Cluster-Assembled Nanostructured Carbon

P. Milani, A. Podestà, E. Barborini

Università degli Studi di Milano, Milan, Italy

CONTENTS

1. INTRODUCTION

Since the discovery of fullerenes and carbon nanotubes and the recent progress in the synthesis of diamond-like nanostructures, carbon has occupied a strategic position in materials science and technology as one of the most versatile and far-reaching materials [1–3]. An arsenal of advanced growth methods now has the potential to provide a large variety of novel carbon materials with tailored properties and functions. In particular, the recent development of cluster assembling techniques has greatly contributed to the notion and practice of nanostructured materials [4]. Nanostructured carbon, in particular, offers a growing number of applications, which apparently depend on its nanoscale constitution. In order to establish a link between nanostructure and materials performances, characterization and manipulation techniques have to be developed and fully mastered on the nanometric scale. In particular, the structural and functional properties of carbon critically depend on the ratio between the numbers of sp (carbyne-like), sp^2 (graphite-like), and sp^3 (diamond-like) bonds. The control of such a ratio, which has become possible through the most recent growth techniques such as, for example, the one based on supersonic cluster beam assembling [4–6], enables one to synthesize a variety of carbon thin films of great interest in tribology (self-lubrication, wear-resistant, superhard coatings), electronics (field emission for flat-panel displays), or electrochemistry (molecular sieves, ionic and molecular insertion for various applications, including supercapacitors) [5].

Carbon particles and soot attracted the attention of the scientific community well before the discovery of fullerenes [7]. The synthesis and characterization of soot are of particular relevance in many fields of pure and applied science such as astrophysics, electrochemistry, and catalysis [5, 7]. Hundreds of different carbon soots generated by arc discharge, pyrolisis, or sooting flames have been studied since the 1960s [7]. The unifying point of all of the different approaches is the nanoscale structure of these materials, where one hopes to recognize universal building blocks and to determine assembling strategies for the production of materials with tailored properties. The structural and functional properties of carbon thin films assembled atom by atom and, in particular, the sp^2/sp^3 ratio, are largely determined by the kinetic energy of the particles impinging on the substrate during the film growth [3]. The use of clusters instead of atoms, as building blocks, can open new possibilities for the synthesis of materials where the structural and functional properties are also determined by the hierarchical organization of units with dimensions ranging from the nanoscopic to the mesoscopic scale [4, 5].

Experimental and theoretical investigations have shown that small carbon clusters (roughly below 40 atoms) have chain or ring structures, whereas larger clusters have the tendency to form three-dimensional cage-like structures characterized by sp^2 coordination [8–17]. The low-energy deposition of different carbon clusters preserving the original structure thus would be a very powerful technique for the creation of materials with controlled hybridization, and hence controlled physicochemical properties [4]. For example, films grown using a cluster mass distribution depleted by the large fullerene-like clusters are expected to have a very disordered compact structure; on the other hand, films grown with a cluster distribution rich in the large fullerene-like component should be characterized by a disorder graphitic structure with a large porosity [18, 19].

2. GAS-PHASE SYNTHESIS OF CARBON CLUSTERS

The deposition process of nanostructured carbon films starting from clusters produced in the gas phase can be divided into the following steps:

1. cluster formation
2. cluster extraction
3. cluster selection
4. cluster deposition.

Gas-phase synthesis of clusters is a very efficient method based on the growth of particles from a monomeric vapor [4, 20, 21]. Typically, a Knudsen cell for the production of atomic beams of thermally vaporizable substances can be used for the generation of cluster beams. However, the presence of clusters in a standard effusive beam as produced by a thermal evaporation source is residual, and therefore a gas-aggregation process should be activated by nonequilibrium cooling [20]. This consists of mixing in a condensation cell the atomic vapor with a cold buffer gas (usually a noble gas). The clusters are then extracted by letting the mixture expand through a nozzle. The geometry and dimensions of the source influence the residence time of the clusters before expansion, and hence the cluster-size distribution [4].

Generally speaking, the requisites that one should look at for assembling nanoparticles are the control of mass distribution, structure, and chemical reactivity. Moreover, one should be able to control the degree of coalescence of the clusters during the formation of the nanostructured materials [4].

The production of clusters of refractory materials like carbon requires an efficient vaporization method, such as laser ablation, arc discharge, sputtering, and so on [4, 22, 23]. These methods must be coupled with an efficient cluster extraction, which can be obtained by a gas stream.

Cluster mass selection is also very important in order to obtain films and materials with tailored properties. This can be achieved by varying the particle condensation conditions prior to extraction; however, only a coarse control of mass distribution is possible with this method [4, 20]. Clusters can also be selected, once extracted from the source, by mechanical or electromagnetic filtering methods [20, 21]. These have the disadvantage of considerably lowering the cluster flux, and thus being impractical for many applications where mass production is required.

2.1. Sputtering and Laser Ablation

The production of carbon-based systems having a structure at the nanoscale due to the incorporation of clusters can be obtained using arc-discharge methods [22, 24]. Carbon films with inclusions of fullerene-like structures and nanotube fragments have been produced with a filtered cathodic arc apparatus, where the arc occurs in a localized high-pressure (10 torr) region. Due to the presence of the inert gas, condensation takes place, and a beam of monomer ions and clusters is formed and deposited. The incorporation of three-dimensional networks, consisting of buckled planes with fullerene-like features, induces the formation of films with very high values of hardness and elasticity [5, 22, 24].

Figure 1 shows a schematic representation of the experimental configuration of the so-called anodic jet carbon arc (AJCA) deposition technique used to deposit nanocomposite carbon films. Nitrogen is injected into the chamber, and is directed toward the arcing region through an orifice at the side of a specially machined hollow anode. During the discharge, the ionization of nitrogen takes place [5, 22, 24]. The working pressure in the chamber is kept below 10^{-3} mbar. The electric arc is driven by an ac voltage of 22–24 V, with the arc current typically between 70 and 100 A. The use of an ac voltage is not very common, and effectively results in each electrode oscillating between being an anode and a cathode [5].

The production of cluster-assembled carbon foams has been reported by using high-repetition-rate laser ablation in inert gas atmosphere [25, 26]. A silicon substrate placed at a distance of 17 cm was used to collect the particles ablated from a graphite target [27]. This form of cluster-assembled carbon is characterized by a coexistence of sp^2 and sp^3 bonds and a very low density similar to that of carbon aerogels [28].

Pulsed laser deposition with an excimer laser (KrF) has also been used to produce a form of nanoporous carbon films. By varying the pressure in the deposition chamber, control of density and porosity has been demonstrated [29].

The above-mentioned approaches do not have control of cluster mass distribution produced during the ablation process or of the kinetic energies of the nanoparticles.

2.2. Supersonic Cluster Beams

Supersonic cluster beam deposition (SCBD) allows a reasonably precise control of cluster mass distribution and kinetic energy, with the possibility of obtaining very large deposition rates [4, 24]. The availability of intense and stable cluster sources makes cluster beam deposition a viable technique for the synthesis of cluster-assembled carbon films [30, 31].

A supersonic beam is schematically described as a gas stream expanding very rapidly from a high-pressure region

Figure 1. Schematic representation of the experimental configuration of the so-called anodic jet carbon arc (AJCA) deposition technique. Reprinted with permission from [5], G. A. J. Amaratunga et al., in "Nanostructured Carbon for Advanced Applications." Kluwer, Dordrecht, 2001. © 2001, Kluwer Academic.

(source), through a nozzle, to a low-pressure region [32]. The characteristics of the beam are mainly determined by the size and shape of the nozzle and by the pressure difference between the two regions. Compared to effusive beams used in molecular beam epitaxy, supersonic beams provide higher intensity and directionality, allowing the deposition of films with very high growth rates [32].

When a heavy species is diluted in a lighter one (as in the case of clusters diluted in He or another inert gas) and the mixture is expanded, there is formation of a seeded supersonic beam. Seeded supersonic beams are extensively used to cool and to accelerate heavy species such as clusters, and they are particularly attractive for cluster beam deposition [4, 33, 34].

A supersonic expansion can be obtained by imposing a pressure ratio less than $P_b/P_0 = 0.478$ across a convergent nozzle driving an isentropic flow expansion, where P_0 and P_b are the stagnation and the background pressures, respectively. The expansion through a convergent nozzle will always take place in a subsonic regime regardless of the amount of the applied pressure ratio. Outside the converging nozzle, depending on the pressure ratio, the flow will supersonically expand to pressures even much lower than the background. A normal shock, known as the Mach disk, matches the pressure inside the jet to the background, and closes an area called the zone of silence. The location of the Mach disk has been empirically determined as being only a function of the pressure ratio, and independent of the fluid nature and nozzle geometry [32].

In general, an isentropic supersonic jet led by a shock-free converging–diverging nozzle is advantageous compared to a nonisentropic underexpanded jet obtained by a convergent nozzle. However, depending on the Reynolds number, a converging–diverging nozzle requires a slow increase in cross-sectional area to avoid boundary layer separation and backflow, which enlarges the nozzle length to inconvenient dimensions. Furthermore, the conical converging part (either in converging–diverging or pure converging nozzles) usually produces some focal points after which particles may diverge [35, 36]. The location of these focal points depends greatly on the particle size and initial position prior to the nozzle.

The sudden free expansion of the flow produces a high outward radial velocity at the beginning of the free jet close to the nozzle outlet. This radial velocity (drag) greatly varies with the radial position, both in the jet and at the nozzle outlet. It is weak at the centerline, and very strong close to the nozzle wall at the outlet. Hence, in contrast to the particles located in the central regions, those far from the axis are exposed to a strong radial drag. Consequently, the trajectories of particles concentrated on the centerline can remain approximately unchanged, while particles far from the axis may strongly diverge in the free expansion. It also should be noted that the response of the particles to these radial drags is a function of the particle size. The above-mentioned radial drag can effectively separate the particles of different sizes, especially if they are not concentrated on the centerline [37]. Small particles can follow the expanding carrier gas, while large particles persist in their original trajectories.

If the particles can be concentrated on the nozzle centerline, only the Brownian diffusion (and lift-force effects

in case of nonspherical particles [38, 39] can perturb/spread the configuration obtained by aerodynamic focusing. Focusing the clusters on the beam center will directly improve the beam intensity, while also having an influence on the other characteristics of the supersonic part of the expansion [40].

Figure 2 shows the principle of operation of the typical apparatus used for a cluster beam, and based on a supersonic cluster source. It consists of three differentially evacuated chambers, and it can operate in the high- and ultrahigh-vacuum regimes. The first chamber hosts the cluster source; the supersonic cluster beam enters the second chamber through an electroformed skimmer. The second chamber can be equipped with a sample holder, which can intersect the beam, a quartz microbalance for beam intensity monitoring; it can also host a beam chopper or a fast ionization gauge for time-of-flight measurements of the velocity distribution of particles in the beam [32]. The third chamber usually hosts a linear time-of-flight mass spectrometer (TOF/MS), which is placed collinearly or orthogonally to the beam axis [4].

3. CARBON CLUSTER BEAM SOURCES

3.1. Laser Vaporization Cluster Source

Carbon clusters can be condensed from species obtained by laser ablation of a solid target [9]. A laser vaporization cluster source (LVCS) was originally developed for the production of clusters in molecular beams by Smalley [41–43]. Since this pioneering work, laser vaporization has become one of the most common techniques for generating cluster beams of refractory materials [4].

The design and realization of LVCS are very simple (Fig. 3), especially if compared to classical hot oven sources. LVCSs are conceptually similar to the chambers used for laser ablation for thin-film deposition [44]; the only relevant difference is that the plasma plume expands in a buffer gas. In an LVCS, the light of a high-intensity pulsed laser is focused onto a target rod, and a small amount of material is vaporized into a flow of an inert carrier gas. The inert gas quenches the plasma, and cluster condensation is promoted. The mixture is then expanded in vacuum, and forms a supersonic beam. LVCSs are operated in a pulsed regime; hence, pulsed valves are used for delivering the carrier gas. This allows the use of a relatively economical apparatus with moderate pumping speed.

Several factors affect the LVCS performance in terms of intensity, stability, and the cluster mass range attainable: quantity of ablated material, plasma–buffer gas interaction, plasma–source wall interaction, and cluster residence time prior to expansion [45].

The characteristics of the cluster population are controlled by the local gas pressure during plasma production, and by the residence time of the particles in the source body. The plasma–gas interaction affects not only the final cluster distribution, but also the subsequent expansion and beam formation.

Increasing the pressure during the ablation results in a shift of the cluster distribution toward larger masses. Laser pulse characteristics influence the quantity and the state of the matter removed from the target. Pellarin et al. showed that the use of a Ti:sapphire laser (790 nm, 30 ns pulse width) can produce very intense cluster beams over a wider mass range [46]. Although the microscopic mechanisms underlying this improvement have not been characterized in detail, the longer pulse duration should be responsible for a more efficient material removal from the target [44].

Smalley and Kroto and co-workers used a disk LVCS for producing carbon clusters and C_{60} [47]. A modified version of this source, with a computer-controlled disk motion and a fast pulsed valve, has been coupled with a Fourier transform ion cyclotron resonance apparatus to characterize large carbon clusters in the beam [10].

Cluster-assembled carbon films have been produced using clusters generated by an LVCS by the group of Melinon [48].

3.2. Pulsed Microplasma Cluster Source

The pulsed microplasma cluster source (PMCS) is based on a microplasma ablation. By confining a plasma in a well-defined region of the target, it is possible to achieve material vaporization with high efficiency. Source geometry and dimensions can be optimized to produce intense and stable cluster beams, while using a relatively low carrier–gas load [30].

Due to its extremely high intensity and stability, the PMCS is a unique tool for the synthesis of nanostructured carbon-based materials, providing long-time stability and high deposition rates [30].

The PMCS is schematically shown in Figure 4. It consists of a ceramic cubic body in which a few cubic centimeters cylindrical cavity is drilled. A channel of 6 mm diameter is drilled perpendicular to the axis of the cavity, and hosts two rods (electrodes) of the material to be vaporized, facing each other and separated by a small gap. A solenoid pulsed valve injects helium at the pressure of several tens of bars through a ceramic nozzle on the back of the cavity. The gap between the electrodes is off axis, in such a way that the gas flushes on the cathode surface. A removable nozzle with a cylindrical shape closes the front of the source.

The principle of operation of the cluster source is the following: the valve delivers an intense He pulse with an opening time of a few hundreds of microseconds, thus forming a small high-gas density region at the cathode surface. After that, a very intense discharge (hundreds of amperes) lasting for few tens of microseconds is fired between the electrodes by applying a voltage ranging from 500 up to 1500 V. Ionized helium sputters a small area of cathode surface at the point where the He flux impinges on the electrode. The mixture of helium-vaporized atoms quenches, and cluster nucleation takes place. The clusters are then carried out through the nozzle by supersonic expansion [30].

Due to the source internal cavity configuration, the ablation process can be localized on a small region of the target, and hence it is very efficient. As in laser vaporization sources [45], the cathode is continuously rotated by means of an external motor in order to allow constant ablation conditions for all pulses and a homogeneous consumption of the rod.

Deposition rates, up to 65 μm/h over an area of 1 cm^2, can be obtained substituting the simple cylindrical nozzle with a more complex one, called a focuser [49]. Exploiting inertial aerodynamic effects [40, 49], the focuser reduces the angular semiaperture of the beam from ~12 to less than 1°, concentrating the cluster on the center of the beam.

Using the typical mass distributions of a PMCS, it is possible to grow films with a density ranging from 0.9 up to 1.4 g/cm^3, depending on the precursor clusters. BET analysis shows a surface specific area of roughly 750 m^2/g [50–52].

Time-of-flight mass spectrometry performed on carbon cluster beams shows that the length of a single pulse is about 10 ms, and the beam intensity decreases exponentially, resembling the gas pressure fall in the source. The velocity

Figure 4. Expanded view of the PMCS. Reprinted with permission from [56], E. Barborini et al., *Chem. Phys. Lett.* 300, 633 (1999). © 1999, Elsevier.

of the carrier gas is about 2000 m/s in the head of the pulse, and slows down to 1000 m/s in the tail. A velocity slip of the clusters with respect to the carrier gas is present, but becomes of some relevance only for the last clusters exiting from the nozzle. The kinetic energy of the clusters is lower than 0.4 eV/atom [53].

The intensity and mass distribution of carbon clusters in the beam can be controlled and optimized by a precise synchronization between gas injection and discharge firing. Cluster intensity is also strongly dependent on the quantity of ablated material, which increases as function of the discharge voltage.

Cluster mass distribution is lognormal, as usually observed in gas-phase-grown particles [21]. For typical operation parameters, it is peaked around 550 atoms/cluster, with a mean size of 850 atoms/cluster, as shown in Figure 5. The mass distribution moves toward larger masses as the residence time increases; for this reason, the population found in the front of the pulse differs from the one in the tail. Figure 5 is representative of the average spectrum obtained by integrating over the whole cluster pulse.

Depending on the application, the PMCS can operate under different conditions. An ultrahigh-vacuum (UHV) PMCS has been developed in order to allow *in-situ* characterization of cluster-assembled carbon [54].

4. CONTROL OF FILM NANOSTRUCTURE BY CLUSTER SELECTION

The assembling of carbon cluster beams has been investigated both experimentally and theoretically in view of the creation of a new class of solids based on nanoscopic structures (chains, fullerene-like units, etc.), otherwise difficult to produce by assembling the film atom by atom [6, 18, 31, 55, 56]. This could be achieved by control of the cluster size distribution prior to deposition. Novel structural and functional properties could be displayed by solids, retaining some of the cluster characteristics [6, 18].

The growth of carbon films via low-energy cluster deposition can be viewed as a random stacking of particles as for ballistic deposition [53, 57]. The resulting material is characterized by a low density compared to that of films assembled atom by atom, and it shows different degrees of order, depending on the scale of observation [25, 26, 31].

The morphology of cluster-assembled carbon films shows different degrees of order and structures, depending on the scale of observation. The characteristic length scales are determined by cluster dimensions and by their fate after deposition: cluster beams are characterized by the presence of a finite mass distribution and by the presence of different isomers with different stabilities and reactivities. Once on the substrate, stable clusters can survive almost intact, while reactive isomers can coalesce to form a more disordered phase.

Classical molecular dynamics simulations tailored for SCBD experiments have been used to characterize and predict the growth of carbon thin films assembled by SCBD [18]. The simulations show that, depending on the cluster mass distribution, films with fullerene structures embedded in an amorphous matrix characterized by threefold coordination and hexagonal bond rings are obtained with large clusters (Fig. 6). Smaller and more fragile clusters such as linear chains produce disordered structures characterized by nonhexagonal rings with twofold coordinated atoms. Structural and elastic properties are in good agreement with the experiments. The large porosity allows the accommodation of mechanical stresses, thus permitting the growth of films with very large thicknesses (>10 μm) [29, 53].

Molecular dynamics simulations have also been performed to describe the deposition of small fullerene-like carbon clusters. C_{28} [19] and C_{20} [58] have been used as elemental building blocks. The growth of hydrocarbon thin films has also been simulated, starting from the deposition of small clusters at various kinetic energies [59].
Figure 6. Atomic structure of amorphous film obtained by deposition of beams with bimodal cluster mass distribution in the range 1–23 atoms/cluster and 46–120 atoms/cluster with relative weight 5:1 [sample (a)] and 1:10 [sample (b)], respectively. 5. STRUCTURAL AND FUNCTIONAL CHARACTERIZATION

5.1. Raman Scattering

An enormous number of papers have been devoted to the Raman characterization of different forms of disordered and nanocrystalline carbon, and many reviews can be found on this subject [60–63]. Raman scattering is perhaps the most popular method for the routine characterization of carbon-based materials [64, 65]. From Raman spectra, it is, in principle, possible to detect the coexistence of different carbon allotropic forms, the degree of order of different structures, the nature of the local bonding, and to follow the structural evolution as a function of the physicochemical treatments of the samples. The popularity of Raman scattering for the study of carbon, however, does not correspond to well-established models for the interpretation of all of the features observed in carbon-based materials: up to now, especially for disordered carbonaceous materials, no satisfactory theory of the Raman effect has been provided [60].

Raman scattering is very sensitive to structural changes that modify the translational symmetry of the perfect crystal. Different carbonaceous materials, characterized by the degree of disorder, ranging from the atomic scale, typical of noncrystalline systems, to nano- and microcrystalline assemblies, should display different Raman spectra.

The coexistence of the contributions coming from localization effects and structural disorder renders it very difficult to extract, from Raman spectra of disordered carbon, information on the structure and dimensions of domains. In particular, the sp^2/sp^3 ratio in amorphous and diamond-like carbon cannot be derived solely from Raman spectra analysis [60].

Raman scattering can be easily interpreted in terms of crystallites dimensions when G and D bands are well separated and distinct. These bands have relatively narrow bandwidths, whereas "nonorganized" or disordered carbon contributes to their broadening. In the case of large broadening and merging of the G and D bands, the extraction of structural information is very difficult, and interpretation of the Raman spectra must be performed very carefully to disentangle the different contributions to the line shapes. Several factors, such as crystallite dimensions and size distribution, bond angle disorder, and stress, affect the Raman line shape with a weight, which is predictable with difficulty [65].

In amorphous carbon, the G and D bands broaden and coalesce; the Raman spectra can be interpreted as being originated by an amorphous carbon matrix of threefold and fourfold coordinated carbon atoms in which a small region of hexagonal rings is embedded [65]. Different synthetic methods can change the sp^2/sp^3 ratio [63]; however, Raman spectra only exhibit small changes, confirming that they are mainly sensitive to the sp^2 content.

The Raman characterization of cluster-assembled materials must address the problem of cluster coalescence and their organization in structures spanning length scales from the nanometer up to the micrometer. The different structures in which the precursor clusters are organized need

experimental probes sensitive to the different length scales typical of intracluster and intercluster interactions. For carbon-based materials, Raman spectroscopy can be used for the characterization on a nanometer scale [66].

Melinon and co-workers [33, 48] characterized the structural and mechanical properties of cluster-assembled carbon films obtained with an LVCS at different operating conditions, which should correspond to different cluster mass distributions. The observation of mass spectra peaked at C_{20}, C_{60}, and C_{900} has been interpreted as an indication of different size distributions; however, a systematic characterization of the cluster beams has not been made by taking into account the residence time of the clusters in the source.

Low-density films (1 g/cm^3), characterized by a granular structure on a scale of several tens of nanometers, show Raman spectra evolving from a graphitic character when large clusters (C_{900}) are used to an amorphous character as the cluster size distribution is reduced to a few tens of atoms per cluster [48].

Melinon and co-workers assumed, from Raman spectra taken with excitation at 532 nm, that films formed with small clusters have an sp^3 character due to the formation of a diamond-like phase by the assembling of cage-like C_{20} clusters. Unfortunately, the available experimental evidence does not support this hypothesis. Despite the uncertainty on the final film structures, these studies showed the existence of a "memory effect" that is the dependence of the final structure of the film on the mass distribution of the precursor clusters [48].

Raman characterization has been performed on nanostructured carbon films deposited with clusters of several hundreds atoms at low kinetic energy by a PMCS [31, 55, 56, 66]. The original graphitic structure of the clusters was essentially conserved after the landing on the surface, producing a porous graphite-like film.

Micro-Raman spectroscopy indicates that the films are formed at a submicrometric scale by two coexisting phases, one amorphous and the other one more graphitic. Figure 7 shows a typical micro-Raman spectrum of a cluster-assembled film. The spectrum can be described as a superposition of contributions coming from amorphous carbon (B) and disordered graphite (C). These two phases are uniformly distributed, and coexist over the whole sample.

The more ordered phase probably originates from the aggregation of large graphitic clusters prior to deposition. Macro-Raman spectra of macroscopic portions of the films show an increase of the graphitic character when the cluster growth conditions favor the formation of large particles. In these films, the graphitic microregions are more abundant.

By changing the PMCS operation parameters, different structures have been grown (Fig. 8). The two main Raman features at about 1550 and 1350 cm^{-1} can be, respectively, identified as the G-band peak of crystalline graphite and the D-band peak due to crystal disorder. It is evident that source parameters (in this case, the amount of He filling PMCS, increasing from A to C) change cluster size distribution and determine different film structures. Spectrum A is typical of amorphous sp^2 carbon, having a broad G structure shifted at 1540 cm^{-1} (G peak of crystalline graphite appears at 1581 cm^{-1}) and just a shoulder as a D structure. Spectrum C shows a well-defined D peak, and a narrow G peak
Figure 7. (A) Micro-Raman spectra of *ns*–C film. This is a superposition of a spectrum typical of amorphous carbon (B), and one typical of polycrystalline graphite (C) with defined *D* and *G* bands. Spectrum (C) was obtained by subtracting (B) from (A). Reprinted with permission from [103], C. Ducati et al., *J. Appl. Phys.* 92, 5482 (2002). © 2002, American Institute of Physics.

centered at 1581 cm^{-1}. This is consistent with a disordered graphitic structure. Different film structures are related to different relative abundances of small (few atoms) clusters and larger fullerene-like clusters.

Keeping constant the thermodynamic conditions in the cluster source, it has been demonstrated that a selection of clusters can be made in the beam by using aerodynamical gas effects [56]. It is possible to separate light clusters from the heavy ones by forcing gas flux lines to make sudden
Figure 8. Micro-Raman spectra of *ns*–C films showing the influence of the PMCS helium pressure during cluster formation. The He pressure increases from (A) to (C) from 8 to 16 torr, and this parameter controls the number of large graphitic nanoparticles present in the beam. Reprinted with permission from [103], C. Ducati et al., *J. Appl. Phys.* 92, 5482 (2002). © 2002, American Institute of Physics.

turns. The light particles will be able to follow the flux line trajectories, whereas the large ones will maintain their original trajectories. By varying the background pressure in the source chamber, a shock wave can be produced in front of the skimmer, causing mass separation effects and changing the final characteristics of the beam (Fig. 9). In particular, due to their different inertia, light species follow diverging streamlines after the shock front, while heavy species are not diverted and can follow straight trajectories through the skimmer. Due to this effect, large clusters are concentrated in the central portion of the beam, whereas the lighter ones are at the periphery. By placing substrates in different portions of the beam, films from different precursor clusters can be grown [56].

Figure 10 reports Raman spectra of films deposited with different portions of the beam. The top spectrum is taken on a region rich with small clusters deposited with the periphery of the beam. The shape and the shift of the peak (*G* band) are typical of amorphous *sp*^{2} carbon. The *D* peak is present as a broad shoulder on the left of the *G* band. Going from the top to the bottom spectrum in Figure 10, one can follow the evolution from an amorphous toward a disordered graphitic structure by shifting the mass distribution from small to large clusters (from the periphery to the center of the beam). This evolution is confirmed by hardening of the *G* peak, the appearance of a well-defined *D* band, and by the narrowing of the two lines. All of these parameters are in agreement with a graphitization of the sample [60].

Cluster separation can also be obtained by using an appropriate nozzle configuration (focusing nozzle) [49]. Films grown using a cluster mass distribution depleted by the large fullerene-like clusters are expected to show a very disordered structure; on the other hand, films grown with a cluster distribution rich in the fullerene-like component should be characterized by a disordered graphitic structure.

Raman spectra show that films deposited with large clusters are characterized by the presence of a high number of distorted *sp*^{2} bonds, whereas when depositing small clusters (few tens of atoms), *sp*^{3} and *sp* coordination is present. These results are in qualitative agreement with XPS measurements [67], although photoemission spectroscopy is
Figure 9. Varying the background pressure in the source chamber, a shock wave can be produced in front of the skimmer, causing mass separation effects and changing the final characteristics of the beam. sensitive to a scale smaller than that of Raman. For large clusters, optical spectra confirm the disordered sp^2 structure, and show the presence of a gap of 0.6 eV [55].

5.2. Brillouin Scattering

Although Raman spectroscopy is a powerful tool for studying the structure of carbon-based materials, the information is restricted to the scale of a few nanometers. The experimental characterization and theoretical modeling of cluster-assembled granular materials must address the problem of cluster coalescence and their organization in structures spanning length scales from the nanometer up to the micrometer. The different structures in which the precursor clusters are organized needs experimental probes sensitive to the different length scales typical of intracluster and intercluster interactions. In order to study the organization of clusters on a scale of hundreds of nanometers, which is the typical scale of thermally excited long-wavelength acoustic phonons, Brillouin light scattering can be used [52]. Films of graphite [68], polycrystalline diamond [69], diamond-like a–C:H [70], fullerite [71], and phototransformed C_{60} [72] have also been studied by Brillouin scattering. From Brillouin spectra, the elastic properties of the material can also be extracted with a higher accuracy compared to nanoindentation measurements, which require a complex analysis and a careful interpretation.

Bulk and surface Brillouin scattering signals have been obtained from cluster-assembled carbon films characterized by a complex structure from the atomic to the hundreds of

nanometers level, showing that this technique also can be used for nanostructured materials with irregular surfaces. The bulk and shear modulus of the material have been determined, giving information on the acoustic properties on a mesoscopic scale. This allows us to infer the nature of the bonding between the carbon aggregates.

Cluster-assembled films are characterized by a mesostructure with low density and high porosity, originated by the coalescence of the primeval clusters. Films produced with large clusters show a surface roughness higher than films produced with small clusters, with comparable thickness. Moreover, roughness evolves more rapidly with respect to thickness in films produced with large clusters. Films produced with small clusters show a more close-packed structure, as revealed by AFM measurements [73].

Thick films (thickness >0.5 μm) and thin films (thickness <0.3 μm) have been studied [51, 52]. In thick films, only damped bulk acoustic phonons have been observed, giving rise to coherent Brillouin scattering of laser light [74]. This indicates that thick films can be modeled as a continuum with translational invariance and effective elastic constants, although structural disorder at smaller scales scatters the phonons significantly. The presence of a rather strong central peak in the spectra has been tentatively ascribed to nonpropagating (overdamped) or to confined vibrational excitations within the films, probably coupled to the confined modes by a relaxation mechanism. In thin films, surface Brillouin spectra have been observed [51, 52].

For films thicker than 1 μm, no surface peaks related to the propagation of surface acoustic phonons could be observed (only a weak longitudinal bulk peak was detectable); in the latter, surface acoustic phonons (Rayleigh wave, RW) together with a longitudinal bulk phonon peak (LB) and a longitudinal resonance peak (LR), were observed. This is the evidence that, at the typical scale of the Brillouin probe (about 200 nm), the film structure changes dramatically as a function of the cluster size distribution: in large clusters, film structural disorder acts as a damping factor for the phonon propagation so that the film cannot be considered as an elastic continuum with well-defined elastic constants. On the other hand, in small-cluster films, the surface is well described by an elastic continuum model, and the elastic constants can be evaluated by direct analysis of the Brillouin spectra.

Other physical properties can be investigated by the analysis of the Brillouin spectra of thick films deposited with small clusters. The presence of both the longitudinal bulk wave and the surface resonance reveals a nonnegligible elastooptic effect. This occurrence permits us to estimate the real part of the refractive index at 514.5 nm ($n = 1.45$ in agreement with ellissometry measurements). A rough evaluation of the elastooptic constants and the imaginary part of the refractive index can be obtained with the calculation of the Brillouin scattering cross section.

5.3. X-Ray Diffraction

The density of films deposited by SCBD has been measured for focused and nonfocused film by means of X-ray reflectivity, showing a low density value (probably due to the high fraction of voids). No interference fringes have been

detected, due to the high surface roughness. The refractive index for X-rays in solids is smaller than unity, and total external reflection occurs at low angles of incidence [75]. From the critical angle, the density of the material can be obtained. If a thick layer is deposited on a substrate, and its density is lower than the density of the substrate (as in the case of cluster-assembled carbon on silicon), X-rays start to penetrate when the incidence angle θ_i becomes greater than the film critical angle (and the reflected intensity sharply falls due to absorption in the film), but they undergo total external reflection at the film–substrate interface. When the incidence angle θ_i becomes greater than the substrate critical angle, they penetrate into the substrate, and a second intensity fall is seen in the reflectivity curve at the substrate critical angle. From the first critical angle, the density of the film can be obtained [76]. The density in the case of films grown by large clusters has a value of 0.8–1.0 g/cm^3, while in the case of films grown using small clusters, the more compact nature of the films is confirmed by the higher density value of $\rho = 1.25 \pm 0.05$ g/cm^3.

5.4. Scanning Electron Microscopy

It is well known that the morphology of thin films shows, regardless of the material, universal characteristics [77]. These ubiquitous features, consisting of arrays of columnar and conical structures, are correlated with low adatom mobility. Since deposition is usually performed on substrates kept at temperatures considerably lower than the melting point of the deposited material, a regime where the impinging particles have a low mobility is common. The general occurrence of morphological similarities, not only between different materials, but also on different length scales, as the growth takes place, suggests that a nonspecific mechanism is responsible for the observed morphologies, and that the formation, growth, and dynamics of film surfaces can be described in terms of scaling relations and universality classes [57]. Different growth mechanisms have been proposed, such as random and ballistic deposition, the critical ingredient for all of the models being surface diffusion.

Cluster beam deposition allows one to investigate how the precursor particle dimensions affect thin-film morphologies and, more generally, whether there is any influence of the particle dimensions on the scaling parameters. Nanostructured carbon film growth mechanisms with cluster beam deposition have been studied experimentally for the very initial stages at submonolayer coverages [33, 78]. The evolution of film structure and film surface roughness is of particular interest for thick films since these parameters evolve with thickness in a way that is not yet clear. In Figure 11, the surface and a section of cluster-assembled carbon films are shown. In Figure 11(a), the surface of a thin film (roughness of approximately 1 μm) is fairly flat at this scale of magnification, whereas, at the same scale, a film 15 mm thick shows a disordered and highly corrugated structure [Fig. 11(b)]. The roughness evolution, characterized by scanning electron microscopy (SEM) and atomic force microscopy (AFM), indicates that the surface may be self-affine. The film section reported in Figure 11(c) shows conical and nodular features typical of a low-mobility deposition regime [57]. Cones and
Figure 11. SEM micrographs of a section of *ns*–carbon film. In (A), conical and nodular defects are visible. The magnification of a region near the film surface is also shown in (B), where the dendritic structure of a protruding nodular defect is apparent. Reprinted with permission from [5], P. Milani et al., in "Nanostructured Carbon for Advanced Applications." Kluwer, Dordrecht, 2001. © 2001, Kluwer Academic.

spherical nodules develop as the film grows. At higher magnification, the cones are composed of dendritic structures. As in the case of atom-assembled films [77, 79], the large number of these defects seems to indicate that the mobility of clusters is very low. The formation of nodular defects is also related to the presence of substrate imperfections or minute distortions in the growth pattern of atom-assembled films. In the case of cluster assembling, one should remember that, due to finite cluster mass distribution, relatively large clusters are somehow "diluted" among small particles. Large clusters can act as seeds for the formation of nodular defects, which evolve like isolated structures protruding from the average thin-film surface. Depending on the initial density of defects, there is a critical film thickness where the nodular structures start to merge. These defects have a profound influence on the evolution of the surface morphology [31, 53].

5.5. Transmission Electron Microscopy

Figure 12 shows a low magnification TEM image of a film deposited using the AJCA technique [5, 24, 80]. The electron beam has been strongly underfocused in order to obtain stronger contrast. Under such conditions, the diffracting species appear darker than the background. Two kinds of diffracting features can be seen in this image. The two very
Figure 12. Low magnification TEM image of a film deposited using the AJCA technique with an N$_2$ jet creating a pressure of 0.8×10^{-3} mbar. Reprinted with permission from [5], G. A. J. Amaratunga et al., in "Nanostructured Carbon for Advanced Applications." Kluwer, Dordrecht, 2001. © 2001, Kluwer Academic.

large diffracting areas (labeled *A* and *B*) are micron-scale macroparticles containing long graphitic layers reminiscent of turbostratic carbon. Secondly, there are numerous small diffracting areas dispersed almost uniformly throughout the film, their size varying between 10 and ~20 nm. Observation at higher magnification under phase contrast imaging conditions (such as in Fig. 13) revealed that most of the latter areas are agglomerates of fullerene-like nanoparticles. Sets of concentric graphene sheets with an interlayer spacing of 3.4 Å are clearly seen in Figure 13. The pattern formed resembles closely packed multiwalled carbon nanotubes imaged along their axes (i.e., aligned along the direction of film growth). Alternatively, the particles seen in Figure 12 could also be more spherical bucky "onion"-type entities. Some of them are distorted with several graphene planes buckling away (at least in projection) toward other nanoparticles. It is proposed that the observed nanoparticle agglomerates are included in the condensing flux [24], rather than formed on the film.

When the same film was examined after it had been etched for 10 min, the surface density of large macroparticles such as *A* and *B* shown in Figure 12 decreased dramatically, and pinholes became apparent in the film surface. Figure 14 shows a plan-view HREM image from an area thinned by the chemical etching. In the majority of cases, we could image fullerene-like fringe structures in the vicinity of the pinhole. The removal of the large graphitic particles suggests that they were not strongly bonded to the film, but simply lying on the film surface. Also, the preferential thinning of some areas, and particularly the existence of nanoparticles at the edge of the pinholes, suggests that the amorphous material surrounding the embedded nanoparticles was preferentially removed by chemical etching.

Figure 12 shows that the featureless matrix takes up most of the film volume. In the interest of electron transport, it is important to examine the microstructure and carbon bonding in it. Figure 15 shows an HREM image of a thin part of the matrix. Figure 15(a) is the image taken directly from the film, while image (b) has resulted from (a) after image processing to remove any contributions to the image from scattered electrons. Although the matrix looks featureless in low magnification, the HREM images of Figure 15 reveal

Figure 14. Plan-view HREM image showing a characteristic pinhole in the film surface observed after 10 minutes of chemical etching. Graphene sheets can be clearly seen on one side of the hole. that the film matrix consists of a mixture of amorphous carbon nitride and features that look similar to fullerene fragments. Since the arcing conditions are shown to definitely result in the formation of cage-like carbon nanoparticles, it can be suggested that these fragments are the seeds needed for nanoparticles to start forming in a carbon arc in the presence of a high gas pressure.

TEM analysis of carbon foam produced by pulsed laser deposition revealed that the foam has a fractal-like structure consisting of particles with average dimaters of 6 nm randomly interconnected into a web-like foam [25, 26].

TEM analysis of naostructured films produced by SCBD has shown that films grown without any selection of the cluster mass distribution contain ordered structures of various sizes, such as nanotubes and onions, embedded into an amorphous matrix, as shown in Figure 16(a). The amorphous matrix in which the nanoparticles are embedded is formed by the coalescence of highly metastable small clusters present with different isomers in the beam [18]. The structure of *ns–C* films obtained with the filtering nozzle does not show the presence of ordered particles, and it is characterized by an amorphous structure where only a few ordered graphene layers are distinguishable [Fig. 16(b)].

A transmission electron microscope analysis of the cluster-assembled films shows that, at this scale, the morphology is reminiscent of the precursor clusters. TEM

micrographs show the presence of an amorphous matrix with small closed shell particles and bundles of graphene sheets [Fig. 16(a)]. The presence of larger onion-like and tubular particles has also been observed.

5.6. Atomic Force Microscopy

Roughness, scale invariance, and spatial correlation of the film surface depend on the cluster precursor size and film thickness. Surface roughness, defined as the standard deviation of surface height (the width of the surfaces), is a function of the growth process. The evolution of the roughness during deposition and the extension of spatial correlation on the surface plane are peculiar to a growth mechanism, and largely independent of the specific physical system [57]. This makes the roughness a useful parameter to describe film morphology, and to obtain a deeper understanding of the aggregation mechanisms of clusters leading to the film formation.

Figure 17 shows typical surface morphologies of cluster-assembled carbon films measured by the atomic force microscope. The observed grains are larger than single clusters in the beam, and they result from an aggregation mechanism. The grain size depends on the precursor size: typical dimensions are shown in Figure 18(A), where the whole size distribution for films grown by small and large clusters is reported. The difference in grain size distribution suggests
Figure 17. Tapping mode AFM topographies at different magnifications of a cluster-assembled carbon film. Typical granular morphology characterized by grain diameter of 10–20 nm can be observed. (A) Scan size 1000 nm × 1000 nm. (B) Scan size 100 nm × 100 nm.
that large precursors aggregate in larger basic units. The grain size distribution seems to be independent of film thickness for a given cluster mass distribution. This fact further corroborates the assumption that grains are the basic units of nanostructured carbon film morphology in the dimension range observed by AFM.

On a micrometric scale, the morphology at a given thickness is the result of the coalescence of the primeval grains into larger units. This observation directly suggests the existence of a statistically scale-invariant morphology repeating itself across a limited number of decades. The scaling range depends on the deposition duration, and hence on the film thickness.

The cluster size strongly affects the velocity of film roughening. This can be seen in Figure 18(B), where the relative weight of roughness (RWR), defined as the ratio of twice the roughness on the film thickness, for films assembled with small and large clusters of different thicknesses, is shown. Extrapolating the two sets of data in the range 100–1000 nm, it can be noticed that the RWR of films grown with large clusters is systematically larger over the whole range of thickness. Films grown with large clusters are generally rougher than films grown with small clusters with the same thickness.

Among a rather smooth distribution of grain dimensions, AFM pictures show the presence of larger isolated features randomly distributed over the film surface. These random nodular defects are protruding from the film surface, in analogy to what is observed for atom-assembled films; their density increases with film thickness until they start to coalesce. The film thickness where coalescence takes place depends on the precursor size. The density of these nodules appears to be higher in the films grown from large clusters.

