules with oil cores from oil-in-water microemulsions.<sup>[4,23–26]</sup> Underhill et al.<sup>[23]</sup> utilized a microemulsion stabilized with surfactants containing

**Fig. 4** Two-dimensional of the synthesis of nanocapsules using a microemulsion as a template. *Source:* From Ref. [23].

polymerizable head groups. Once the microemulsion has been formed, subsequent steps lead to the polymerization of the surfactant with a comonomer to form a robust shell around the oil droplet. McDonald, Bouck, and Chaput<sup>[24]</sup> also used microemulsions, but utilized the change in solubility between monomers and polymers to force a polymer shell to form at the interface between the oil droplet and the aqueous continuous phase. The monomer was dissolved in the oil along with a hydrophobe and an initiator. The hydrophobe was chosen such that it was not miscible with the polymer; thus as the reaction progressed, the polymer was forced to segregate to the oil–water interface, leaving the hydrophobe forming the oil phase in the core. Typically, the hydrophobe is removed via vacuum or steam stripping. The hydrophobe diffuses through the shell to create hollow nanocapsules.<sup>[24]</sup> This is because the shell is porous enough to allow the hydrophobe to diffuse through the polymer. In the case of Jang and Ha,<sup>[26]</sup> the hydrophobe was isooctane, which is a lightweight volatile organic. If the hydrophobe is not removed, then oil-filled nanocapsules result (Table 1).

### Preformed Polymer Assembly

The alternate method to form nanocapsules is to self-assemble preformed polymers around an oil droplet (Fig. 5). Again the droplet acts as a template. This

**Fig. 5.** Two-dimensional schematic of the layer-by-layer self-assembly of two different polymers (gray and black) on the surface of a template, which may be either a colloidal particle or an oil droplet. Source: Adapted from Refs.<sup>[27]</sup> and <sup>[28]</sup>

method avoids the issue of the reactivity of the cross-linkable group and the possible side reactions. The drawback is that there is less control of the size and size distribution of the resulting nanocapsules.<sup>[9]</sup>

Nanocapsules, via the self-assembly of polymers at the interface of a droplet, can be made using natural (e.g., liposomes) and/or man-made [e.g., poly(ethyleneimine)] polymers. The deposition of a pre-made polymer at the surface of a droplet can be performed following a method introduced by Lvov et al.<sup>[27,28]</sup> in the mid-1990s. The shell wall of a nanocapsule is made via layer-by-layer assembly through alternate adsorption of oppositely charged components onto a template.<sup>[29]</sup> Uncharged polymers can be used if the precipitation method is changed. In this case, the polymer is dissolved in the organic phase, which is mixed under high shear with an aqueous phase containing a hydrophilic surfactant. As the nanometer-sized droplets of oil form, the polymer precipitates at the interface with the aqueous phase and the whole nanocapsule is stabilized by the surfactant. The resulting nanocapsules can be fine-tuned to provide the desired characteristics by changing the type and amount of polymers, oils, and/or surfactants. The ratio of the organic phase to the aqueous phase also plays a role in the chemical nature of the nanocapsule.<sup>[9]</sup>

The number of layers adsorbed to the surface determines the thickness of the shell. As an alternative to adsorbing polymers to the surface, colloidosomes have

colloidal particles adsorbed to an emulsion droplet, resulting in a selectively permeable membrane, which allows submicron particles to diffuse in but excludes larger particles.<sup>[5,6,30–33]</sup> In this case, the resulting capsules exceed the size limit imposed on the definition of nanocapsules. Despite this limitation, it is plausible that this technique could be used for smaller entities. Of concern may be that with perfectly packed spheres, the pores are approximately  $0.15d$ , where  $d$  is the diameter of the adsorbed spheres. Thus as the spheres decrease in size, so will the basic pore size, resulting in decreased permeability (Table 2).

## APPLICATIONS

Submicrometer-sized hollow particles have been explored for the encapsulation of a variety of guest molecules into their cores. They have an advantage over solid nanoparticles because their cores provide for high loading capacity. Different authors have referred to them differently; some examples include microspheres,<sup>[34,35]</sup> hollow nanoparticles,<sup>[36,37]</sup> silica particles,<sup>[38,39]</sup> nanocapsules,<sup>[11,40,41]</sup> solid lipid nanoparticles,<sup>[42]</sup> and host–guest carriers.<sup>[43,44]</sup> One of the advantages of oil-filled systems is that hydrophobic chemicals can be encapsulated and then transported at concentrations higher than their normal solubility in transport media. Supramolecular chemistry has involved numerous types of polymeric assemblies providing enhanced properties (e.g., stealth<sup>®</sup>, which is the ability of a nanoparticle to remain invisible to defense mechanisms within the body, and molecular recognition, which gives the nanoparticles the ability to target specific areas within the body). One of the limitations of such assemblies is their weak stability under changing environmental conditions. Therefore a combination of self-assembly followed by covalent bonding to create novel macromolecular architectures may be employed. The SCK nanostructured particles are being investigated for application in areas as broad as drug delivery, encapsulating agents from fragrances to food flavors, coatings, dye dispersants, pollutant removal systems, and catalysis. In the case of drug delivery, nanocapsules may be advantageous by providing protection against proteolytic degradation. In the case of the food and fragrance industries, nanocapsules are desirable because their use in encapsulating odors leads to a persistence of the odor long after application. This means a longer-lasting perfume, or a food product, which does not go “stale” as rapidly. Further variation over the three-dimensional (3-D) shape of polymer structures (e.g., the preparation of cylindrical or needle-shaped particles) is expected to generate materials of unique behavior.