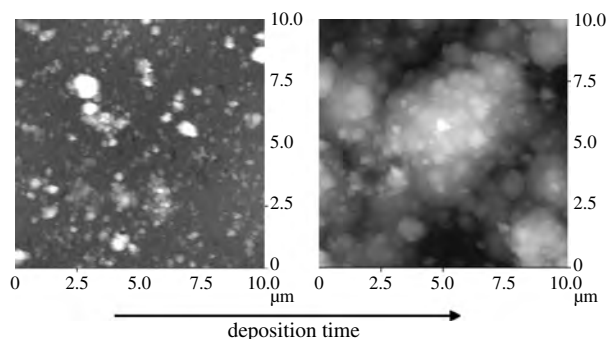
The presence of nodular defects plays an important role in the development of a rough scale-invariant morphology, where the larger units can no longer be distinguished as isolated. This happens over typical critical thicknesses around 200 and 2000 nm for samples assembled by small and large clusters, respectively. Figure 19 qualitatively shows the roughening process leading to scale-invariant morphology. This process is qualitatively similar for films grown with clusters of different sizes. Small grains and nodular defects coexist at low coverage (Fig. 19, left). At high coverage (Fig. 19, right), a cauliflower-like scale-invariant morphology develops. The tuning of the precursor mass distribution


Figure 19. Tapping mode AFM pictures showing the roughening process during the growth of nanostructured carbon. A fine raster of grains and isolated nodular defects coexist at low coverage (left), while a cauliflower-like scale-invariant surface develops at high coverage (right). The behavior is similar for films grown with clusters of different sizes, although the thicknesses at which roughening occurs are different.

allows controlling the relative weight of roughness in the film, together with the film granularity [73].

In a simple picture of growth, basic morphological units (the grains) aggregate in larger and larger superunits, leading to a scale-invariant morphology. Such a morphology is self-affine, rather than self-similar because of its anisotropy due to the existence of a preferred direction, the direction of growth [57]. Scale invariance extends up to three decades in our thick films. Typical correlation lengths for films assembled by small clusters range from 50 nm to 4 μm. The lowest value refers to film where the density of nodular defects is low and their coalescence has not taken place. Apart from isolated nodules, large structures are not present, and consequently, the correlation length closely reflects the size of the basic morphological units. As long as the morphology develops and larger and larger features appear, the correlation length increases. A similar behavior is seen for films assembled by large clusters, and it is observed at considerably lower thickness.

5.7. Scanning Tunnel Microscopy

The first stages of growth of films assembled by carbon cluster deposition have been investigated by scanning tunnel microscopy (STM) in ultrahigh-vacuum conditions ($P < 8 \times 10^{-10}$ torr) [78]. Carbon clusters have been deposited at room temperature on a stepped Ag (110) surface in a regime of submonolayer coverage to study the consequent formation of islands. Figure 20 shows an STM image of carbon particles on the terraces of the silver substrate. A preferential location of the islands at the step edges is found. From this observation and from the analysis of the size distribution of the islands, it has been concluded that the clusters can diffuse on the metallic surface. A simulation of the cluster aggregation mechanism highlights that a mere two-dimensional case is incompatible with the experimental data [78]. We observe a correlation between the averaged apparent height of the islands and the corresponding mean diameter well matched with a preferential three-dimensional growth of the islands together with a small contribution of the two-dimensional aggregation mechanism.
Figure 20. STM images of cluster aggregates on stepped Ag(1 1 0) surface ($T_{dep} = 300$ K, $t_{dep} = 20$ s) for several scanning area: (a) 300×300 nm^2, (b) 150×150 nm^2, (c) 210×210 nm^2, and (d) 50×50 nm^2. Siviero et al., *Surf. Sci.* 513, 381 (2002). © 2002, Elsevier Science.

A transition from two different growth modes occurs, and the final appearance of the film can be strongly affected by the first stages of growth. As reported in Section 5.6, AFM analysis of nanostructured films (from about 100 nm up to a few microns) shows that their morphology evolves toward a self-affine structure with increasing surface roughness. This suggests the possibility of changing the growth dynamics of a thick film acting on the parameters that determine the first stages of nanostructured carbon growth.

5.8. Electronic Spectroscopy

X-ray photoemission spectroscopy (XPS) and electron-energy-loss spectroscopy (EELS) can provide information on how the nanostructure influences the electronic properties of cluster-assembled carbon [67].

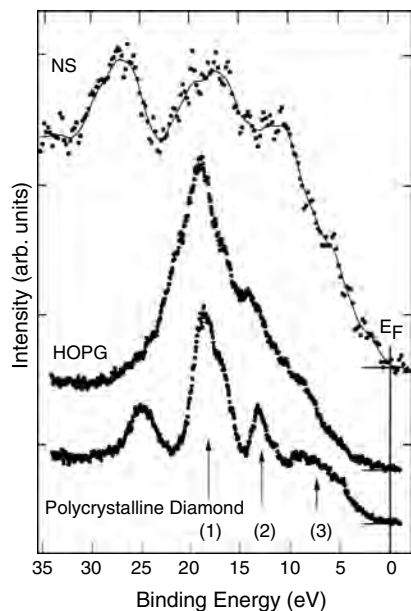
The XPS valence-band (VB) spectra of polycrystalline diamond, of the HOPG sample, and of the nanostructured sample are shown in Figure 21. Despite the structural inhomogeneities of the film, no significant changes have been observed in the VB spectra for materials deposited with small or large clusters. In Figure 21, each spectrum shows a broad and intense peak (1) at about 20 eV, a second peak (2) between 10 and 15 eV, and a third not well-defined shoulder (3) between 10 eV and the top of the valence band. The first peak is ascribed to structures of primarily C 2s character, the second peak has a mixed sp origin, while the structure (3) can be related to 2p_σ and 2p_π orbitals [81]. The NS sample spectrum also shows a structure at 26 eV, which is assigned to O 2s due to contamination. On the other hand,


Figure 21. Valence band XPS spectra of HOPG, polycrystalline diamond, and the nanostructured carbon sample. The solid line is obtained after smoothing, and it is shown as an eye guide. the O $2p$ structure is significantly attenuated with respect to the O $2s$ feature due to its smaller cross section [82].

Electron-energy-loss spectra of nanostructured films produced with large and small clusters and a HOPG sample are shown in Figure 22 after subtracting the contributions from double scattering and the background. It is worth
Figure 22. Electron-energy-loss spectra of nanostructured films produced with large and small clusters and an HOPG sample. RLC: rich in large clusters region; RSC: rich in small clusters region. The $\sigma + \pi$ peak is resolved into Gaussian components. Reprinted with permission from [67], E. Riedo et al., *Solid State Commun.* 116, 287 (2000). © 2000, Elsevier Science.

observing that, differently from the XPS analysis and similarly to Raman characterization, EELS reveals some important differences between small clusters and large clusters. The spectrum of HOPG shows loss features at 6.6 and 27.6 eV, representing the collective excitations of two groups of valence electrons present in the sp^2 bonded system. The former is a π plasmon due to the π electrons alone, and the latter is the plasmon due to all of the valence electrons [83]. The loss spectra of the RLC and RSC regions display two loss features attributed to the π and $\sigma + \pi$ plasmons. The $\sigma + \pi$ plasmon appears at 23.4 and 21.7 eV for the RLC and RSC regions, respectively. This is, in both cases, at a reduced energy as compared to HOPG. This can be due to the lower atomic density of cluster-assembled carbon with respect to graphite.

These data indicate that XPS is not sensitive to different structures originating from different cluster precursors at variance with Raman and EELS, which show spectral signatures of the predominant precursor clusters. In cluster-assembled systems, a mixture of various chemical environments local to the carbon site is always present. The density of states, as probed by XPS, is thus expected to average over a variety of spectral contributions representative of these carbon site inhomogeneities. Even though different weights of these specific components are expected to vary depending on the precursor mass distribution, it is likely that the overall DOS is not significantly affected. In contrast, EELS is much more specific in its spectral response since it sees primarily how many "delocalized electrons" are present in different systems with respect to the valence-band electron bound into more localized configurations, as might be the case for fivefold or sevenfold rings.

In-situ electron spectroscopy investigation of carbon clusters produced via SCBD and deposited on Ag(100) and Si(100)–(2 × 1) surfaces has been reported [84]. This avoids oxygen or moisture contaminations. Already at very low coverages, the cluster-assembled material shows an electronic structure dominated by features typical of amorphous sp^2 carbon. No significant changes of the electronic structure have been observed up to the formation of a thick film. The resulting nanostructured carbon is characterized by a semimetallic behavior. Postdeposition thermal annealing of nanostructured carbon deposited on Si(100)–(2 × 1) brings about the formation of an SiC film (Fig. 23). The conversion to SiC initiates at temperatures lower than usually seen when the precursors are fullerene molecules.

The coordination of carbon atoms in a nanostructured film can be obtained by near-edge X-ray absorption fine structure spectroscopy (NEXAFS). X-ray absorption at the carbon K edge depends principally on the atomic number Z, and consequently, the cross section is independent of the carbon atom coordination. The $1s \rightarrow \pi^*$ and $1s \rightarrow \sigma^*$ resonances in sp^2 carbon and $1s \rightarrow \sigma^*$ resonance in sp^3 carbon present a distinguishable difference in energy, and a simple identification of each contribution can be made. Thus, a quantitative determination of the amount of sp^2 can be performed [66].

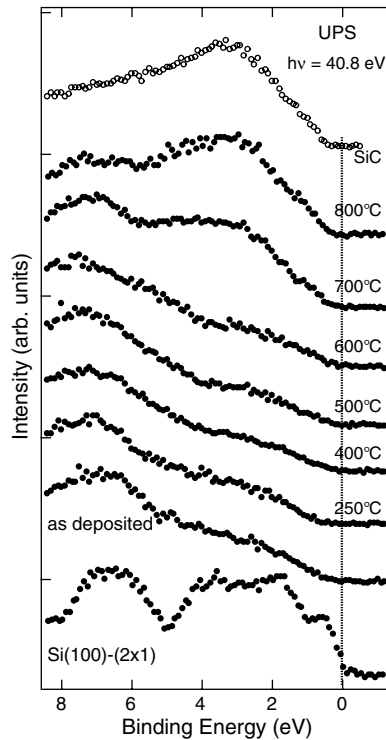
The NEXAFS C K-edge spectra of as-deposited nanostructured (SCBD) and amorphous (a–C) films are shown in Figure 24. For comparison, the spectra of graphite and diamond are also reported.


Figure 23. UPS spectra of a thin film (≈ 1 nm) deposited on Si(100)–(2×1) at different annealing steps. The typical features of an SiC layer appear above 700 °C. Figure 24. NEXAFS C *K*-edge spectra of as-deposited nanostructured and amorphous carbon films. The samples of the two pairs [S#3(CBD)–S#4(CBD) and S#1(*a*–C)–S#2(*a*–C)] differs with respect to the growth conditions (see text). The anodic deposit grown in the cluster source is indicated as "Anode." It has been used as a 100% sp^2 reference sample for the evaluation of the sp^2 content of the carbon films. For comparison, the spectra of graphite and diamond powder are also shown. Reprinted with permission from [66], C. Lenardi et al., *J. Appl. Phys.* 85, 7159 (1999). © 1999, American Institute of Physics.

The shape of the graphite spectrum is similar to that of graphite spectra reported in the literature [85]. The diamond spectrum shows the characteristic feature at 302.7 eV related to the second absolute gap [86]. Nevertheless, the sharp core exciton peak [87] at about 0.2 eV below the onset of $1s \rightarrow \sigma^*$ transitions (~ 288.5 eV) cannot be resolved. In Figure 24, the spectra of *a*–C and SCBD samples show a preedge resonance at about 285.3 eV due to transitions from the C $1s$ level to unoccupied π^* states of sp^2 (C=C) sites, with eventually, also, the contribution of sp (C≡C) sites if present. This peak is also present in the diamond spectrum, and originates from a graphitic phase contained in the material already detected by X-ray diffraction measurements. Another relevant peak arises at 288.8 eV, more evident in the amorphous carbon films and reduced after etching in the SCBD samples. The as-deposited SCBD samples also show a prominent resonance at 286.8 eV partially reduced after etching and implantation. The amorphous nature of the films induces a spread of the σ^* resonances, and no recognizable structures can be identified. Thus, the broad band between 290 and 310 eV is the result of overlapping C $1s \rightarrow \sigma^*$ transitions at sp, sp^2, and sp^3 sites.

The position of the peaks in the preedge region can be determined by means of the second-order derivative of the spectrum, as described in [86]. Four principal minima appear, and the corresponding energies can be used as the initial inputs of the peak positions in the fit procedure. The preedge resonances can be fitted with symmetrical Gaussian

curves. The width of these peaks is dominated by the disordered nature of the deposit. The edge jump at the ionization potential is represented by an erf function multiplied by an exponential decay. Since various shifts of the C $1s$ due to different chemical states are present, the use of only one step edge could be regarded as too rough an approximation. For this reason, it may be useful to consider the step width as a free parameter in the fit in order to include many different ionization potentials within a single broad step. For the best fit, a step width of about 0.9 eV is obtained. The σ^* resonance region has been fitted with two Gaussian curves having an exponential tail at higher energies, and dropping down in a similar fashion to the step function at the absorption edge. The first peak (at 285.3 eV) is due to π^* antibonding orbitals principally originating from C=C bonds. The amount of this bond type can be partially overestimated in the case of CBD films since, in these layers, a certain proportion of C≡C bonds seems to be present (usually disregarded in amorphous films), and may therefore contribute to the area of $1s \rightarrow \pi^*$ resonance of the C=C bond. The averaged full width at half maximum (FWHM) of the peak at 285.3 eV for the as-deposited *a*–C films is 1.9 eV, and for the as-deposited CBD films is 1.7 eV. After the *N* implantation and/or sputtering, the value is 1.9 eV. For the graphite, the FWHM is evaluated to be 1.1 eV, and for the anode, 1.3 eV. The width of the $1s \rightarrow \pi^*$ resonance of the C=C bond is

thus considered as an index of disorder on a local scale. This effect is correlated with the presence of different distorted sp^2 sites and defects. Furthermore, the peak position lies at lower energy (a shift of 0.4 eV) with respect to the graphite and the anode for both types of prepared samples. From NEXAFS peak analysis, an sp^2 of 63% can be evaluated.

6. PROPERTIES AND APPLICATIONS

6.1. Electrical Transport

Conductivity in disordered carbon materials has been ascribed to the segregation of sp^2 phases with conjugation of π bonds that in a mixed sp^2/sp^3 system can cause the appearance of complex transport phenomena [61, 88]. Carbon materials with resistivities rather uniformly distributed in the whole range from graphite to diamond have been observed [89]. The development of an industrially scalable carbon film deposition technique providing a continuous tuning of the conductivity, over even a part of this range, would be a valuable tool for the production of electronic devices. The study of electrical conduction in nanostructured carbon-based materials is thus of great interest, both for developing new applications and for fundamental studies.

The electrical conductivity of cluster-assembled films is quite sensitive to the properties of the deposited clusters: the resistivity may change by up to three orders of magnitude by changing the cluster dimensions, and even more by introducing metallic impurities in the beam [90]. This feature suggests the possibility of producing materials with tailored electrical properties.

Moreover, due to the high porosity, the conductivity of ns–C films is strongly sensitive to the gaseous environment: this property should make this nanostructured material suitable for the production of gas sensors.

The I–V characteristic of nanostructured carbon films deposited by SCBD indicates a strict ohmic behavior all over the measured electric field range. Conductivity values ranging from 7×10^{-6} to 4×10^{-4} $(\Omega \cdot m)^{-1}$ have been measured in-$situ$. Different behaviors have been observed, depending on the substrate roughness and precursor clusters used for deposition. In particular, films grown with small clusters exhibit a lower conductivity. Exposure to air causes a decrease of the conductivity whose evolution has been followed up to six months after deposition. The difference between films assembled with large and small clusters significantly reduces after air exposure. Current–temperature characteristics measured in-$situ$ at various temperatures indicate a thermally activated conductivity with energy of 0.3 eV. The different conductivity regimes and their dependence on film thickness suggest that this cluster-assembled material has transport properties significantly different from atom-assembled thin films [91, 92].

The electrical conduction properties of ns–C films have been studied under different thermal and environmental conditions, showing a clear ohmic behavior when I–V characteristics were recorded at any experimental condition. The conductivity appears to be influenced by the gaseous environment, and in particular, it is strongly reduced after the first exposure of the sample to ambient air. This evidences that electrical characterization on porous carbon systems should be carried out under accurately controlled environments. Furthermore, very slow kinetics of adsorption–desorption processes have been observed, sometimes on the scale of several days.

6.2. Field Emission

Electron field emission (FE) of carbon-based materials has been widely investigated in view of the production of stable and inexpensive cold flat cathodes [93]. Interesting emission properties in terms of low turn-on fields and high emission currents are typical of various systems such as a–C:H, a–C:N, and diamond-like films [94–96]. However, these materials show severe limitations in terms of site emission density.

FE properties are determined by the coexistence of sp^2 and sp^3 bonding to form "chemical inhomogeneities" [97] and, more generally, by the presence of a structure at the nanoscale. Systems based on carbon nanotubes, nanocrystalline diamonds, and carbon clusters have been proposed as a promising alternative to more conventional materials in terms of extraction fields, current densities, and site emission densities [98–101].

The presence of sp^2 clusters and their organization play a very important role in determining the FE performances; it is then important to control the size, structure, density, and mutual interaction of these clusters in order to understand the basic mechanisms underlying the observed phenomena, and to produce materials with tailored properties [102].

Figure 25 shows representative current density J versus electric field E curves obtained during field-emission measurements. The sample was first measured as grown, and was remeasured after chemical etching in an HF:NH$_4$F solution for 10 min. By defining the threshold field Eth as that required to get a field emission current density of 10^{-9} A/cm^2, Eth was 3.8 V/μm for the as-grown film, decreasing to 2.6 V/μm after chemical etching.

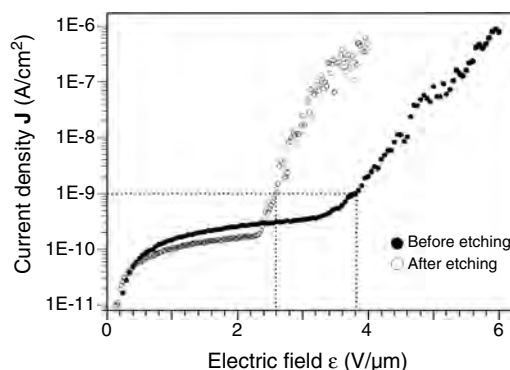
Carbon thin films were deposited using a modified carbon arc method, where a jet of nitrogen gas was used to create a high-pressure region in the vicinity of the electric


Figure 25. Current density (J) versus applied electric field (E) for the AJCA material before and after etching. In this case, the material has been deposited at room temperature, using an arc current of 140 A with a nitrogen jet creating a background pressure of 1×10^{-3} mbar. arc. HREM analysis demonstrated that the material includes clusters of fullerene-like nanoparticles. Field-emission measurements revealed that the resultant material has a relatively low threshold field and a high field-emission current. Correlating the HREM and field-emission results suggests that the good field-emission properties are related to the protrusion of clusters of nanoparticles, which are topographically and electronically suitable to cause a concentration of the external electric field over their tips. This is further supported by the fact that the field-emission characteristics of the nanocomposite films examined were broadly similar to those achieved with nanotube suspension films. Chemical etching of the material deposited by the AJCA method resulted in a further improvement of the field-emission characteristics. It is proposed that the removal of the amorphous material from the vicinity of the carbon nanoparticles during chemical etching results in an increase in the number of emission sites that are close to the dielectric matrix–vacuum interface, while the change of the dielectric medium around the tips of the nanoparticles that are exposed to vacuum leads to an increase of the local value of the electric field applied over the exposed tip. This consequently leads to easier emission of electrons from the protruding nanoparticles [5].

The field-emission properties of cluster-assembled carbon films deposited by SCBD have been investigated [101, 103]. A typical example of the emission stages for a cluster-assembled film is shown in Figure 26. Initially, the current is constant, or weakly increasing with the applied field. Above a certain value of the field, about 15 V/μm in this case, an irreversible process occurs, and the dependence becomes stronger, leading to a large hysteresis between the upward and downward voltage ramps. The next cycles follow the new track with little hysteresis, and give stable emission characteristics. This process is often called conditioning [104]. In the cycles after conditioning, the emitted current increases exponentially up to 10^{-6} A, and then saturates to about $5 \cdot 10^{-4}$ A. High-resolution SEM confirmed that no morphological damage, that is, crater formation, on the nano- and mesoscale occurred upon conditioning.

The cluster-assembled films show an emission behavior, characterized by an initial turn-on field above 10 V/μm,
Figure 26. *I–F* characteristics of a cluster-assembled carbon film. The relevant steps of the conditioning process are shown (the cycles are named after the max voltage applied during the ramp). The turn-on field is 12.5 V/mm in the first cycles, and decreases to 4 V/mm after high field conditioning. Reprinted with permission from [103], C. Ducati et al., *J. Appl. Phys.* 92, 5482 (2002). © 2002, American Institute of Physics.

decreasing to 2–5 V/μm at the end of the conditioning process. The average threshold field, that is, the field that corresponds to an emission current density J of 1 μA/cm^2, ranges between 9.4 and 16 V/μm for the samples deposited at room temperature, and between 6 and 10 V/μm for the samples heated during the deposition. For the latter case, threshold fields as low as 4 V/μm were measured at the end of the conditioning process. The emission site density (ESD) measured in a parallel-plate configuration is on the order 10^2 cm^{-2} after a long conditioning process.

Films deposited with small clusters (that means with no large graphitic particles) showed a poor emission performance: a high turn-on and threshold field, a low saturation current (one–two orders of magnitude lower) and an ESD of 1 cm^{-2}. Since the filtering nozzle eliminates the high-mass component from the cluster beam, it leads to a low number of graphitic inclusions in the film, and hence to a more resistive, amorphous material that is hard to condition.

A strong correlation exists between substrate heating and the effectiveness of the conditioning process, leading to a larger variation of the field-emission parameters for the samples annealed during or after deposition. A similar trend was observed for the ESD: thicker samples heated during deposition showed a larger increase in the number of emitting spots. Upon annealing, unsaturated or defective metastable clusters undergo bonding rearrangements and aggregation. This could cause the clusters to sinter together and to eliminate defects (dangling bonds, nonsix-member rings), decreasing their series resistance. The higher connectivity of the heated samples seems to make their conditioning process softer and more effective, with the final turn-on field shifting to 2 V/μm (compared to 5 V/μm of the unheated samples).

An interpretation of the results might follow the model proposed by Ilie et al. [102] for sp^2 bonded clusters in an amorphous matrix. Cluster-assembled films can be modeled as a nanostructured matrix containing graphitic nanoparticles in analogy with the systems described by Alexandrou et al. [24]. The density, size, and spatial distribution of these particles affect the field-emission properties. Tubes, onions, and, in general, large graphitic clusters can be linked together to form an sp^2 correlated conductive channel perpendicular to the surface plane. The field lines focus onto the gap states of the sp^2 channel, creating a negative space charge in the film. The large local field lowers the surface barrier, giving rise to preferential emission from the channel tip.

Heating during deposition seems to favor intercluster linking and rearrangement of metastable species toward more ordered conductive structures. This sintering increases the size of the emission channels, either in length or in gap state density, relative to those of the unheated samples. The difference between the two growth conditions is evident at the first stages of emission, where the field enhancement for the heated samples is nearly twice as large as for the unheated ones (i.e., double channel "length" for the same film thickness). In the intermediate regime, the applied field might induce an extension in the sp^2 channels in the unheated samples to a size comparable to that of the heated ones, so that they exhibit the same field enhancement. The final stage of the measurement not only opens new emission

channels, but also completely develops the sp^2 channels of the heated samples, whereas the unheated ones do not show any further development either in the slope/channel length or in the intercept/emission area. The material deposited with the filtering nozzle, lacking ordered sp^2-bonded regions on the mesoscopic scale, proved to be highly resistive and unsuitable for field-emission applications [103].

6.3. Mechanical and Tribological Properties

The hardness of carbon films containing fullerene and onion-like nanoparticles has been measured by nanoindentation using a 5 nN load. The elastic recovery was obtained by load-displacement curves [22]. The hardness and elasticity values were found to be 42 ± 4 Gpa and 60%, respectively, while the same parameters for conventional carbon films obtained by arc deposition were found to be 27 ± 3 Gpa and 40%. This suggests that the incorporation of fullerenes and nanotubes in the amorphous matrix improves the mechanical properties of the system.

From Brillouin scattering data, the mesoscopic elastic properties of SCBD carbon films have been obtained [51, 52]. The shear modulus and the bulk modulus turned out to be, respectively, $\mu = 4.0$ GPa and $B = 3.67$ GPa, corresponding to a very low Poisson's ratio ν. The numerical value of μ is in the range of the C_{44} elastic constant of hexagonal crystalline graphite, and equals the value of its shear modulus along the c axis, as reported in [105–107]. This last result can be compared with Raman measurements discussed above, which point out the mainly sp^2 carbon bonding present in the disordered granular structure of the films on a nanometer scale. Yet the cluster-assembled carbon is not elastically identical to nanocrystalline graphite: in fact, the values of B (and, consequently, of the Poisson's ratio) are significantly different [106, 107].

Elastic properties of films grown with small clusters can be evaluated from the propagation velocities of the observed modes in the thick film spectrum. Knowing the longitudinal velocity v_L and using $v_L = \sqrt{C_{11}/\rho}$ (with the previously discussed density value $\rho = 1.25 \pm 0.05$ g/cm^3), we found 5.4 ± 0.4 GPa for the C_{11} elastic constant. The value 2.5 ± 0.2 GPa for the shear modulus $\mu = C_{44}$ was determined using the relation $v_T = \sqrt{C_{44}/\rho}$. Since for a semi-infinite medium the transverse bulk wave velocity v_T depends only on v_L and on the Rayleigh wave velocity v_R, we found v_T solving numerically the corresponding equation. Knowing C_{11} and C_{44} allows completely characterizing the elastic properties of an isotropic material and other elastic constants such as the bulk modulus B, Poisson ratio ν, and Young modulus E. We found $E = 5.3$ GPa, $B = 2.1$ GPa, and $\nu = 0.07$. The comparison with diamond elastic constants $E = 1141$ GPa, $B = 442$ GPa, and $\nu = 0.07$ indicates a very soft and highly deformable material [76].

Cluster-assembled carbon films have also shown the capability of accommodating mechanical stresses. This provides the opportunity to grow films with a thickness of several microns without delamination [18, 29, 53].

The understanding and control of friction, adhesion, lubrication, and wear in nanostructured systems are essential requisites to validate the use of nanomaterials for highly demanding structural applications [107, 108]. The rapidly growing number of applications based on micro-electromechanical systems (MEMS) and the new perspectives opened by the production of nanoelectromechanical systems (NEMS) make necessary the development of an entirely novel class of protective and lubricant coatings with improved mechanical properties at the nanoscale [109]. Diamond and the various types of amorphous carbon show interesting tribological properties such as high elastic moduli, good lubrication properties, low stiction surfaces, and so on [110]. These properties are controlled by a combination of physicochemical properties of the surfaces such as sp^2/sp^3 ratio, surface roughness and porosity, and by the presence of contaminant layers [111]. Because of the peculiar control of these parameters, which is allowed by the SCBD technique, the tribological properties of SCBD nanostructured carbon are worth being investigated.

Friction force microscopy [112, 113] is the state-of-the-art technique for the quantitative characterization of important friction parameters, such as the friction coefficient, and other tribological parameters, such as adhesion and wear at the submicrometer scale. At these scales, moreover, the mechanical behavior is influenced by several parameters that must be taken into account in order to extract quantitative and reproducible results. Among them, the morphological parameters, such as roughness, granularity, and power spectrum of the surface, play an important role [114–116]. Because of its ability to simultaneously acquire topographic and friction maps, AFM turns out to be a privileged candidate to perform quantitative nano- and microtribological characterization of materials having a corrugated surface. The case of nanostructured materials is somehow peculiar since the typical size of the AFM probe is close to or even comparable to cluster size. In this case, peculiar tip–sample interactions and topographic effects should be expected. Eventually, it must be considered that the sub-micron tribological properties measured with an FFM–AFM apparatus are not directly comparable to the macroscopic ones. However, a study at the submicron scale may help identify the effects of physicochemical and environmental parameters on the tribological performances at larger scales.

The tribological properties of nanostructured carbon films grown by SCBD have been characterized [117]. Films grown with large and small clusters in dry and humid nitrogen environments have been investigated. It has been found that the friction behavior of nanostructured carbon at the nanoscale is well described by a modified Amonton's law (linear dependence on *total* load plus offset), typical of a multi-asperity friction regime, demonstrating that a nanometer-sized contact such as the one realized in FFM experiments does not necessarily lead to a single-asperity friction regime. The value of the friction coefficient measured in FFM experiments was about 0.081–0.086 ± 0.01. Friction coefficients measured on carbon-based materials span from 0.009 (for HOPG in air) to 1 for DLC in UHV [118]. Molecular dynamics simulations of FFM experiments on the same samples (simulated themselves with MD [18]) support this interpretation, and show a qualitative agreement with the experiments. Simulations show a linear trend of the friction versus load curve with a finite offset, different from zero in the limit of the experimental error. The quantitative discrepancy between theoretical and experimental results is not

surprising, and it can be attributed to the parameterization of the interaction potentials and in the choice of using carbon tips in the simulations of the FFM experiments.

As confirmed also by MD simulations, in the limit of the experimental error, the nanostructure of the films seems to have very weak or no influence on the friction coefficient. In analogy to the macroscale, one could expect that films grown with large clusters, and hence containing a larger number of well-organized graphitic regions, should show a lower friction coefficient [118]. This is not observed. The friction coefficient is also found to be independent of relative humidity. Null or weak dependence of friction coefficient and adhesion on the relative humidity was reported in literature for carbon-based materials [119–121]. One possible explanation for the behavior of our films in a dry environment is the hydrophilic nature of cluster-assembled carbon [122]. The low density and large porosity of these systems in conjunction with a nonnegligible wettability may favor the formation of a water layer lasting even in dry nitrogen, with the formation of a water meniscus between the tip and the surface.

Buzio and co-workers also reported on the friction characterization on cluster-assembled carbon films produced by SCBD [123, 124]. A nonlinear dependence of friction on load, well fitted by the Hertzian-plus-offset model, using a silicon tip with a radius of 30 nm and a scan length of 50 nm, has been found. On the other hand, a linear dependence of friction on load is found by scanning on an area of 1 μm square, with a friction coefficient of about 0.13–0.20. The nonlinear dependence has been attributed to a possible passivation of the sample surface, and to the presence of a water layer, which would induce a transition from a multiasperity to a single-asperity contact (i.e., from a linear to a power-law dependence), as explained in the framework of the composite-tip model [125]. For a larger scan length and relatively larger scan velocity, the tip–sample interface is broken and reformed rapidly, and the smoothing action of water and impurities is less effective. This hypothesis is confirmed by the results of Podestà et al. [117], apart from differences observed in the numerical values of the friction coefficients.

Summarizing, FFM experiments on nanostructured carbon films grown by SCBD show that a modified Amonton's law, typical of a multiasperity contact, can describe the friction behavior at the submicron scale. The presence of water and the high reactivity of sp^2–sp^3 material play an important role in determining a multiasperity-like contact also at these very small scales. Molecular dynamics simulations support this interpretation, and show a qualitative agreement with the experiments. On smaller scales, the passivation of the surface by contaminants and water can lead to a single-asperity friction regime. The friction regime was thus found to depend on the length scale considered. This suggests that the tribological behavior of a nanostructured solid is "scale sensitive," and one should always consider the scale factor before making a comparison or extrapolations. Although numerical comparison with other carbon-based systems must be considered with high caution, cluster-assembled carbon shows a low friction coefficient, even in a dry environment.

6.4. Gas Storage

The nanostructured carbon films under investigation exhibit a specific surface area of 665.3 m^2/g, and a mesoporous structure with the pore size distribution showing a maximum at 34 Å.

NEXAFS measurements indicate the presence of chemisorbed hydrogen. With this technique, we cannot assess if the chemisorption is induced by the photon beam, which is able to disrupt (with unknown efficiency) physisorbed water or hydrogen molecules, or is a process taking place during exposures. However, the mechanism of hydrogen chemisorption can be favored by the high number of defects contained in our carbon films. They cause electronic localization which can induce a sacrificial donor effect for the photosplitting of water or a hydrogen molecule. Moreover, at present, information on the sorption kinetics is still missing. The exposure parameters (pressure less than 1 bar, 30 min, room temperature) could not be suitable for a relevant adsorption of hydrogen from the nanostructured carbon. In any case, the capacity of these films to adsorb hydrogen and releasing it, under moderate heating treatment, in a reversible way is evident. On the other hand, TPD analysis completes the picture, showing the population of physisorption sites. The hydrogen content of the sample exposed to H$_2$, as estimated from NEXAFS spectra, was about 0.5 wt%, in good agreement with the values for not alkali-doped carbon nanotubes and graphite reported in [126]. Nevertheless, the large area under the C–H* peak in the as-deposited sample indicates that nanostructured carbon could have a bigger adsorbing capacity with respect to the evaluated one. In spite of the limits in data interpretation addressed above, the obtained results on the absorption of hydrogen in nanostructured carbon material are encouraging with regard to the possible use of this material in hydrogen storage devices. Further investigations are planned for a deeper understanding of the sorption mechanism, and for an accurate evaluation of the hydrogen uptake capacity.

The hydrogen uptake by carbon-based materials has aroused large interest in the scientific community [127, 128]. Very high adsorption of molecular hydrogen in carbon nanotubes [129–131] and in alkali-doped nanotubes [132] was reported. Similarly, pure graphite nanofibers (GNF) [133, 134] seem to show a very high H$_2$ adsorption capacity [128]. Theoretical work [135–137] was also stimulated by experimental results since the mechanism of adsorption of such a high quantity of hydrogen is not completely explained.

The porous structure of nanostructured carbon makes this material a good candidate for the storage of gases such as hydrogen. The porosity of the films and their absorptive capacity were investigated by a gas adsorption–desorption technique (BET) model. Particular attention was paid to establishing if the process is reversible. The hydrogen adsorption was observed by temperature-programmed desorption (TPD) and a near-edge X-ray absorption fine structure (NEXAFS) [50]. Since the hydrogen absorption seems smaller in films deposited with large clusters, and a high deposition rate is a fundamental requirement for competitive applications, the investigations on hydrogen uptake capacity involved the films assembled with small-sized carbon clusters.

The adsorption of H_2 has been probed by means of TPD analysis. The specific surface area has been determined by BET characterization. The obtained value for the specific surface area was 665.3 m^2/g. The pore size distribution showed a maximum for pores having a diameter of 34 Å.

TPD analysis for a blank sample and an H-exposed sample shows a correlation between the increment of the TPD signal and the increase of the line for the sample exposed to hydrogen (Fig. 27). In addition, no correspondent increments were observed for other monitored lines, principally related to water, molecular oxygen, and a few hydrocarbon fragments. The TPD peak at approximately 230 °C represents a population of physisorbed H_2 sites. This peak was very small in the first cycle due to the sorption of water and hydrocarbon radicals during air exposure after the deposition. The heating up to 700 °C allowed the release of sites suitable for physisorption. The exponential behavior starting at approximately 500 °C is related to the desorption of chemisorbed hydrogen. This branch is present in both samples, and its intensity decreases from cycle to cycle. This can be due to the presence of hydrogen-containing contaminants which are strongly reduced by iterating the TPD processes. The mass of each sample was very low, and no reliable quantification of the desorbed hydrogen can be made with the experimental apparatus used.

A series of X-ray absorption measurements was performed in order to verify the capacity of nanostructured carbon deposits in absorbing and releasing hydrogen in a reversible way, and the possible structural changes induced by the thermal treatments. In the carbon K-edge NEXAFS spectra, it was followed by the evolution of the C–H peak 288.5 eV of a film grown with the focalizer for different sample treatments (see Fig. 28). The $1s \rightarrow \sigma^*_{C-H}$ resonance indicates the presence of C–H carbon hydrogen bonds. Dissociation of hydrogen-containing physisorbed species, in particular water and H_2, can be induced by X-ray beam photons or by catalytic properties of the deposits themselves. Thus, with these measurements, it is not possible to discriminate the cause of the hydrogen sorption; nevertheless, the response of the nanostructured carbon to hydrogen exposure can be reliably analyzed, as will be described in the following.
In Figure 28, the NEXAFS spectra are presented in the order with which they were acquired from bottom to top, together with two reference samples: natural diamond, and highly oriented pyrolitic graphite (HOPG). The sample was subjected to a first degassing (500 °C, 20 min). Subsequently, the sample was exposed first to air, and then to air with high relative humidity. Afterwards, the sample was again degassed under the same conditions, and finally exposed, inside a prechamber, to hydrogen maintained at a pressure of 800 mbar for 30 min at room temperature. The trend of the C–H peak is evident: after the first annealing, the resonance is strongly reduced, and only partially restored after air exposure; the second air exposure does not lead to an increase of the peak, indicating a sort of saturation of the sorption sites; the second degassing again reduces the peak, whereas the hydrogen exposure partially restores it. Moreover, there was no evidence of relevant modifications of the film structure, even if the heating yields to an increment of

Figure 27. Second cycle of temperature-programmed desorption (TPD). (a) Thermal conductivity detector (TCD) signal. (b) Quadrupole current–temperature dependence of the $m/e = 2$ line. Figure 28. Carbon K-edge NEXAFS spectra of a carbon film subjected to a series of treatments: degassing, air exposure, and hydrogen exposure. The measured reference spectra of HOPG and natural diamond are also shown. Reprinted with permission from [50], C. Lenardi et al., *Diamond Rel. Mater.* 10, 1195 (2001). © 2001, Elsevier.

sp^2 sites, as can be argued from the small increase of the C–C resonance at 285.3 eV. In order to point out the C–H contribution of the sample after the different treatments, a subtraction between the spectra has been made.

After calculations on NEXAFS measurements, the presence of chemisorbed hydrogen in nanostructured carbon films is clearly evident. With NEXAFS, it is not possible to assess if the chemisorption is induced by the photon beam, which is able to disrupt with unknown efficiency physisorbed water or hydrogen molecules, or is a process taking place during exposures. However, the mechanism of hydrogen chemisorption can be favored by the high number of defects contained in our carbon films. They cause electronic localization, which can induce a sacrificial donor effect for the photosplitting of water or hydrogen molecule.

The exposure parameters (pressure less than 1 bar, 30 min, room temperature) could not be suitable for a relevant adsorption of hydrogen from the nanostructured carbon. In any case, it is evident that the capacity of these films is able to adsorb hydrogen and then release it, under moderate heating treatments and in a reversible way. The hydrogen content of the sample exposed to H_2, as estimated from NEXAFS spectra, was approximately 0.5 wt%, in good agreement with the values for not alkali-doped carbon nanotubes and graphite reported in [132].

6.5. Electrochemical Properties (Supercapacitors)

Electrical energy can be stored in faradaic (redox) batteries and in electrostatic capacitors. Batteries are characterized by high-energy density, that can rise up to 150 W·h/kg, but poor power density, that with difficulty reaches 100 W/kg. The batteries suffer from several weaknesses that cause a rapid decrease of their performances. The origin may be the fast charging and discharging or the cold environmental temperature. Moreover, they also have a limited lifetime, and require expensive maintenance. Conversely, due to the completely different physical principle on which electrical energy storage is based, a capacitor has lower energy density but higher power density. Power density depends on the velocity characterizing the energy transfer: capacitors are much faster than batteries in delivering or accumulating their energy. Therefore, while slow storage processes may be performed with batteries, the fast ones have to be realized with capacitors. Examples of technological applications that could benefit from the employing of capacitors as fast energy storage devices are the following.

- Engine starter: Today, the energy required to crank a small or a big engine is stored in batteries, either Pb or Ni–Cd. Because of their high internal resistance, which limits the initial peak current, they have to be oversized. Fast discharges and the cold environmental temperature could heavily affect battery properties.
- Hybrid vehicle: The mean power of a small car is about 30 kW, and its peak power should be about 60 kW. Capacitors may supply the power to the electrical vehicle required to meet the city road traffic conditions, where power is suddenly requested or could be taken from braking.

- UPS: The uninterruptible power supplies may have some economical interests by using capacitors, thanks to the suppression of an inverter and the suppression of the maintenance. The energy supply during a limited time, at a voltage much higher than that of batteries, is easy to perform with capacitors. The limit of actual capacitor technology lies in the fact that the capacitance values obtained in real devices is too low for most of the practical requirements. In fact, the energy in a capacitor, being proportional to the capacitance, the achievable energy density values are problematically small.

Besides different types of capacitor technology, the electrochemical double-layer capacitor (EDLC), also designed as a supercapacitor or supercaps, shows the highest energy density. The performances of this device could fill the gap between the batteries and the classical capacitors: it shows the properties of a capacitor, but has the technology design of a battery. Supercaps are attractive for their high energy and power densities, and their long cycle life (>100,000). In addition to the high specific power, the energy storage in supercapacitors is simpler and more reversible than in conventional batteries [138].

Supercapacitors are formed by two polarizable electrodes: a separator and an electrolyte. The electrical field is stored at the interfaces between the electrolyte and the electrodes. The layer of the charges in the electrode and the layer of solvated ions of opposite sign constitute the so-called "double layer." The dielectric medium is the high-permittivity electrolyte. The electrode surface is extremely huge, and the distance between the opposite charges is in the nanometer scale due to the double layer. The double-layer phenomenon at the boundary between an ionic liquid and a solid was been discovered in 1879 by Helmholtz, and studied by several authors [139]. A theoretical treatment can be easily found in electrochemistry textbooks, for example, [140, 141].

At the surface of a metal in an electrolyte, the following exchange reaction occurs, depending on the energies of the different species in the electrode and in the electrolyte:

$$Me^{z+} + Ze^- \leftrightarrow Me$$
Here, Me^{z+} is the solvated metal ion (Z indicates the valence), Ze^- are the exchanged electrons, and Me is the solid metal constituting the electrode. The positive or negative charges in the electrode are compensated by a layer of cations or anions adsorbed at the surface of the electrode (the double layer). If a potential is applied, the charge of the double layer can be changed, that is, increased or decreased, or even the sign of the charge may change. If the electrode is immersed in an inert electrolyte, no reaction can occur upon a potential change; only the double layer is charged. There is no charge transfer between the electrode and an electrolyte as long as the potential is smaller than the dissociation potential of the electrolyte.

As reported in Figure 29, the double-layer thickness is defined as half the diameter ($a/2$) of the adsorbed solvated ions. This simple model of the Helmholtz double layer is called a rigid double layer [142], and corresponds to a two-plate capacitor where the plates are at a distance of $a/2$.
Figure 29. Helmholtz double layer in the approximation of rigid layer. Correspondingly, the electric potential is reported as a function of the distance from the electrode surface: ϕ_{Me} is the electrode potential, ϕ_{oH} is the potential at the outer Helmholtz layer, and ϕ_{El} is the potential of the electrolyte. Reprinted with permission from [142], O. Stern, *Z. Electrokem.* 30, 508 (1924). © 1924,

The potential decreases linearly with distance to the electrolyte potential within the adsorbate rigid layer (also called the Stern layer). Due to thermal diffusion, the potential decreases exponentially outside the outer Helmholtz surface ($\xi = 0$). At $\xi = \chi$, the potential is decreased to $1/e$ of the total potential ($\Delta\phi = \Delta\phi_{rigid} + \Delta\phi_{diff}$). The value of χ is approximately 10 nm, and decreases with increasing ionic concentration of the electrolyte. For an electrolyte concentration greater than 0.1 mol/l, χ decreases to the outer Helmholtz surface (0.1 nm). Therefore, the Helmholtz double layer is a capacitor in which the charges of different sign are separated by just a few nanometers: this allows EDLC to have a high capacity.

The working voltage of an ECDL capacitor is determined by the decomposition voltage of the electrolyte. For a single cell and an organic electrolyte, it is approximately 2.5 V_{DC}. In addition, the operating voltage depends mainly on the environmental temperature, the current intensity, and the required lifetime. The capacitance of an ECDL capacitor can be very large, for example, several thousands of farads, thanks to the very small distance which separates the opposite charges at the interfaces between the electrolyte and the electrodes, and thanks to the very huge surface of the electrodes. These capacitances are several orders of magnitude greater than that of conventional capacitors.

The goal of ECDL capacitor research is to reach the highest energy and power densities to get the smallest component volume and weight for a given application. These goals have been fixed by the U.S. Department of Energy (DOE) to 15 W·h/kg for the energy density and 2000 W/kg for the power density. To meet these values, it is necessary to increase the capacitance density, to reduce the series resistance (see below), and to increase the cell operating voltage. The efforts are concentrated on the study of the electrode surface, the electrode accessibility, and the electrolyte decomposition voltage.

Nanostructured materials based on the assembly of carbon nanotubes are attracting increasing interest in view of energy storage applications [143]. Several requirements still remain to be fulfilled before the development of a nanotube-based technology, in particular, the production and manipulation of macroscopic quantities of nanotubes with controlled structure and dimensions. In this sense, if compared with other applications, electrochemical ones are less demanding since a controlled nanostructure is required without internal atomic perfection. The use of nanotube mats and, in general, of nanostructured carbon materials thus offers great potential for electrochemistry and, in particular, for the production of porous electrodes for supercapacitors.

Since the capacitance is proportional to the surface area, electrochemical inert materials with the highest specific surface area are utilized for supercap electrodes in order to form a double layer with a maximum number of electrolyte ions [144]. Therefore, carbonaceous materials in their various forms have been studied as electrodes for the construction of rechargeable ECDL capacitor energy storage devices. Activated carbon composites and fibers [145] with surface areas up to 2000 m^2/g (measured by gas absorption), as well as carbon aerogels [138] with surface areas up to 850 m^2/g have been investigated. Unfortunately, a significant part of the surface area resides in nanopores (sizes below 2 nm) which are not accessible to the electrolyte ions. The surface area that remains electrochemically accessible (mesopores, macropores) reveals capacitance values well below the estimated values. Therefore, the pore size distribution, together with the surface area, are important for the determination of the double-layer capacitance.

Niu et al. [143] realized supercap electrodes with free-standing mats of catalytically grown nanotubes. The nanotube electrodes (diameter of 0.5 in) have shown a surface area of 430 m^2/g, and a measured specific capacitance up to 113 F/g with an aqueous electrolyte, resulting in a power density above 8 kW/kg. Although very promising, the use of nanotubes in practical devices is limited by the complex production/purification method, the small area of the free-standing nanotube films, and the adhesion of nanotube mats to large surfaces which have to be wound into a capacitor.

The morphological features of nanostructured carbon films match the requirements on supercap electrodes. The hierarchical organization of clusters in grain structures covering a wide range of length scales (from nanoscopic up to mesoscopic) accounts for high porosity and low density, and particularly fulfills the demand for a high specific surface. As other forms of carbon, this material appears to be inert with respect to the electrochemical processes involved in a supercap. Difficulties could arise from the high resistivity of cluster-assembled nanostructured carbon film [146], which limits the power density.

With respect to nanotube-based technology, requiring a complex sequence of steps to obtain the electrodes from the as-grown material, supersonic cluster beam deposition appears to be a simpler and versatile technique. Moreover, the presence in the beam of clusters of different masses

could allow the selection of precursors, thus modifying the properties of the deposited electrode. Granularity and conductivity should be the main properties to be controlled.

A single ECDL cell device was fabricated with two nanostructured carbon electrodes with a thickness $d = 0.8$ μm and a surface of 6 cm $\times$ 6.6 cm (for each electrode) deposited on an aluminum substrate (30 μm thick) serving as a collector. The two carbon electrodes were separated by a 36 μm thick polymer separator as a membrane. The cell is impregnated using a quartenary ammonium salt soluted in propylene carbonate (PC) as an organic electrolyte. Impregnation was performed under controlled conditions (argon inert atmosphere) in a glove box. The carbon-coated electrodes and the separator were stacked between two 3 mm thick aluminum plates. Finally, the stack was pressed together for better contact, and was sealed. A dc voltage is used to charge the supercapacitor to its nominal voltage $V_0 = 2.7$ V. The capacitance C and the equivalent series resistance ESR are determined by measuring the voltage over the contacts of the ECDL cell during discharge over an external circuit resistance R_e of 100 Ω. A schematic view of the cell and the setup for the C and the ESR measurement methodology is shown in Figure 30.

The equivalent circuit of an ECDL capacitor consists of a capacitance C, a parallel resistance Rp responsible for the self-discharge, an inductivity L, and the equivalent series resistance ESR representing the internal resistance of the capacitor. The series resistance keeps the current low, and therefore limits the power of the component and is responsible for the electric losses. The key factors determining the high energy and power density are the capacity (maximum C is required) and the series resistance (minimal ESR is required), respectively. The time constants of the charging and discharging circuits are equal to $(R_e + \text{ESR}) \times C$, while the time constant of the self-discharge is equal to $R_p \times C$. In order to minimize the self-discharge, R_p should be as large as possible.

The electrolyte itself strongly influences the capacity as well as the series resistance of the ECDL capacitor. Tanahashi et al. [145] did a comparison between aqueous and organic electrolytes, showing on one side that organic electrolytes can operate at higher voltages (up to 3 V compared to 1.2 V for aqueous electrolyte), desirable for high energy and power densities. On the other side, the aqueous electrolyte reveals a higher capacity and an ESR lower by a factor of 10. The lower ESR of the aqueous electrolyte, desirable for high-power densities, is due to the higher conductance of the ions, resulting in a voltage drop by a factor

of 10 lower than for organic electrolytes at the beginning of the capacitor discharge.

During tests, the nanostructured carbon ECDL prototype was discharged over an external circuit resistance R_e. The voltage drop ΔU at the beginning of the discharge of the capacitor allows us to determine ESR, while C is determined on the basis of ESR after 20 and 30 s of discharge. The capacity C and the equivalent series resistance ESR were determined with the following equations:

$$C = \frac{-t}{(\text{ESR} + R_e) \cdot \ln\left((\text{ESR} + R_e) \cdot \frac{U_t}{U_{1,\,t=0} \cdot R_e}\right)}$$

$$\text{ESR} = \frac{\Delta U}{i_{t=0}} = \Delta U \cdot \frac{R_e}{U_{1,\,t=0} - \Delta U}$$

where t is the time, and U_t is the voltage at time t.

For the single-cell device, the best results are ESR $= 1.13 \pm 0.09$ Ω and $C = 0.099 \pm 0.004$ F; per surface unit: ESR $= 45.7$ Ω/cm^2 and $C = 0.003$ F/cm^2. Based on these values and with a density of 1 g/cm^3, the specific capacity of one electrode is $c = 2C/d = 75$ F/g. The maximal energy density is given by $P = U_{\max}^2/(4 \times \text{ESR})$, and with its nominal voltage $V_0 = 2.7$ V, it results in 76 W·h/kg. The maximal power density is 506 kW/kg [147]. These results demonstrate that cluster-assembled carbon films are very attractive for supercapacitor realization. The optimization of parameters such as electrolyte accessibility, film conductivity, and interface resistance is currently underway. The scale up of the cluster deposition parameters to match industrial requirements will also be explored.

6.6. Nano- and Microfabrication with Carbon Cluster Beams

The fabrication of functional devices based on nanostructured materials requires the ability to assemble nanoparticles in micrometer and submicrometer patterns with high precision and compatibility with planar technology [148]. Physical and chemical deposition techniques are used for the patterning of semiconductor, metallic, and polymeric films and the production of dot arrays. These techniques require putting resists or stamps in contact with a substrate that undergoes different pre- or postdeposition etching or thermal treatments [149–151].

The effect of etching or thermal treatments on cluster-assembled materials has not been investigated systematically; however, several problems due to the "granularity" of nanostructured materials can be expected.

For nanostructured films, a noncontact patterning has been demonstrated based on the principle of depositing particle beams on a substrate through a stencil mask [152]. Due to the use of supersonic cluster beams, this process has a high lateral resolution, large area deposition, high deposition rate, and low temperature processing [153].

SCBD can be used for the fabrication of patterns of micrometer-size cluster-assembled objects. By exploiting the high intensity and collimation typical of supersonic expansions, it is possible to create structures with a high aspect ratio and controlled shape, arranged in ordered arrays on any kind of substrate at room temperature.

Figure 30. Schematic view of an ECDL cell and the setup for the capacity C and the equivalent series resistance ESR measurement methodology.
Figure 31. (A) SEM images of *ns*–carbon pillars deposited on a polymeric substrate. A standard metallic TEM grid with round holes of 20 μm diameter is used as a mask. The mask–substrate distance is about 0.3 mm. (B) The same sample is tilted to show the 3-D nature of the deposit.

Figure 31 shows SEM images of a pattern of nanostructured carbon pillars obtained by deposition of carbon clusters. The pattern has been obtained by using a round hole grid. Atomic force microscope analysis reveals granularity at a nanometer scale based on the assembling of grains with a mean diameter of 20 nm. Dots with complex geometries and a high aspect ratio, as well as self-standing microstructures can be obtained with this technique.

Key issues for micropatterning applications of SCBD are process speed, resolution, surface finish, and substrate compatibility [152]. Supersonic cluster beam sources are characterized by high directionality and high intensity. These properties have been used for the thin-film metallization of flat and microstructured surfaces [152]. SCBD allows the creation of micrometer-size objects having a structure on the nanoscale. The stencil mask is not in contact with the substrate; patterns on different substrates such as silicon, aluminum, copper, stainless steel, and polyethylene can be deposited at room temperature.

Lateral resolution depends not only on the sharpness of the mask edges, but also on the beam collimation. Supersonic expansions have a higher collimation compared to effusive beams [49]; however, clusters in supersonic beams can still have a nonnegligible thermal divergence and a broad mass distribution [49]. With a standard supersonic beam, a step produced with a straight edge mask is very noisy, and not well defined [49]. In order to increase the step sharpness, one should increase the degree of supersonicity of the beam, but this will require a huge pumping system [4, 49]. The use of a focusing nozzle can circumvent this problem by concentrating the clusters on the center beam, keeping intact the other expansion parameters. A step with a width of 450 nm using a mask placed at 0.33 mm from the substrate has been reported.

7. APPLICATIONS OF CLUSTER-ASSEMBLED CARBON

Nanostructured carbon-based materials and, in particular, those assembled from nanotubes, are attracting an increasing interest in view of a wide variety of applications ranging from micromechanics to electronics and energy storage [154]. The use of cluster-assembled carbon films can be an interesting alternative for applications in the above-mentioned fields.

Nanostructured carbon films are good field emitters, showing reasonably high current densities and stability [101, 103]. The use of supersonic beams allows deposition at very high rates over sizable areas at room temperature. This is a considerable advantage since it allows us to overcome limitations for the thermal sensitivity of many substrates. Compared to other emissive carbon films, cluster-assembled carbon films can be deposited, for example, onto glass substrates. In contrast, nanotubes can so far be formed only under high-temperature conditions [155].

Pulsed-laser-induced electron emission has also been observed from *ns*–carbon films. These properties may be of interest for the construction of photoemitting cathodes with applications for accelerator injectors [156].

Due to its high porosity and highly accessible surface area, *ns*–carbon is a good candidate for the production of supercapacitors [147]. Films with a density of 1 g/cm^3 have shown, in a dc regime, a specific capacitance per electrode of 75 F/g and energy and power densities of 76 W/kg and 506 kW/kg, respectively [147]. *ns*–carbon films, once deposited, do not require further chemical purification or thermal annealing. The use of cluster beams allows the deposition of films on thin foil films compatible with the actual manufacturing processes for supercapacitors [157].

Cluster-assembled carbon grown by pulsed laser deposition has been used for the production of preconcentrators for gas trace analysis by gas chromatography microsensors [29].

GLOSSARY

Cluster Aggregate of atoms, whose number of constituents can vary from a few units to many thousands.

Nanostructured materials Materials whose building blocks, instead of single atoms, are nanometer-sized units (i.e. clusters).

(Supersonic) molecular beam A stream of molecules or atoms, possessing high directionality, propagating in a vacuum environment. In the case of supersonic beams, mean velocity is larger than the local velocity of sound.

Supersonic cluster beam deposition (SCBD) Technique for the deposition of films exploiting a supersonic beam of clusters. The film is grown in high or ultra-high vacuum, intercepting the cluster beam with a suitable substrate.

Colloidal Gold

Victor H. Perez-Luna, Kadir Aslan, Pravin Betala

Illinois Institute of Technology, Chicago, Illinois, USA

CONTENTS

1. INTRODUCTION

There is currently enormous interest in the field of nanoscale science and engineering because of (i) the novel properties of matter found at the intermediate scale between molecules and bulk materials and (ii) phenomena that occur only at the nanoscale regime. Over the last decade the number of publications in the field of nanoparticle synthesis has increased enormously. Gold nanoparticles in particular are receiving renewed interest because of novel applications being developed with this material. One of the reasons for this renewed interest is the attractive combination of its optical properties, which depend on the electronic properties rather than molecular structure, and the facile functionalization of this material with a variety of molecules. Despite being known and used for centuries, the use of this material is currently exhibiting a boom, particularly in the field of materials science.

1.1. History

Accounts on the use of colloidal gold can be found throughout history. The oldest object containing gold nanoparticles is frequently cited as being the Lycurgus Chalice from fifth century Rome [1, 2]. However, accounts of colloidal gold preparations may extend further back in time. Colloidal gold is found in treatments in the alternative medicine Ayurveda

(the traditional medical system of India), which has its written origins in the Vedas, the sacred texts of India. The Vedas are believed to be the oldest writings in the world. More recent accounts of colloidal gold are its uses in alchemia by Paracelsus around 1600 [3], incorporation of gold into molten silica to create "ruby glass" [attributed to Johann Kunckel (1638–1703)] [4, 5], and the experiments by Michael Faraday that led him to attribute the color of ruby glass and his aqueous solutions of gold (colloidal gold) to finely divided gold particles [6, 7].

In addition to the early experiments by Faraday, colloidal gold was considered a useful research tool for particle science in the early 19th century. This led to important advances in the development of novel synthetic methods for colloidal gold [8]. However, its main applications were still relegated to the production of dyes for glass and fabrics. The development of a reproducible method through the sodium citrate reduction method to produce colloidal gold with controlled and reproducible properties [9] eventually made possible its application to the fields of particle science and cell biology [10–14]. Until recently, the wide use of colloidal gold for labeling studies in cell biology was one of the more important applications of this material with a good number of textbooks devoted to the subject [10–14]. However, during the last few years there has been a resurgence of interest in colloidal gold because of the potential of this material for a variety of applications related to nanoscale science and engineering. The scope of this chapter will concentrate on these latest developments, particularly in their relationship to nanoscale science and engineering.

1.2. Properties

Due to its large free electron density, colloidal gold has been used extensively in applications involving electron microscopy. As it turns out, the free electrons of metallic nanoparticles also impart them with unique optical properties, which can be explained in terms of classical free-electron theory and simple electrostatic models of electrostatic polarizability [7, 14]. It was Michael Faraday who first explained the characteristic colors of colloidal dispersions of gold and ruby glass. Although his theoretical framework was mostly qualitative, it formed the foundations for

more elaborate theories on the colors of metallic colloidal dispersions.

The optical properties of metallic nanoparticles with radius, R, much smaller than the wavelength, λ, of light ($2R/\lambda \ll 1$) can be estimated by assuming that the size dependent interaction of the particles with light is static (a direct result of $2R/\lambda \ll 1$) while the dielectric properties of the free electrons in metallic nanoparticles are considered dynamic. Under these assumptions, the theory predicting the optical properties of metallic clusters is represented by the sets of equations known as the Maxwell-Garnett formula [14–18].

The polarizability α of a small spherical particle in a static electric field is

$$\alpha = 4\pi\varepsilon_0\varepsilon_m R^3 \frac{\varepsilon - \varepsilon_m}{\varepsilon + 2\varepsilon_m} \qquad (1)$$

with ε_0 being the dielectric constant of vacuum, ε_m the dielectric constant of the media the nanoparticles are embedded into, and ε the dielectric constant of the particle (assumed equal to that of the bulk metal). For metals, the dielectric constant is a complex number related to the index of refraction n and absorption coefficient k as

$$\varepsilon = \varepsilon_1(\omega) + i\varepsilon_2(\omega) = (n + ik)^2 \qquad (2)$$

and the magnitude of ε_1 and ε_2 are strong functions of the frequency of the applied electric field (wavelength of the incident light).

A direct result of Eqs. (1) and (2) is that the polarizability of a metallic nanoparticle will be maximum when the term $\varepsilon + 2\varepsilon_m$ is minimum, that is, when $(\varepsilon_1 + 2\varepsilon_m)^2 + \varepsilon_2^2 =$ minimum. During a typical ultraviolet-visible measurement the extinction coefficient γ is related to k as $\gamma = 4\pi k/\lambda$. The overall absorption was obtained first by Mie [19] by integrating over a medium filled with nanoparticles according to

$$k = 9/2\varepsilon_m^{3/2}(N4/3\pi R^3)\frac{\varepsilon_2}{(\varepsilon_1 + 2\varepsilon_m)^2 + \varepsilon_2^2} \qquad (3)$$

where N is the number density of the nanoparticles. The term in parentheses represents the filling factor $f = (N4/3\pi R^3)$.

For dilute dispersions, Eq. (3) describes the absorption of noninteracting particles. However, when the filling factor is large, each particle will be subjected to an average polarization field due to surrounding particles. Under these conditions, it is helpful to calculate an effective dielectric constant

$$\varepsilon_{\text{eff}} = \varepsilon_m \frac{1 + 2N\alpha/(3\varepsilon_0\varepsilon_m)}{1 - N\alpha/(3\varepsilon_0\varepsilon_m)} = \varepsilon_m \frac{1 + 2f\Lambda}{1 - f\Lambda} \qquad \text{with}$$

$$\Lambda = \frac{\varepsilon - \varepsilon_m}{\varepsilon + 2\varepsilon_m} = \frac{\alpha}{3\varepsilon_0\varepsilon_m V} \qquad (4)$$

Equation (4) is known as the Maxwell–Garnett formula. A direct consequence of the static approximation is that the effective optical properties are independent of particle size. The imaginary part of the refractive index is

$$k = \sqrt{0.5\left(-\varepsilon_{\text{eff},1} + \sqrt{\varepsilon_{\text{eff},1}^2 + \varepsilon_{\text{eff},2}^2}\right)} \qquad (5)$$

In order to calculate an extinction coefficient it is necessary to first obtain an estimate of the dielectric constants. For metals, the dielectric constants can be approximated by the Drude model [20]. According to this model the real and imaginary parts of the dielectric constant are given by

$$\varepsilon_1 = 1 - \frac{\omega_p^2}{\omega} \qquad \text{and} \qquad \varepsilon_2 = 1 - \frac{\omega_p^2}{\omega^3}\omega_d \qquad (6)$$

where $\omega_p = \sqrt{ne^2/\varepsilon_0 m_e}$ is the bulk plasma frequency, n is the concentration of free electrons in the metal, and m and e are the effective mass and charge of the electron respectively. The term $\omega_d = v_F/l$ represents the relaxation or damping frequency with v_F being the velocity of the electrons at the Fermi level and l the electron mean free path [14–17, 20, 21]. The Drude model allows an estimation of the dielectric constants. In addition, tabulated values of experimentally determined dielectric constants for bulk metals can be found in the literature [22]. Figure 1 shows the simulated extinction coefficient of 10 nm gold nanoparticles embedded in media with different dielectric constants. Tabulated experimental values of the dielectric constants of gold were used to simulate the spectra [22]. This figure shows the sensitivity of the absorbance of the nanoparticles to the dielectric medium surrounding them. Two features that emerge from this figure are a slight redshift in the surface plasmon resonance (SPR) peak position and an increased intensity of the SPR absorption band. Thus, changing the dielectric constant of the media surrounding the nanoparticles results in changes on their optical absorption spectra. Interactions of other materials with the nanoparticles' surfaces can induce similar changes.

The optical properties of gold nanoparticles are also susceptible to the degree of interaction (aggregation) among the particles. For a particle pair with a small enough center-to-center separation, D, the oscillations of the surface plasmons differ significantly from those of isolated particles. In aggregated pairs, two excitation modes can exist, parallel or perpendicular relative to the axis pair. Longitudinal in-phase oscillations differ significantly from transversal oscillations with the former being significantly different from noninteracting particles while the latter is only slightly redshifted. When interacting nanoparticle pairs are exposed to

Figure 1. Simulated optical absorption spectra for 10 nm gold particles embedded in media with $\varepsilon_m = 1.0, 1.77, 2.0,$ and 2.5.

an applied electrical field E, the resulting dipole moments, μ_{1j} and μ_{2j}, of the two spheres are given by

$$\mu_{1j} = \alpha_1 E^* + \frac{\alpha_1 \mu_{2j} j}{4\pi\varepsilon_0\varepsilon_m D^3} \qquad \text{and}$$

$$\mu_{2j} = \alpha_2 E^* + \frac{\alpha_2 \mu_{1j} j}{4\pi\varepsilon_0\varepsilon_m D^3} \qquad (7)$$

with $j = 1$ representing the transversal mode and $j = 2$ the longitudinal mode of oscillation. If the angle between the electric field vector and the longitudinal axis of the particle pair is θ, then $E^* = E\cos\theta$ for the longitudinal mode and $E^* = E\sin\theta$ for the transversal mode. The pair polarizability for the longitudinal and transversal modes can be calculated with these equations.

For nanoparticle pairs in a two-dimensional (2D) plane, the average polarizability $\Lambda_{\text{pair, 2D}}$ is obtained when integrating over all possible orientations of the longitudinal and transversal modes, giving

$$\Lambda_{\text{pair, 2D}} = \frac{\eta}{2}((1 - 2\eta(R/D)^3)^{-1} + (1 + \eta(R/D)^3)^{-1}) \quad (8)$$

where $\eta = (\varepsilon - \varepsilon_m)(\varepsilon + 2\varepsilon_m)$. With the average polarizability $\Lambda_{\text{pair, 2D}}$, an effective dielectric constant and the absorption can be calculated with Eqs. (4) and (5), respectively. Figure 2 shows the simulated absorption spectra of 10 nm gold nanoparticles embedded in dielectric medium with $\varepsilon_m = 2.5$ at various separation distances between the nanoparticles. When the particles are separated by a large distance they behave as independent particles and the simulated spectrum is similar to that obtained from Eq. (3). However, when the separation becomes comparable to the radius of the particle, longitudinal and transversal resonance peaks can coexist. The longitudinal mode is significantly redshifted while the transversal mode is only slightly redshifted from that of noninteracting particles. Furthermore, the magnitude and shift of the longitudinal mode become significant when the separation distance is smaller than the diameter of the particles and this effect becomes stronger as the separation distance of the particles becomes smaller. The previous approximation is valid for 2D particle-pair aggregates. For many particle aggregates, more complex calculations are
Figure 2. Simulated optical absorption spectra of 10 nm gold nanoparticles at varying separation distances between the particles with $R/D = 0.0001, 0.444, 2.5,$ and 2.0.

necessary [23, 24]. In this case, additional resonances appear at lower frequencies (longer wavelengths) that are even more separated than those calculated for 2D particle pairs. In fact, their optical absorption spectra can show broad bands that extend into the near infrared region depending on the size of the aggregates and the number of particles in the aggregate [17, 18, 23–25].

Because particle size, degree of aggregation, and the dielectric constant of the media determine its optical properties, applications of colloidal gold exploiting the strong dependence of optical properties with aggregation and surrounding dielectric media have been implemented through proper surface modification of the nanoparticles or by embedding them in different dielectric media. The following sections summarize preparation methods, surface modification, characterization, and modern applications. Traditional applications (e.g., immunostaining) are only briefly discussed since there is already a wide body of literature on these applications and the techniques are well established [10–14].

2. PREPARATION METHODS

2.1. Gold Nanoparticle/Colloidal Gold Synthesis

Metallic nanoparticles can be synthesized by a variety of methods such as chemical [10, 12–14, 17], sonolytic [26], radiolytic [27–30], and photolytic reactions [31–37]. However, the reduction of metal salts by added reducing agents is the oldest established procedure for the preparation of aqueous suspensions of nanoparticles. A wide range of reducing agents have been used in gold nanoparticle synthesis; the most frequently used ones include sodium citrate [38, 39], sodium borohydride [10, 12–14, 40], tannic acid [10, 12–14], white phosphorus [6, 10, 41] hydrazine [42–44], hydrogen [45, 46], carbon monoxide [47], hydroxylamine [48–50], and mild agents like ascorbic acid [51, 52]. Reducing solvents such as alcohols [53–55], formamide [56], and ethers [54, 57] can also be used in the synthesis of metallic nanoparticles.

In 1951, Turkevich et al. [58]. established the first reliable procedure for the preparation of gold sols with well-controlled size distributions. Such a method is based on reduction of chloroauric acid by trisodium citrate and has become a standard for histological staining applications.

Other approaches to the synthesis of colloidal gold nanoparticles have been used. Among those is a two-phase system, first introduced by Faraday [6], who reduced aqueous gold salt with phosphorus vapor in carbon disulfide. Later, a combination of the two-phase approach with the more recent techniques of ion extraction and formation of self-assembled monolayers (SAMs) of alkanethiols on gold led to a one-step method for the synthesis of derivatized gold nanoparticles by Brust et al. [59, 60]. The technique consists of simultaneous reduction of gold salts and SAM formation. The redox reactions can be carried out by an appropriate choice of reducing and phase-transfer reagents in the two phases. In the original procedure, an aqueous solution of chloroaurate is mixed with a solution of the phase-transfer reagent tetraoctyl ammonium bromide in

toluene and the mixture is vigorously stirred until all tetra-chloroaurate was transferred to the organic layer. The alka-nethiol is then added to the organic phase followed by the reducing agent. This procedure led to the formation of sta-ble gold nanoparticles protected by a self-assembled mono-layer that imparted the nanoparticles different properties depending on the functional group at the surface. These lat-ter systems are also commonly referred to as monolayer pro-tected clusters, which have the characteristic that they can be treated as unique chemical entities because they can be manipulated with a variety of physicochemical procedures while maintaining their identity (*vide infra*) [59–61].

2.2. Polymers in the Synthesis of Gold Nanoparticles

The preparation of nanocomposites with an inorganic core such as metal nanoparticles and a protective organic shell of small molar mass compounds or polymers is a route to obtain materials suitable for hierarchical self-organization into nanoassemblies. Incorporation of nanoparticles into polymer matrices is particularly advantageous for materials engineering and the study of nanoparticle–matrix interac-tions. The adsorption of polymers onto a wide variety of nanoparticles is of broad industrial relevance in such areas as pharmaceuticals, photography, paints and coatings, foods, wastewater treatment, rubbers, and composite materials and is ubiquitous in natural aqueous environments as well as in many biological organisms. Recently, nanocomposites of π-conjugated polymers and inorganic particles have received much attention [62–68], due to the interesting high electrical conductivity [69] and redox properties [70] of π-conjugated polymers and their extensive applications ranging from bat-teries to light-emitting devices [71]. The adsorption or graft-ing of environmentally responsive "smart" polymers onto surfaces holds potential applications in controlled modula-tion of interfacial properties, as demonstrated in thermally switchable cell culture of anchorage-dependent mammalian cells [72, 73] and to control bacteria fouling [74]. Consid-ering the wide range of applications, the combination of polymers with nanoparticles has driven lot of interest in its research.

Overall there have been two different approaches to achieve nanoparticle–polymer composites. The first tech-nique consists of the *in-situ* preparation of the nanoparticles in the matrix. This is effected either by the reduction of metal salts dissolved in the polymer matrix [75–77] or by the evaporation of metals on the heated polymer surface [78]. A second technique involves polymerizing the matrix around the nanoparticles [79].

Lennox et al. [80]. proposed a desirable approach that involved blending premade nanoparticles into a presynthe-sized polymer matrix. Coating gold nanoparticles first with a polymer ligand chemically similar to the polymer matrix made mixing of the gold nanoparticles with the polymeric matrix thermodynamically more favorable and thus more compatible as compared to coatings with polymer ligands that were chemically different from the matrix [81]. The sur-faces of gold nanoparticles were decorated with covalently bound thiol-capped polystyrene macromolecules (PS–SH) and these were dispersed in a PS matrix. Because of its

high glass-transition temperature, PS allows for the for-mation of robust films at room temperature. The PS–SH macromolecules were synthesized by anionic polymeriza-tion and the polystyrene anion was titrated with one unit of propylene sulfide to generate the thiol end group [82]. The PS–Au nanoparticles were prepared following modi-fied Ulman reaction conditions [83], using lithium triethyl-borohydride as a reducing agent. Incorporation into the PS matrix was effected by dissolving both PS–Au and PS matrix in a small amount of chloroform. The PS–Au nanoparticles were found to be evenly dispersed. This method provided for the full synthetic control over both the nanoparticles and the matrix.

Novel π-conjugated polymer-protected metal (Pd, Au, Pt) nanoparticles have been prepared via reduction of the metal ions by a π-conjugated poly(dithiafulvene) (PDF) having strong electron-donating properties. For the synthesis of gold nanoparticles, the PDF is dissolved into a dimethyl sulfoxide solution of $HAuCl_4$ and the reaction mixture is stirred for 24 hours at room temperature. The reaction mixture changes gradually from yellow to purple, indicat-ing nanoparticle formation. It has been proposed that elec-tron transfer from the π-conjugated PDF to the Au ions results in the formation of Au nanoparticles embedded in the polymeric matrix. The oxidized π-conjugated polymer might possess a delocalized positive charge and provide both steric and electrostatic stabilization, protecting the Au in stable colloidal form [84]. Nanoparticles encapsulated in π-conjugated polymers show interesting characteristics, particularly in dielectric properties, energy storage, catalytic activity, and magnetic susceptibility [85].

Hybrid polymeric systems with metal nanoparticles located inside specific areas of the material have been developed by Svergun et al. [86]. In this approach, a self-assembled multilayered polymer, poly(octadecylsiloxane), provided a nanostructured matrix for the incorporation of gold and platinum compounds and for metal nanoparticle formation. The size distributions of the nanoparticles and the changes in the internal structure of the matrix as a result of nanoparticle formation for different reducing agents and reaction media were studied.

In addition to the examples mentioned, a variety of other polymers used for the preparation and study of polymer–gold nanocomposites can be found in the literature [87–91]. Further uses of polymers also involve surface modification of nanoparticles as described in Section 3.5.

2.3. Laser Ablation

In recent years, gold nanoparticles with diameters less than 10 nm have attracted much attention because of their size dependent physical and chemical properties: a gold nanoparticle in the size range of less than 5 nm in diame-ter shows a dramatic decrease of the melting point [92, 93], exhibits intense photoluminescence [94], and catalyzes CO oxidation even at low temperatures (200 K) when used with TiO_2 [95, 96]. Traditionally, chemical reduction of gold salt into gold nanoparticles in reverse micelles has been one of the most successful methods to obtain gold nanoparti-cles with diameters less than 10 nm in solution [97]. In this method, the size of the nanoparticles depends on that of the

reversed micelles, so that nanoparticles with a desired size can be obtained by introducing a proper amount of water inside the reverse micelles through adjustment of the molar ratio of water to nonpolar solvent.

Alternatives to chemical synthesis for the preparation of gold nanoparticles with diameters less than 10 nm have been developed that involve laser ablation of a gold plate in solution [98]. These methods are currently under investigation by several research groups [99–102]. In this method, a gold metal plate, which is placed at the bottom of a glass vessel filled with an aqueous solution of a surfactant (e.g., sodium dodecyl sulfate or SDS), is irradiated with a Nd:YAG pulsed laser (1064 nm) and gold nanoparticles are formed [101].

Formation of gold nanoparticles occurs by a SDS concentration dependent mechanism [103]. After laser ablation, a dense cloud of gold atoms is built over the laser spot of the metal plate and the atoms aggregate as fast as they are supplied. This continues until the atoms in close vicinity are depleted almost completely. As a result an embryonic particle is formed in a region void of atoms. However, the supply of atoms outside the region by diffusion causes the particle to grow slowly even after rapid growth ceases. The surfactant (SDS) plays an important role determining the stability and size of the nanoparticles, because the termination of the particle growth is controlled by the diffusion and attachment rates of SDS on the nanoparticle. Gold nanoparticles end up coated with a double layer of SDS, such that in the first layer the SDS molecules orient with the hydrophilic $-SO_4^-$ end toward the nanoparticle and the hydrophobic $-C_{12}H_{25}$ end outward while in the second layer they orient in the opposite direction. The fact that the nanoparticles end up coated with a double layer of SDS ensures the stability of gold nanoparticles in solution.

Gold nanoparticles produced upon laser irradiation (1064 nm) to the gold plate have typical size distributions of 1–15 nm with average diameters less than 10 nm. However, when the nanoparticles form, it is very difficult to change their size, and the aggregation of the ablated atoms can hardly be controlled. In order to address this problem, further size reduction of the gold nanoparticles can be induced by laser irradiation (532 nm) in the vicinity of the wavelength of SPR excitation of the gold nanoparticles (520 nm) [98, 104, 105]. Gold nanoparticles in solution do not absorb photons at 1064 nm, but they absorb photons at 532 nm and fragment into smaller particles. Dissociation of the gold nanoparticles by absorption of 532 nm photons can be achieved by first preparing nanoparticles by laser ablation of the metal at 1064 nm followed by irradiation with a 532 nm laser. The mechanism of laser-induced size reduction along with experimental evidence of the hypothesis was proposed by Takami et al. [106]. In this scheme, when the laser (532 nm) irradiates the gold nanoparticles, the plasmons in the gold nanoparticles absorb photons and the electrons are excited. The temperature of the nanoparticles rises above the melting point such that they melt and become liquid. Further size reduction takes place due to vaporization of the gold nanoparticles when the temperature rises to the boiling point such that atoms and/or small particles are ejected via vaporization. The amount of ejected atoms depends on the absorbed laser energy. The maximum diameter is determined by the equilibrium between the ejected atoms and the deposition of ejected atoms back onto the nanoparticle surface. Because the ejected atoms are very unstable in aqueous solution, they tend to agglomerate and/or deposit on the gold nanoparticles remaining in the solution.

Laser-induced size reduction of gold nanoparticles that are produced by laser ablation of gold plates is a promising new technique for the preparation of size-selected nanoparticles with diameters less than 10 nm in solution. This technique is very simple, is versatile compared to other preparation techniques, and can be applied to other metals.

2.4. Ultrasonic Irradiation

In the preceding sections, stabilizers were used to control the particle nucleation and growth processes along with parameters such as the initial concentration of the reactants. Although there is an enormous amount of research being conducted with nanoparticles prepared by these methods, there are only few reports elucidating the relationship between the rates of reduction of metal ions and the size of the formed gold nanoparticles due to experimental difficulties in solution systems. Some of the difficulties include (a) the precise determination of the rate of reduction of metal ions because the reaction is often too fast to track the course of the reduction experimentally, and (b) the quantitative analysis for the concentration of unreduced metal ions that are still present in the reaction medium.

In recent years the formation of gold nanoparticles in an ultrasound field has been studied as an alternative to other methods [98, 107–109]. Caruso et al. [98]. summarizes the description of the ultrasonic irradiation phenomenon and the details of this method can be found in the references therein. The mechanisms of formation of gold nanoparticles have also been proposed before. [106, 107] In short, ultrasonic irradiation causes pyrolysis of water and other organic compounds present in an aqueous solution resulting in formation of free radicals at extremely high temperatures and pressures. These radicals reduce the gold (III) ions into gold (II), gold (I), and finally gold (0). The reduction of gold (III) with sonochemically formed radical species can be followed by a colorimetric method using NaBr. The rate of gold (III) reduction and the size of the gold nanoparticles can be controlled by the ultrasound irradiation conditions such as temperature, intensity of the ultrasound, and positioning of the reactor. However, this method yields polydisperse gold nanoparticles, which is an important problem for some applications where monodisperse solutions of gold nanoparticles are required.

2.5. Anisometric Gold Nanoparticles

The preparation and characterization of nanostructured materials has grown constantly because of their distinctive properties and potential use in technological applications. Since the electronic, magnetic, catalytic, and optical properties of metallic nanoparticles depend mainly on their size and shape (or morphology), shape control is one of the alternative tools to adjust these properties for various applications.

Nonspherical gold nanoparticles in the shapes of plate-like triangles [58, 110, 111], rods [112, 113], oblate or pancakelike [114–117], prolate or needlelike [114–117], hexagonal [110], ellipsoidal, quasi-ellipsoidal [110], and noncentrosymmetric [118] have been prepared and studied by a number of groups around the world. Some of the techniques that have been exploited to prepare shape controlled gold nanoparticles include the template synthesis method [115–117, 119–125], ultraviolet (UV) irradiation photoreduction [110], electrochemical synthesis [126], poly(tetrafluoroethylene) (PTFE) friction transfer approach [127], and grazing incidence vacuum deposition [128, 129].

In the template method, different materials are used as templates for the synthesis of anisometric gold nanoparticles. Schönenberger et al. [130]. reported the synthesis of Au nanowires using polycarbonate track-etched membranes as templates. Martin and co-workers [114–117, 119–122, 125] have explored the properties of gold nanowires prepared by electrochemically depositing Au within the pores of alumina membranes. Noncentrosymmetric gold nanoparticle structures with diameters of 26–28 nm were prepared in porous anodic aluminum films via a modified template synthesis procedure [118]. Figure 3 shows the schematic preparation of nanoparticles in an alumina template. The electrochemical preparation of nanoporous alumina films utilized a two-electrode temperature-controlled anodization cell with lead foil serving as the cathode and the polished aluminum plate as the anode. With constant stirring of the cell, anodic aluminum oxide film was grown to produce pores with 32 nm diameter and film thickness of 40–60 μm. Separation of the alumina film was achieved using a voltage reduction procedure, which created small branched pores in the barrier layer of oxide film. After rinsing and drying, the barrier side of the film was sputtered with silver and gold was potentiostatically
Figure 3. Schematic of nanoparticle synthesis: (1) porous anodic alumina film after detachment from Al substrate; (2) one face of alumina film coated with silver using plasma deposition; (3) electrodeposit silver foundation into pores; (4c) electrodeposit gold onto silver foundation to form centrosymmetric gold particles; (4n) electrodeposit layers of gold, silver, and then a second gold layer to form noncentrosymmetric gold particles; (5c and 5n) immerse film in nitric acid to remove silver foundation and silver spacing segments. deposited on a silver foundation to produce centrosymmetric and noncentrosymmetric gold nanoparticles [118].