As seen in the previous paragraph, oil-filled nanocapsules have a variety of applications. There are a number of articles in the literature, which outline their use in drug application technologies (see Refs. [9, 13, 34] and the references therein). Some of the biologically active compounds that nanocapsules have been proposed to encapsulate are hormonal substances, antibiotics, insulin, proteins, antigens, viruses,<sup>[45]</sup> bacteria,<sup>[38]</sup> or cells.<sup>[46]</sup> One non-biomedical application is in the cosmetic/dermatology industry. L'Oréal has been using liposomes since the early 1970s to encapsulate cosmetic ingredients.<sup>[47]</sup> Liposomes have several problems associated with their use in cosmetics.<sup>[48]</sup> First, encapsulation does not improve the bioavailability of the active ingredient. Second, liposome loading efficiency is low.<sup>[48]</sup> Last, the liposomes are not necessarily stable over all environments. Nanocapsules are superior to liposomes for this application because they address all these problems.

L'Oréal's nanocapsules have been on the market since 1995.<sup>[45,47–49]</sup> L'Oréal uses nanocapsules to encapsulate active ingredients such as vitamin A (retinol), vitamin E, vitamin C, and beta-carotene, which are most effective when they reach the deeper layers of the skin. Vitamin A is necessary for new cell generation and overall correct functioning of the epidermis.<sup>[48]</sup> Vitamin E “mops up” harmful oxygen free radicals. Both vitamins are more efficient when transported through the surface of the skin to the deep layers beneath. The nanocapsules facilitate transportation to these deep layers. The nanocapsules have a biodegradable shell, which is attacked by cutaneous enzymes, releasing the contents to the deep layers of the skin.<sup>[48]</sup>

The nanocapsules created by L'Oréal, in collaboration with the French National Research Ministry (CNRS), are made using a microemulsion technique. Two solvent phases are present, both being totally miscible with each other. The first solvent  $S_1$  is a volatile liquid (e.g., acetone), which is used to dissolve the polymer (which will constitute the shell; e.g., poly- $\epsilon$ -caprolactone), the oil phase (which will be the core), the lipophilic active compound (which will be transported within the nanocapsule), and a surfactant (which will prevent the nanocapsules from agglomerating once they are formed). The second solvent  $S_2$  is in aqueous phase and is a non-solvent for the constituents dissolved in  $S_1$ . Both  $S_1$  and  $S_2$  are mixed together via a fine stream and nanometer droplets of oil are formed, surrounded by the polymer, which is insoluble in both  $S_1$  and  $S_2$ , thus creating nanocapsules. The surface is coated with a stabilizing surfactant. As a final step, the acetone is removed under vacuum.<sup>[48]</sup>

A method of delivery alternate to the nanocapsules is the use of microemulsions. Nanocapsules are superior in terms of stability. Microemulsions can be destabilized by changes in the environment such as

temperature and pH. Nanocapsules also provide increased bioavailability because their shells protect the active ingredient(s) in the core from cutaneous enzymes, which may degrade them. Nanocapsules have been shown to penetrate the epidermis further than microemulsions (up to 30  $\mu\text{m}$ ).<sup>[45]</sup> In the case of vitamin A, the nanocapsules act as reservoirs in the uppermost layers of the epidermis, thus “stockpiling” the vitamin until the skin needs it.<sup>[48]</sup>

## CONCLUSION

Oil-filled nanocapsules consist of spherical structures typically <200 nm in diameter with a distinct core-shell structure, where the core is fluidlike and lipophilic. Oil-filled nanocapsules can be synthesized by either the polymerization of a shell, or by the self-assembly of preformed polymers around a lipophilic compound. Differing monomers, polymers, and hydrophobes have resulted in various sizes and morphologies on nanocapsules. Oil-filled nanocapsules have been examined using SEM, TEM, and SFM.