Esumi et al. [112]. used hexadecyltrimethylammonium chloride (HTAC) (25–30 wt%) as a template for an ultraviolet irradiation technique to synthesize colloidal Au particles with morphologies ranging from spherical to needle shapes. For a 25% (w/w) HTAC concentration, spherical particles were obtained for $HAuCl_4$ concentration below 1 mM and rodlike gold particles at concentrations 5 mM and above. It was discussed that when an aqueous solution of $HAuCl_4$ is added to an aqueous solution of a cationic surfactant, $AuCl_4^-$ forms a 1:1 complex with the cationic surfactant, resulting in a precipitate. With a further increase of the surfactant concentration, the precipitate is redispersed and the solution becomes clear. This situation is understood by the view that $AuCl_4^-$ binds preferentially to the surface of rodlike micelles because of the hydrophilic property of $AuCl_4^-$ and the neutralization of micellar charge. It seems likely that binding of $AuCl_4^-$ to the surface of rodlike micelles reduced by UV irradiation results in formation of rodlike gold particles.

In the procedure developed by Chen et al. [110], an aqueous solution of $HAuCl_4$ is mixed with polyvinyl alcohol (PVA), which is used as capping material and irradiated for 48 h, resulting in platelike triangular Au nanoparticles, which developed into hexagonal shapes of about 25 nm with increased $HAuCl_4$ concentration. Also the increase in the duration of irradiation resulted in the formation of more regular platelet triangular shapes. It was reasoned that there was enough time for the reduction of $HAuCl_4$ into elemental Au, which aggregated and grew into more regular triangular shapes. But further study revealed that the crystal morphology of Au nanoparticles was predominantly hexagonal rather than triangular. The variation in Au morphology might be the result of excess gold in the solution, which facilitates the formation of hexagonal Au nanoparticles. The concentration of the capping material played an important role in the formation and morphology of Au nanoparticles. The polymer capping materials acted as molecularly dissolved surface modifiers and steric stabilizers, which influenced the crystallization of the growing Au nucleus site in a specific manner. For PVA concentrations smaller than 1.0 wt%, spherical particles were obtained and a further increase in PVA concentration was found to favor the formation of polyhedral-shaped Au nanoparticles. When polyethylene glycol was used in place of PVA as the capping material, Au nanoparticles with quasi-ellipsoidal morphology were obtained.

Gold nanorods with different aspect ratios have also been prepared with the aid of shape-inducing micelles using an electrochemical oxidation/reduction method [126]. Appropriate surfactants were employed as both the supporting electrolyte and the stabilizer for the resulting Au nanoparticles. In this approach, a gold metal plate is used as an anode and a platinum plate is used as a cathode. Both plates are immersed in an electrolytic solution consisting of a cationic surfactant (e.g., hexadecylmethylammonium bromide) and a rod-inducing cosurfactant (e.g., tetraoctylammonium bromide/tetradecylammonium bromide). A controlled-current electrolysis is carried out under constant ultrasonication and controlled temperature, resulting in the formation of cylindrical nanoparticles with a typical transverse diameter of 10 nm. The ratio of the two surfactants controls the length of

the gold nanorods formed. Hence the surrounding medium, often referred to as capping material, is of great importance as it prevents aggregation and provides the formation of the desired nanorods [113]. It has been observed, in general, that the particle size and shape are influenced by the concentrations of the capping "micellar" materials. Gold nanorods with very large aspect ratios (up to 18) have been prepared following a seed-mediated growth procedure [131, 132].

Wittman and Smith developed the friction-transfer method [133], wherein a block of PTFE is translated across the surface of a glass slide. As a result the glass surface is coated with highly oriented chains of PTFE, which can in turn orient a wide variety of substances from small molecules to polymers [133, 134] and liquid crystals [135]. Alkanethiol coated gold nanoparticles in organic solvents were introduced onto the polymer substrate and subsequently rubbed and flame treated, resulting in strong linear dichroism in the visible spectrum. The gold structures appeared as chains of spherical and rodlike particles with definite gross alignment. The elongated structures appear to be the result of heat-induced particle agglomeration [127].

Ravaine et al. [136]. demonstrated that gold nanoparticles could be formed upon UV irradiation of Langmuir–Blodgett (LB) films of positively charged amphiphiles deposited from an aqueous $HAuCl_4$ subphase. Different LB templates led to different types of Au particles. Single crystals, irregularly shaped crystals, or multiply twinned particles of different size are formed depending on the nature of the amphiphile used to prepare the LB matrix [137, 138]. Most of the particles prepared by this method are platelike particles with sizes ranging from 20 to 800 nm.

2.5.1. Optical Properties of Anisometric Gold Nanoparticles

In addition to the interest in controlling the shape of gold nanoparticles, the optical properties of these particles have attracted many researchers since the early 20th century. The optical properties of spherical gold nanoparticles were briefly discussed in Section 1.2 in terms of the surface plasmon resonance absorption peak. The surface plasmon depends on the size of the nanoparticles and many attempts have been made to experimentally correlate the absorption maximum and plasmon bandwidth to the actual size. Several factors, such as nonhomogeneous size distribution and surrounding media, complicate a strict correlation between the theory and experimental results.

The optical properties of anisometric gold particles are also of interest because, in addition to size, the absorption spectra are also strongly dependent on the shape of the nanoparticle. In the case of gold nanorods, the optical absorption spectra become split into two SPR modes: a longitudinal mode along the long axis of the rod and a transverse mode perpendicular to the first mode. The magnitude of these modes is also sensitive to the orientational order of the gold rods. With incident light polarized parallel to the main axis of the particles that are fully aligned, the spectrum displays only the longitudinal resonance. In the case of perpendicular polarization of the incident light, the spectrum displays only transverse resonance [113]. The first theoretical calculations were made by Gans [139], who extended

Mie's theory [19] to prolate and oblate spheroidal particles averaged over all orientations. The Gans theory predicts that the longitudinal resonance shifts to longer wavelengths with increasing aspect ratio (length to diameter ratio), whereas the transverse resonance shifts only slightly to shorter wavelengths [139]. Experimental evidence supporting this theory was obtained by Skillman et al. [140]. who studied the optical properties of silver ellipsoids embedded in gelatin. They found a shift in the longitudinal resonance at longer wavelengths with increasing aspect ratios of the particles.

Figure 4 shows a transmission electron microscopy (TEM) picture of gold nanorods synthesized by electrochemical reduction of $AuCl_4H$ in a micellar solution [113, 141, 142]. The same figure shows the UV-visible (UV-vis) absorption spectrum of this system. The presence of transverse and longitudinal SP modes is evident and points out to the special optical properties of these nanoparticles.

In summary, spherical gold nanoparticles differ from gold nanorods not only in shape but also in terms of the optical properties. Spherical gold nanoparticles display only one size dependent absorption maximum, whereas gold rods have two maximums depending on the aspect ratio with the longitudinal mode being more intense and shifted to longer wavelengths.

2.6. Nanoshells

Nanoshells are nanoparticles normally composed of a dielectric core (usually silica) coated by a thin metallic film, from which the term nanoshell is derived. Synthesis of these particles usually involves formation of dielectric cores (silica nanoparticles) followed by further attachment of very small colloidal gold particles on their surface that will act as nucleation sites for further reduction of gold chloride so that the dielectric nanoparticles become covered by a continuous metallic film. These colloidal systems have similar optical properties to colloidal gold in the sense that they also exhibit SPR absorption. The optical properties of these materials strongly depend on the size of the dielectric core, the thickness of the metallic thin film, and the surrounding media [143–159]. In contrast to colloidal gold, however, where the SPR peak is weakly dependent on particle size, nanoshells allow tuning the SPR peak across the visible and infrared

Figure 4. Right: Experimental UV-vis absorption spectrum of a gold nanorod sample is referred to as the transverse plasmon resonance, while the one centered at 740 nm is called the longitudinal plasmon absorption. Left: TEM image of the same solution. Reprinted with permission from [142], M. A. El-Sayed, *Acc. Chem. Res.* 34, 257 (2001). © 2001. American Chemical Society.

region over a wavelength range of hundreds of nanometers [143, 144, 147, 148, 151, 152, 156]. Thus, while nanoshells have similar properties to colloidal gold, they also allow flexibility in "tuning" their optical properties. Because of this, nanoshells have been investigated as platforms for surface enhanced raman spectroscopy [146], to decrease the rate of photo oxidation of semiconducting polymers [150], and in controlled drug delivery applications [149, 153]. In the latter, the nanoshells can be conjugated to a thermoresponsive polymer carrying a drug. Since tissue can transmit light in the near infrared region with little attenuation, transmitting infrared light to the site where release of the bioactive substance is desired can induce drug release from the thermoresponsive hydrogel [149].

In addition to the tunable optical properties of gold nanoshells composed of a dielectric core, gold nanoshells consisting of a metallic core have also been recently reported [159]. Gold nanoshells with a silver core show larger sensitivity to changes in the properties of the surrounding medium, which makes them attractive materials for biosensing applications. Additionally, these silver/gold core/shell particles also have the advantage of being tunable in their optical properties, in very much the same way as those formed with a dielectric core. Since the outer shell consists of gold, they can also be functionalized in a way similar to conventional colloidal gold [159].

2.7. Other Methods

Apart from the chemical and physical synthesis methods, biological production of gold nanoparticles using microorganisms has also been studied by several research groups utilizing the ability of these living organisms to convert Au^{3+} ions into gold nanoparticles. Beveridge and co-workers [160–163] have shown that gold nanoparticles readily precipitate in bacterial cells when the cells are incubated with Au^{3+} ions. Mukherjee et al. [164]. demonstrated that the exposure of fungus, *Verticillium sp*. (AAT-TS-4), to aqueous $AuCl_4^-$ ions resulted in the reduction of the metal ions and formation of gold nanoparticles (diameter of 20 nm). Although the exact mechanism is not known it is speculated that the gold nanoparticles are formed on both the surface and within the fungal cells (on the cytoplasmic membrane) by means of reductases. According to this speculation, the first step involves the trapping of the $AuCl_4^-$ on the surface of the fungal cells. Then, the gold ions are reduced by enzymes within the cell leading to the aggregation of metal atoms and the formation of gold nanoparticles. TEM images of the cells show the presence of gold nanoparticles on the cytoplasmic membrane, which indicates that some of the metal ions/gold nanoparticles diffuse across the cell wall and are localized on the cytoplasmic membrane. It is possible that the enzymes present on the cytoplasmic membrane also participate in the reduction of gold ions.

Following this report the same group [165] demonstrated the extracellular formation of gold nanoparticles using another fungus, *Fusarium oxysporum*. In this case, the formation of gold nanoparticles is believed to be due to reductases released by the fungus into the solution, which causes the reduction of gold ions in the solution. Although these results are promising, more research has to be done in order

to understand the mechanisms of the formation of gold nanoparticles.

Braun et al. [166] have also demonstrated that gold nanoclusters can be formed on specific surface sites of protein molecules in analogy to thin film formation of noble metals on inorganic substrates. In the early stages of thin film growth during vacuum deposition, metals first form nanometer size clusters or islands on the substrate if the condensing atoms are more strongly bound to each other than to the substrate (Volmer–Weber mode) [167]. These adsorbed metal atoms are mobile on the surface until they encounter other mobile atoms and come across special sites that have high adsorption and diffusion energies compared to the neighboring places where they are "trapped" and form clusters or islands. Nucleation theories and experimental evidence demonstrate that these clusters are formed in linear arrays (or so-called "decoration lines"), which are caused by steps on the substrate surface as well as the deviation from the perfect crystal surface leading to preferred nucleation of metal clusters on predetermined sites. These principles are also valid for metal condensation on protein molecules and their crystals. During vacuum condensation of gold on frozen enzyme complexes of lumazine synthase (from *B. subtilis*), proteasome (from *T. acidophilum*), and GTP cyclohydrolase (from *E. Coli*), nanoclusters are formed at specific surface sites (decoration). It was found that, under the experimental conditions outlined by Braun et al. [164], gold decorates the surface areas consisting of polar but uncharged residues. The quality of the decoration pattern can be influenced by the temperature of the substrate as well as by attaching dominant trapping sites onto the surface via chemisorption of small molecules or ions such as a polytungstate complex. The decoration sites on the enzyme complexes can be viewed by electron microscopy and their atomic surface structures can be determined with X-ray crystallography. These results opened ways to analyze the binding mechanism of nanoclusters to small specific sites on the surface of hydrated bio-macromolecules by physical–chemical methods. Although very little is known about the nature of the special sites on protein surfaces and why they enhance or impede cluster formation, understanding the binding mechanism may lead to decoration techniques with much fewer background clusters. This would improve the analysis of single molecules with regard to their symmetries and their orientation in the adsorbed state and in precrystalline assemblies as well as facilitate the detection of point defects in crystals caused by misorientation or by impurities.

3. SURFACE MODIFICATION AND FUNCTIONALIZATION OF GOLD NANOPARTICLES

In order to fully take advantage of the unique properties of gold nanoparticles, it is necessary to impart them with different surface functionalities. This allows the nanoparticles to be readily dispersed in nonpolar media and make them more compatible with a matrix during the formation of nanocomposites, or it can provide the nanoparticles with the specific molecular recognition capabilities of biomolecules.

A variety of methods for surface modification exist that can be implemented with nanoparticles.

Maintaining the stability of the nanoparticles upon surface modification is important. However, gold nanoparticles often tend to aggregate upon surface modification, especially when the surface functionalization proceeds with elimination of the negative charges on colloidal gold that normally keeps these particles from aggregating in aqueous solutions. Such is the case with the formation of self-assembled monolayers of alkanethiolates on colloidal gold [168, 169]. Chemical modification of gold surfaces can be performed by using alkanethiols, polymers, dendrimers, and other molecules as stabilizers. This can be achieved either by surface modification of already available colloidal gold or by the synthesis of colloidal gold with an organic monolayer in a one-step procedure. The following section gives a brief description of surface modification techniques for colloidal gold.

3.1. Monolayer Protected Clusters

Chemisorption of alkane thiols offers a facile route for creating well-defined surface chemistries on gold substrates. This area of research has been extensively explored during the last two decades [170–177]. Surface modification of colloidal gold using alkane thiols would appear to be a logical choice to modify the surface chemistry of these nanoparticles. However, chemisorption of alkane thiols eliminates the charges on colloidal gold that impart these particles with their stability in aqueous environments, leading to destabilization and hence irreversible flocculation [168, 169].

It is possible to synthesize stable thiol-functionalized gold nanoparticles in a one-step procedure. Common synthetic procedures to achieve this goal are most commonly based on modifications to the synthetic procedure originally reported by Brust et al. (described briefly in Section 2) [59, 60]. This method results in nanoparticles protected by an organic monolayer, which are commonly referred to as monolayer-protected clusters (MPCs). The alkanethiolate molecules protecting the gold nanoparticles have the potential to develop novel technological applications such as chemical sensing, catalysis, colorimetric assays for DNA detection, biosensors, etc [61, 178]. Understanding the properties of the alkanethiolate ligands may expand the range of applications of these nanoparticles. A wide variety of thiol molecules such as straight-chain alkanethiols [179, 180], glutathione [181], tiopronin [182], thiolated poly(ethylene glycol) [183], p-mercaptophenol [184], aromatic alkane thiol [185], phenyl alkanethiols [186], and γ-mercaptopropyl)-trimethoxysilane [187] have been used to prepare MPCs.

Several research groups have undertaken extensive efforts toward the synthesis and characterization of MPCs. Notable among these are the papers of Murray et al. who followed the first reports of Brust et al. [59, 60]. to develop elaborate characterizations of the gold clusters stabilized by monolayers of alkane thiols and a route to mixed monolayers of alkane thiols and ω-alkane thiols ligands on these nanometer-sized clusters [188]. The monolayers on these nanoparticles confer these systems with new surface properties and with extraordinary stability. In fact, they can be isolated and manipulated with a variety of chemical and physical procedures to the extent that they can be dried

and resuspended in solution again without compromising the stability of MPCs. Subsequent reports by this group have shown that a variety on alkanethiol chain lengths (C_3–C_{24}) [179, 180], ω-functionalized alkane thiols [189], and dialkyl disulfides [190] can be employed in the same protocol. Several groups in the world are now actively involved in the study and synthesis of these nanoparticles [40, 61, 191–197].

3.2. Place-Exchange Reaction

Although the synthesis of a number of alkanethiolate functionalized MPCs is reported in detail in the literature, more diverse surface properties can be achieved by altering the surface with different chemical groups. One method to accomplish further functionalization of MPCs is the place-exchange reaction, which has been used to obtain a wider variety of MPCs by various research groups [61, 188, 198–203]. Noteworthy are the efforts during the last decade of Murray et al. to produce MPCs with a variety of ligands by the place-exchange reaction [198, 199, 202]. In this method, the alkanethiolates of MPCs are displaced by chemisorption of other alkanethiols during incubation in a concentrated solution of alkanethiols. Two routes can be applied toward producing poly-hetero-ω-functionalized clusters: (a) *simultaneous*, exchange of a mixture of thiols onto an MPC and (b) *stepwise*, progressive exchange of different thiols, isolating and characterizing the cluster product after each step. During a typical place-exchange reaction, MPCs with alkanethiolate monolayers (RS) are functionalized with $R'S$ groups according to

$$x(R'SH) + (RS)_m MPC \rightarrow x(RSH) + (R'S)_x(RS)_{m-x} MPC$$
where x and m are the numbers of new and original ligands [188], respectively.

The rate and equilibrium stoichiometry, x, of this reaction, are controlled by factors such as the mole ratio of R′SH to RS, their relative steric bulk, and R versus R′ chain lengths [199]. The stepwise place-exchange reaction additionally reveals the extent to which an exchange reaction can displace ω—functionalized versus nonfunctionalized alkanethiolate ligands from a cluster. An important observation is that ligands with longer chains tend to displace those with short linker chains, but the displacement of ligands with long linker chains by those with short linker chains is less likely to occur. Also, short chain length, bulky, ω-functionalized alkanethiolates are the least thermodynamically stable ligands, consistent with the fact that they have a varying density of chain packing around the gold core [199].

Detailed studies of the dynamics and the mechanism revealed that the place-exchange reaction (a) has a 1:1 stoichiometry, (ii) is an associative reaction, (iii) yields the displaced ligand in solution as a thiol, and (iv) does not involve disulfides or oxidized sulfur species [198]. The time-dependent rate of place exchange has been interpreted as reflecting a hierarchy of different core surface binding sites with associated susceptibility (vertexes, edges, terraces) to place exchange [193, 198, 199]. These observations are similar to the displacement of alkanethiols on self-assembled monolayers on flat substrates [204].

3.3. Chemisorption of Alkanethiols

As mentioned, surface modification of gold nanoparticles by chemisorption of alkane thiols is a logical choice for surface functionalization of gold nanoparticles provided that the proper steps to avoid irreversible aggregation are taken. The interaction of alkanethiols with the gold nanoparticle surface causes the thiol molecules self-assemble in a well ordered, densely packed manner on the nanoparticle surface (similar to SAMs on flat substrates). Common precursors of these SAMs are aliphatic thiols with the structure of $HS–(CH_2)_nR$, where the functional group, R, stands for a variety of functionalities [172–181]. In principle, these groups can allow for further functionalization of the gold nanoparticles with ligands, proteins, and other biomolecules.

Direct chemisorption of alkanethiols on already synthesized colloidal gold produces functionalized nanoparticles similar to MPCs. However, there are some disadvantages associated with this method. Under some conditions (pH, ionic strength, alkane thiol chain length, and alkane thiol functionality) and during their functionalization, the nanoparticles can undergo irreversible aggregation or flocculation [172, 173]. This limits the use of this method for surface modification purposes. Although used to some extent by several research groups [25, 205–207], the conditions under which this method is employed usually require dilute solutions and the modified particles lack stability over long periods of time or under extreme conditions of pH, ionic strength, and temperature.

Our group has recently proposed a method that greatly facilitates the formation of SAMs of alkanethiols on colloidal gold [208]. The approach to obtain stable alkanethiol modified gold nanoparticles using this method consists of performing the chemisorption of carboxyl terminated alkane thiols in the presence of a nonionic surfactant [polyoxyethylene (20) sorbitan monolaurate (Tween 20)]. This method was developed from the observation that the physisorption of Tween 20 prior to chemisorption of alkanethiols provides a protective, stabilizing layer around the nanoparticles preventing them from aggregation by means of steric hindrance caused by the oligo(ethylene glycol) moieties on this surfactant molecule. Since the physisorption of Tween 20 on the gold nanoparticles is weak compared to the chemisorption alkane thiols, the weakly adsorbed surfactant can be displaced by alkanethiols chemisorbing onto the gold surface. The alkane thiol modified gold nanoparticles obtained by this method have remarkable stability in the sense that they can be frozen or dried and resuspended with mild sonication without suffering irreversible aggregation. Further derivatization of these particles with other molecules is possible and it is accomplished easily without formation of particle aggregates.

Often, surface functionalization with alkanethiols is only an intermediate step toward further functionalization of nanoparticles. This is the case for the place exchange reaction and further derivatization of chemically reactive groups. [182, 198–203] Another strategy involves a noncovalent coupling of ligands by means of hydrophobic interactions that consists on the formation of interdigitated bilayers [209–212]. The latter appears to be versatile enough for derivatization with a variety of compounds and the modified surfaces are remarkably stable in aqueous environments which makes this method attractive for biological applications.

3.4. Proteins and Antibodies (Immunogold)

Identification and localization of components of biological systems (e.g., visualization of proteins within a cell) using gold nanoparticles attached to an antibody that binds specifically to a protein is a commonly used method in electron microscopy studies of cells. The combination of the reliable immunological methods for producing good quality monoclonal and polyclonal antibodies and the techniques for complexing proteins onto gold nanoparticles to form immunological probes allows the investigation of a vast range of antigens in cells and tissues.

These gold conjugates can be used in a wide range of applications. The major reason for their use in electron microscopy studies is the high electron density of the gold nanoparticles coupled with the ease with which different particle sizes can be used for examination at different magnifications. Also the strong emission of secondary electrons and backscattered electrons from gold nanoparticles make the gold probes ideal for study of surface antigens and macromolecules with scanning electron microscopy (SEM) [213]. Immunogold probes give the highest possible spatial resolution to obtain structural information at the macromolecular level. Also nanogold is known to produce a more punctuate labeling pattern than eosin photo-oxidation and thus has advantages in electron microscopic quantitation and resolution of binding sites. Immunogold gives more intense stains compared to other stains and this permits much higher dilutions of primary antibody and gold conjugate, resulting in lower background.

Colloidal gold labeling techniques were first introduced by Faulk and Taylor when they absorbed antisalmonella rabbit gamma globulins to gold particles for one-step identification and localization of salmonella antigens [214]. Indirect labeling techniques with gold probes were subsequently introduced by Romano et al. who also reported gold labeling with protein A for detection of primary immunoglobulins [215]. The application to thin sections for electron microscopy was described in detail by Roth et al. and since then colloidal gold has been used in TEM for ultrastructural studies of cellular antigens [216]. Electron imaging of gold particles has also been combined with X-ray emission using an energy dispersive analyzer in SEM for immunolabeling studies [217]. To date, the method of application of gold probes to the tissues has been well documented [218]. Gold probes in sizes ranging from 1 to 40 nm have been in use for electron microscopy. But the possibility of ambiguity between small gold particles and tissue structures indicates that larger particle sizes are preferred and are best visualized by backscattered electron imaging. While all sizes of gold probes may be used to label tissue proteins, the sizes most commonly employed for SEM studies are 20–30 nm.

Gold nanoparticles may be conjugated to primary antibodies for one-step identification of antigens (e.g., with anti Human IgG) but are more usually employed as secondary antibody/protein labels. Also multiple labeling of different

cellular proteins on the same structures using different sizes of gold probes or gold probes in conjunction with other labels has become a popular method [219, 220].

On cells of eukaryotic origin, which have a net negative surface charge from anionic plasma membrane components, the membrane charge distribution is thought to be important in the movement of various soluble macromolecules across cell walls. Various methods have been employed to analyze the spatial distribution of anionic sites in tissues and to study the role played by surface charges in intracellular and intercellular dynamics. Cationic colloidal gold is one of the most used probes for this study [221–224].

Cationic gold results from the conjugation of colloidal gold particles with poly-L-lysine, which exhibits a strong positive charge at physiological pH [223]. A one-step incubation with these conjugates reveals subcellular sites bearing a net negative charge and such gold probes may be used at physiological pH and ionic strength. Cationic gold can also be tested for use in paraffin and resin embedded sections.

Gold cluster complexes offer several advantages over conventional colloidal gold for labeling. A number of different reactive groups may be incorporated during synthesis and used for covalent, site-specific attachment to biomolecules. An example of this nanogold cluster is a gold core of 1.4 nm in diameter, stabilized by tris(aryl)phosphine ligands. This is a neutral molecule, stable over a wide range of pH and ionic concentrations. It has been used to label IgG molecules, Fab' fragments, streptavidin, and other proteins, as well as smaller molecules such as peptides [225], oligonucleotides [226], and lipids [227], which cannot be directly labeled with colloidal gold.

3.5. Dendrimers and Polymers

Dendrimers and polymers can also be used to functionalize gold nanoparticles. Section 2.2 provided a description on the use of polymers for the preparation of colloidal gold. From that, it is obvious that gold nanoparticles can also be functionalized with polymers and examples of this abound in the literature. Citrate-capped gold nanoparticles have been efficiently grafted with nonionic hydrophilic polymers bearing hydroxyl groups, using disulfide anchors by the "grafting-to" strategy (in which a covalently attached polymer monolayer is formed by simple contact of the metal surface with dilute solutions of polymers) enabling their use in biological applications [228]. The resulting monolayers can be derivatized for specific recognition of analytes using unsymmetrical bifunctional linker groups or directly when the polymer bears activated sites. Two monomers used in this approach are N-[tris(hydroxymethyl)methyl]acrylamide (NTHMMAAM) and N-(isopropyl)acrylamide (NIPAAM). Derivatization of the gold surface by the disulfide bearing polymers (NTHMMAAM or NIPAAM) improved the stability of nanoparticles toward aggregation. They remained water-soluble during all the synthesis steps and could also be lyophilized and redispersed in water, indicating the complete protection of gold colloids by the polymer monolayer. Additionally, gold nanoparticles coated with the thermoresponsive polymer poly(NIPAAM) underwent conformational collapse with increased temperature, resulting

in controlled and reversible thermally induced aggregation [228].

End functionalized 3D SAMs on gold nanoparticles have been used to initiate a living cationic ring-opening polymerization reaction directly on gold nanoparticle surfaces, by the "grafting-from" technique (in which a reactive group is created on the surface that is able to initiate the polymerization, and the propagating polymer chain is growing *from* the surface) [229, 230]. Using appropriate initiators and 2-oxazoline monomers (2-phenyl-2-oxazoline/2-ethyl-2-oxazoline), ring-opening polymerization can proceed in a living manner in a "one-pot multistage" reaction, creating complex core–shell morphologies of amphiphilic nanocomposites [231]. This combination of a grafting–from reaction resulting in polymer "brush-type" shells of linear macromolecules and the introduction of a terminal mesogen by means of a termination reaction can result in stable, amphiphilic, core–shell materials with a well defined hydrophilic/lipophilic balance. Based on the synthetic concept developed for preparing dense polymer brushes on planar gold substrates [232, 233], the exposure of 11-hydroxyundecane-1-thiol (HUT)-functionalized gold nanoparticles to a trifluoromethanesulfonic anhydride vapor/nitrogen stream results in the conversion of the HUT hydroxyl groups to triflate functional groups. Addition of dry chloroform and the freshly distilled monomer (2-ethyl-2-oxazoline or 2-phenyl-2-oxazoline) at 0 °C under vigorous stirring followed by subsequent heating in an oil bath allows for polymerization to take place on the surface of the nanoparticles. The polymerization can be terminated by addition of N, N-di-n-octadecylamine (for 2-ethyl-2-oxazoline) solution in dry chloroform or piperidine [for poly(2-ethyl-2-oxazoline)] at 0 °C. The surface-bound triflate SAM is a highly efficient initiator for the cationic ring-opening polymerization of oxazolines and the triflate gegenion ensures a strictly ionic mechanism of the propagation reaction, ensuring a living and stoichiometric polymerization [232, 233].

A similar procedure for the preparation of terminally functionalized poly (N-propionylethylenimine) (PPEI) by cationic living ring-opening polymerization of 2-ethyl-2-oxazoline in a one-pot multistep reaction, by the so called "grafting-onto" approach (which involves the chemisorption of macromolecules), involves a direct combination of the fast initiation technique and a selective quantitative termination reaction [234]. The chain ends of the linear hydrophilic polymers can be further functionalized with different lipophilic moieties (methyl-, n-hexadecyl- (C_{16}), and 1,2-O-dioctadecyl-sn-glyceryl- [(C_{18})$_{2-}$]) and a monofunctional silane-coupling group. By varying the length of the double functionalized hydrophilic PPEI chain ($n = 10$, 20), surface active amphiphilic lipopolymers of controlled hydrophilic–lipophilic balance for surface functionalization can be obtained in high overall yields [234].

The fabrication of surfaces with controlled modulation of interfacial properties (e.g., wettability) involving the adsorption or grafting of "smart" (environmentally responsive) polymers onto surfaces has also been implemented on metallic nanoparticles. Chilkoti et al. [235]. used the change in optical properties of colloidal gold upon aggregation to develop an experimentally convenient colorimetric method

to study the interfacial phase transition of an elastinlike polypeptide (ELP). This thermally responsive, genetically encoded biopolymer was covalently attached to mercaptoundecanoic acid functionalized gold nanoparticles. Raising the solution temperature from 10 to 40 °C thermally triggered the hydrophilic-to-hydrophobic phase transition of the adsorbed ELP resulting in formation of large aggregates due to interparticle hydrophobic interactions, causing a color change from red to violet. Below the phase transition temperature, the Au–ELP colloids in suspension have an average interparticle distance several times greater than the colloid radius and hence appear red. Upon raising the temperature of an Au–ELP suspension, the adsorbed ELP undergoes an intramolecular hydrophilic to hydrophobic transition and the interparticle distance of the colloids in the aggregated state approaches the colloidal radius, which results in a redshift in the absorbance spectrum (*vide supra*, Section 1.2), and the suspension consequently appears violet. Cooling the suspension back to 10 °C causes the ELP to transition back to the hydrophilic state, which dissociates the colloidal aggregates and returns the absorbance maximum to 535 nm. Figure 5 shows the schematic of the reversible aggregation of ELP-functionalized gold nanoparticles [235].

In addition to linear polymers, hyperbranched molecules called dendrimers can also be used to functionalize gold nanoparticles. Dendrimers are attracting increasing attention because of their unique structures and properties [236–243]. These aesthetically appealing synthetic macromolecules are monodispersed and hyperbranched polymers constructed from AB_n monomers (AB is a monomer, n usually 2 or 3) rather than the standard AB monomers, which produce linear polymers. Their synthesis in an iterative fashion leads to a nonlinear, stepwise synthetic growth wherein the number of monomer units incorporated in each successive iteration roughly doubles (AB_2) or triples (AB_3) that in the previous cycle. Thus each repetition cycle leads to the addition of one more layer of branches—called a *generation*—to the dendrimer framework. The generation

number of the dendrimer is equal to the number of repetition cycles performed and may be easily determined by counting the number of branch points as one proceeds from the core to the periphery [236–243].

Dendrimer stabilized nanocomposite materials have unique potential for applications such as catalysis which require stable colloidal particles having surfaces that are not completely passivated by a stabilizing adsorbate. Because of the low mass density within the dendrimer interior, such monolayers are highly permeable to small molecules [244]. Thus, dendrimers can serve the dual purpose of acting as a "nanofilter" that passes small and specifically charged species, prevents other molecules from interacting with the colloid, and can function as a stabilizer.

Dendrimers are also recognized as monodispersed nanoreactors, possessing architectures that allow the preorganization of metal ions within their interiors [245]. Several noble metal nanoparticles have been prepared in the presence of dendrimers, in which the size of the nanoparticle can be controlled by the size of the dendrimers [246–250].

Two molecules of this type that are frequently used are polyamidoamine (PAMAM) dendrimers and polypropylene imine dendrimers. Au colloids in the 2–3 nm size regime have been prepared by one-phase *in-situ* reduction of an aqueous solution of $HAuCl_4$ in the presence of either second- or fourth-generation (G2 or G4, respectively) PAMAM dendrimers using $NaBH_4$ as the reducing agent. The dendrimers encapsulated the colloids, imparting stability to the aqueous colloidal solutions. The driving force for the interaction of the colloids with the dendrimers was an association of Au with the primary amine terminal groups (and perhaps the interior secondary and tertiary amines) of the dendrimer. The dendrimer generation used in such syntheses controlled the size of the resultant colloids: lower generation dendrimers gave rise to larger, less monodisperse and more aggregated colloids than those prepared using higher generation dendrimers, for a constant ratio of primary amine groups to $AuCl4^-$. Also the stability of nanoparticles decreased sharply when either the solvent or the excess free dendrimer was removed from the solution [247, 251].

Sugar-persubstituted PAMAM dendrimers (sugar balls) were synthesized by Aoi et al. [252]. Since sugar balls have highly ordered structure with arranged saccharides on the peripheries of the dendrimers and terminal hydroxyl residues that can operate as reductants, sugar balls were used to act as protective agents for gold nanoparticles, against flocculation. When Au^{3+} ions are reduced with the hydroxyl groups of the sugar balls, the hydroxyl groups are oxidized to carbonyl groups. Thus it is found that sugar balls can act as protective agents as well as reductants for the preparation of gold nanoparticles [253].

Fourth-generation PAMAM dendrimers [254] having terminal groups partially or fully functionalized with thiol groups have also been explored for the functionalization and synthesis of gold nanoparticle [255]. Diluted solutions of thiolated dendrimers and tetrachloroauric acid can be mixed and reduced with $NaBH_4$ to produce stable dendrimer functionalized gold nanoparticles. The enhanced stability with thiolated dendrimers compared to amine-stabilized materials is due to the low concentration of dendrimer required to prepare the nanocrystals.

Figure 5. Reversible aggregation of gold nanoparticles caused by the environmentally triggered phase transition of adsorbed ELP: (A) Au–ELP in the hydrophilic phase with spectra typical of isolated gold colloid and (B) aggregates which exhibit a redshift in their absorbance spectra compared to that of individual colloid in (A). 3.6. Sol–Gels

As explained in the previous sections, surface modification of gold nanoparticles imparts these systems with a variety of functionalities that makes them useful on a wide variety of applications. Surface modification can be achieved as a series of sequential steps starting with the synthesis of the particles or in a one-step procedure. For most applications the ligands are selected such that they are used both as stabilizing agents and as functional surface groups for the immobilization of other molecules onto the nanoparticle surface. With the availability of a variety of ligands, the choice of ligands is almost entirely dependent on the application in which the gold nanoparticle will be used. Most of the time, alkane thiols, polyelectrolytes, and dendrimers are used for the purpose of both surface modification and stabilization of gold nanoparticles. Often, the ligands employed may affect the electronic (optical, chemical) properties of the nanoparticles, for example, adsorption of a nucleophilic molecule on gold nanoparticles results in a redshift in surface plasmon resonance and an increase in absorbance at higher wavelengths [22, 99].

Alternative methods of preparing surface modified gold nanoparticles have been explored such as functionalization with silica by sol–gel processing. Silica has recently been utilized for the stabilization of metallic nanoparticles [256–261]. Sol–gel processing is a powerful technique that offers unique opportunities for the synthesis of optical materials in the form of thin films, fibers, and fine powders [262]. Several general approaches have been reported for the functionalization of gold nanoparticles with silica by sol–gel processing. Martino et al. used sol–gel processing in reverse micelle solutions and sequential reduction of gold salt for the creation of gold–silicate nanodispersions [263]. However, the presence of gel precursors destabilizes the inverse micelles resulting in larger nanoparticles and wider particle size distributions. Liz-Marzan et al. synthesized silica coated gold nanoparticles in a two-step process, where gold nanoparticles are first reduced by citrate and the nanoparticles are coated with silica using a silane coupling agent [256].

During the synthesis of silica coated gold nanoparticles a monolayer of a silane coupling agent [e.g., (3-aminopropyl) trimethoxysilane or *N*-(3-trimethoxysilyl) propyl ethylenediamine] is allowed to adsorb onto gold nanoparticles where the strong affinity of gold for amine groups is exploited [187, 256, 261]. In a second step, active silica (sodium silicate) is added to the dispersion promoting the formation of a thin, dense, and relatively homogeneous silica layer around the nanoparticles using the silanol groups as anchor points. At this stage, the nanoparticles can be transferred into ethanol and the silica layer thickness can be increased in a controlled way. With this method, the morphology and the concentration of gold nanoparticles over a wide range can be controlled without sacrificing the stability, and the optical properties of the gold nanoparticles agree extremely well with the predictions of Mie theory [256]. Thus, the preparation and surface modification of gold nanoparticles via sol–gel processing is another alternative to the well-established gold–alkane thiol method. Moreover, similar procedures can be used for other nanoparticles such as platinum, silver, and palladium and semiconductor particles.

4. CHARACTERIZATION

A variety of techniques are used to characterize gold nanoparticles. In general a combination of techniques is needed in order to characterize these systems because no single analytical technique can provide complete information on nanoparticles.

One of the most commonly used techniques in the study of colloidal gold is UV-vis spectroscopy. The absorption maximum, which is due to excitation of surface plasmons on the metallic nanoparticles, is observed around 520 nm for spherical gold nanoparticles. The position of this peak is only weakly dependent on the size of the gold nanoparticles [22]. However, changes in the dielectric medium around the particles can have a significant effect on the position of the SPR peak, shifting to longer wavelengths with increased values of the dielectric constant of the medium. Additionally, the SPR position also depends on the shape of the particles and their proximity to each other [17, 18, 22–25, 139]. When the separation distance between metallic nanoparticles is smaller than their radius additional resonances occur at longer wavelengths. Thus, if the individual particles approach each other to within less than one particle diameter the absorption spectra broadens and shifts to longer wavelengths. These changes in the absorption spectrum are routinely used to determine the presence of interparticle interactions such as aggregation and have also been exploited for DNA detection.

Optical absorption spectroscopy can give semiquantitative information on colloidal gold aggregation. However, the state of aggregation and the size distribution of the nanoparticles can be more accurately assessed with TEM. TEM is a very effective (and commonly used) technique for the characterization metallic nanoparticles due to their high density of free electrons. TEM gives immediate visualization of the gold nanoparticles by capturing the contrast created when a high-energy electron beam is passed through them. As electrons hit the nanoparticles on the sample grid, some of them will be scattered while the remainder are focused onto a photographic film to form an image. Unfocussed electrons are blocked out by the objective aperture resulting in an enhancement of the image contrast. The resolution limits of modern TEM are sufficient enough to image gold nanoparticles in the 1–10 nm size range. Although atomic resolution and lattice imaging are required for detailed structural analysis, a particle size distribution can be obtained at moderately low resolution for gold nanoparticles with mean diameter less than 10 nm [264–268].

Since modern applications of colloidal gold have exploited the capability to functionalize their surfaces with a variety of ligands the composition of the nanoparticles also needs to be characterized. It may be necessary to find the oxidation state of gold or the entire composition of the monolayer. X-ray photoelectron spectroscopy (XPS) is a surface sensitive technique that can provide this information [269]. Additionally, XPS can help determine the presence of contaminants remaining from the preparation procedures for gold nanoparticles (e.g., adsorption of unreduced gold cations and their corresponding anions during gold salt reduction). XPS can also be used to determine the composition of these species with high accuracy [268, 270].

Nuclear magnetic resonance (NMR) can also be used for the characterization of gold nanoparticles. This technique is based on the difference between the resonant frequency of a metal and a diamagnetic compound such as a complex or ionic solid. This difference (NMR shift or the Knight shift) is a consequence of the interaction of a metal nucleus with the conduction electrons and is measured as a fraction of the applied field. The NMR shift for [197] Au is +1.4%. This means that in a field in which a standard such as $[PtI_6]^2$ resonates at 100 MHz, the ^{197}Au resonance for metallic gold is shifted by 1.4 MHz. The measurement of the NMR shift of gold in small particulate form provides crucial information on the size at which gold nanoparticles begin to develop metallic properties, which is an important topic in nanotechnology. Moreover, NMR spectroscopy is particularly informative about the structure and chemical composition of MPCs and alkane thiol modified gold nanoparticles [180, 182, 183, 186, 271, 272]. For monolayer characterization ^{1}H and ^{13}C NMR resonances are usually measured, since mostly hydrogen and carbon are present in the monolayers adsorbed on the gold clusters/nanoparticles. In this case, strong NMR shifts are observed due to the interaction of the adsorbate nuclei with the conduction electron density of the gold surface.

Fourier transform infrared spectroscopy (FTIR) can also be used to elucidate the surface chemistry of molecules adsorbed on gold nanoparticles [272–274]. Information on the order–disorder (*gauche* defects) of the chains of the molecules or the defects near gold nanoparticle surface is obtained by measuring the vibrational energy levels of each bond (C–H, C–C, C–N) in the infrared region of the spectrum. These energy modes are characteristic to each bond and shifts in the vibration modes provide the necessary information on the structure and content of the molecules adsorbed on gold nanoparticles.

Fourier transform infrared spectroscopy can provide valuable information on the conformation and order of alkyl chains on monolayers, particularly through analysis of the (CH_2) bands. However, symmetrical bonds such as C–C appear as very weak bands or may not be detectable at all by FTIR. Thus, FTIR normally does not produce this information [275]. Symmetrical bonds, however, are readily detected using Raman spectroscopy. Thus, this technique can provide complementary information on the C–C backbones of monolayers. Other bands present in alkanethiol SAMs such as C–S and S–H bands can be analyzed easily by Raman spectroscopy, thus providing structural and chemical insight into the interaction between the alkanethiolates and the metal substrate [128, 246, 275–277]. For example, the S–H bond of alkanethiols is cleaved upon chemisorption to gold [275]. Thus, the relative intensity of the (S–H) band of free thiol and gold thiolates samples can indicate the progression of alkanethiol chemisorption. The (C–S) band in the Raman spectrum also indicates the chemisorption process and the resultant structure of the alkyl chains near the surface of gold [275, 278]. Thus, FTIR and Raman spectroscopy provide complementary information on the vibration modes in the chemisorbed monolayers on metallic nanoparticles. In this context, it is a fortunate fact that metallic nanoparticles further enhance the Raman signals [128, 146].

5. APPLICATIONS

Although colloidal gold has been used for hundreds of years, the number of applications has been limited until recently. For centuries, its main applications were as a stain for glass and fabrics and to a minor extent as a purported therapeutic agent. However, there is currently a boom on its applications, particularly within the realm of nanoscale science and engineering. In the following, a number of newer applications developed within the last decade are described. It is likely that newer applications will be developed because of the large interest in nanotechnology.

5.1. Colorimetric Assays

One of the most remarkable applications of gold nanoparticles reported in recent years is the colorimetric detection of oligonucleotides based on the optical properties of the gold nanoparticles [206, 279]. This simple and highly selective detection method has many advantages over other sequence-specific DNA detection methods currently applied in the diagnosis of pathogenic and genetic diseases. Most of the current systems make use of the hybridization of an immobilized target oligo- or polynucleotide probes labeled with radioactive ^{32}P or ^{35}S reporter groups [280–283]. Although this technique offers high sensitivity, the use of radioactive labels creates certain problems such as the disposal of the probes, the requirement of specially trained personnel, and the short shelf life. In other techniques, the radioactive labels are replaced with nonradioactive labels such as organic dyes, and the hybridization of target DNA molecules is detected by fluorescence or luminescence spectroscopy with high sensitivity [280–283]. However, the labels and the monitoring equipment are relatively expensive increasing the cost of the method.

The detection of oligonucleotides using gold nanoparticles has many desirable features such as rapid detection, a colorimetric response, and little or no required instrumentation [206, 284]. This approach involves two gold nanoparticle probes with covalently bound oligonucleotides that are complementary to a target of interest. When exposed to target strands, these nanoparticle probes are cross-linked through DNA hybridization and form networks of aggregates composed of thousands of nanoparticles. The aggregation process is accompanied by red-to-blue color change of the solution, which occurs due to changes in the SPR frequency of the gold nanoparticles. The detection mechanism is based upon the fact that when the interparticle distance between the nanoparticles is greater than the average nanoparticle diameter, the color of the aggregated appears red, but as the interparticle distance decreases the color shifts to blue providing a means of detection. Also, the melting characteristics of these networks (they have sharp melting transitions) allow one to differentiate a perfectly complementary target strand from a strand with a single base mismatch. Moreover, the color changes associated with hybridization are significantly enhanced and easily visualized even with the naked eye if the hybridized sample is processed on a solid support [284]. This method provides a simple, fast, qualitative response for the detection of mismatches in the DNA sequence [206, 284–286].

With this approach, quantitative responses can be obtained using larger gold nanoparticles [285] and incorporating silver nanoparticles into the system that allows the responses to be obtained by an inexpensive flatbed scanner [286, 287]. Since the molar extinction coefficient of 50 nm gold nanoparticles is 10^{11} M^{-1} cm^{-1} (10^8 M^{-1} cm^{-1} in case of 13 nm nanoparticles), the use of larger gold nanoparticles provides higher sensitivity assays and allows quantitative colorimetric detection. It was shown that increasing the nanoparticle size resulted in significant improvement in the extinction dampening of the surface plasmon band (indicative of oligonucleotide hybridization-induced nanoparticle aggregation) as evidenced via melting analyses. A detection range of 50 pM to 5 nM was obtained [286]. Another way to increase the sensitivity of detection and quantify the hybridization process is by incorporation of silver (Ag) to gold (Au) nanoparticles in a so-called "core–shell" scheme. In this method, silver ions are reduced to silver metal on gold nanoparticles creating core–shell Au/Ag nanoparticles that can be easily modified alkylthiol-oligonucleotides. The molar extinction coefficient of the core–shell nanoparticles is very similar to that for the silver nanoparticles alone and is larger than that for gold nanoparticles of the same size. These oligonucleotide-modified core–shell nanoparticles show similar but enhanced changes in the optical spectrum and has similar melting properties as oligonucleotide-modified gold nanoparticles when they are aggregated due to hybridization. This process increases the scanned intensity by a factor as large as 10^5 and target oligonucleotides concentrations as low as 50 fM can be measured [287].

The strong dependence of the SPR absorption band on the degree of aggregation of gold nanoparticles has also been exploited to detect heavy metals. Various metal ions like zinc, manganese, nickel, lead, cadmium, and mercury may be present in water at parts per million concentrations or higher. Some of these are toxic metal ions that pose significant public health hazards when present in drinking water. For absolute identification and total concentration assessment, ion-coupled-plasma spectroscopy is commonly used as a characterization method. However, more efficient detection can be implemented using colloidal gold.

In gold nanoparticles covered with capping agents like mercaptocarboxylic acid, the surface carboxyl groups can enable chelation of metal ions [288–290]. The principle of metal-cation based aggregation has been used by Murray and co-workers to initialize the formation of metal films and solution-phase aggregates [291, 292] similar to the aggregation of DNA-functionalized metal nanoparticles that has been used for the sequence-specific detection of the oligonucleotides [206, 279].

A colorimetric technique, particularly appropriate for otherwise largely spectroscopically silent species like trace mercury, cadmium, and lead has been demonstrated using the principle of change in color from red to blue due to the ion-chelation based aggregation of functionalized gold nanoparticles. The aggregation process produces a shift in plasmon band energy and a substantial increase in long wavelength Rayleigh scattering, which has been employed for visual detection of these ions. In this method functionalized gold nanoparticles are aggregated in solution in the presence of divalent metal ions by an ion-templated chelation process.

This caused a measurable change in the absorption spectrum of the particles. The aggregation also enhanced the hyper-Rayleigh scattering (HRS) response from the nanoparticles solutions, providing an inherently more sensitive method of detection. The increase in the HRS intensity appeared to be due to both symmetry lowering and an increase in the effective size of the chromophoric entity responsible for plasmon-enhanced HRS [293].

One of the challenges in devising colorimetric methods for the identification of these ions has been the identification of appropriately strongly binding leuco dyes capable of yielding sufficiently intensely absorbing metal/dye complexes. Thus appropriately functionalized gold nanoparticles could be used as exceptionally high extinction dyes for colorimetric sensing of heavy metal ions [293].

Rao et al. [294] investigated the effect of concentration of metal ions on the interaction of nanoparticles and chelation of ions. Figure 6 shows the ion-chelation mechanism binding two nanoparticles. Gold nanoparticles capped with α-lipoic acid were interacted with various metal ions like Cu, Fe, Ni, Mn, Cd, Zn, and Pb. It was found that in the dilute metal-ion concentration regime the metal ions bound to the carboxyl functional group of the α-lipoic acid and thereby caused observed dampening of the plasmon band. The chelation/aggregation process was reversible via addition of a strong metal ion chelator such as EDTA. The intermediate metal-ion concentration regime was characterized by the aggregation and irreversible chelation accompanied by an increase flocculation. Further increase in concentration resulted in precipitation.

Another study by Szulczewski et al. [295] on the adsorption of Hg atoms on the gold and silver nanoparticles revealed the influence of particle size on the properties of the nanoparticles. The adsorption of Hg on nanoparticles resulted in a blueshift of the surface plasmon mode, the shift being more pronounced for the smaller particles than the larger particles for the same Hg shell thickness. More research in this field is to be done in terms of improving the modest colorimetric detection limits, enhancing the chemical selectivity and sensitivity, and study of properties in the presence of metal ions.

5.2. Fluorescence Assays

Besides their unique optical properties, metallic nanoparticles metals can also exert an important influence in the fluorescence emission characteristics of fluorophores positioned in their vicinity. Two different phenomena can be observed depending on the separation distance between the surface of gold nanoparticles and the fluorophores. In general, when the separation distance is smaller than 5 nm,

Figure 6. Ion–chelation binding of two nanoparticles. Reprinted with permission from [294], S. Berchmans et al., *J. Phys. Chem. B* 106, 4647 (2002). © 2002, American Chemical Society.

strong quenching of the emission of fluorescence and dramatic reduction in the lifetimes of the excited states of fluorophores is observed [296–299]. On the other hand, when the separation distance is between 10 and 20 nm, enhanced emission of fluorescence is observed due to local concentration of the incident excitation field by the gold nanoparticles [299–303]. Although these phenomena are well known, to date, only a very limited number of applications involving nanoparticles are reported in the literature for the detection of molecules [303, 304].

In 2002, Maxwell et al. [303] reported the use of gold nanoparticles in the detection of DNA sequences and single-base mutations based on the quenching of fluorescence emission of fluorophores that are attached to the oligonucleotides. The gold nanoparticles were 2.5 nm in diameter and functioned as a "nanoscaffold" for the attachment of fluorophore-labeled oligonucleotides and as a quencher (or energy acceptor). The fluorophore-labeled oligonucleotides assembled into a constrained archlike conformation on the gold nanoparticle surface such that the thiol group and the fluorophore adsorb on the same nanoparticle. In this state, the fluorescence emission of the fluorophore is quenched by the gold nanoparticle. Upon binding of the target DNA, the constrained conformation opens, and the fluorophores separate from the surface because of the structural rigidity of the hybridized DNA, leading to an increased emission of fluorescence. Desorption of the fluorophore from the gold surface was attributed to the fact that the hybridization energy of the DNA ($\Delta H = 80$–100 kcal/mol) is considerably larger than that of adsorption energies of organic dyes on gold ($\Delta H = 8$–16 kcal/mol) [305]. Since the separation distance between the fluorophore and the gold nanoparticle in the open state is about 10 nm, nonradiative energy transfer from the excited fluorophores to gold nanoparticles was considerably decreased upon hybridization because when the nanoparticles are small (2–3 nm), nonradiative energy transfer occurs within 1–2 nm from the gold nanoparticle surface, thus resulting in a dramatic increase of fluorescence upon hybridization [306, 307].

Our group has researched how to use gold nanoparticles as platforms for displaying ligands in fluorescence-based assays that exploit the quenching phenomena exerted by gold nanoparticles on fluorophores. For this, alkanethiol functionalized gold nanoparticles are used in this detection scheme because the thickness of the SAMs is in the order of 1–3 nm [174–177], which positions the fluorophores in a region from the gold surface where the fluorescence emission is more sensitive to changes in the separation distance [296–299]. Proof on concept demonstration of this biosensing system is shown in Figure 7. The specific interaction of biotinylated gold nanoparticles with fluorophore-labeled antibiotin caused a decrease in the fluorescence emission intensity. Upon addition of soluble D-biotin, competitive dissociation of bound antibiotin caused a recovery in the fluorescence emission intensity. When the binding sites of antibiotin were saturated with D-biotin prior to the interaction with biotinylated gold nanoparticles, there was no change in the fluorescence emission, which further shows the specific nature of the interactions taking place between the biotinylated gold nanoparticles and the labeled antibody.
Figure 7. Binding and dissociation of fluorescently labeled antibiotin to biotinylated gold nanoparticles.

The biosensing scheme described could be easily generalized to other ligand–protein pairs where specific molecular interactions at the surface of the gold nanoparticles cause the separation of fluorophore labeled biomolecules from the gold nanoparticle.

5.3. Monolayers

In addition to their use in surface-enhanced Raman scattering gold nanoparticles can have uses in electro-optics and molecular electronics in the form of thin films. These applications require the assembly of the nanoparticles on solid surfaces in the form of desired one-, two-, and three-dimensional structures. Some of the strategies for the formation of gold nanoparticle thin films on solid surfaces take advantage of the ionic nature of gold [308] as well as its affinity toward thiol or amine molecules, while in some applications polymers such as poly(allylaminehydrochloride), poly(sodium 4-styrene sulfonate), and poly(ethylene imine) are used [309].

Natan and his research group exploited one of the earliest approaches to assemble gold nanoparticles onto chemically functionalized substrates [264–266, 308, 310]. In this approach, organosilanes with different functional groups are used as the linker between the glass substrates and the gold nanoparticles. Gold nanoparticles are strongly bound to the surface through covalent bonds to pendant functional groups such as CN, NH_2, or SH. The general assembly protocol is carried out completely in solution: clean glass substrates are immersed in methanolic solutions (or in toluene) of organosilanes, rinsed, and subsequently immersed in aqueous gold nanoparticle solutions. Two-dimensional arrays spontaneously form on the organosilane surface. The resulting substrates can be characterized by UV-vis spectroscopy, TEM or atomic force microscopy, and SERS. The flexibility and control that this method provides are noteworthy, such that by manipulating the particle size, particle–silane interactions and the physical and chemical properties of the substrate the nanoscale architecture can be controlled. This solution-based assembly protocol makes the substrate

fabrication routine and it also allows one to fabricate substrates with any shape or size. Therefore, gold nanoparticles monolayers can be prepared on glass/quartz slides and TEM grids. The same strategy has also been used by other groups [311–313].

Another approach to making thin films of gold nanoparticles on solid substrates is by functionalization of both substrate and the nanoparticles and chemically coupling them via functional groups [273]. Gold nanoparticles can be functionalized with a ligation partner such as ketone and then chemoselectively immobilizing them onto planar gold substrates presenting SAMs of aminooxy groups. Ketone and aminooxy groups react selectively to form a chemically stable oxime, and they are unreactive toward thiol that is essential for the preparation of gold nanoparticles as well as the monolayer film. The resulting films of ketone-functionalized gold nanoparticles are fairly stable and can be characterized with ellipsometry, grazing-angle infrared spectroscopy, and electrochemistry. Since this technique requires mutually exclusive reactivity of pairs of functional groups, even among a number of potentially reactive functional groups, only the two chemoselective ligation partners will react with each other. Because the reaction can tolerate the presence of a diverse functionality so that protecting-group manipulations are unnecessary, it has been also used to conjugate peptides and proteins onto surfaces [314].

Metal nanoparticle loading on surfaces can be increased by the use of additional linker molecules to bind more nanoparticles to the surface [265, 292, 315] by the modification of the surface by preadsorption of polyelectrolytes (layer-by-layer adsorption) [316, 317] or by repeated washing and reexposure of the substrates to nanoparticles solutions [318, 319]. In the layer-by-layer adsorption method, functionalized molecular linkers are first immobilized onto a substrate followed by dipping into a solution of unmodified gold nanoparticles to immobilize a layer of nanoparticles on the linker layer. The resulting nanoparticle layer is then immersed again into the solution of linkers for further immobilization. Repeating sequentially the adsorption processes results in a multilayer film. While this method is attractive for producing well-defined multilayers, corruption of the films may occur via the repetitive immersion and rinsing process and the issue of how this method can be applied to thin film fabrication on any desired substrates is yet to be addressed. In order to overcome this problem, Leibowitz et al. [313]. suggested an alternative and simpler pathway for the production of thin films on substrates of any type. The procedure involved a one-step, exchange–cross-linking–precipitation route, where ligands (that is, alkanethiols) on gold nanoparticles were place-exchanged with α, ω-functionalized dithiols, which in turn caused crosslinking and precipitation of gold nanoparticles on the surface of the substrates. This route may be written as

$$(Au)_n - SR + HSR'SH \rightarrow SR'S - (Au)_n \cdots$$
$$\rightarrow -[SR'S - (Au)_n]_m - precipitation$$
in which (HSR'SH) is the dithiol and (SR) is the alkane thiol. The structural and electronic properties of the thin films produced by this method were found to be comparable with thin films derived from a stepwise layer-by-layer

method. Moreover, since one can produce thin films in a single step using this method, it offers a much simpler route for preparing nanoparticle thin films on almost any substrate.

5.4. Biosensors

Current research in biosensor technology is leaning toward the use of gold nanoparticles as an important component of biosensing platforms due their unique optical and electronic properties. Recently, Jia et al. [320]. constructed a horseradish peroxidase (HRP) biosensor using sol–gel processing and gold nanoparticles in a three-dimensional network. In this study, gold nanoparticles were chemisorbed onto thiol groups on the sol–gel network, and HRP was adsorbed onto the surface of gold nanoparticles. Here, gold nanoparticles acted as tiny conduction centers that facilitated the transfer of electrons (produced in the enzymatic reaction where hydrogen peroxide was oxidized) to the electrode surface. Since gold nanoparticles were assembled into a multilayer, the enzyme loading on the biosensor was increased resulting in better signals. Also, both gold nanoparticles and sol–gel had little effect on enzyme activity, imparting the biosensor with high sensitivity and good stability.

In 1996, Chen et al. [321] reported that the addition of gold nanoparticles with sizes ranging from 10 to 30 nm to a glucose biosensor resulted in the enhancement of glucose oxidase (GOD) activity. They found that 10 nm gold nanoparticles caused more increase in the GOD activity than 30 nm gold nanoparticles. In their following report, they used even smaller gold nanoparticles (less than 10 nm) to investigate further enhancement in the enzymatic activity. The enhanced activity of GOD was attributed to the quantum size effect, which is related to electron transfer between the nanoparticles and protein molecules, which could elucidate the enhancement of enzyme activity. According to this concept, the surface of metallic clusters is always electron deficient, and the redox potential of nanoparticles is closely related to particle size and is relatively high. When the atoms contained in a particle decrease as the particle size decreases, the redox potential of the nanoparticle increases causing stronger affinity to electrons. Although the enhancement effect of gold nanoparticles on enzyme activity is observed qualitatively and further investigation is necessary, it was an important step for the development of better glucose biosensors.

Based on the observations made on the glucose sensor in which gold nanoparticles enhanced the enzymatic activity, it was considered that gold nanoparticles could also be useful for DNA sensors [322–328] considering that gold nanoparticles allow immobilization of biomolecules and could be assembled on gold substrates. The quartz crystal microbalance (QCM) is widely used for DNA sensing and allows real-time measurement of DNA binding and hybridization at the nanogram level. Its potential for DNA hybridization detection has been demonstrated recently. The detection limit of this device could be improved by using DNA-functionalized gold nanoparticles in a probe/target/probe-nanoparticle sandwich fashion where the amount of DNA hybridized is increased significantly by introducing DNA-functionalized gold nanoparticles on the QCM surface. This

method causes an amplified frequency shift and substantially extends the sensitivity limits of the QCM detection system. Liu et al. [327] studied the effect of the size of gold nanoparticles on the detection sensitivity enhancement of a QCM system, and they found that the amount of mass change on the QCM sensor increased as the gold nanoparticle size increased until 40 nm and decreased thereafter.

Signal enhancement using gold nanoparticles is not just limited to QCM; Lyon et al. [329] utilized gold nanoparticles in the signal enhancement of SPR immunosensing. When gold nanoparticles are incorporated into the SPR biosensing surface such that surface immobilized antibody interacts with antigen–gold nanoparticle conjugate, an increased SPR sensitivity to protein–protein interactions was observed. Picomolar (pM) detection of human IgG has been realized using gold nanoparticle enhancement, with theoretical detection limits for this technique being much lower [328].

6. CONCLUSIONS

The rapid growth in the number of applications that colloidal gold has found during the last decade has expanded to new levels. It is likely that this material will be considered more than a simple stain for glass, a marker for TEM studies in molecular biology, or a good model system for colloidal science. Novel applications will be found in the field of nanotechnology and particularly in combination with biological molecules. Ordered assemblies and arrays of these particles may provide materials with novel properties. Supramolecular crystals have been explored and may find novel applications. More importantly, novel technologies will emerge that use this material and exploit its unique optical and electronic properties. One of the fields that will likely encounter fast growth in the near future is the implementation of metallic nanoparticles in fluorescence detection schemes. Nanoparticle alloys of gold and other noble metals such as silver will allow further flexibility in fine-tuning the optical and electronic properties of this material. Additionally, the optical properties of anisotropic nanoparticles could be implemented to great advantage in surface enhancement of fluorescent emission and Raman scattering. For example, nanorods of this material would concentrate the electric field at the end of the nanorod and this could be exploited to greatly increase the natural fluorescence of biological molecules such as DNA. It is likely that electronic properties such as coupling of SPR modes could be directed at the nanoscale level using assemblies of nanorods for spatially directed transduction of electronic and/or optical excitations. The boom in the number of applications of this material is only likely to continue expanding into more sophisticated applications during the coming years.

GLOSSARY

Anisometric gold nanoparticles   Nonspherical gold nanoparticles.

Deoxyribonucleic acid (DNA)   A macromolecule consisting of one or two strands of linked deoxyribonucleotides.

DNA hybridization   Formation of the double helical structure of DNA by pairing of two complementary single strands of DNA.

Fluorescence   The emission of light by a substance after absorbing energy from light of usually shorter wavelength. When an incident light source excites the electrons of a substance these will jump to higher excited levels. When they return to the ground level then energy is released as photons.

Fluorescence resonance energy transfer (FRET)   The radiationless transfer of excitation energy from a donor to an acceptor. When this transfer occurs the emission of fluorescence by the donor is decreased. The acceptor may or may not be fluorescent. If the acceptor is fluorescent, emission will occur from the acceptor instead of the donor. FRET is a distance-dependent interaction that occurs over distances of 1–10 nm.

Monolayer protected clusters (MPCs)   Metallic clusters covered by an organic monolayer that prevents their irreversible aggregation. These nanoparticles are most commonly formed by reduction of a noble metal salt in the presence of a surface-active substance that forms a monolayer on the surface of the growing clusters, thus limiting their further growth and stabilizing them against aggregation.

Nanoshells   Metallic nanoparticles consisting of a metallic shell surrounding a dielectric core. Recently nanoshells have also been prepared that consist of a metallic core surrounded by a metallic shell consisting of a different metal.

Self-assembled monolayers   Molecular assemblies that are formed spontaneously by immersion of a substrate in to a solution of active surfactant in a solvent.

Surface enhanced emission of fluorescence   The increased emission of fluorescence resulting when fluorophores interact with the enhanced electromagnetic field around metallic nanoparticles.

Surface enhanced Raman spectroscopy (SERS)   The dramatic increase in the intensity of an otherwise weak Raman signal produced by rough metallic surfaces. This increase can be as high as 10^4–10^6 or even 10^8–10^{14} for some systems. The main contribution to this enhancement is due to the concentration of the electromagnetic field in the vicinity of rough metallic surfaces.

Surface plasmons   The free electrons on the surface of a metal that behave like a quasi-free electron gas. They represent the quanta of the oscillations of surface charges and can behave like real surface waves. They can be excited by the electric field of electromagnetic radiation.

Surface plasmon resonance (SPR)   The condition at which the frequency of the incident electromagnetic radiation couples with that of the oscillating electrons on the surface of a metal.

CONTENTS

1. INTRODUCTION

Only a few years ago technology had mainly to do with macroscopic systems and aggregates with micrometer-scale properties. The situation changed fundamentally with the rise of nanotechnology; this technology will have an essential influence on the development of new devices in all or almost all fields of technology, medicine, biology etc., and these developments will influence our future life considerably.

It is well known that nanosystems can have properties which are distinctly different from those of macroscopic systems: properties which are well defined and clearly fixed in the bulk are very often no longer typical features in nanophysics and nanotechnology. If the particle number is decreased so that the size of the system is in the nanometer region, new effects emerge which have no counterpart in other fields of physics, chemistry, and technology.

Let us give an example. The melting temperature of a macroscopic system is usually well defined, and the system is thermally stable up to the melting point. Of course there can be phase transitions but the various phases define stable configurations. In contrast to macroscopic systems, the melting temperature of a nanosystem in general depends on the particle number and is also a function of the outer shape of the system. Moreover, the melting temperature of certain nanosystems is not defined and not clearly fixed, which can be explained by the faster occurrence of sublimation compared to the melting process.

This is a completely new situation, in particular in connection with materials research. Clearly, the construction of nanomachines and other aggregates is based on components whose material properties have an essential influence on the function on such systems. Therefore, the definition and classification of material properties at the nanolevel is a particular challenge and is just at the beginning. Within such a program not only do further sophisticated experiments have to be prepared, but also specific methods for the theoretical treatment of such systems have to be selected and refined carefully.

Nanotechnology will also lead to drastic new insights in connection with biological systems, not only by the manipulation of the features of existing biological structures, but also with respect to questions as "What is a biological system?" or, quite generally "What is life?" It is usually assumed that biological features are strongly correlated with systems of sufficiently large complexity, in particular, in connection with complex molecules. But do we really need complex systems and complex organic molecules, respectively, for all phenomena which arise in connection with biological (living) systems? Obviously this must not be the case [1], a sufficiently small system consisting of an inorganic monatomic material (aluminum) shows surprisingly new effects in analogy to those which are typical for biological systems. How far has such an Al system to be reduced in order to show such features? In the micrometer realm the system behaves completely nonbiologically. However, if the size is of the order of a few nanometers, such new effects emerge.

What is the adequate theoretical treatment of such and similar nanoeffects? How relevant in this context are the usual methods of solid state physics, which have been successfully applied to the bulk state? In order to be able to answer these questions more specifically, let us mention the following often observed characteristics of nanosystems.

The properties of nanosystems vary strongly with temperature—much more than in the bulk of the crystal. This fact can lead to the effect that certain nanosystems (e.g., nanomachines) work properly only within a relatively

small temperature window, since components (or even the whole nanosystem) lose their stability outside this temperature window.

The reason for this temperature sensitivity is obvious and is explained by the following fact [2]. As the surface atoms are, in general, less bonded than bulk particles we expect that the structure and dynamics are more sensitive to variations in temperature. This is for example, the case for the mean-square displacements at the surface and also for anharmonic effects, leading to the effect of premelting; that is, the crystal is molten in the surface region already below the melting temperature. Since the relative number of surface atoms increases with decreasing size of the system, these effects are large in the case of nanosystems and, as we have already remarked, the melting temperature T_{mn} of the whole nanosystem is in general far below the melting temperature T_m of the bulk. Furthermore, below T_{mn} various specific structure transformations [3] can take place in connection with systems of nanometer size. All these effects can influence the function of nanosystems and have to be considered carefully.

Also this behavior of nanosystems makes clear that the basic principles of solid state physics can hardly be extended to the realm of systems with nanometer size. For example, the concept of phonons cannot be extended to nanosystems and we have to use other methods for the determination of the particle dynamics in such systems. Only a few concepts, which work well in the description of bulk states, can be used for the characterization of nanosystems. In conclusion, the typical features of the solid in the bulk (periodic structure, harmonic behavior) can be no basis for the theoretical description of nanosystems, and the system under investigation has to be analyzed carefully with respect to the theoretical treatment.

However, the principles of modern surface physics are often useful within the analysis of nanometer-scale properties. The reason is obvious: In the case of nanosystems a great fraction of atoms belong to the surface region of the system and determine essentially their behavior, and such nanosurface effects can be much larger than those of semi-infinite surface systems. For example, in the case of sufficiently small nanoclusters no particle of the system can be considered as a bulk particle since the distances of all the particles to the surface are smaller then the cutoff radius for the interaction.

In this chapter we introduce methods which are adequate for the theoretical treatment of nanosystems. These methods have been discussed critically and, in some cases, proposals are made to improve them under consideration of recent research results. The material is not only an introduction to the state of the art for researchers and professors, but is also benefits advanced students.

In this work we had to restrict ourselves to the study of the structure and dynamics of the atoms which form nanosystems (machines, aggregates, clusters etc.); we do not deal with nanostructured materials or with electronic properties of nanosystems (quantum dots, quantum computers, etc.). Clearly, the structure and dynamics of atoms are determined by the electrons, but only in connection with the interaction

between the particles, and these interactions are of fundamental importance for the understanding of the structural and dynamical behavior of nanosystems.

In the study given here we will concentrate on the *molecular dynamics* method, since this method is the most powerful tool in the theoretical treatment of nanosystems; within this method the structure and dynamics of the particles can be investigated as a function of temperature. This is important since the nanometer-scale properties are in general very sensitive to small variations in temperature, as we have already outlined above. The molecular dynamics method is described in detail, and also models and methods for the description of interaction potentials which are needed in connection with molecular dynamics calculations.

We also discuss the Monte Carlo method. While this tool is restricted to the study of structural properties, it has, on the other hand, the advantage that it can be used to treat quantum systems.

We start our considerations with the quantum-theoretical treatment of nanosystems, that is, with the methods of quantum chemistry. Here the discussion concentrates on the Hartree–Fock method and the density-functional formalism. However, we have restricted ourselves to a few brief statements. The reason is the following: until now, these methods only allowed the determination of *zero-temperature* properties, and as we have already discussed, temperature effects are of considerable importance in connection with nanosystems. In particular, the nanoproperties are in general very sensitive to small variations in temperature and, therefore, it should hardly be possible to conclude from *zero-temperature* data (Hartree–Fock method, density-functional formalism) to *non-zero-temperature* properties.

2. QUANTUM-THEORETICAL TREATMENT OF NANOSYSTEMS

2.1. Approximations

For sufficiently small systems, that is, systems with a particle number not larger than a few hundred, the methods of theoretical quantum chemistry are useful. The main disadvantage of these approaches is that they are only applicable for systems at zero temperature, and this is a far-reaching restriction in connection with nanosystems, since temperature effects play a central role here, at least for metallic nanosystems. Furthermore, quantum chemistry is not able to say something about the dynamics of the atoms as, for example, the phonons.

The central problem of quantum chemistry is to find an approximation for the electronic Schrödinger equation. The nuclei are fixed at first; only the electrons are treated quantum mechanically (Born–Oppenheimer approximation). In a further step the displacements of the nuclei can be easily treated.

The direct solution of the electronic Schrödinger equation

$$\widehat{H}\Psi = E\Psi \tag{1}$$

is not possible, either in an analytical way nor within the frame of numerical methods. The approximate solution of

(1) can only be achieved on the basis of relatively drastic simplifications for the wave function Ψ. The loss of precision is only then acceptable when a certain inaccuracy is compensated by another; only in this way can we obtain useable results for the structure and the binding energies of the system under investigation [4].

2.1.1. Hartree–Fock Approximation

For systems with more than 300 electrons only the most simple ansatz for the wave function Ψ is applicable, and this is expressed by the Hartree–Fock approximation [5] which has the following form:

$$\Psi_{HF} = [\varphi_1(\mathbf{r}_1), \ldots, \varphi_n(\mathbf{r}_n)] \tag{2}$$

where n is the number of electrons. Each electron is modeled by a wave function $\varphi_i(\mathbf{r}_i)$ and includes a spin function. The brackets $[\cdots]$ in (2) denote antisymmetrization and consider the Pauli principle. The optimization of the wave functions $\varphi_i(\mathbf{r}_i)$, which is necessary because ansatz (2) is very simple, leads within the frame of the variational procedure to the Hartree–Fock equations

$$\widehat{F}\varphi_i = \varepsilon_i\varphi_i \tag{3}$$

In other words, the three-dimensional Hatree–Fock Eq. (3) replaces the $3n$-dimensional Schrödinger equation (1), and this is a drastic simplification. However, the Fock operator depends on the wave functions $\varphi_i(\mathbf{r}_i)$ which one actually wants to know and, therefore, for the solution of (3) an iteration procedure is needed.

Despite the enormous simplifications the Hartree–Fock equations are only applicable to simple cases, for example, atoms or small molecules. Therefore, it is necessary to approximate the wave functions $\varphi_i(\mathbf{r}_i)$ by a superposition of basis functions $b_\nu(\mathbf{r})$:

$$\varphi_i(\mathbf{r}) = \sum_\nu B_{\nu i}b_\nu(\mathbf{r}) \tag{4}$$

This approach is called linear combination of atomic orbitals (LCAO) since for the functions $b_\nu(\mathbf{r})$ atomic orbitals have been used in the early stage. Presently almost exclusively "contracted Gauss-type orbitals" (CGTOs) are used,

$$b_\nu = \left\{\sum_\gamma d_\gamma \exp(-\eta_\gamma r^2)\right\} x^k y^l z^m \tag{5}$$

which are centered at the nuclei of the system. By the use of these basis functions the Hartree–Fock method becomes an efficient procedure [4]. More details and specific techniques, respectively, are given in the solid state literature, in particular in [5].

2.1.2. Density-Functional Formalism

The theoretical foundations of this method have been developed by Hohenberg and Kohn in 1964 [6]. Within the conventional treatment of the n-electron system the external potential $v_{ex}(\mathbf{r})$, produced by the charge of the nuclei, determines uniquely—together with the n electrons—the Hamiltonian of the system and, therefore, the properties of the ground state, at least in principle. In the work by Hohenberg and Kohn it is outlined that in the case of a nondegenerated ground state instead of n and $v_{ex}(\mathbf{r})$ also the one-particle density $n(\mathbf{r})$ can be used for the unique characterization of the many-electron system.

The external potential $v_{ex}(\mathbf{r})$ of the n-electron system is uniquely determined by the one-electron density $n(\mathbf{r})$. Also the energy E_0 of the ground state is a unique functional of this density $n(\mathbf{r})$:

$$E_0 = E_0[n(\mathbf{r})] \tag{6}$$

Since the one-particle density $n(\mathbf{r})$ determines the number of electrons (with the normalization condition $n = \int n(\mathbf{r})d\mathbf{r}$), it contains the information about the wave function of the ground state. Here, the external field $v_{ex}(\mathbf{r})$ is not restricted to Coulomb potentials; $v_{ex}(\mathbf{r})$ has merely to be local and, therefore, it can also be applied to external electrical fields. Further, a variational principle exists for the one-particle density $n(\mathbf{r})$: The functional of the total energy $E[n(\mathbf{r})]$ becomes stationary if $n(\mathbf{r})$ is given by the density of the ground state. Let us consider the electron density $n'(\mathbf{r})$ with $n'(\mathbf{r}) \geq 0$ and $n = \int n'(\mathbf{r})d\mathbf{r}$. Then, the energy $E[n'(\mathbf{r})]$ is always larger than the exact energy of the ground state E_0: $E[n'(\mathbf{r})] \geq E_0$, and we have $E[n'(\mathbf{r})] = E_0$ in the case of the exact ground state density $n(r) = n'(r)$. If $E[n(\mathbf{r})]$ can be differentiated, the Euler–Lagrange equation

$$\frac{\delta E[n(\mathbf{r})]}{\delta n(\mathbf{r})} = \mu \tag{7}$$

can be deduced if the particle number n remains constant; μ is the chemical potential.

Although the details of the density-functional formalism are not given here, it should be mentioned that Kohn and Sham proposed a method for the treatment of the kinetic energy [7]: In the treatment of the many-particle problem the kinetic energy is not easy to determine since this energy part is large in comparison to the entire energy and, therefore, the kinetic energy has to be calculated very precisely. Kohn and Sham proposed a method for that which is presently the basis for most numerical calculations in connection with the density-functional formalism.

2.1.3. Discussion

The Hartree–Fock method begins conceptionally with the description of individual electrons interacting with the nuclei and all the other electrons of the system. In contrast to this picture within the density-functional formalism the total energy of the whole electron system is considered. There are three terms: the kinetic energy, the Coulomb energy due to the electrostatic interactions among all the charged particles, and the so-called exchange-correlation energy for which the actual expressions are unknown. Within the LDA

the exchange-correlation energy is taken from the many-electron interactions in an electron system of constant density, which are known, or more specifically: Within the LDA it is assumed that the exchange-correlation energy of an inhomogeneous system is given in an infinitesimal volume $d\mathbf{r}$ by that of a homogeneous system. The LDA turned out to be convenient in connection with numerical calculations and is surprisingly accurate. The LDA is exact for an ideal metal where the electron density is a constant and, therefore, this approximation is less precise for systems with a varying electron density. Within the density-functional formalism instead of the electron density we have the one-electron densities, which are expressed by one-electron wave functions which are similar to those used within the Hartree–Fock approximation, that is, the wave functions $\varphi_i(\mathbf{r}_i)$ (Section 2.1.1).

It is not clear *a priori* which of the two approaches, the Hartree–Fock method or the local density-functional formalism, gives a better description. For the applicability of both methods the effective interaction range of the electrons is of importance. The Hartree–Fock method works better if the interaction range is of the order of several interatomic distances. This is because the molecular orbitals, which are used in Hartree–Fock based methods for the description of correlation effects, are quite large (they are extended over several interatomic distances). On the other hand, if the range of many-body effects is short, that is, smaller than interatomic distances, then the local density-functional formalism should be applied; in such cases a description with mathematical objects like molecular orbitals is extremely slowly converging.

For large molecules there is a further method which has been applied successfully [4]. This approach extends the Hartree–Fock method and is known as the MP2 approach (MP2: Möller–Plesset, second order perturbation theory). This MP2 approach can only be applied if already a good Hartree–Fock result for the system under investigation could be obtained. On the basis of this Hartree–Fock result an improved description is possible if the approximations typical for the Hartree–Fock approach are corrected by means of perturbation theory (MP2). It turned out that results based on MP2 calculations are more accurate than those obtained by the density-functional formalism [4].

2.1.4. Applications

Hartree–Fock Method A lot of interesting applications exist in connection with the Hartree–Fock method. Here we would like to list some selected works that are typical for various topics in connection with this method.

Specific Nanosystems Articles include: theoretical study of the catalytic properties of Pt/Fe nanoclusters [8], ion channeling on nanofilms [9], structure and thermodynamics of carbon and carbon/silicon precursors to nanostructures [10], size-dependent oxidation of hydrogenated silicon clusters [11], tomonaga–luttinger parameters for quantum wires [12], interactions in chaotic nanoparticles [13], Hartree–Fock dynamics in highly excited quantum dots [14], and Coulomb interactions in carbon nanotubes [15]. Further information is given in [16–40].

Surface Investigations Articles include: Hartree–Fock studies of surface properties of $BaTiO_3$ [41], effect of basis set superposition error on the water-dimer surface [42], *ab initio* Hartree–Fock study on surface desorption process in tritium release [43], *ab initio* Hartree–Fock study of Bronsted acidity at the surface of oxides [44], and structure and bonding of bulk and surface theta-alumina from periodic Hartree–Fock calculations [45]. More information concerning surface investigations is given in [46–54].

Molecules Articles include: a comparison of finite difference and finite basis set Hartree–Fock calculations for the N_2 molecule [55], exact solution of the Hartree–Fock equation for the H_2 molecule in the linear-combination-of-atomic-orbitals approximation [56], from the nonplanarity of the amino group to the structural nonrigidity of the molecule [57], and coupled Hartree–Fock calculations of origin-independent magnetic properties of benzene molecule [58]. Further information is given in [59–67].

Metals Articles include: metal dissolution in aqueos electrolyte: semi-empirical Hartree–Fock and *ab initio* molecular dynamics calculations [68], density-functional computations of transition metal NMR chemical shifts: dramatic effects of Hartree–Fock exchange [69], electronic structure and orbital ordering in perovskite-type $3d$ transition metal oxides studied by Hartree–Fock band structure calculations [70], Hartree–Fock ground state of the composite fermion metal [71], and localized-orbital Hartree–Fock description of alkali-metal clusters [72]. More information about metals is given in [73–84].

Biological Systems Articles include: *ab initio* quantum mechanical study of hydrogen-bonded complexes of biological interest [85], combining implicit solvation models with hybrid quantum mechanical/molecular mechanical methods: a critical test with glycine [86], and an efficient coupled Hartree–Fock computational scheme for parity-violating energy differences in enantiomeric molecules [87]. Further information about biological systems is given in [88–95].

Islands Articles include: shape and stability of heteroepitaxial metallic islands: effects of the electronic configuration [96], spin depolarization in quantum dots [97], and magnetic-field dependence of the level spacing of a small electron droplet [98]. More information is given in [99–103].

Specific Application (Hartree–Fock)

Ab Initio Models for ZnS Clusters The Hartree–Fock molecular orbital method has been applied in the study of ZnS clusters [104–106]. The electronic structure of ZnS is localized; this can be shown, for example, by the density matrix approximation. The influence of vacancies and cluster edges on the charge distribution have distinct damping effects on it. The influence of the ZnS vacancy on the electronic structure of the $6 \times 6^*2$ cluster is shown in Figure 1, where the cluster is labeled according to the rings and layers [104–106]. According to Figure 1 the changes are local and there is a distinct damping near the vacant site on both the sulfur and the more metallic Zn ending surfaces.
Figure 1. Charge density isosurface of the $6 \times 6^{*}2$ cluster, where the ZnS monomer is removed from the middle of the zinc (left) and sulfur (right) surfaces. The isosurface is colored according to the density difference between the clean and the defect clusters. Courtesy of J. Muilu, Biomedicum, Helsinki.