Oil-filled nanocapsules are a rapidly developing technology that shows promise in a number of areas. The areas of application are broad, and include the areas of drug delivery<sup>[9,13]</sup> and removal,<sup>[23]</sup> food science,<sup>[50]</sup> cosmetics/dermatology,<sup>[47]</sup> paints/inks and coatings, pollutant removal systems, and vessels for catalysis (e.g., nanoreactors).<sup>[8]</sup> The commonality in all these applications is the need for a reservoir or host to encapsulate a guest moiety, which otherwise may not be soluble, or may be degraded by the environment in which it is needed. When used as nanoreactors, oil-filled nanocapsules can be considered as local areas of high concentration even if the overall solution concentration is low. This may help catalysis and reactivity.

Research groups currently working on nanocapsules for drug delivery acknowledge that the nanocapsules would be more effective if the surface were altered to allow for stealth abilities (stealth refers to the nanocapsules' ability to remain invisible to the body's defense mechanisms, e.g., white blood cells). This is possible through surface functionalization with poly(ethylene oxide). Nanocapsules would also be more efficient drug delivery vessels if they could target the specific site for drug delivery (e.g., a tumor). This is known as active targeting.<sup>[13]</sup> This can be achieved if the surface of the nanocapsule is modified with ligands, which are selectively recognized by receptors on the cells of interest (e.g., tumor cells). This is of importance because it provides maximum efficiency of the drug dosage and minimizes the side effects of the drug associated with it coming into contact with non-target tissues.

In the future, nanocapsules will be better applied to topical, biomedical, cosmetic, and dermatological

applications if a biomimetic approach is adopted. The nanocapsule structure will need to be engineered such that it resembles more closely the structure of single-celled organisms. The result would be a delivery device, which would deliver its contents to a specific activity site.

Nanocapsules have already shown their utility in a number of areas and continue to show promise with the possibility of adapting them to a number of circumstances with a little bit of imagination.

## ACKNOWLEDGMENTS

The author would like to thank the members of the George and Josephine Butler Polymer Laboratory and the Engineering Research Center for Particle Science and Technology at the University of Florida as well as DRDC Atlantic for their support, both scientific and financial. Special thanks are given to Dr. R. S. Duran and Dr. G. Liu for their mentorship, and my colleagues at the DRDC Atlantic for their help and encouragement.

## INTRODUCTION

As the desire for smaller components heightens, techniques to fabricate materials and building blocks for materials that take advantage of the nanorealm continue to proliferate. Since the discovery of carbon nanotubes in 1991,<sup>[1]</sup> nanoscale objects fabricated from various compounds with various shapes have emerged. Although many synthetic techniques have surfaced to fabricate materials with nanoscale dimensions, there is a significant need to then arrange these materials into active and useful materials. Because of the requirement of smaller components for microelectronics, electrically conducting polymers have captured interest as materials of which nanoscale objects would be highly desirable.

Since the discovery that polyacetylene can be doped so that the electrical conductivity can be controlled over 11 orders of magnitude,<sup>[2]</sup> many studies have been carried out to better understand and improve the conductivities and properties of these polymers.<sup>[3–5]</sup> Intrinsically conducting polymers have attracted a great deal of interest as potential chemical sensors,<sup>[6]</sup> single-molecular transistors,<sup>[7]</sup> electron emitting flat panel displays,<sup>[8]</sup> and other microelectronic devices.<sup>[9]</sup> Intrinsically conducting polymers are attractive in many applications as their conductivity can be tuned by chemical manipulation of the polymer backbone, by selection of the dopant, by alteration of the doping degree, or by mixing with a matrix material producing a composite. In addition, conducting polymers offer advantages over metals and other semiconducting materials because of their good mechanical properties, stability, ease of processing, and relatively low price. Because of the desirable properties of intrinsically conducting polymers and the elevated conductivity by molecular alignment, a number of techniques have arisen to synthesize 1-D nanostructures of conducting polymers. In this entry we will review techniques that are currently available to synthesize 1-D nanoscale structures of electrically conducting polymers both in solution and on surfaces.

As conventional lithographic techniques cannot be applied to produce conducting lines in the sub-100-nm regime, the ability to render high quality 1-D wires of  $\pi$ -conjugated polymers with these dimensions is of great interest. Additionally, as the conductivity of  $\pi$ -conjugated polymers is dictated in part by molecular alignment, and the radius of gyration of polymers is generally in the tens of nanometer range, 1-D nanostructures of  $\pi$ -conjugated polymer would likely afford elevated conductivities. Although other methods do exist, techniques to fabricate 1-D nanostructures of conducting polymers evolve from the use of templates in the form of either solid materials or arranged molecules. We will begin our discussion with methods to produce 1-D nanostructures of conducting polymers in bulk solution by using “hard” or “soft” templates, and follow with techniques to fabricate 1-D nanostructures directly on surfaces.

## 1-D $\pi$ -CONJUGATED POLYMER NANOSTRUCTURES SYNTHESIZED USING “SOLID” TEMPLATES