Density-Functional Formalism Also, many interesting studies in connection with the density-functional formalism have been published. We have selected some of them which we think are important. The density-functional formalism has been applied to the following problems.

Nanostructures Articles include: organic and inorganic nanostructures: an atomistic point of view [107], *ab initio* study of quantum confined unpassivated ultrathin Si films [108], surface effective-medium approach to the magnetic properties of 3d adatoms on metals [109], towards controlled production of specific carbon nanostructures—A theoretical study on structural transformations of graphitic and diamond particles [110], and semiclassical density functional theory: Strutinsky energy corrections in quantum dots [111]. More information about this topic is given in [112–123].

Nanoparticles, Nanoclusters, and Clusters, Including Cluster Methods Articles include: theoretical study of the catalytic activity of bimetallic RhCu surfaces and nanoparticles towards H_2 dissociation [124], adhesion of nanoparticles to vesicles: a Brownian dynamics simulation [125], influence of quantum confinement on the electronic and magnetic properties of (Ga,Mn)As diluted magnetic semiconductors [126], first mixed valence cerium-organic trinuclear cluster as a possible molecular switch: synthesis structure and density functional calculations [127], Structures of small gold clusters cations: Ion mobility measurements versus density functional calculations [128], a theoretical study of Si_4H_2 cluster with *ab initio* and density functional theory methods [129], new insights into the structure of supported bimetallic nanocluster catalysts prepared from carbonylated precursors: a

combined density functional theory and EXAFS study [130], and Structures and spectra of gold nanoclusters and quantum dot molecules [131]. Further information is given in [132–181].

Molecules Articles include: infrared spectra and density functional calculations of the $SiCO_4$ molecule in solid argon [182], a density functional model for tuning the charge transfer between a transition metal electrode and a chemisorbed molecule via electrode potential [183], a density functional study of possible intermediates of the reaction of dioxygen molecule with non-heme iron complexes [184], and van der Waals interaction of the hydrogen molecule: an exact implicit energy density functional [185]. More information about molecules is given in [186–197].

Biological Systems Articles include: density functional theory-based molecular dynamics of biological systems [198], a self-consistent charge density functional based tight binding scheme for large biomolecules [199], density functional theory and biomolecules: a study of glycine, alanine, and their oligopeptides [200], compared performances of the molecular orbital and density functional theories for fragments of biomolecules [201], DFT calculations on the energy thresholds of DNA damages under irradiation conditions [202], and electronic structure of wet DNA [203]. Further information about biological systems can be found in [204–229].

Droplets and Islands Articles include: heterogeneous nucleation on mesoscopic wettable particles: a hybrid density functional theory [230], electronic properties of model quantum-dot structures in zero and finite magnetic fields [231], structure and stability of superfluid He_4 systems with cylindrical symmetry [232], effect of oxide vacancies on metal island nucleation [233], arsenic flux dependence of island nucleation on InAs(001) [234], and first-principles studies of kinetics in epitaxial growth of III–V semiconductors [235]. Further information is given in [236–253].

Metals Articles include: investigation of the metal binding site in methionine aminopeptidase by density functional theory [254], generalized spin orbital density functional study of multicenter metal systems [255], density functional theory study on the geometric, electronic and vibrational structures of alkali metal porphyrin complexes [256], and infrared spectra and density functional theory calculations of group 4 transition metal sulfides [257]. More information about metals is given in [258–270].

Nanotubes Articles include: first principles calculations for electronic band structure of single-walled nanotube under uniaxial strain [271], theoretical study of structure-dependent Coulomb blockade in carbon nanotubes [272], theoretical tools for transport in molecular nanostructures [273], electronic structures of capped carbon nanotubes under electric fields [274], and Fullerene based devices for molecular electronics [275]. More information concerning nanotubes is given in [276–290].

Nanowires Articles include: Fe nanowires on vicinal Cu surfaces: *Ab initio* study [291], Pentagonal nanowires: A first principles study of the atomic and electronic structure [292], Simulation of quantum transport in nanoscale systems: Application to atomic gold and silver wires [293], Quantum transport through one-dimensional aluminum wires [294]. Further information about wires and nanowires, respectively, is given in [295–304].

Specific Application (Density-Functional Theory)

1. Electronic conductance through monatomic Na wires coupled to electrodes has been studied using the LDA and the Friedel sum rule. Conductance (G) is found to exhibit even–odd behavior. When the number L of atoms in wires is odd, G has the quantized value of

$$G_0 = \frac{e^2}{\hbar \pi}$$

which is stable with respect to variations of the wire geometry. On the other hand, G is smaller than G_0 for even L and is dependent on the wire geometry in this case. This behavior results from the charge neutrality and resonant character due to the sharp tip structure of the electrodes and may appear in other monovalent atomic wire such as gold. More details concerning this study are given in [305, 306] and in Figure 2.

2. On the basis of density-functional calculations of model systems for the active site, Rod et al. have suggested a mechanism for the ammonia synthesis catalyzed by the enzyme nitrogenase [307, 308] (see also Fig. 3). The mechanism can explain many experimental observations including the obligatory H_2 release. The authors have also suggested a mechanism behind the observed CO frequency shift upon CO adsorption on the FeMo co-factor [308]. In [309] the enzyme catalyzed reaction with the reaction catalyzed by a Ru surface is compared and it is explained why the two reactions need different conditions (low temperature and pressure as opposed to high pressure

Figure 3. Left panel: The MoFe protein, component of the enzyme nitrogenase, which catalyzes the ammonia synthesis from atmospheric nitrogen. The active sites, where the synthesis is going on, are depicted by atom specific coloring, while the remaining atoms are colored green. Atoms have been removed from the structure in order to make the active sites visible. Right panel: The FeMo cofactor $MoFe_7S_9$ (homocitrate) is the active site, where N_2 bins and react with protons and electrons. Courtesy of T. H. Rod, The Scripps Research Institute, Department of Molecular Biology, La Jolla.

and temperature). On the basis of that, the authors give suggestions to how the ammonia synthesis can be (electro)catalyzed at low temperature and pressure on a surface; they also discuss the properties that such a surface should have. Reference [310] is basically a summary of the above plus work by Per Siegbahn, but with emphasis on what we can learn from the cross interaction between surface science and biological science.

The methods, which the authors have applied, are pretty much standard surface science density-functional theory methods, namely density functional calculations using a plane wave basis with cutoff energy of 25 Rydberg. They have used Vanderbilt ultrasoft pseudopotentials [311] and soft pseudopotentials [312] (for sulfur) to describe the core part of the atoms. The generalized gradient approximation in the form of Perdew–Wang [313] and revised Perdew–Burke–Enzerhoff [314] has been used to describe the exchange-correlation term. The FeMo co-factor is antiferromagnetic, so spin dependent exchange-correlation functionals have been used.

Remarks Concerning Metallic Systems

The quantum theoretical treatment of metal systems, for example, clusters, is a particular challenge. The reason is that the electronic structure of such systems is rather complex which is directly connected with the features of metals. Metal clusters obviously cannot be treated within the Hartree–Fock method [4]; accurate calculations are only available for very small clusters (up to Al_6). However, the density-functional formalism works well and reliable for larger clusters (for example, Al_{146}). More details are given in [315].

2.1.5. Density-Functional Formalism at Nonzero Temperature

The Hartree–Fock method and the density-functional formalism are only able to describe systems at zero temperature. However, the structure and also the dynamics of metallic nanosystems (for example, Al clusters) are sensitive to small variations in temperature: Relatively small changes in temperature can lead to drastic effects in connection with the atomic structure and dynamics, and the properties at zero temperature can become meaningless. Therefore, the following question arises: Can the methods of theoretical quantum chemistry be extended to nonzero temperatures? In principle, this is possible within the framework of density-functional formalism. Since this point is important for future developments, let us discuss the situation in somewhat more detail, in particular, with respect to the changes in the formalism when we go from zero to nonzero temperatures.

Within the density-functional formalism the density $n(\mathbf{r})$ is of relevance and its determination is in any case a quantum mechanical problem for all temperatures. Let us consider a system of N electrons of mass m and charge $-e$ which are distributed around positive charges of magnitude $Z_1 e, Z_2 e, \ldots$ at positions $R_1, R_2, \ldots$. The Hamiltonian $\widehat{H}$ is given in the second-quantized representation by

$$\widehat{H} = \widehat{T} + \widehat{U} + \widehat{W} \tag{8}$$

where

$$\widehat{T} = \frac{\hbar^2}{2m} \int \nabla \psi^+(\mathbf{r}) \nabla \psi(\mathbf{r}) \, d\mathbf{r} \tag{9}$$

is the kinetic energy operator. $\psi(\mathbf{r})$ and $\psi^+(\mathbf{r})$ are annihilation and creation operators. The operator $\widehat{U}$ describes the mutual repulsion, both among the electrons and the ions:

$$\widehat{U} = \frac{1}{2} \iint d\mathbf{r} \, d\mathbf{r}' \frac{e^2}{|\mathbf{r} - \mathbf{r}'|} \psi^+(\mathbf{r}) \psi^+(\mathbf{r}') \psi(\mathbf{r}') \psi(\mathbf{r})$$
$$+ \frac{1}{2} \sum_{\substack{i,j \\ i \neq j}} \frac{Z_i Z_j e^2}{|\mathbf{R}_i - \mathbf{R}_j|} \tag{10}$$

$\widehat{W}$ in (8) is given by

$$\widehat{W} = \int dr \, v(\mathbf{r}) \psi^+(\mathbf{r}) \psi(\mathbf{r}) \tag{11}$$

where $v(\mathbf{r})$ is an external potential arising from the nuclei. The electron density $n(\mathbf{r})$ is given in the ground state $|\phi\rangle$ by the expectation value

$$n(\mathbf{r}) = \langle \phi | \psi^+(\mathbf{r}) \psi(\mathbf{r}) | \phi \rangle \tag{12}$$

For *zero temperatures* Kohn and co-workers [6, 7] showed that for a nondegenerate $|\phi\rangle$, $v(\mathbf{r})$ is (to within a constant) a unique functional of $n(\mathbf{r})$ and the correct $n(\mathbf{r})$ minimizes the ground state energy

$$E_0 = \langle \phi | \widehat{H} | \phi \rangle \tag{13}$$

which is a unique functional of $n(\mathbf{r})$:

$$E_0 = E_0[n(\mathbf{r})] \tag{14}$$

With (12) we have

$$E_0[n(\mathbf{r})] = \int v(\mathbf{r}) n(\mathbf{r}) \, dr + F[n(\mathbf{r})] \tag{15}$$

where

$$F[n(\mathbf{r})] = \langle \phi | \widehat{T} + \widehat{U} | \phi \rangle \tag{16}$$

Equation (15) defines a variational principle for the ground state energy of an electron gas in an external potential $v(\mathbf{r})$, in which $n(\mathbf{r})$ is the variable function. However, from this density-functional formalism we can only extract *zero-temperature properties* for an electron gas, which fundamentally determines the system properties; all calculations reported in literature have been done on the basis of this zero-temperature approach.

It is, however, possible to extend this formalism to nonzero temperatures, and this has been done by Mermin [316]. In the case of nonzero temperatures the equilibrium electron density in a grand canonical ensemble is given by

$$n(\mathbf{r}) = \text{Tr}\{\rho_0 \psi^+(\mathbf{r}) \psi(\mathbf{r})\} \tag{17}$$

where ρ_0 is the grand canonical density matrix

$$\rho_0 = \frac{\exp\left[-\frac{\widehat{H} - \mu \widehat{N}}{k_B T}\right]}{\text{Tr}\left\{\exp\left[-\frac{\widehat{H} - \mu \widehat{N}}{k_B T}\right]\right\}} \tag{18}$$

μ is the chemical potential, and $\widehat{N}$ is the particle number operator. Mermin showed [316] that in a grand canonical ensemble for a given temperature T, chemical potential μ, and external potential $v(\mathbf{r})$ the quantity

$$\Omega[n(\mathbf{r})] = \int d\mathbf{r} \, v(\mathbf{r}) n(\mathbf{r}) + G[n(\mathbf{r})] - \mu \int d\mathbf{r} \, n(\mathbf{r}) \tag{19}$$

with

$$G[n(r)] = \text{Tr}\{\rho_0 (T + U + k_B T \ln \rho_0)\} \tag{20}$$

is equal to the grand potential

$$\Omega = k_B T \ln \text{Tr}\left\{\exp\left(-\frac{\widehat{H} - \mu \widehat{N}}{k_B T}\right)\right\} \tag{21}$$

when $n(\mathbf{r})$, expressed by (17), is the correct equilibrium density. In particular, Merwin showed that the correct density minimizes (19) over all density functions that can be associated with an external potential $v(\mathbf{r})$.

Since the properties of systems with surface (for example nanosystems) are very sensitive to variations in temperature, zero-temperature approaches, such as the Kohn–Hohenberg–Sham formalism, are not appropriate for the treatment of such systems (in particular metallic nanosystems). It is, in our opinion, in many cases an insufficient approximation to use zero-temperature methods for

the determination of the electronic properties, which determine chiefly the entire properties of the system. Such an analysis is only correct for zero temperatures but has often been used for the determination of the structure and dynamics for nonzero temperatures, in particular in connection with molecular dynamics calculations (see Sections 5.3.4 and 5.3.5, embedded-atom method and quantum molecular dynamics introduced by Car and Parrinello). Such calculations can be misleading since nonzero temperature data are coupled with zero-temperature properties. Therefore, instead of the Kohn–Hohenberg–Sham approach Mermin's formalism, briefly discussed above, should be used in such calculations. But to the authors knowledge there exists no analysis on the basis on Mermin's non-zero-temperature formalism.

3. BASIC PROPERTIES AT THE NANOLEVEL

Specific material properties of nanosystems can be essentially different from the corresponding properties of macroscopic systems (the solid in the bulk). This has been demonstrate in [317] in connection with the thermal stability and the melting temperature of specific nanostructures.

An essential reason for this tendency is the fact that a great fraction of the particles (atoms, molecules) of such small systems belong to the surface region and the surface particles are less bonded than the particles in the bulk, leading to relatively strong anharmonicities even at low temperatures, that is, far below the melting temperature. Even the melting process takes place far below the bulk melting temperature or is simply not defined as has been demonstrated in connection with the nanosystem discussed in [317]. The thermal behavior of such systems is a complex function of the particle number and the outer shape of the systems. This must have consequences for the theoretical description of the material properties for systems of nanometer size. Let us discuss this point in more detail.

3.1. Relevance of the Theoretical Bulk Methods for the Description of Nanosystems

In modern materials research, solid-state physics becomes more and more relevant, in particular, the microscopic structure and dynamics. For sufficiently large systems, the *standard model* of solid-state physics is in most cases adequate for the description of material properties. The standard model of solid-state physics is based on the *ordered structure* and on the assumption that the vibrational amplitudes of the atoms are sufficiently small, so that it can work within the *harmonic approximation*. In other words, the dynamics is expressed by phonons. For example, the specific heat at constant volume is expressed in terms of phonons by the expression [318, 319]

$$c_V = k_B \sum_{p,q} \frac{\alpha^2 \exp(\alpha^2)}{(\exp(\alpha) - 1)^2} \qquad (22)$$

with

$$\alpha = \frac{\hbar \omega_p(\mathbf{q})}{k_B T} \qquad (23)$$

where $\omega_p(\mathbf{q})$ are the phonon frequencies, $\mathbf{q}$ is the wave vector, and p labels the phonon branches.

Electronic properties are of course also essential. For example, for the understanding of superconductivity, the electron–phonon interaction is important.

In conclusion, within conventional materials research, the basis for the microscopic description of the material properties is the ordered structure and the harmonic approximation; the properties of a solid are given in terms of phonons $\omega_p(\mathbf{q})$, where the phonon frequencies $\omega_p(\mathbf{q})$ are dependent on the crystal structure and the electronic properties.

That is the situation in connection with macroscopic systems. But this can no longer be the basis for the description of the properties of nanosystems.

As was outlined in [317], nanosystems do not behave in such a simple way: They are in most cases disordered and the dynamics cannot be approximated by phonons because the harmonic approximation is not applicable. Therefore, at the nanolevel materials research gets a new dimension. Even the melting temperature is no longer a fixed material property, as is demonstrated in connection with the nanostructure discussed in [320].

Nanosystems are already disordered at relatively low temperatures and the harmonic approximation breaks down completely; that is, even at relatively low temperatures, phonons are no longer definable. In such cases the anharmonicities cannot be considered as small perturbations to the harmonic case.

In other words, the standard model of solid-state physics breaks down at the nanolevel in many cases, and we have to introduce other methods and quantities for the description of material properties. This is the case for any anharmonic and disordered system (for example, liquids in the bulk) and, for simplicity, we want to explain the principal points by means of a bulk liquid.

In the case of liquids, usual crystallography and phonons are not relevant but the structure must be described by statistical mechanics, that is, in terms of correlation functions, for example, the pair correlation function $g(r)$, which can be measured; r is the relative distance between the atoms and molecules, respectively. In the case of metals, the interaction is given by the pair potential $v(r)$, where r is again the relative distance between two particles.

In conclusion, instead of the phonons $\omega_p(\mathbf{q})$, correlation functions like $g(r)$ and the interaction potential $v(r)$ become the relevant quantities:

$$\omega_p(\mathbf{q}) \rightarrow g(r), v(r)$$

For example, the isothermal compressibility χ_T is defined by the expression [320]

$$\frac{1}{\chi_T} = -\frac{1}{V} \left(\frac{\partial p}{\partial V} \right)_T \qquad (24)$$

and we need an expression for the pressure p (V is the volume); that is, we need the "equation of state," which can be formulated in terms of $g(r)$ and $v(r)$ as follows:

$$p = \rho k_B T - \frac{\rho^2}{6} \int r \frac{\partial v(r)}{\partial r} g(r) \, d\mathbf{r} \qquad (25)$$

If we apply Eq. (25) to Eq. (24), the isothermal compressibility χ_T can be expressed in terms of $g(r)$ and $v(r)$:

$$g(r), v(r) \rightarrow \chi_T$$

In the case of nanosystems, the anharmonicities are very strong and the thermal expansion becomes a relevant quantity. Moreover, a great fraction of the atoms belong to the surface region and it turns out that the thermal expansion at the surface is distinctly larger than in the bulk. Therefore, the theoretical picture must be able to describe the thermal expansion.

The thermal expansion coefficient α_p can be expressed by the isothermal compressibility χ_T and the thermal pressure coefficient γ_V:

$$\alpha_p = \chi_T \gamma_V \qquad (26)$$

In order to get the thermal expansion coefficient α_p, we have to calculate both the quantities χ_T and γ_V. We already did that for χ_T, and for the description of

$$\gamma_V = \left(\frac{\partial p}{\partial T} \right)_V \qquad (27)$$

we need again the pressure p, that is, the equation of state, which is given for the bulk by Eq. (25).

In other words, the thermal expansion coefficient α_p can also be expressed in terms of $g(r)$ and $v(r)$,

$$g(r), v(r) \rightarrow \alpha_p$$

and this is the case for all material properties (in some cases, higher order correlation functions are needed).

It should be mentioned that the thermal expansion is zero for the harmonic case; that is, within the phonon picture the thermal expansion cannot be described.

In conclusion, in the case of disordered systems with strong anharmonicities (e.g., liquids in the bulk and nanosystems), phonons are not suitable for the adequate description of such systems but must be expressed in terms of $g(r)$ and $v(r)$.

In the case of nanosystems, a great fraction of particles belong to surface regions, and the quantities of $g(r)$ and $v(r)$ are not simply dependent on the relative distance r of the particles but are also dependent on the distance of the particles from the surface. Because there is in general more than one surface in the vicinity of a particle the situation can be very complex.

Even for systems with only one surface—for example, a semi-infinite liquid—the situation is already rather complex. In this case, the surface (defining the x, y plane) separates the liquid from the vapor phase, and the density ρ varies with respect to the coordinate z (the coordinate perpendicular to the surface), so that we have $\rho = \rho(z)$.

In the liquid–vapor transition zone, the pressure p cannot be described by Eq. (25); that is, p is no longer a constant and independent of the coordinates but becomes an anisotropic quantity [321]: At any point z in the transition zone, we have a normal pressure component p_1 and a tangential component p_2. While p_1 and p_2 are different from each other in the liquid–vapor transition zone both quantities are of course identical in the isotropic bulk phases. With $\mathbf{r}_{12} = (x_{12}, y_{12}, z_{12})$, the statistical mechanical expressions for p_1 and p_2 take the form [321, 322]

$$p_1 = \rho(z)k_B T - \frac{1}{2} \int \rho(z)^2 \rho^{(2)}(\mathbf{r}, z) \nabla v(r) \frac{z_{12}^2}{r} \, d\mathbf{r} \quad (28)$$

$$p_2 = \rho(z)k_B T - \frac{1}{2} \int \rho(z)^2 \rho^{(2)}(\mathbf{r}, z) \nabla v(r) \frac{x_{12}^2}{r} \, d\mathbf{r} \quad (29)$$

where we assumed for simplicity that the pair potential at the surface is the same as in the bulk. In Eqs. (28) and (29) the distribution function $\rho^{(2)}(\mathbf{r}, z)$ is used instead of the correlation function $g(\mathbf{r}, z)$.

The pressure components p_1 and p_2 can be used for the determination of the surface tension γ which is expressed by

$$\gamma = \gamma(T) = \int_{-\infty}^{\infty} [p_1 - p_2(z)] \, dz \qquad (30)$$

With Eqs. (28) and (29), the statistical mechanical expression for the surface tension is expressed by

$$\gamma(T) = \frac{1}{2} \int_{-\infty}^{\infty} \rho^{(2)}(\mathbf{r}, z) \nabla v(r) \frac{x_{12}^2 - z_{12}^2}{r} \, d\mathbf{r} \, dz \qquad (31)$$

As outlined in [321], the surface tension and its temperature dependence are of particular interest in the description of thermodynamic properties.

In the case of nanosystems, the situation concerning the statistical mechanical description is more complex than for semi-infinite systems. This is because various surfaces, which are most often close together, have to be considered. Therefore, the statistical mechanical expressions [in analogy to Eqs. (28), (29) and (31)] will hardly be relevant in connection with theoretical investigations. A certain potential for applications should be given in the case of disordered nanofilms that are positioned on surfaces.

The more direct way is to perform *molecular dynamics* calculations (details of this computational method are given in the next section). In such calculations the interaction potential, in particular the pair potential $v(r)$, is of fundamental relevance and, therefore, in Section 5 we will give a brief overview of this topic.

3.2. Wear at the Nanolevel

Within the frame of Hamiltonian systems, such as molecular dynamics systems, *friction* in the macroscopic sense is not defined. At the microscopic, molecular dynamics level, the forces are formulated as quantities which are dependent on the structural configuration (particle positions) but not on the particle velocities. Therefore, a force which is proportional to the velocity cannot be introduced at the microscopic level and, therefore, a friction constant in the macroscopic sense is not definable at the microscopic

level of modern materials research. In the case of non-Hamiltonian systems friction can be studied by nonequilibrium molecular dynamics; this topic is briefly discussed in Section 4.2.4.

At the nanolevel, wear is described by specific complex processes. Let us discuss this point by means of an example: Figure 4 shows a molecular dynamics model for a wheel which is pressed on a surface. The wheel rotates with 10^{12} revolutions in a second. The wheel has a temperature of 300 K and it has a diameter of approximately 10 nm. If the wheel is pressed on a surface, wear effects emerge and, according to the magnitude of the force vertically applied, the wheel can even be destroyed, as can be observed in Figure 4.

In summary, friction (wear) at the microscopic level is a complex process and cannot be characterized by only one constant as is the case of macroscopic friction. In our example (Fig. 4), wear is dependent on the specific structure of the surface and also on the shape of the wheel.

3.3. Conclusions

Theoretical materials research at the nanolevel not only needs solid-state physics but due to the strong anharmonicities and the strongly disturbed structure of many nanosystems (even far below the melting temperature of the corresponding bulk state) the basics of statistical mechanics and the theory of liquids are very often more appropriate as the basis for the theoretical description of such systems. In such cases the standard model of solid-state physics [ordered structure and harmonic approximation, here summarized by the symbol $\omega_p(\mathbf{q})$] is not suitable, and we come to the description in terms of correlation functions and interaction potentials that we have briefly characterized by $g(r)$ and $v(r)$. Within this statistical mechanical description time correlations are of course included, for example, the velocity autocorrelation function whose Fourier transform has to be considered as the generalized phonon density of states.

Figure 4. A molecular dynamics model for a wheel consisting of aluminum atoms; it rotates with 10^{12} rev/s and its diameter is approximately 10 nm. The molecular dynamics method is discussed in more detail in Section 4.

However, due to the strong anharmonicities, the dynamics of such systems is characterized by a broad range of different dynamical states including small local vibrations and complex diffusion processes. This situation indicates that the development of a suitable *standard model* for the theoretical description of nanosystems will hardly be possible; even in the case of liquids in the bulk a standard model could not be found up to now.

Therefore, the most important tool for the investigation of nanosystems is the molecular dynamics method since anharmonicities are treated within this method without approximation, and this is important because the typical anharmonicities in connection with nanosystems cannot be considered as small perturbations to the harmonic approximation. No other microscopic method in condensed matter physics allows one to treat anharmonicities without approximation; this is only possible in connection with phenomenological models. Thus, the molecular dynamics methods should be considered as the *standard method* for the theoretical description of nanosystems. On the basis of these considerations we come to the following rough classification scheme:

$$
\begin{array}{c}
\omega_p(\mathbf{q}) \\
\text{(standard model for the solid)} \\
\downarrow \\
g(r),\, v(r) \\
\text{(statistical mechanics)} \\
\downarrow \\
\text{molecular dynamics} \\
\text{(standard method for nanosystems)}
\end{array}
\tag{32}
$$

In other words, with decreasing particle number disorder effects and anharmonicities increase and this has an influence on the theoretical treatment. In Section 4.2.3 more details concerning the molecular dynamics method will be given.

4. MODELING OF NANOSYSTEMS

4.1. The Hamiltonian

4.1.1. General Formulation

The quantum mechanical modeling of a system with N particles of masses m leads to the Hamiltonian

$$
\widehat{H} = \sum_{i=1}^{N}\left(-\frac{\hbar^2}{2m_i}\nabla_i^2 + V_i(\mathbf{r}_i)\right) + \sum_{\substack{i,\,k=1 \\ i\neq k}}^{N} V_{ik}(\mathbf{r}_i,\mathbf{r}_k)
\tag{33}
$$

Here $V_i(\mathbf{r}_i)$ is an externally applied potential in which the ith particle is located, where $\mathbf{r}_i = (x_i, y_i, z_i)$ is the position of the ith particle; $V_{ik}(\mathbf{r}_i,\mathbf{r}_k)$ denotes the interaction potential between the two particles i and k. To analyze or to describe the characteristics of the system one has to solve the according many-particle Schrödinger equation

$$
\widehat{H}\psi = E\psi
\tag{34}
$$

where E is the total energy of the N-particle system. The wave function ψ depends on the $3N$ coordinates (configuration space) of all particles:

$$\psi = \psi(x_1, y_1, z_1, \ldots, x_N, y_N, z_N) \qquad (35)$$

If we consider nanosystems, most often external potentials are not present and the particles involved are atoms which in turn have to be divided into nuclei and electrons. In this case the interaction potential in Eq. (33) is given by the Coulomb potential

$$V_{ik}(\mathbf{r}_i, \mathbf{r}_k) = \frac{Z_i Z_k e^2}{|\mathbf{r}_i - \mathbf{r}_k|} \qquad (36)$$

where Z is the according particle charge number including the sign of the charge.

With a closer look at this many-particle problem it becomes clear that an exact quantum mechanical solution can probably never be achieved. Here is an example: A relatively small nanocluster of only 100 argon atoms consists of 100 nuclei and 1800 electrons, which is a total of 1900 particles. In this case the configuration space consists of 5700 dimensions. The key point with numerical solutions of the Schrödinger equation is the spatial integration. With the assumption that a division of each dimension into 100 steps is sufficient for an accurate calculation we would have to compute the summation of 10^{11400} volume elements. Needless to say, this is not possible without further, most intensive simplifications and approximations.

4.1.2. Approximations

The treatment of many-particle systems in condensed matter physics is usually based on the fact that core electrons do not influence the properties of such many-particle systems and, therefore, the system can be divided into ions and valence electrons. A further approximation is to treat the ions and electrons separately (Born–Oppenheimer approximation) which leads to two Schrödinger equations—one for the electrons, where the ion positions appear as parameters only, and another for the nuclei, where the electron energy E_{el} acts as an effective potential—so that the Hamiltonian for the ions takes the form

$$\widehat{H} = \sum_{i=1}^{N_I} \left(-\frac{\hbar^2}{2m_i} \nabla_i^2 + V_i(\mathbf{r}_i) \right) + V(\mathbf{r}_1, \ldots, \mathbf{r}_{N_I}) \qquad (37)$$

with

$$V(\mathbf{r}_1, \ldots, \mathbf{r}_{N_I}) = V_I(\mathbf{r}_1, \ldots, \mathbf{r}_{N_I}) + E_{\text{el}}(\mathbf{r}_1, \ldots, \mathbf{r}_{N_I}) \qquad (38)$$

where N_I is the number of ions. Equation (38) means that the dynamics of the ions take place within an effective potential V which is formed by the potential energy of the direct ion–ion interaction V_I and the entire electronic energy E_{el}, where E_{el} depends on the coordinates of the ions and therefore plays the role of an indirect ion–ion interaction. But it must be emphasized that an unique splitting into ions and valence electrons is not always possible.

Under the assumption that the change of the electronic arrangement (core electrons) around each ion or atom is sufficiently small the potential energy V may be expanded:

$$V(\mathbf{r}_1, \ldots, \mathbf{r}_{N_I}) = \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^{N_I} v_{ij} + \frac{1}{6} \sum_{\substack{i,j,k=1 \\ i \neq j \neq k}}^{N_I} v_{ijk} + \cdots \qquad (39)$$

Here the terms on the right of Eq. (39) represent pair, triplet, and many-body contributions of the ionic or atomic interactions and $\mathbf{r}_1, \ldots, \mathbf{r}_N$ are the positions of the N ions or atoms.

If the polarization of the core electrons is negligibly small, then—compared with the pair terms—the triplet and higher terms diminish rapidly in significance. Then the obvious final step of approximation is to neglect them entirely. This is called the pair potential approximation,

$$V(\mathbf{r}_1, \ldots, \mathbf{r}_{N_I}) = \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^{N_I} v_{ij} = \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^{N_I} v(|\mathbf{r}_i - \mathbf{r}_j|) \qquad (40)$$

with $|\mathbf{r}_i - \mathbf{r}_j| = r_{ij}$.

Referring to our example with the 100 argon atoms, with Eq. (40) the problem has been reduced to a 9900-fold sum of values from one pair potential function v with only one dimension, which is the distance of two particles. This simplification expands the calculability of the many-particle problem with today's computer power up to millions of particles—at least under certain conditions. On the other hand, such a far-reaching, if not to say brute simplification, has a strong influence on the applicability as can be easily imagined [323].

In almost all cases the ions or atoms behave classically and, furthermore, only the pair interaction is effective. Then, instead of the Hamiltonian (39) we get the classical Hamilton function in the pair potential approximation. For monatomic systems it reads

$$H = \sum_{i=1}^{N_I} \frac{p_i^2}{2m} + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^{N_I} v(r_{ij}) \qquad (41)$$

If three or higher body forces are effective, instead of the pair potential approximation for the potential energy the expansion (39) has to be used. Pair potentials and many-body forces will be discussed in more detail below.

4.2. Description of Nanosystems

4.2.1. Simple Models

How can we determine the properties of a many-particle system on the basis of a given Hamiltonian? In the conventional treatment of this problem we need simple models. Quite generally, simple models can be obtained by controlled approximation from the general cases (37) and (41). In connection with many-particle systems the general mathematical formulation of the problem is in most cases so complex that simplifying models have to be chosen but often cannot be obtained by controlled simplifying steps from the

general cases (37) and (41), respectively. It is therefore a rule to introduce simple models just for convenience.

The "simple model" of solid state physics is the crystalline solid in the harmonic approximation (Section 3.1). On the basis of this model one is able to determine successfully the properties of a lot of materials. However, there are also a lot of cases where this simple model is not applicable, even when it is extended by specific assumptions. For example, the silver subsystem of the solid electrolyte α-AgI is highly disordered and shows strongly anharmonic behavior [324–326]; a simple model for α-AgI and similar materials is not available. Also in the case of liquids and gases "simple models" have not been found. Even in the case of gases with low densities we cannot simply restrict ourselves to the first terms in the virial expansion in the calculation of the pressure. This is because the expansion obviously converges slowly and, therefore, even in the case of low density one has to consider more than the first two terms [327]. The virial coefficients can be expressed in terms of the pair potential $v(r)$ [see Eq. (40)], but the expressions are getting complicated for the higher order virial coefficients and in practical calculations only the first terms are accessible. The virial expansion would define a "simple model" if for a broad class of gases a restriction on the first two terms would be realistic.

In summary, only for a specific class of many-particle systems could a "simple model" be found: It is the crystalline solid in the harmonic approximation, but in most cases anharmonicities cannot be considered as small perturbations to the harmonic approximation (see also the discussion in Section 3.1). This is also the case for typical nanosystems since a great fraction of atoms are more or less close to the surface region of the system, and surface particles behave strongly anharmonically. In small nanosystems (for example, clusters with a few hundred of atoms) even the innermost particles cannot be treated as bulk particles since the cutoff radius for the interaction potential is larger than the distance to the surface. The atoms at surfaces are less bonded than in the bulk and, therefore, the mean-square amplitudes of the atoms are significantly larger than at the surface leading to relatively strong anharmonicities. This phenomenon can be observed even at low temperatures—low in comparison to the melting temperature of the bulk system.

4.2.2. Dynamical-Matrix Solutions

Surfaces not only give rise to *quantitative* effects but can also be the source for new qualitative phenomena. For example, the phonons, which describe the dynamics of the system, are expressed by the dynamical-matrix solutions, and these solutions are obviously not complete for systems with surfaces.

In order to show that in more detail let us consider a monatomic crystal with a free surface and let M be the mass of the atoms of the crystal. In this semi-infinite system there is only a two-dimensional invariance of the force constants which implies that the normal-mode solutions of the equation of motion

$$\ddot{u}_\alpha(\mathbf{l}) = -\sum_{l',\beta} \frac{1}{M} \Phi_{\alpha\beta}(\mathbf{l},\mathbf{l}')u_\beta(\mathbf{l}') \qquad \alpha,\beta = x,y,z \qquad (42)$$

is a superposition of two-dimensional Bloch functions

$$u_\alpha(l_{12},m) = \sum_{n_1,n_2,j} u_{\alpha,j}(m,\mathbf{q})\exp\{i[\mathbf{q}\cdot\mathbf{r}_0^{l_{12}} - \omega_j(\mathbf{q})t]\} \qquad (43)$$

where $\mathbf{l} = (l_1,l_2,m)$. Here u_α is the displacement from the equilibrium positions in the α-direction, $l_{12} = (l_1,l_2)$ specifies the points in the layers parallel to the surface, and m labels the planes of the crystal which are parallel to the surface starting with $m = 1$ for the outermost layer. The frequencies $\omega_j(\mathbf{q})$ are given by the solutions of the dynamical matrix, where j is the branch index. Further, n_1, n_2, denotes summation over the wave vectors $\mathbf{q} = (n_1,n_2)$; the allowed values of n_1 and n_2 are determined by the periodic boundary conditions: $n_i = 0,\pm1,\ldots,\pm N_i/2$, $(i = 1,2)$ where N_1 is the particle number in the x-direction and N_2 in the y-direction of layer m.

Now we consider the center-of mass velocity of layer m, and we want to distinguish between the bulk and surface contributions. Summation of $u_{\alpha=z}(l_{12},m)$ over all the particles in layer m and the use of well-known identities yields

$$\varepsilon_z(m) = \sum_{l_{12}} \dot{u}_z(l_{12},m) = \varepsilon_{b,z}(m) + \varepsilon_{s,z}(m) \qquad (44)$$

where

$$\varepsilon_{a,z}(m) = -i\sum_{n_1,n_2,k} \omega_k(\mathbf{q})u_{z,k}(m,\mathbf{q})\exp\{-i\omega_k(\mathbf{q})t\}$$
$$\times N_1 N_2 \delta_{n_1,0}\delta_{n_2,0} \qquad a = b,s \qquad (45)$$

which leads to

$$\varepsilon_{a,z}(m) = -i\sum_k \omega_k(0)u_{z,k}(m,0)\exp\{-i\omega_k(0)t\}$$
$$a = b,s \qquad (46)$$

$\varepsilon_{b,z}(m)$ and $\varepsilon_{s,z}(m)$ are the contributions of the bulk modes b and the surface modes s to the center-of-mass motion. $\varepsilon_{b,z}(m)$ is by definition not localized at the surface and, therefore, it is independent of m. From Eq. (46) follows that only those surface modes contribute to $\varepsilon_{s,z}(m)$ for which $\omega \neq 0$ in the limit of $\mathbf{q} \to 0$; that is, only optical surface modes contribute to $\varepsilon_{s,z}(m)$ (the acoustic surface phonons only give rise to a uniform translational motion at $\mathbf{q} \to 0$).

From the analysis of the motion of the atoms relative to each other follows that the excitation described by the amplitude $A_\varepsilon(m)$ of $\varepsilon_{s,z}(m)$ cannot be an optical surface mode. Moreover, it has been discussed in literature (see, for example, [328]) that in the long-wave limit monatomic systems with only one particle in the three-dimensional unit cell admit only acoustic surface waves which do not contribute to $\varepsilon_{s,z}(m)$. In other words, the dynamical-matrix solutions would lead to

$$\varepsilon_{s,z}(m) = 0 \qquad (47)$$

and the center-of-mass motion is entirely given by $\varepsilon_{b,z}(m)$ and must be independent of m. However, molecular dynamics calculations (see Section 4.2.3) show that the amplitude $A_\varepsilon(m)$ of the center-of-mass motion is strongly dependent on m [323]. In particular, it is shown in [323] that this

excitation is localized at the surface: Its amplitude $A_\varepsilon(m)$ decreases with increasing m, and its penetration depth into the crystal is only a few interatomic distances. All this is in contrast to Eq. (47). In other words, the center-of-mass motion at the surface, described by $\varepsilon_{s,z}(m)$, cannot be described by the dynamical-matrix solutions, and it is shown in [323] that this effect is large; the dynamical-matrix solutions are obviously not complete for systems with surfaces, and in connection with *nanosystems* a relatively great fraction of atoms belong to surface regions.

4.2.3. Molecular Dynamics

The relatively strong anharmonicities in nanosystems are not negligible even at low temperatures. Furthermore, we have discussed in the last section in connection with the center-of-mass motion that surfaces can be the source for new qualitative phenomena. Since the dynamical-matrix solutions are obviously not complete the following questions arise: How can the dynamics of nanosystems be described? What method or basic model is adequate? Since only for the ideal solid does such a basic model exist [other simplifying principles at the microscopic level could not be found for many-particle systems (Section 4.2.1)], we have to describe such systems on the basis of the most general formulation. In the case of classical systems this can be done on the basis of Eq. (41) if the pair potential approximation can be applied and if many-body interactions can be neglected [Eq. (39)]. Such a general description can be achieved within the framework of *molecular dynamics calculations* which have to be performed for the characterization of nanosystems. We already came in Section 3.1 to this conclusion [scheme (32)]. In the following we would like to give more details concerning the molecular dynamics method.

Basic Information Only on the basis of the general formulation the relatively strong anharmonicities can be treated without approximation. In other words, the general description of the properties of classical many-particle systems (for example, nanosystems) can be done by means of molecular dynamics calculations without the use of "simple models" (Section 4.2.1) or other simplifying assumptions (Fig. 5). As already mentioned several times, such "simple models" and simplifying assumptions, respectively, are not known at the microscopic level and can only be introduced in a phenomenological or empirical way.

Within the framework of molecular dynamics Hamilton's equations

$$\dot{p}_{x_i} = -\frac{dH}{dx_1}, \ \ldots, \ \dot{p}_{z_N} = -\frac{dH}{dz_N}$$
$$\dot{x}_1 = \frac{dH}{dp_{x_i}}, \ \ldots, \ \dot{z}_N = \frac{dH}{dp_{z_{Ni}}} \tag{48}$$

are solved by iteration with the help of a high speed computer, and we obtain the following information for the

Figure 5. If a "simple model" is available, the properties of many-particle systems—including those of nanometer size—can be determined on the basis of such a model; in most cases additional assumptions are necessary. The advantage of molecular dynamics is that the description can be done without simple models and other additional assumptions. This is important since in most cases such systems are so complex that simplifying models have often been chosen for convenience and could not always be obtained by controlled simplifying steps from the general case (41). For nanosystems a simple model could not be found up to now. Therefore, the molecular dynamics methods is of particular importance in the nanometer-scale realm.

$N = N_I$ atoms:

$$q(t_1), p(t_1)$$
$$q(t_2), p(t_2)$$
$$\vdots$$
$$q(t_i), p(t_i) \tag{49}$$
$$\vdots$$

where

$$q(t_i) = (x_1, y_1, z_1, \ldots, x_N, y_N, z_N)$$
$$p(t_i) = (p_{x_1}, p_{y_1}, p_{z_1}, \ldots, p_{x_N}, p_{y_N}, p_{z_N}) \tag{50}$$

In other words, as solutions of the classical equations of motion we obtain the coordinates and momenta for all particles of the system as a function of time t. The time step in the iteration process is $\Delta t = t_{i+1} - t_i$. With k iteration steps the information about the system consisting of N particles is given in the time interval $\tau = k \cdot \Delta t$. Equation (49) contains the total information of the many-particle system. On the basis of this information the properties of the system, in particular experimental data, can be determined—at least in principle. In the following we will give some remarks about the determination of typical functions on the basis of information (49).

Correlation Functions In the analysis of many-particle systems correlation functions

$$\langle a(t')b(t'') \rangle \tag{51}$$

of two quantities $a(t')$ and $b(t'')$ are of particular interest, where

$$a(t') = a(q(t'), p(t'))$$
$$b(t'') = b(q(t''), p(t'')) \tag{52}$$

The angular brackets $\langle \cdots \rangle$ in (51) denote a thermodynamic average, which will be discussed in connection with molecular dynamics calculations in the next section. The time evolution of the system is given in statistical mechanics by the operator $\widehat{S}(t)$:

$$a(q(t'), p(t')) = \widehat{S}(t' - t'')a(q(t''), p(t'')) \quad (53)$$

where $\widehat{S}(t)$ can be written in terms of the Liouville operator $\widehat{L}$,

$$\widehat{S}(t) = \exp(i\widehat{L}t) \quad (54)$$

with

$$\widehat{L} = i\sum_{i=1}^{3N}\left[\frac{\partial H}{\partial q_i}\frac{\partial}{\partial p_i} - \frac{\partial H}{\partial p_i}\frac{\partial}{\partial q_i}\right] \quad (55)$$

where q_i and p_i denote all the $3N$ coordinates and momenta, respectively.

In general it is difficult to determine the time evolution of many-particle systems on the basis of Eq. (54). However, on the basis of the molecular dynamics information (49) it is straightforward to determine correlation functions of type (51).

In connection with time correlation functions of type (51) it is important to mention that they are not dependent on the time origin; that is, in Eq. (51) $t'' - t'$ are relevant but not t' and t'':

$$\langle a(t')b(t'')\rangle = \langle a(0)b(t'' - t')\rangle \quad (56)$$

Let us briefly discuss an example: With $a(0) = \mathbf{v}(0)$ and $b(t) = \mathbf{v}(t)$ we get the velocity autocorrelation function

$$\phi(t) = \langle \mathbf{v}(0) \cdot \mathbf{v}(t)\rangle \quad (57)$$

where $\mathbf{v}(t)$ is the velocity at time t for one atom of the ensemble. With $\phi(t) = \phi(-t)$ the Fourier transform of $\phi(t)$ is given by

$$f(\omega) = \frac{2}{\langle \mathbf{v}(0)^2\rangle \pi}\int_0^\infty \phi(t)\cos \omega t \, dt \quad (58)$$

where $f(\omega)$ is normalized to unity:

$$\int_0^\infty f(\omega)d\omega = 1 \quad (59)$$

In the case of the harmonic solid $f(\omega)$ is just the frequency spectrum of the normal modes, that is, the phonons. The frequency spectrum $f(\omega)$ defined by (57) is quite general and is applicable to systems with strong anharmonicities like nanosystems. $f(\omega)$ describes the complete dynamics of many-particle systems; that is, all kinds of excitation are included—even diffusion processes. The diffusion constant is directly expressed by $f(\omega)$ [329]:

$$D = \frac{\pi}{2}\frac{k_B T}{m}f(\omega = 0) \quad (60)$$

In particular, using $f(\omega)$ in the description of the dynamics no problems appear in connection with systems with surfaces where the dynamical matrix solutions are obviously not complete as we have demonstrated in Section 4.2.2.

How can we calculate the velocity autocorrelation function $\phi(t)$ and other properties from the basic molecular dynamics information (49)? In order to answer this question we have to outline how thermodynamic averages $\langle \cdots \rangle$ can be treated within the framework of molecular dynamics, which we have introduced in the context with Eq. (51). In the next section we will give some principal remarks.

Average Values Imagine a space of $6N$ dimensions whose points are determined by $3N$ coordinates $q(t_i) = (x_1, y_1, z_1, \ldots, x_N, y_N, z_N)$ and $3N$ momenta $p(t_i) = (p_{x_1}, p_{y_1}, p_{z_1}, \ldots, p_{x_N}, p_{y_N}, p_{z_N})$. This space is the so-called phase space where each point at time t corresponds to a mechanical state of the system. The evolution with time of the system is completely determined by Hamilton's equations (40) and is represented by a trajectory in phase space. The trajectory passes through the element $dq\,dp$ at point (q,p) of the phase space and it can pass it several times. This process defines a "cloud" of phase points indicating how often the elements of the phase space have passed through by the trajectory. In other words, instead of the trajectory we have now a "cloud" of phase points. The "cloud" is a great number of systems of the same nature, but differing in the configurations and momenta which they have at a given instant.

In summary, instead of considering a single dynamic system we consider a collection of systems, all corresponding to the same Hamilton function. This collection of systems is the so-called statistical ensemble (see also, for example, [330–337]). The introduction of the statistical ensemble is very useful in regard to the relationship between dynamics and thermodynamics.

The statistical ensemble can be described by a density function

$$\rho(q_1, \ldots, q_{3N}, p_1, \ldots, p_{3N}) \quad (61)$$

in phase space. The number of points in the statistical ensemble is arbitrary and, therefore, $\rho(q, p)$ has to be normalized:

$$\int \rho(q, p, t)\,dq\,dp = 1 \quad (62)$$

The quantity

$$\rho(q, p, t)\,dq\,dp \quad (63)$$

can be considered as the probability of finding at time t a system of the ensemble in the element $dq\,dp$ at the point (q,p) of the phase space. The introduction of the density (61) is meaningful only if the density takes an asymptotic value for long times t:

$$\lim_{t\to\infty}\rho(q, p, t) = \rho(q.p) \quad (64)$$

where $\rho(q, p)$ is the density function of the statistical ensemble. When the trajectory $q(t), p(t)$ is able to produce, over

a long period of time, the function $\rho(q, p)$ (ergodic hypothesis) then we have equivalence between the time average and the average over the statistical ensemble of a function $f(q(t), p(t))$:

$$\langle f \rangle = \frac{\int f(q, p)\rho(q, p)\, dq\, dp}{\int \rho(q, p)\, dq\, dp} \tag{65}$$

$$\langle f \rangle = \lim_{t \to \infty} \frac{1}{\tau} \int_0^x f(t)\, dt \tag{66}$$

Different expressions exist for the density function $\rho(q, p)$. These expressions depend on the thermodynamic environment: (1) *microcanonical ensemble* (an isolated system, N, V, and E are given, where E is the energy and V the volume); (2) *canonical ensemble* (a closed isothermal system, N, V, and T are given, where T is the temperature); (3) *grand canonical ensemble* (V, T, and μ given, where μ is the chemical potential). In molecular dynamics calculations in most cases N, V, and E are given and, therefore, such models represent microcanonical ensembles.

In connection with nanosystems the following discussion is relevant: Within the thermodynamic limit

$$\begin{aligned} N &\to \infty \\ V &\to \infty \\ \frac{N}{V} &= \text{const} \end{aligned} \tag{67}$$

the microcanonical, the canonical, and the grand canonical ensemble are equivalent; that is, within the thermodynamic limit we obtain in all three cases the same value for the statistical average of $\langle f \rangle$ of $f(q, p)$. This is not fulfilled in the case of nanosystems since the properties of nanosystems are in general dependent on the particle number N.

For nanosystems two points are important:

(1) What can we say about the dependence of the particle number N?
(2) What does a long period of time [$\tau \to \infty$ in Eq. (66)] mean?

Discussion Concerning Point (1)   The properties of nanosystems are in general dependent on the particle number. This is the reason we investigate nanosystems. In order to study this point in more detail one has to study the statistical average $\langle g \rangle$ of a suitable quantity $g(q, p)$ as a function of N and if there is

$$\langle g \rangle_{N'} = \langle g \rangle_{N''} = \langle g \rangle_{N'''} \tag{68}$$

with

$$N' < N'' < N''' \tag{69}$$

we may consider the system under investigation for $N \geq N'$ no longer as a nanosystem. On the other hand, if N' is the critical particle number we may consider the system for $N < N'$ as a nanosystem.

Discussion Concerning Point (2)   With Eq. (64) and using the well-known expression for the velocity distribution

$$\rho(q, p) = \rho(v) = 4\pi \left(\frac{m}{2\pi k_B T} \right)^{3/2} v^2 \exp\left(-\frac{mv^2}{2k_B T} \right) \tag{70}$$

we obtain for the mean-square velocity

$$\begin{aligned} \langle v^2 \rangle &= 4\pi \left(\frac{m}{2\pi k_B T} \right)^{3/2} \int_0^\infty v^4 \exp\left(-\frac{mv^2}{2k_B T} \right) dv \\ &= 3\frac{k_B T}{m} \end{aligned} \tag{71}$$

On the other hand let us consider a single particle of the N-particle system and let $v_i(t)$ be the velocity of the ith particle at time t where the index i has been chosen arbitrarily. If we define a function $v^2(\tau)$ by

$$v_i^2(\tau) = \int_0^\tau v_i^2(t)\, dt \tag{72}$$

we expect [according to (65) and (66)] that

$$\lim_{\tau \to \infty} v_i^2(\tau) = \langle v^2 \rangle \tag{73}$$

That is, there is equivalence between the average over the time and the average over the statistical ensemble [Eq. (71)]. In other words, we expect that after a sufficiently large time τ the velocity $v_i(t)$ of a single atom of the N-particle system, which can be arbitrarily chosen, has passed through all the states given by Maxwell's distribution (70).

In connection with molecular dynamics calculation the following question is of particular interest: How large is the time τ in order to fulfill (73) in a good approximation? Specific calculations showed that τ is relatively small; to fulfill Eq. (73) one needs not more than 10^3 iteration steps (i.e., τ is of the order of 10^{-11} s if the time step is 10^{-14} s).

Clearly, within molecular dynamics calculations averages will not be calculated on the basis of a statistical ensemble (65) or with Eq. (66). The calculated information expressed by (49) already represents the data in thermal equilibrium. Therefore, it is straightforward to determine averages on the basis of (49). For the mean-square velocity [see Eq. (71)] the molecular dynamical average is

$$\langle v^2 \rangle = \frac{1}{N_\theta} \frac{1}{N} \sum_{j=1}^{N_\theta} \sum_{i=i}^{N} v_i^2(\theta_j) \tag{74}$$

The average is formed over all N particles and various times θ_j.

Time Evolution of Molecular Dynamics Systems   From the solutions of Hamilton's equations (48) we obtain the coordinates and momenta (velocities) of all N particles as a function of time [see Eq. (49)]; this is the total *microscopical* information of the system under investigation. However, the solutions of Hamilton's equations require *initial values* for the coordinates and the velocities of the N particles.

In the case of gases and liquids the initial values for the coordinates can be distributed randomly with the appropriate density. In connection with crystals (with and without surfaces, and nanosystems) the particles will be situated

within the array so that the perfect lattice structure appropriate to the system under investigation is generated.

Without external forces acting on the system, the *directions* of the initial values for the velocities should be distributed randomly so that the momentum of the whole system is approximately zero at the initial time t_0, and it must remain zero for all times t (conservation of momentum).

In thermal equilibrium the *magnitudes* of the particle velocities are distributed according to Maxwell's distribution. However, it is more convenient to choose for all particles the same magnitude of the velocities, and this means that the system is initially not in thermal equilibrium. With the help of the function

$$\alpha(t) = \frac{\frac{1}{N} \sum_{i=1}^{N} \left[\mathbf{v}_i(t)^2 \right]^2}{\left[\frac{1}{N} \sum_{i=1}^{N} \mathbf{v}_i(t)^2 \right]^2} \tag{75}$$

where $\mathbf{v}_i(t)$, $i = 1, \ldots, N$, are the velocities obtained from the molecular dynamics calculations, we can study at which point in time Maxwell's distribution (70) is reached. In the case of (71) the function $\alpha(t)$ in (75) takes the value of

$$\alpha(t) = \frac{5}{3} \tag{76}$$

for all times t. However, if all particles have the same initial magnitude of the velocities we get for $\alpha(t)$ at time t_0

$$\alpha(t) = 1 \tag{77}$$

It can be demonstrated by realistic molecular dynamics calculations that thermal equilibrium ($\alpha(t) = 5/3$) is reached after a few hundred time steps if we start from $\alpha(t_0) = 1$. Due to the finite number of particles $\alpha(t)$ fluctuates around its equilibrium value of 5/3 (see also Fig. 6); these fluctuations are getting small with increasing particle number N and are physically realistic. Clearly, in the case of macroscopic systems ($N \to \infty$) the fluctuations are zero.

Figure 6. Schematic representation of $\alpha(t)$. The system is initially ($t_0 = 0$) not in thermal equilibrium ($\alpha \neq 5/3$). After a few hundred molecular dynamics time steps thermal equilibrium (Maxwell's distribution) is reached. Due to the finite number of particles the system fluctuates around 5/3.

The *temperature* of molecular dynamics systems is dependent on time t and is defined by the relation

$$\frac{1}{2} m \overline{\mathbf{v}(t)^2} = \frac{3}{2} k_B T(t) \tag{78}$$

With

$$\overline{\mathbf{v}(t)^2} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{v}_i(t)^2 \tag{79}$$

we get for the temperature as a function of time

$$T(t) = \frac{m}{3 N k_B} \sum_{i=1}^{N} \mathbf{v}_i(t)^2 \tag{80}$$

As in the case of $\alpha(t)$ also the temperature $T(t)$ fluctuates in finite systems around the mean temperature (see Fig. 7):

$$T = \lim_{\theta \to \infty} \frac{1}{\theta - \theta_1} \int_{\theta_1}^{\theta} T(t) \, dt \tag{81}$$

θ_1 is the time where the system has reached equilibrium, and θ is the time of investigation (i.e., for which Hamilton's equations have been solved after equilibrium is reached).

As in the case of $\alpha(t)$, the temperature fluctuations (see Fig. 7) are physically real. From these fluctuations we can extract the specific heat at constant volume (per particle)

$$c_V = \frac{1}{N} \left(\frac{\partial E}{\partial T} \right)_V \tag{82}$$

It is straightforward to show that in the case of a microcanonical ensemble the specific heat is expressed by [338, 339]

$$c_V = \frac{3}{2} \left[1 - \frac{3N}{2\overline{T^2}} (\overline{T^2} - \overline{T}^2) \right]^{-1} \tag{83}$$

where $\overline{T}$ and $\overline{T^2}$ are obtained by averaging over a sufficiently large time interval. For example, $\overline{T^2}$ is given by

$$\overline{T^2} = \lim_{\theta \to \infty} \frac{1}{\theta - \theta_1} \int_{\theta_1}^{\theta} T(t)^2 \, dt \tag{84}$$

Figure 7. The temperature as a function of time (schematic representation). T is the mean temperature; θ_1 is the time where the system has reached equilibrium. Due to the finite number of particle the temperature fluctuates around its mean value T.

In other words, the temperature fluctuations are a direct measure of the specific heat, indicating that these fluctuations are not an artificial element of the method.

4.2.4. Nonequilibrium Molecular Dynamics

A few remarks should be given in connection with nonequilibrium molecular dynamics which has been developed in addition to equilibrium molecular dynamics (Section 4.2.3) and which has been known since the early 1970s [340–342]. This method was introduced in order to compute efficiently transport coefficients. To establish the nonequilibrium situation of interest, an external force is applied to the system. Then the response of the system to these forces is determined from the simulation. This method has been used for the calculation of diffusion coefficients, the shear and bulk viscosity, and thermal conductivity [343]. Further basic literature concerning nonequilibrium molecular dynamics is given by [344–349]. Recent interesting results can also be found in [350–355].

Non-Hamiltonian systems can be studied by means of nonequilibrium molecular dynamics [356], for example, dissipative systems, that is, systems which involve friction in one of its various forms. In such cases, particle trajectories are calculated from the equations of motion which are, however, not consistent with any Hamilton function.

5. INTERACTION POTENTIALS

Clearly, in order to be able to perform molecular dynamics calculations not only are the initial values for the coordinates and momenta (velocities) for all the N particles of the system needed as input (Section 4.2.3), but in particular the interaction potential between the particles, which reflects the specific characteristics of the system under investigation.

For a reliable description of material properties precise knowledge of the interaction potential is required. We will outline below that surface properties in general, as well as in connection with nanosystems, are particularly sensitive to potential variations. Both the repulsive and the attractive parts of the potential have to be determined carefully. However, the determination of accurate pair potentials for systems of interest (e.g., metals and materials with covalent bonding) is rather difficult even for the bulk, and the nanoproblem, where a great fraction of atoms belong to the surface region, is much harder because of the change in electronic states and other relevant properties near the surfaces of the nanosystem.

In this section we would like to discuss methods which—from the authors point of view—are relevant for the determination of interaction potentials. In literature a lot of theoretical studies can be found—in particular, in connection with molecular dynamics calculations—in which the potentials are used in a rather uncritical way: The potentials have not been tested carefully, in some cases even not at all. Serious research in nanoscience requires just the opposite: Since the properties of nanosystems are particularly sensitive to potential variations, the potentials have to be determined thoroughly for such systems.

5.1. Types of Interactions in Condensed Matter Physics

Basically, in condensed matter physics we have to distinguish between four binding types (see, for example, [357]): (1) *ionic interactions* (4–14 eV), (2) *metallic bonds* (0.7–6 eV), (3) *van der Waals interactions* (0.02–0.3 eV), and (4) *covalent bonds* (1–10 eV), where the numbers denote the typical binding energies. Also the *hydrogen bridge bond* (0.1–0.5 eV) is a characteristic binding type but will not be discussed in the following.

5.1.1. Ionic Binding

The ionic interaction is characterized by different atoms (for example, Na and Cl) which have exchanged electrons, so that the many-particle systems consist of positive and negative charged ions. The interaction law as a function of distance r between the ions is simply described by Coulomb's law if the distances are larger than $r_+ + r_-$, where r_+ and r_- are the radii of the positively and negatively charged particles. For distances $r < r_+ + r_-$ the interaction is repulsive due to the overlap of the electron cores.

5.1.2. Metallic Binding

In the case of certain atoms (for example, Al) the electrons of the outer shell are only weakly bonded. If a many-particle system is formed with such atoms the weakly bonded electrons leave the according atoms and move through the whole system. These are the conduction electrons. In other words, in metals we have the following situation: There are positively charged ions which move through the sea of conduction electrons. In metals the ion–ion interaction is not simply given by the Coulomb potential since the ions are screened by the conduction electrons and that makes its determination complicated. Such a modeling of the ion–ion potential can be performed, for example, within the frame of pseudopotential theory; in Section 5.3.1 we give some details concerning this method.

5.1.3. Van der Waals Interaction

The motion of the electrons around the atomic nucleus means that there is a certain probability that the atoms have at instant t an electrical dipole moment which, however, becomes zero when it is averaged over the time. In a many-particle system these momentary dipole moments interact with each other leading to an attractive potential between the atoms of the system. Typical van der Waals systems are noble gases. Clearly, repulsive core effects have to be considered also in the description of the interaction potential at small distances.

5.1.4. Covalent Bonds

In the case of covalent binding the interaction between particles is given by the fact that part of their electrons belong to several particles at the same instant. The probability of finding an electron, which is responsible for binding, is relatively large in the environment between the particles leading to the interaction between them. In most cases this process is based on the formation of spin saturated electron

pairs, where each atom contributes an electron so that the electron shells take a noble gas configuration. Examples for substances with covalent bonds are carbon, amorphous semi-conductors, hydrogen molecules, etc.

Remarks Concerning Phenomenological Potentials
In connection with realistic calculations phenomenological potential functions are used very often, which are most often not strictly constructed with respect to the basic inter-action types discussed above. As a typical example for a phenomenological potential let us briefly discuss the poten-tial of Morse [358] which has been extensively used in the study of lattice dynamics [359], the defect structure in metals [360–368], the inert gases in metals [369, 370], the equa-tion of state [371, 372], elastic properties of metals [373], the interaction between gas atoms and crystal surfaces [374], and in studies of other specific problems [375–381].

In order to calculate the energy levels for diatomic molecules, Morse required some conditions for the inter-atomic potential of the atoms of the molecule [323] which describes the spectroscopy of the molecules. Morse chose the potential function

$$v(r) = \alpha_0 \exp[-2\alpha(r - r_0)] - 2\alpha_0 \exp[-\alpha(r - r_0)] \quad (85)$$

where r_0 is the intermolecular separation. The solution of the radial part of Schrödinger's equation using this potential yielded the correct energy level representation.

In conclusion, the Morse potential has not been con-structed on the basic interaction types discussed above but is based on the spectroscopy of molecules. Nevertheless, the potential has been used extensively in the study of various many-particle properties, but there is no physical justifica-tion for that.

There are many other phenomenological approaches for the interaction (for example, the Buckingham potential [382–385]), but we do not want to discuss these functions here because in most cases there is no or almost no physi-cal background for their introduction; these potentials have often been chosen for purely pragmatic reasons and, there-fore, they have to be considered only as fitting functions.

Since there is a strong potential sensitivity in connection with the properties of systems with surfaces (for example, nanosystems), we have to construct the potentials very care-fully. In the next sections we would like to discuss some relevant theoretical methods for the construction of model potentials.

5.2. Sensitivity of System Properties against Potential Variations

Before we discuss specific model potentials let us first give some remarks about the sensitivity of the system properties on the interaction between the particles which form the sys-tem. It turned out that the properties of many-particle sys-tems are very sensitive to small variations in the interaction potentials. Therefore, in the description of system properties on the basis of the particle interaction the potentials have to be modeled very carefully. What does "sensitive to small variations in the interaction potentials" mean?

Let us demonstrate that by means of krypton [386]. In connection with nanosystems surface properties are of par-ticular interest and, therefore, let us study the sensitivity of surface properties on the potential function.

As is well known, krypton is a noble gas, and in con-trast to metals, the potential functions of noble gas systems (solid, liquids, nanosystems, etc.) do not depend on density and temperature, respectively, and they are the same at the surface as in the bulk of the crystal. At free metal surfaces the local background may be changed from its average bulk value and produces concomitant changes in the potential functions. Such difficulties do not arise at noble gas surfaces and, therefore, in the study of the potential sensitivity we want to restrict our study to noble gas (krypton) surfaces.

For krypton a reliable potential, the so-called Barker potential, is available [387]; its form is rather complex and will not be outlined here. The Barker potential is more real-istic than the famous Lennard-Jones potential

$$v(r) = 4\varepsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right] \quad (86)$$

because it undoubtedly correlates accurately a much wider range of experimental data. Although the shapes of the Lennard-Jones potential and the Barker potential are sim-ilar (see Fig. 8) the results for the relaxation are *qualita-tively different* from each other: The Barker potential leads to a *contraction* and, on the other hand, the Lennard-Jones potential leads to an *expansion*, as has been demonstrated by molecular dynamics calculations for the Kr (111) sur-face and 539 atoms [388]. The contraction is confirmed by low energy electron diffraction (LEED) data [388]. Figure 9 shows that the molecular dynamics model calculations agree well with the experimental data. The interlayer spacing $d_\perp$ at the surface is always smaller than the corresponding value for the bulk within the temperature range studied. As already mentioned above, the lattice contraction result-ing from the model and the experiments is in contradiction to the results of model calculations with the Lennard-Jones potential (leading to an expansion), indicating that investigations—for example, in connection with dynamical

Figure 8. Pair potentials for krypton: (a) Barker potential, (b) Lennard-Jones potential.
Figure 9. Temperature dependence of the interlayer spacing $d_\perp$ measured by LEED experiments ($\Diamond$) for electron energies $E = 53$ eV (a) and $E = 125$ eV (b) together with the results obtained by molecular dynamics calculations ( ) [in (a) for the outermost interlaying spacing and in (b) averaged for the outermost two layer spacings]. The solid lines show the interlayer spacings for the bulk as determined by X-ray experiments. The error bars in the experimental data are mainly due to the error for the effective inner potential. The error bars with respect to the molecular dynamics results are due to the statistical fluctuations.

processes in nanosystems—on the basis of the Lennard-Jones potential can be seriously in error.

It should be emphasized here that the Lennard-Jones potential is the most used interaction function in literature, and sometimes it is even used for the description of metals [389], but there is no physical basis for that since the interaction type (van der Waals forces) described by the Lennard-Jones potential has nothing to do with the interaction type dominant in metals.

In conclusion, the properties of many-particle systems (in particular those with surfaces like nanosystems) are obviously very sensitive to small variations in the interaction between the particles. We have shown that the relatively small quantitative differences between the Lennard-Jones potential and the Barker potential (Fig. 8) give rise not only to quantitative effects but also to qualitative differences. This example shows that one has to be very careful in the selection of interatomic potentials, especially when modeling nanosystems, since a great fraction of particles belong to the surface region.

With respect to the interaction problem we have still to mention that the Lennard-Jones potential as well as the Barker potential are descriptions within the pair potential approximation (Section 4.1.2). However, in principle many-body forces [three-body interactions etc.; see Eq. (39)] might also play a role. What can we say about the influence of three-body interactions?

The calculations in connection with Figure 9 have been done for the noble gas krypton which is a typical van der Waals system. For such systems a three-body potential exists

(Axilrod–Teller potential [390])

$$v_3(i, j, k) = \nu \frac{1 + 3\cos\theta_1 \cos\theta_2 \cos\theta_3}{r_{ij}^3 r_{il}^3 r_{jl}^3} \tag{87}$$

where ν is a constant; r_{ij}, r_{il}, r_{jl} and θ_1, θ_2, θ_3 are the sides and angles of the triangle formed by the particles i, j and l. $v_3(i, j, l)$ can be repulsive and attractive, which depends on the shape of the triangle formed by the three atoms i, j, and l. Are those Axilrod–Teller interactions relevant in connection with the results given in Figure 9?

We cannot exclude that the three-body potential (87) together with the Lennard-Jones potential may lead to good results for the relaxation at the surface. However, it is shown in [391] that the influence of $v_3(i, j, l)$ on structural data is relatively small and, therefore, we cannot expect that the Lennard-Jones potential together with $v_3(i, j, l)$ gives good results for the relaxation and other quantities of relevance.

On the other hand, the Barker potential is expressed by a lot of parameters, and these parameters were fitted by a lot of experimental data; this fact can be expressed formally by

$$v = v(r, a, b, \dots) \tag{88}$$

where a, b, etc. are the fit parameters. In other words, such kinds of potentials should not be considered as pure pair potentials in the sense of Eq. (39) in Section 4.1.2 but rather play the role of effective interaction potentials $v(r, a, b, \dots) = v_{\text{eff}}(r, a, b, \dots)$ which in particular consider approximately many-body forces. Therefore, we may express Eq. (39) in Section 4.1.2 by

$$V(\mathbf{r}_1, \dots, \mathbf{r}_N) = \frac{1}{2} \sum_{\substack{i, j \\ i \neq j}}^{N} v_{ij} + \frac{1}{6} \sum_{\substack{i, j, k \\ i \neq j \neq k}}^{N} v_{ijk} + \cdots$$

$$\cong \frac{1}{2} \sum_{\substack{i, j \\ i \neq j}}^{N} v_{\text{eff}}(r_{ij}, a, b, \dots) \tag{89}$$

That is, the effective potential simulates approximately many-body forces. This is due to the fact that the potential parameters a, b, etc. are fitted to experimental data which may be more or less sensitive to many-body forces.

5.3. On the Determination of Pair Potentials in Metals

5.3.1. Remarks Concerning Pseudopotential Theory

As outlined in Section 5.1 metals consist of ions of positive charge and electrons. In the case of the ionic interaction the potential between the particles is simple and is given by the Coulomb potential. In metals the situation is more complicated since the ions are surrounded of conduction electrons. The ions are screened by the electrons; in particular, there are quantum-mechanical correlation and exchange effects among the electrons. All these facts have to be considered in the construction of ion–ion potentials $v(r)$ in metals, where r is the distance between the two ions of the system. Within the framework of pseudopotential theory

(see, for example, [392]) all these effects (screening, correlation, and exchange effects) can be adequately considered.

The pseudopotential method is often used for the determination of the interaction between the ions in metals. Within the frame of this theory the problem can be treated on various levels, and a lot of pseudopotential models exist in literature. Let us briefly discuss here a typical example for a monatomic system. This example shows how all the previously mentioned effects (screening, correlation, and exchange effects) can be treated mathematically and how they are interrelated.

As already outlined, the metal system has to be considered as a conglomerate of ions which are embedded in an uniform compensating background of negative charge (conduction electrons). Within the framework of pseudopotential theory the ion–ion potential $v(r)$ can be divided into two parts [392, 393],

$$v(r) = v_d(r) + v_{ind}(r) \tag{90}$$

where $v_d(r)$ is the so-called direct interaction between the ions, and $v_{ind}(r)$ is the ion–electron–ion interaction, which has the meaning of an indirect interaction. In most cases $v_d(r)$ is approximated by the Coulomb potential

$$v_d(r) = \frac{Z^{*2}e^2}{r} \tag{91}$$

of the point charges Z^*e [392]. The deviations of the effective valency Z^* from the valency Z are in most cases less than 10% [393]. The difference Z^*–Z can be thought of as resulting from the orthogonalization of plane waves to the core states which gives an extra charge on the ion.

The local approximation of the indirect ion–ion interaction $v_{ind}(r)$ [see Eq. (90)] can be expressed by [392]

$$v_{ind}(r) = \frac{\Omega_0}{\pi^2} \int_0^\infty F(q) \frac{\sin qr}{qr} q^2 \, dq \tag{92}$$

Following Sham [394] and Heine and Abarenkov [395] for the function $F(q)$ the following ansatz can be chosen:

$$F(q) = -\frac{\Omega_0 q^2}{8\pi e^2} |\langle k+q|k\rangle|^2 \frac{\varepsilon(q)-1}{\varepsilon(q)[1-C(q)]} \tag{93}$$

with

$$\varepsilon(q) = 1 + [1-C(q)] \frac{me^2}{2\pi k_F \hbar^2 x^2} \left(1 - \frac{1-x^2}{2x} \ln\left|\frac{1+x}{1-x}\right|\right) \tag{94}$$

and

$$C(q) = \frac{q^2}{2[q^2 + k_F^2 + k_s^2]} \tag{95}$$

where Ω_0 is the specific volume, k_F is the Fermi wave number vector, $x = q/2k_F$, $k_s = 2k_F/\pi a_0$, and a_0 is the Bohr radius.

The matrix element $\langle k+q|w_0|k\rangle$ is the unscreened pseudopotential form factor, which is independent of k in the local approximation. With $C(q)$ exchange and correlation effects among the electrons are taken into account approximately in the dielectric function $\varepsilon(q)$. If $C(q)$ is taken equal

to zero in Eq. (94), $\varepsilon(q)$ is equal to the static Hartree dielectric function. It should be mentioned that there exist various models for the dielectric function $\varepsilon(q)$ in literature [392], and the form of $\varepsilon(q)$ essentially depends on the material under investigation.

The Fourier transform $w_0(R)$ of the matrix element $\langle k+q|w_0|k\rangle$ can be considered as the unscreened potential $v_0(R)$ between the ion and the conduction electron at distance R. $v_0(R)$ must be corrected by an orthogonalization potential $v_{orth}(R)$ in the core region due to the orthogonalization of the plane waves to the core states [392],

$$w_0(R) = v_0(R) + v_{orth}(R) \tag{96}$$

where $w_0(R)$ is related to $\langle k+q|w_0|k\rangle$ by

$$\langle k+q|w_0|k\rangle = \frac{4\pi}{\Omega_0} \int_0^\infty w_0(R) \frac{\sin qR}{qR} R^2 \, dR \tag{97}$$

$v_0(R)$ in Eq. (96) is expressed by the Coulomb interaction between the conduction electron and the excessive point charge Ze of the ion:

$$v_0(R) = -\frac{Ze^2}{R} \tag{98}$$

The function $v_{orth}(R)$ in Eq. (96) has to be modeled. For example, within the often used Ashcroft model [396] we have

$$v_{orth}(R) = \frac{Ze^2}{R} [1 - \theta(R - r_c)] \tag{99}$$

with

$$\theta(R - r_c) \begin{cases} = 0 & R \leq r_c \\ = 1 & R > r_c \end{cases} \tag{100}$$

where r_c is the core radius. Within the Ashcroft model the Coulomb potential is canceled within the core region.

A typical feature of the ion–ion potential $v(r)$ in metals is that, due to the conduction electrons, the long-range part oscillates. This is schematically shown in Figure 10 in comparison to a Lennard-Jones-type potential which

Figure 10. The schematic representation of different potential types: (a) the ion–ion interaction $v(r)$ for a metal; (b) the typical atom–atom potential in a noble gas.

describes noble gases, that is, systems without conduction electrons.

Equations (90)–(100) represent the basic model, but it turned out [397] that there can obviously be additional effects which are due to the cores of the ions. These are van der Waals-type interactions. Without going into detail the analysis of this problem [397] leads to additional inter-action terms with respect to the direct interaction $v_d(r)$ between the ions [see Eq. (91)] and the unscreened inter-action $v_0(R)$ between the conduction electron and the ion [see Eq. (96)],

$$v_d(r) = \frac{Z^{*2}e^2}{r} - \frac{\alpha_1}{r^6} - \frac{\alpha_2}{r^4} \tag{101}$$

$$v_0(R) = -\frac{Ze^2}{R} - \frac{\alpha}{R^4} \tag{102}$$

where the r^{-6} term in (101) represents a dipole–dipole inter-action, and the r^{-4} and R^{-4} terms in (101) and (102) reflect monopole–dipole potentials. The constants α, α_1, and α_2 can be estimated quantum mechanically [397].

Pseudopotentials have often been applied to various prob-lems. Some typical articles are: Avoided crossings in the interaction of a Xe Rydberg atom with a metal surface [398], The theoretical spin-orbit structure of the RbCs molecule [399], *ab initio* study of the adsorption of In on the Si(001)-(2 × 2) surface [400], *ab initio* study of iron and Cr/Fe001 [401], and Dilute Bose gas in a quasi-two-dimensional trap [402]. Further information is given in [403–415].

5.3.2. Model-Independent Potentials

The interaction models which are based on pseudopotential theory work well in many cases [392, 397], provided the var-ious terms, which compose the model, have been carefully prepared. Nevertheless, such models are complicated and contain a lot of assumptions and simplifications which are often based on more or less uncontrolled calculation steps. Therefore, it would be desirable to find methods which allow one to determine *model-independent* interaction potentials. Such a way is still less developed but should attract more attention in the future since the properties of systems are in general very sensitive to small variations in the interac-tion potential (Section 5.2); this is in particular the case in connection with nanosystems where a great fraction of the particles belong to the surface of the system. However, model-independent potentials can already be determined for liquids. The according method could in principle also be applied to nanofilms. Because of its principal meaning let us briefly discuss this method.

The method [416] is based on experimental data for the liquid structure and allows one to determine the interaction without the use of any parameter in a self-consistent way. Since the method is model-independent, it is applicable for all interaction types. The liquid structure is characterized by the pair correlation function $g(r)$, which can be deter-mined experimentally. $g(r)$ is an essential quantity because important thermodynamic functions (pressure, energy, etc.) are only dependent on $g(r)$—provided we can work within the pair potential approximation.

Let us start from the expansion for $g(r)$ in powers of the particle number density n (see, for example, [417, 418]),

$$g(r) = \exp\left[-\frac{v(r)}{k_B T}\right]\gamma(r) \tag{103}$$

with

$$\gamma(r) = 1 + na(r) + n^2 b(r) + \cdots \tag{104}$$

where k_B is Boltzman's constant and T is the absolute tem-perature of the system. The coefficients of each power of n are cluster integrals (more details concerning Eq. (104) are given in [417]). The detailed form of $v(r)$ will only have a small influence on $\gamma(r)$ because $\gamma(r)$ plays the role of an integral quantity in the determination of $\gamma(r)$. This means that different pair potentials can lead to the same function $\gamma(r)$—at least in principle. In other words, if we know a potential $v_1(r) \neq v(r)$ which satisfies the condition

$$\gamma_1(r) \cong \gamma(r) \tag{105}$$

we can calculate the unknown pair potential $v(r)$ by

$$v(r) \cong v_1(r) - k_B T \ln\left[\frac{g(r)}{g_1(r)}\right] \tag{106}$$

where

$$g_1(r) = \exp\left[-\frac{v_1(r)}{k_B T}\right]\gamma_1(r) \tag{107}$$

and $g(r)$ in (106) is the experimentally determined $g(r)$. Since Eq. (107) is in general an expansion with slow conver-gence, $g_1(r)$ should be calculated from the known potential $v_1(r)$ by molecular dynamics and not by (107) on the basis of (104). It is difficult to fulfill Eq. (105) in the first step and, therefore, instead of (106) we get the following itera-tion scheme:

$$\begin{aligned}
v_2(r) &= v_1(r) - k_B T \ln\left[\frac{g(r)}{g_1(r)}\right] \\
v_3(r) &= v_2(r) - k_B T \ln\left[\frac{g(r)}{g_2(r)}\right] \\
&\quad\vdots \\
v_i(r) &= v_{i-1}(r) - k_B T \ln\left[\frac{g(r)}{g_{i-1}(r)}\right] \\
v_i(r) &= v_{i-1}(r) \\
&= v(r)
\end{aligned} \tag{108}$$

with

$$g_{i-1}(r) = g(r) \tag{109}$$

The unknown pair correlation functions $g_k(r)$, $k = 1, \ldots, i - 1$, can be calculated using $v_k(r)$, $k = 1, \ldots, i - 1$, by molecular dynamics. After the $(i - 1)$th iteration the molecular dynamical calculated pair correlation function $g_{i-1}(r)$ agrees with the experimental $g(r)$ [Eq. (109)] within the limit of accuracy dictated by the molecular dynamics calculation.

For the applicability of the self-consistent method con-vergence of the scheme (108) is necessary. This depends on

the potential $v_1(r)$ which we have to know in the first iteration step. In all calculations (see, for example, [416]) the approximation for low densities [$\gamma(r) = 1$, Eq. (103)]

$$v_1(r) = -k_B T \ln g(r) \tag{110}$$

worked well, where $g(r)$ is again the experimental pair correlation function.

The pair potential $v(r)$ is sensitive to small variations in $g(r)$ which means that $g(r)$ has to be measured very accurately. This has been done for liquid gallium [419]. In [416] the self-consistent method has been applied to liquid gallium; the details are discussed there.

The self-consistent method could also be applied to nanosystems. For example, it should be possible to determine the pair potential for the particles of nanostructures on surfaces. On the other hand, other model-independent methods should be developed which correlate the potential with suitable measurable quantities, that is, methods which are not based on the experimentally determined pair correlation function $g(r)$ but on other relevant experimental input data leading to new schemes.

5.3.3. Microscopic Considerations

The pseudopotential theory as discussed in Section 5.3.1 leads to more or less phenomenological potentials with parameters which can be fitted to experimental data, in particular to data for systems with surfaces, for example, nanosystems. However, the surface properties can be considered from the beginning if we work more microscopically within the framework of first principles calculations. Let us briefly discuss this point.

The electron density in metals must drop from a characteristic interior average value within the system to zero outside the surface. The ion–ion potential in metals is dependent on the electron density, and the charge redistribution at the surface has the effect that the potential at the surface is different from that in the bulk of metals. How can we determine the pair potential at metal surfaces, that is, in connection with nanosystems? Let us give an example.

For sufficiently low temperatures the pair interactions outside and inside the metal surface have been calculated microscopically in [420] on the basis of the static electronic response function. The basic points of the approach are the following: An ensemble of ions with the positions $\mathbf{R}_i$, $i = 1, \ldots, N$, are surrounded by a neutralizing electron charge of density $n(\mathbf{r})$. An infinitesimal displacement of ion k with the position $\mathbf{R}_k$ introduces a perturbating potential $\delta V_k(\mathbf{r} - \mathbf{R}_k)$ and an energy change which is given by

$$\Delta E = -\frac{1}{2} \sum_{\mathbf{R}_i, \mathbf{R}_j} \int d\mathbf{r} \int d\mathbf{r}' \, \delta V_i(\mathbf{r} - \mathbf{R}_i)$$
$$\times \chi(\mathbf{r}, \mathbf{r}') \, \delta V_j(\mathbf{r} - \mathbf{R}_j) \tag{111}$$

where $\chi(\mathbf{r}, \mathbf{r}')$ is the static electronic response function appropriate to the electronic density $n(\mathbf{r})$. $n(\mathbf{r})$ can be determined by the density functional formalism (see also Sections 2.1.2 and 2.1.5). How is the function $\chi(\mathbf{r}, \mathbf{r}')$ correlated to the quantities defined by the density functional theory? As we have already outlined in Section 2.1.5, within

this approach instead of the complicated wave function $\psi(\mathbf{r}_1, \ldots, \mathbf{r}_N)$ for the N-particles the electron density

$$n(\mathbf{r}) = \frac{\int d\mathbf{r}_1 \cdots d\mathbf{r}_N \sum_{i=1}^{N} \delta(\mathbf{r} - \mathbf{r}_i) \psi^*(\mathbf{r}_1, \ldots, \mathbf{r}_N) \psi(\mathbf{r}_1, \ldots, \mathbf{r}_N)}{\psi^*(\mathbf{r}_1, \ldots, \mathbf{r}_N) \psi(\mathbf{r}_1, \ldots, \mathbf{r}_N)} \tag{112}$$

is introduced as a variable. According to Kohn, Hohenberg, and Sham [6, 7] $n(\mathbf{r})$ is given in the ground state by

$$n(\mathbf{r}) = \sum_{i=1}^{N} \phi_i^*(\mathbf{r}) \phi_i(\mathbf{r}) \tag{113}$$

with

$$\int n(\mathbf{r}) \, d\mathbf{r} = N \tag{114}$$

The wave functions $\phi_i(\mathbf{r})$ satisfy

$$\left\{ -\frac{\hbar^2}{2m} \nabla^2 + V_{\text{eff}}(\mathbf{r}) \right\} \phi_i(\mathbf{r}) = \varepsilon_i \phi_i(\mathbf{r}) \tag{115}$$

where

$$V_{\text{eff}}(\mathbf{r}) = V(\mathbf{r}) + V_H(n(\mathbf{r})) + V_{\text{xc}}(n(\mathbf{r})) \tag{116}$$

with $V(\mathbf{r})$ being an arbitrary external potential. $V_H(n(\mathbf{r}))$ and $V_{\text{xc}}(n(\mathbf{r}))$ are the usual Hartree and exchange-correlation potentials which are functionals of $n(\mathbf{r})$.

The static susceptibility $\chi(\mathbf{r}, \mathbf{r}')$ in (111) is a ground state response and, therefore, it is a functional of $n(\mathbf{r})$ and can be described by $\phi_i(\mathbf{r})$. On the basis of (111) the ion–ion interaction outside and inside a metal jellium surface has been calculated [420].

In order to check the reliability of such potentials it would be most helpful to use them in molecular dynamics calculations for the description of nanosystems and compare the results carefully with experimental data. In this way, valuable insight into the validity of such potentials can be achieved. Another approach, extensively used in connection with molecular dynamics, is given by the so-called embedded-atom method; in the next section we discuss the basic principles of this method.

5.3.4. Embedded-Atom Method

An alternative to the pair potential description has been proposed by Daw and Baskes [421, 422]; as in Section 5.3.3 also within this approach density-functional ideas are used. This approach, the so-called embedded-atom method, has also been used in connection with molecular dynamics for the description of various complex physical situations. First we give a brief description of the method and after that we quote some applications.

The basic idea behind the embedded-atom method is the following (see, for example, [423]): The density-functional formalism allows one to formulate the total electronic energy for an arbitrary arrangement of nuclei as a unique functional of the total electron density. The method starts with the approximation that the total electron density in a metal can be expressed by the linear superposition of contributions from the individual atoms. Then, the electron density around each atom can be described as a sum of the

density contributed by all the surrounding atoms plus the electronic density of the atom in question. The first contribution is assumed to be a slowly varying function of position. If the problem is simplified by the assumption that this background electron density is a constant, the energy of the atom in question is given by the energy associated with the electron density of the atom plus the constant background density. On the basis of this ideas the total energy of a system with N atoms is given by

$$E_{\text{tot}} = \sum_{i=1}^{N} \left[F_i(\bar{\rho}_i) + \frac{1}{2} \sum_{\substack{j=1 \\ j \neq i}}^{N} u(r_{ij}) \right] \tag{117}$$

where $F_i(\bar{\rho}_i)$ is the energy required to embed atom i into the background electron density $\bar{\rho}_i$ at side i, and $u(r_{ij})$ is the core–core pair interaction potential between atom i and j separated by the distance r_{ij}.

As already remarked, the host electron density $\bar{\rho}_i$ is approximated by a linear superposition of the spherically averaged electron densities of the n_i atoms neighboring atom i,

$$\bar{\rho}_i = \sum_{\substack{j=1 \\ j \neq i}}^{N} \rho(r_{ij}) \tag{118}$$

where $\rho(r_{ij})$ is the electron density of atom j at a distance r_{ij} from the nucleus of atom i. If the atomic density $\rho(r)$ and the pair interaction $u(r)$ are both known, the embedding energy F can be uniquely defined by matching a certain equation for the cohesive energy of the metal as a function of the lattice constant. This can be used to fit $F(\bar{\rho})$ to experimental results.

The embedded-atom method has been applied with success to several problems: for face-centered cubic (fcc) metals and their alloys [423], phonon spectra in metals [424], and the structure of liquid metals [425]. It has also successfully been used for the determination of surface energies and geometries including reconstruction phenomena [426]. Other relevant topics have been studied on the basis of the embedded-atom method. In this connection let us quote the following selected studies: Numerical evaluation of the exact phase diagram of an empirical Hamiltonian: embedded-atom model for the Au–Ni system [427], Development of modified embedded-atom potentials for the Cu–Ag system [428], Atomistic process on hydrogen embrittlement of a single crystal of nickel by the embedded-atom method [429], Kinetic pathways from embedded-atom-method potentials: Influence of the activation barriers [430], and Structural and thermodynamic properties of liquid transition metals with different embedded-atom method models [431]. More information concerning the embedded-atom method is given in [432–444] and in Section 6.1.

5.3.5. Quantum Molecular Dynamics

An interesting procedure has been developed by Car and Parrinello (see [445] and, for example, [446–448]) which directly combines quantum theory with classical mechanics: The equations of the density-functional formalism [6, 7] are solved simultaneously to the classical equations of motion, so that a time-consuming iterative self-consistent procedure is not needed. This method, designated as quantum molecular dynamics, is equivalent to the self-consistent solution of the equations of the density-functional theory.

Within quantum molecular dynamics the classical Lagrange equations of the atomic positions R_j and velocities $\dot{R}_j$ are extended by a fictitious dynamics of the Kohn–Sham wave functions ϕ_i [6, 7] and their time derivations $\dot{\phi}_i$:

$$L = \sum_i \mu \int d\mathbf{r} |\dot{\phi}_i(\mathbf{r})|^2 + \frac{1}{2} \sum_j m_j \dot{R}_j^2 - E[\{\phi(\mathbf{r})\}, \{\mathbf{R}_i\}]$$
$$+ \sum_{i,j} \Lambda_{ij} \left\{ \int d\mathbf{r} \, \phi_i^*(\mathbf{r}) \phi_i(\mathbf{r}) - \delta_{ij} \right\} \tag{119}$$

The first two terms describe the kinetic energy of the nuclei and that of the orbital motion with the fictitious mass μ. The third term contains the functional of the energy as an element of the density functional formalism. The fourth term of Eq. (119) guarantees orthonormality of the wave functions, where the quantities Λ_{ij} are the Lagrange multipliers. Using this Lagrange equation we obtain the equation of motion for the nuclei

$$m_j \ddot{\mathbf{R}}_j = -\frac{\partial E}{\partial \mathbf{R}_j} \tag{120}$$

as well as the "equation of motion" for the electronic system:

$$\mu \ddot{\phi}_i(\mathbf{r}, t) = -\frac{\partial E}{\partial \phi_i(\mathbf{r}, t)} + \sum_j \Lambda_{ij} \phi_j(\mathbf{r}, t) \tag{121}$$

Equation (121) enables one to determine the wave functions $\phi_i(\mathbf{r}, t)$ as a function of time with a simultaneous motion of the atoms. It must be emphasized that this equation describes the fictitious dynamics of the electronic system and does not reflect the motion of the electrons in the field of the nuclei.

The essential difference between quantum molecular dynamics and classical molecular dynamics is that within the classical approach the forces are calculated by more or less empirically determined potentials (see Sections 5.3.1 and 5.3.2), whereas in the quantum case the forces are directly calculated from the quantum-mechanically determined potential ($E[\mathbf{R}_1, \mathbf{R}_2, \dots]$) of the system. More details concerning the principles of quantum molecular dynamics are given, for example, in [447, 448].

For a system of about 100 atoms such calculations (accurately performed) are about 1000 times slower than force field calculations and the time scale is reduced considerably. Therefore, the Car–Parrinello method in general is reduced to the picosecond time range.

Selected Studies Articles include: Wannier function analysis for understanding disordered structures generated using Car–Parrinello molecular dynamics [449], Hybrid Car–Parrinello/molecular dynamics modelling of transition metal complexes: Structure, dynamics and reactivity [450], Car–Parrinello molecular dynamics simulation of liquid water [451], A Hamiltonian electrostatic coupling scheme for hybrid Car–Parrinello molecular dynamics simulations [452], and Nonadiabatic Car–Parrinello molecular dynamics [453]. More details are given in [454–467] and in Section 6.1.

Final Remarks Molecular dynamics is in any case a *non-zero-temperature* method. On the other hand, within quantum molecular dynamics the density-functional formalism is used which is a *zero-temperature* approach and, therefore, in the case of quantum molecular dynamics non-zero-temperature data are coupled to the zero-temperature properties of the electronic part of the system. Since systems with surfaces (for example nanosystems) are in general very sensitive to small variations in temperature (in particular in connection with metals) such a treatment can lead to misleading and less relevant results, respectively, because non-zero-temperature data are mixed with zero-temperature properties. Therefore, instead of the density-functional formalism given within the Kohn–Hohenberg–Sham approach (Section 2.1.2) Mermin's formalism, briefly discussed in Section 2.1.5, should be used within quantum molecular dynamics calculations. To the authors' knowledge no calculations are reported yet on the basis on Mermin's non-zero-temperature formalism.

5.4. Covalent Binding

Many-body potentials have to be used mainly for the description of interactions within covalent bonded systems and materials, respectively, and for phenomena at higher energy levels. In metals many-body forces are less relevant because the interactions due to the conduction electrons (Section 5.3.1) are dominant.

Allinger developed widely used models (MM2, MM3) for a broad range of organic structures [468–471] which are based on the separation of the total interactions between the particles, that are significant for a bond, into a sum of single potentials with respect to *bond stretching*, *bond angle bending*, and *bond torsion*. Within the MM2 model nonbonded interactions are described by the well-known Buckingham (exp-6) potential (Section 5.1).

For the development of the interaction of such bond models a lot of *a priori* knowledge is necessary to classify all the different bond types and to treat the special cases. The MM2 and MM3 models are established to characterize within *molecular mechanics* the minimum energy configuration of structures, their stiffness, bearing properties, and the like [471], and they have become standards in literature.

The term "molecular mechanics" means the following: "Many of the properties of molecular systems are determined by the molecular potential energy function. Molecular mechanics models approximate this function as a sum of 2-atom, 3-atom, and 4-atom terms, each determined by the geometries and bonds of the component atoms. The 2-atom and 3-atom terms describing bonded interactions roughly correspond to linear springs" [471]. Molecular mechanics studies are given, for example, in [471].

Because of the basic meaning of *bond stretching*, *bond angle bending*, and *bond torsion* let us briefly discuss often used models for these interaction types [471]:

Bonds tend toward an equilibrium length r_0 and, therefore, they resist stretching and compression. Bond stretching is treated with cubic pair potentials; that is, within the MM2

model anharmonicities are taken into account. The potential energy of *bond stretching* is given by the expression

$$v_s = \frac{1}{2}k_s(r - r_0)^2\{1 - k_{cubic}(r - r_0)\} \qquad (122)$$

where r is the actual bond length, k_s is the stretching stiffness, and k_{cubic} is the parameter for describing anharmonicities.

Bond angle bending is modeled in the form of sextic three-body potentials (MM2 model) depending on the angle between two bonds to a shared atom. The potential energy v_θ for this model is given by

$$v_\theta = \frac{1}{2}k_\theta(\theta - \theta_0)^2\{1 + k_{sextic}(\theta - \theta_0)^4\} \qquad (123)$$

where θ_0 is the equilibrium bond angle, θ is actual bond angle, k_θ is the angular spring constant, and k_{sextic} is the sextic bending constant.

Bond torsion follows an expression depending on the torsion angle between two bonds within the same plane and a third one, thus acting as four-body potential; this potential describes the variation in energy associated with rotation about a bond and is expressed by

$$v_\omega = \frac{1}{2}\{V_1(1 + \cos\omega) + V_2(1 - \cos 2\omega)$$
$$+ V_3(1 + \cos 3\omega)\} \qquad (124)$$

Parameters for all the models described by (122), (123), and (124) are quoted for some common bond types in [471].

5.4.1. Models for Many-Body Potentials

Due to their complexity and difficult derivation there are basically just a few three-body potentials available which are well suited for molecular dynamics calculations and Monte Carlo studies. A comparative study and discussion of some of these empirical potentials, which have been applied mainly to carbon and silicon and other semiconductor materials, is given in [472] and the references therein.

The potentials discussed here are those of Pearson, Takai, Halicioglu, and Tiller (PTHT) [473], Stillinger and Weber (SW) [474], Biswas and Hamann (BH) [475], Tersoff (T2 and T3) [476, 477], and Dodson (DOD) [478]. These potentials constitute a good representative sample among the existing potentials (Brenner's potential will be discussed seperately); they differ in their degree of physical level, mathematical form, and range of interaction. In [472] the potentials have been tested with respect to clusters (for example, Si_2–Si_6), bulk states, and surface properties. Similarities and differences between these potentials are discussed by a systematic comparison, although a theoretical justification for the potential functions can hardly be given. They have to be considered more or less as fitting functions, since they have mostly been chosen for purely pragmatic reasons.

The potentials given by PTHT, BH, and SW can be classified as cluster potentials, the others as cluster functionals. The SW, DOD, T2, and T3 models only consider first-nearest neighbors (by the bond bending term second-neighbor interactions are implicitly considered). Interactions up to the third and seventh shell, respectively, are included in the potentials of BH and PTHT.

Cluster Potentials The cluster potentials describe bonding by means of classical two- and three-body interactions. The potential energy V can be written as

$$V = \frac{1}{2} \sum_{i,j}{}' V_2(r_{ij}) + \sum_{i,j,k}{}' V_3(r_{ij}, r_{ik}, r_{jk}) \qquad (125)$$

where all summations are distinct which is indicated by the primes. In connection with the PTHT model the potential $V_3(i, j, k)$ is symmetric with respect to an interchange of i, j, k and we have to use $i < j < k$ in the triple sum. The BH and SW models are only symmetric in j and k and the condition $j < k$ has to be used. The two-body potential is generally given by

$$V_2(r) = f_c(r)[A_1\phi_1(r) - A_2\phi_2(r)] \qquad (126)$$

where f_c is a cutoff function and ϕ_s, $s = 1, 2$, decays monotonically with r. The forms of the three-body interactions differ from each other and will be given for each potential discussed next.

The PTHT Potential Within this model the functions which define V_2 and V_3 are given by

$$f_c(r) \begin{cases} = 1 & \text{if } r < R_c \\ = 0 & \text{otherwise} \end{cases}$$

$$\phi_s(r) = r^{-\lambda_s}, \qquad s = 1, 2$$

$$V_3(r_{ij}, r_{ik}, r_{jk}) = Z\psi(r_{ij})\psi(r_{ik})\psi(r_{jk})g(\theta_i, \theta_j, \theta_k) \qquad (127)$$

$$\psi(r) = \frac{f_c(r)}{r^3}$$

$$g(\theta_i, \theta_j, \theta_k) = 1 + 3\cos\theta_i \cos\theta_j \cos\theta_k$$

where R_c is the cutoff radius and θ_1, θ_2, and θ_3 are the angles of the triangle formed by the particles i, j, and k. Within the PTHT model the two-body interaction V_2 is the Lennard-Jones potential (Section 5.2) since the exponents of $\phi_s(r)$ were chosen to be $\lambda_1 = 12$ and $\lambda_2 = 6$. V_3 is the Axilrod–Teller potential (Section 5.2).

The use of these potentials for the description of V_2 and V_3 is more than doubtful since both potentials are appropriate for noble gases but not to describe bonding in covalent system; there is simply no physical justification for that. Thus, these potentials must be viewed as fitting functions.

The PTHT model has been extensively used in the description of various materials, with and without surfaces, and it has been extended to binary and ternary systems (e.g., GaAs); more details are given in [472].

The BH Potential Within this model for the radial functions $\phi_s(r)$ Gaussians have been used, and for the cutoff function f_c a Fermi-like expression; the three-body potential function is separable. In particular, we have

$$f_c(r) \begin{cases} = \left[1 + \exp\left\{\frac{r - \sigma}{\mu}\right\}\right]^{-1} & \text{if } r \le R_c \\ = 0 & \text{otherwise} \end{cases}$$

$$\phi_s(r) = \exp(-\lambda_s r^2) \qquad s = 1, 2$$

$$V_3(r_{ij}, r_{ik}, \theta_i) = \sum_{s=1}^{2} Z_s\psi_s(r_{ij})\psi_s(r_{ik})g_s(\theta_i) \qquad (128)$$

$$\psi_s(r) = \exp(-\alpha_s r^2)f_c(r)$$

$$g_s(\theta_i) = [\cos\theta_i - \cos\phi_0]^{s+1}$$

The BH model has been used for the study of bulk and surface effects, for example, in connection with microclusters and bulk point defects [475]. More details are given in [472], in particular with respect to the determination of the parameters.

The SW Potential The radial function $\phi_s(r)$ is identical with that of the PTHT potential. The other expressions are given by

$$f_c(r) \begin{cases} = \exp\left[\frac{\mu}{r - R_c}\right] & \text{if } r \le R_c \\ = 0 & \text{otherwise} \end{cases}$$

$$V_3(r_{ij}, r_{ik}, r_{jk}) = Z\psi(r_{ij})\psi(r_{ik})g(\theta_i) \qquad (129)$$

$$\psi(r) = [f_c(r)]^{\alpha}$$

$$g(\theta_i) = (\cos\theta_i - \cos\theta_0)^2$$

f_c not only acts as a cutoff function but also defines the attractive branch of V_2 (since $\lambda_2 = 0$) and the radial components of V_3 and, therefore, the model is very sensitive to small variations in R_c.

The SW potential is mostly used in the description of systems with covalent bonds, for example, in connection with clusters, lattice dynamics, bulk point defects, etc. The potential has been applied to Si, Ge, sulfur, and fluorine and to the Si–F system [472].

Cluster Functionals Of particular interest are the cluster functionals of Tersoff type, where the bonding is described by means of pairwise interactions, but many-body interactions are effectively included with respect to the attractive term of the pair interaction which is dependent on the local environment. The potential energy takes the form

$$V = \frac{1}{2} \sum_{i,j}{}' f_c(r_{ij})\{A_1\phi_1(r_{ij}) - A_2\phi_2(r_{ij})p(\xi_{ij})\} \qquad (130)$$

where ξ_{ij} is the effective coordination number and determines p which is a measure of the bond order, where we have to consider that p has in general the property

$$p(\xi_{ij}) \ne p(\xi_{ji})$$

ξ_{ij} is given by

$$\xi_{ij} = \sum_{k \ne i,j} V_3(r_{ij}, r_{ik}, \theta_i) \qquad (131)$$

with

$$V_3(r_{ij}, r_{ik}\theta_i) = \psi(r_{ij}, r_{ik})g(\theta_i) \qquad (132)$$

Rewriting (130) the two-body energy term can be extracted and we get

$$V = \frac{1}{2}\sum_{i,j}{}' V_2(r_{ij}) + \frac{1}{2}\sum_{i,j}{}' A_2\phi_2(r_{ij})f_c(r_{ij})$$
$$\times \{1 - p(\xi_{ij})\} \qquad (133)$$

It can be shown by simple manipulations that the second term of (133) effectively includes many-body effects [472].

The DOD Potential Dodson chose the following form for the model functions:

$$f_c(r)\begin{cases} = \frac{1}{2}\left[1 - \cos\left(\frac{\pi(r - R_c)}{\mu}\right)\right] \\ \qquad \text{if}\quad R_c - \mu < r < R_c \\ = 1 \qquad \text{if}\quad r \le R_c - \mu \\ = 0 \qquad \text{otherwise} \end{cases}$$

$$\phi_s(r) = \exp(-\lambda_s r) \qquad s = 1, 2$$
$$p(\xi_{ij}) = \exp(-\xi_{ij}^n) \qquad (134)$$
$$\psi(r_{ij} r_{ik}) = \left[\frac{\phi_2(r_{ik})f_c(r_{ik})}{\phi_2(r_{ij})f_c(r_{ij})}\right]^\alpha$$
$$g(\theta_i) = \frac{\beta}{\eta + \exp(-\delta \cos\theta_i)}$$

This potential has been used for studying surface reconstructions and low-energy beam deposition of Si. It should be mentioned that the DOD potential is similar to the first Tersoff potential [479].

The Tersoff Potential (T_2 and T_3) Here two different parametrizations are used for the same potential, leading to the T_2 and T_3 potentials. The expressions for f_c and ϕ_s are identical with those used within the DOD potential. The other functions have been chosen as follows:

$$p(\xi_{ij}) = (1 + \xi_{ij}^n)^{-1/2n}$$
$$\psi(r_{ij}, r_{ik}) = f_c(r_{ik})\exp(\alpha^3(r_{ij} - r_{ik})^3) \qquad (135)$$
$$g(\theta_i) = \beta + \frac{\eta^2}{\delta^2} - \frac{\eta^2}{\delta^2 + (\cos\theta_i - \cos\theta_0)^2}$$

The potential parameters for Si were fitted to the cohesive energy, lattice parameter, and bulk modulus of the diamond structure, and the cohesive energy of bulk polytypes of silicon [480, 481]. In connection with the T_3 model an additional constraint was used in order to fit the three elastic constants.

The T_2 and T_3 potentials have been used to study lattice dynamics, microclusters, bulk point defects, the liquid and amorphous states, surface reconstructions, etc. More details are given in [472].

It should be emphasized that the Tersoff formalism is obviously similar to the embedded-atom method (Section 5.3.4) since by a proper choice of functional forms and model parameters the two expressions for the potential energy can be made identical [482].

Other Potentials Further expressions for the potential form exist in the case of covalent binding, but here we only want to quote the empirical potential by Brenner [483] which has often been used in the description of numerous processes including the nanometer-scale indentation of diamond surfaces, the deformation of carbon nanotubes, the formation of fullerenes from graphitic ribbons, etc. [484]. The Brenner potential (the so-called hydrocarbon potential) can be formulated as follows [483]: The binding energy for the potential is formulated as a sum over bonds as

$$E_b = \sum_i \sum_{j>i}[V_R(r_{ij}) - \overline{B}_{ij}V_A(r_{ij})] \qquad (136)$$

where the repulsive pair term is given by

$$V_R(r_{ij}) = f_{ij}(r_{ij})D_{ij}^{(e)}/(S_{ij} - 1)e^{-\sqrt{2S_{ij}}\beta_{ij}(r - R_{ij}^{(e)})} \qquad (137)$$

and the attractive pair term has the form

$$V_A(r_{ij}) = f_{ij}(r_{ij})D_{ij}^{(e)}S_{ij}/(S_{ij} - 1)e^{-\sqrt{2S_{ij}}\beta_{ij}(r - R_{ij}^{(e)})} \qquad (138)$$

The function $f_{ij}(r)$ restricts the pair potential to nearest neighbors and is given by

$$f_{ij}(r)\begin{cases} = 1 \qquad r < R_{ij}^{(1)} \\ = \frac{1}{2}\left[1 + \cos\left\{\frac{\pi(r - R_{ij}^{(1)})}{(R_{ij}^{(2)} - R_{ij}^{(1)})}\right\}\right] \\ \qquad R_{ij}^{(1)} < r < R_{ij}^{(2)} \\ = 0 \qquad r > R_{ij}^{(2)} \end{cases} \qquad (139)$$

We do not want to discuss the details of this potential and refer to [483], but the following should mentioned: If $S_{ij} = 2$, then the pair terms have the form of the usual Morse potential (Section 5.1) and, furthermore, the equilibrium distance $R_{ij}^{(e)}$, the well depth $D_{ij}^{(e)}$, and the parameter β_{ij} are equal to the parameters for the usual Morse potential (independent of the value of S_{ij}). Critical remarks concerning the Morse potential are given in Section 5.1.

Applications The potentials introduced above are important for the description of covalent systems, in particular, in connection with carbon and silicon systems, respectively. Let us quote here some selected studies which are based on the often used potentials by Stillinger and Weber, Tersoff, and Brenner.

Stillinger–Weber Potential Articles include: Nearest neighbor considerations in Stillinger–Weber type potentials for diamond [485], Development of an improved Stillinger–Weber potential for tetrahedral carbon using *ab initio* (Hartree–Fock and MP2) methods [486], Computed energetics for etching of the Si(100) surface by F and Cl atoms [487], Boson peak in amorphous silicon [488], and Strain profiles in pyramidal quantum dots by means of atomistic simulation [489]. Further information is given in [490–499].

Tersoff Potential Articles include Modeling chemical and topological disorder in irradiation-amorphized silicon carbide [500], Atomic diffusion at solid/liquid interface of silicon: Transition layer and defect formation [501], Predictive study of thermodynamic properties of GeC [502], Orientation dependence in C_{60} surface-impact collisions [503], Parameter optimization of Tersoff interatomic potentials using genetic algorithm [504], etc. [505–522].

Brenner Potential Articles include: Monte Carlo simulations of carbon-based structures on an extended Brenner potential [523], Numerical study of shapes of fullerenes with symmetrically arranged defects [524], Energy window effect in chemisorption of C_{36} on diamond (001)-(2 × 1) surface [525], Reconstruction of diamond (100) and (111) surfaces: Accuracy of the Brenner potential [526], Phonon spectra in model carbon nanotubes [527], and Interaction among C_{28} clusters and diamond (002) surfaces [528]. More information is given in [529–541].

6. MOLECULAR DYNAMICS

In this section we give an overview about recent results in the field of molecular dynamics. Clearly, not all studies could be considered but we selected interesting investigations which, on the other hand, also reflect a broad variety of applications in connection with nanometer-scale molecular dynamics. First a brief overview about various topics is given. Then some specific molecular dynamics models will be discussed which is followed by a more detailed study of metallic nanosystems.

6.1. Design at the Nanolevel

6.1.1. Recent Developments

Selected studies about the following topics are compiled: nanomachines, metallic nanosystems, biological systems, nanostructures and nanostructured materials, nanoclusters and nanoparticles, nanotubes and fullerenes, nanowires, and silicon and carbon.

Nanomachines Articles include: Molecular mechanics and molecular dynamics analysis of Drexler–Merkle gears and neon pump [542], Docking envelopes for the assembly of molecular bearings [543], dynamics of He/C_{60} flow inside carbon nanotubes [544], On the importance of quantum mechanics for nanotechnology [545], dynamics and fluid flow inside carbon nanotubes [546], Dynamics of a laser-driven molecular motor [547], and The dynamics of molecular bearings [548].

Metallic Nanosystems Articles include: Simulation of chemical mechanical planarization of copper with molecular dynamics [549], Atomistic simulations of solid-state materials based on crystal-chemical potential concepts: Applications for compounds, metals, alloys, and chemical reactions [550], Metallic nanoislands: Preferential nucleation, intermixing and electronic states [551], Large-scale molecular dynamics study of the nucleation process of martensite in Fe–Ni alloys [552], Molecular dynamics simulation of the grain-growth in nano-grained metallic polycrystals [553], and Melting and freezing of gold nanoclusters [554]. Further studies can be found in [555–594].

Biological Systems Articles include: Completion and refinement of 3-D homology models with restricted molecular dynamics [595], Simulation of biological ionic channels by technology computer-aided design [596], Interfacing molecular dynamics with continuum dynamics in computer simulation: Towards an application to biological membranes [597], Structural properties of a highly polyunsaturated lipid bilayer from molecular dynamics simulations [598], Comparison of aqueous molecular dynamics with NMR relaxation and residual dipolar couplings favors internal motion in a mannose oligosaccharide [599], Molecular dynamics simulation of thymine glycol-lesioned DNA reveals specific hydration at the lesion [600], A molecular dynamics study based post facto free energy analysis of the binding of bovine angiogenin with UMP and CMP ligands [601], and Molecular dynamics of DNA quadruplex molecules containing inosine, 6-thioguanine and 6-thiopurine [602]. More information about molecular dynamics in connection with biological systems is given in [603–637].

Nanostructures and Nanostructured Materials Articles include: Molecular dynamics in nanostructured polyimide–silica hybrid materials and their thermal stability [638], Computer simulation of displacement cascades in nanocrystalline Ni [639], Mechanical properties of nanostructured materials [640], Sintering, structure, and mechanical properties of nanophase SiC: A molecular dynamics and neutron scattering study [641], Multiresolution algorithms for massively parallel molecular dynamics simulations of nanostructured materials [642], Computer modeling the deposition of nanoscale thin films [643], and Molecular dynamics simulation of lattice distortion region produced by rounded grain boundary in nanocrystalline materials [644]. Further information about this topic is given in [645–689].

Nanoclusters, Nanoparticles Articles include: Charge dependence of temperature-driven phase transitions of molecular nanoclusters: Molecular dynamics simulation [690], Theoretical study of the atomic structure of Pd nanoclusters deposited on a MgO(100) surface [691], Melting of bimetallic Cu–Ni nanoclusters [692], Structure and properties of silica nanoclusters at high temperatures [693], Platinum nanoclusters on graphite substrates: A molecular dynamics study [694], and Study of self-limiting oxidation of silicon nanoclusters by atomic simulations [695]. More information about molecular dynamics in connection with nanoclusters and nanoparticles is given in [696–731].

6.1.2. Specific Molecular Dynamics Investigations on Nanosystems

Nanogears Concerning nanogears interesting models have been studied by Globus and co-workers from the NASA Advanced Supercomputing Division (see, for example, [922]). A typical example is given in Figure 11: The operation of these nanogears was simulated using molecular dynamics calculation and Brenner's hydrocarbon force field (Section 5.4.1). The study showed that if one gear is turned by an external force, the second gear will turn as well. Furthermore, if the gears are driven too fast (input rate >0.4

Figure 11. On the basis of fullerene nanotechnology it is possible to construct nanomachines, for example, nanogears. A typical gear configuration, designed by A. Globus (NASA Advanced Super-computing Division), is shown in the figure (see, for example, also [822]). The operation of these nanogears was simulated using molecular dynamics calculation on the basis of Brenner's hydrocarbon force field (Section 5.4.1). Courtesy of NASA.

rotations per picosecond), then slippage occurs but bonds do not break and normal operation will resume when the rotation rate slows.

Bending of Nanotubes The bending of a (8,8) nanotube has been simulated in [923]. The study was performed on the basis of molecular dynamics calculations. For the interatomic interaction Brenner's potential has been used (Section 5.4.1). The results are shown in Figure 12. The 21 nm long tube contained 2688 atoms. In the simulation a portion of 3.6 Å was fixed from both ends of the tube. One of the ends was forced to move on a half-circular path at a constant rate. The radius of the circular path was a half of the tube length. The total bending time was 250,000 fs during which the simulation temperature was kept at 300 K.

Atomistic Simulations of Plastic Deformations in Glassy Amorphous Polymers [924] as the demand for polymers with superior properties increases, an understanding of the fundamental connections between the mechanical behavior and underlying chemical structure becomes imperative. In this work, the thermo-mechanical behavior and the molecular-level origins of elastic and plastic deformation in an amorphous glassy polymer were studies using molecular dynamics simulations (Fig. 13a). A velocity Verlet integration scheme with a Berendsen barostat and a Nose–Hoover thermostat were used to study a system of united atom polyethylene. These simulations provide detailed atomic information that has been used to verify experimental results. Stress-induced mobility has been directly observed within these simulations (Fig. 13b), corroborating similar observations in nuclear magnetic resonance experiments of Loo et al. [925]. Dihedral angle transition rates are observed to increase during active deformation and drop off again when deformation ceases. These simulations also show that there is no correlation between local volume and dihedral angle transitions in this system.

Models of the Dodecamer DNA Double Stranded Segment Molecular dynamics simulations were performed on models of the dodecamer DNA double stranded segment [d(CGCGAATTCGOG)], in which each of the adenine residues, individually or jointly, was replaced by the water-mimicking analog 2′-deoxy-7-(hydroxymethyl)-deazaadenosine (hmdA). The simulations, when compared to the dodecamer itself, show that incorporation of the analog affects neither the overall DNA structure nor its

hydrogen-bonding and stacking interactions when a single individual base is replaced by the analog. Furthermore, the water molecules near the basis in the single-substituted oligonucleotides are similarly unaffected (Fig. 14). Double substitution lead to differences in all the aforementioned parameters with respect to the reference sequence [926].

Visualization of the Pathway of Diffusants in Amorphous Polymers   The diffusion in nanoconfined polymers has been studied by Boshoff and co-workers [527] in order to study the effects of polymer structure and dynamics on the molecular mechanism of diffusion (see also Fig. 15).

6.2. Metallic Nanosystems

As we have outlined, the interaction potentials for nanosystems have to be constructed carefully since surface properties are in general very sensitive to small variations in the potential shape, and in the case of nanosystems a great fraction of atoms belongs to the surface region of the system. This effect is particularly significant in the case of metals.

The determination of pair potentials for metals can be done, for example, by means of pseudopotential theory that

Figure 14. Molecular dynamics simulations were performed on models of the dodecamer DNA double-stranded segment, in which each of the adenine residues, individually or jointly, was replaced by the water-mimicking analog 2′-deoxy-7-(hydroxymethyl)-deazaadenosine (hmdA). Water molecules within hydrogen bonding distance (proton–acceptor distances < 2.5 Å and angle donor–proton acceptor > 120 to the acceptor/donor groups of the GAATIC bases) were selected and are shown superimposed (for a better understanding the oxygen atoms of the water molecules are shown as vdW spheres with a reduced radius). The DNA atoms are vdW representation. The analog bases are shown in gray. More details are given in the text. we have discussed in Section 5.3.1. In this section we would like to study molecular dynamics results for Al (as a typical example for a metal system); the specific behavior of *clusters* will be discussed, but also some remarks in connection with
Figure 15. A diffusion pathway of a tracer He atom in a glassy, amorphous polypropylene model. Each colored sphere represents a snapshot of the He atom's position along a 150 ps trajectory (starting at blue and ending at red), as calculated by molecular dynamics at 233 K. Snapshot are spaced 0.1 ps apart. The polymer is represented by carbon–carbon bond for clarity. Courtesy of J. Boshoff, Chemical Engineering, University of Delaware.

nanoengineering will be given. The potential for Al used in this study has been determined in accordance with the principles outline in Section 5.3.1.

6.2.1. Interaction Potential for Al

In the case of noble gases (for example, krypton [928]) the temperature dependence of system properties can be treated in a good approximation on the basis of temperature-independent pair potentials. That is in general not possible in the case of metals. Why?

As we have already outlined in Section 5.3.1, a metal consists of ions and conduction electrons. The interactions between the ions are strongly influenced by the *screening* of the conduction electrons, and the screening is sensitive to the density of the conduction electrons, which is, on the other hand, temperature dependent. Therefore, we may conclude that the pair potential in metals is in general dependent on temperature. This property is reflected in the dielectric function $\varepsilon(q)$, which in turn is important for the determination of the pair potential within the framework of pseudopotential theory.

How large are such temperature effects for Al? In a first attempt [929] a pseudopotential was used, developed by Dagens et al. [930]. This potential is a nonlocal pseudopotential; the screening is described by the Geldart–Taylor dielectric function. However, this potential was not sufficient to describe certain properties at the surface. Therefore, another model has been chosen for the pseudopotential which is obviously more realistic [931]. Concerning this model, the essential point is the consideration of interactions of *van der Waals type* in the determination of the direct ion–ion potential as well as in the ion–electron part of the interaction. (Numerical calculations for liquid rubidium near the melting point showed that van der Waals-type interactions are distinctly reflected in the metal potential [932].)

The pair potential for Al based on this kind of potential is shown in [933] for two temperatures (300 and 1000 K; the melting temperature is 933 K). The free parameters were fitted with the help of crystal and liquid data for various temperatures and, therefore, the temperature-dependent Al potential describes a wide range of experimental bulk and surface properties:

(1) The crystal is stable up to the melting point. The phonon density of states at $T = 300$ K is described well. (2) The structure and dynamics of the liquid state are also described adequately by the potential: The structure factor (Fourier transform of the pair correlation function) of the liquid state agrees well with experimental data, and the correct value of the diffusion constant is obtained. (3) The melting temperature (933 K) of Al is reproduced by the potential. (4) We found for the outermost layer an inward relaxation, which is confirmed by experiments [934]. (5) The mean-square displacements at the surface agree well with LEED data [934]. (6) The molecular dynamics results indicate that there are relatively strong anharmonic effects already at low temperatures; this is confirmed by experiments [934], too. (7) The onset of premelting ($T > 650$ K) resulting from the molecular dynamics calculations agrees excellently with the experimental observations.

6.2.2. Metastable Cluster-States

Molecular dynamics calculations have been performed for cubic nanoclusters with (001) surfaces consisting of $N = 500$ atoms [935]. For this system the classical Hamilton equations were solved by iteration. The time step in the calculation was 10^{-15} s. The number of time steps was 4000 (4 ps). The initial values for the positions were chosen to be the bulk structure. In the case of Al and $N = 500$ particles, the box size of the clusters is approximately 20 Å. The cutoff radius for the interaction potential was chosen as the sixth nearest neighbor distance.

The initial velocities have been set according to a temperature of 50 K followed by an equilibration phase of 2000 time steps (2 ps). In the following $t = 0$ refers to the end of the equilibration phase (i.e., the time at which the system has reached thermal equilibrium). The initial directions of the velocities were distributed randomly, so that the velocity averaged over all particles was zero and remained zero for all time steps.

The amplitudes of the velocities determine the temperature T of the system [Eq. (80), Section 4.2.3] and also the α-function [Eq. (75), Section 4.2.3] which can be used for the study of the thermodynamic state. As already outlined in Section 4.2.3, due to the finite number of particles T and α fluctuate around mean values.

Figure 16 shows the temperature T and the α-function as a function of time t. As can be seen, there are three different phases: (1) In the interval $0 \leq t \leq 1$ ps the cluster remains in thermal equilibrium (α fluctuates around 5/3) at a mean temperature of 50 K (with the usual, stable fluctuations). (2) Within the interval $1 \leq t \leq 2$ ps a transition takes place without any external influence, and within this time interval the temperature rises up to 160 K. (3) Finally, for $t > 2$ ps
Figure 16. Temporal development of the temperature and the α-function for a cubic Al_{500} cluster with (001) surfaces. Initially, the cluster remains in thermal equilibrium at about 50 K for 1 ps ($\alpha = 5/3$ indicates thermal equilibrium, Section 4.2.3). Then, during a transition phase the cluster temperature increases to 160 K. During the transition phase of 1 ps the cluster leaves equilibrium. After this process, the mean temperature remains at 160 K for all times and the system also remains in thermal equilibrium. It should be emphasized that the whole process takes place without external influence; that is, there is no outer effect causing the transition.

the cluster temperature remains at 160 K and in thermal equilibrium (α fluctuates around 5/3).

How can we interpret this transition? What is the driving force behind this phenomenon and, furthermore, under what conditions does it occur?

The cluster is obviously in a metastable state within the first phase (50 K), and in the third phase (160 K) it is in a stable state. Further, due to the energy conservation of the system the potential energy of the cluster in the stable state has to be smaller compared to that in the metastable state. Therefore, the structure of the metastable state should be different from that of the stable state, since the potential energy depends on the relative distances of the atoms. Let us first study the structure and after that the Dynamics of the cluster in the metastable state as well as in the stable state.

Structure The structure of the different cluster states has been studied by means of the structure factor (see, for example, [393])

$$S(q) = \frac{1}{N} \sum_{i,\,j=1}^{N} \langle \exp[i\mathbf{q}(\mathbf{r}_i - \mathbf{r}_j] \rangle \qquad (140)$$

where $\langle \cdots \rangle$ denotes again statistical averaging, $\mathbf{q}$ is the wave vector, and $\mathbf{r}_i$ is the position vector of the ith particle. By averaging of $\mathbf{q}$ over all directions, $S(\mathbf{q})$ only depends on the magnitude of $\mathbf{q}$: $S(q)$ with $q = |\mathbf{q}|$.

Figure 17 shows the results of $S(q)$ for the metastable and the stable state together with the results for the bulk state (500 particles with periodic boundary conditions). As can be seen, the typical double peak of fcc-structured materials at about 2.7 and 3.1 Å^{-1} appears also for the other states (indicated in Fig. 17 by gray bars). However, the metastable cluster state additionally exhibits a well pronounced peak at 3.4 Å^{-1} which is missing in the stable state as well as in the bulk (indicated by the yellow bar). This peak can be interpreted as a superstructure that has been formed within the metastable cluster due to a periodical particle shift.

Dynamics The cluster dynamics has been studied by means of the generalized phonon density of states $f(\omega)$, and this quantity can be calculated from the velocity autocorrelation function $\phi(t)$ by means of a Fourier transform (Section 4.2.3). As already outlined in Section 4.2.3, the Fourier transform of $\phi(t)$ yields a frequency spectrum which is, in the case of the *harmonic* solid, the frequency spectrum of the normal modes. Thus, for an *anharmonic* system, for example, clusters, we can define a generalized phonon density of states $f(\omega)$ by means of the Fourier transform of $\phi(t)$.

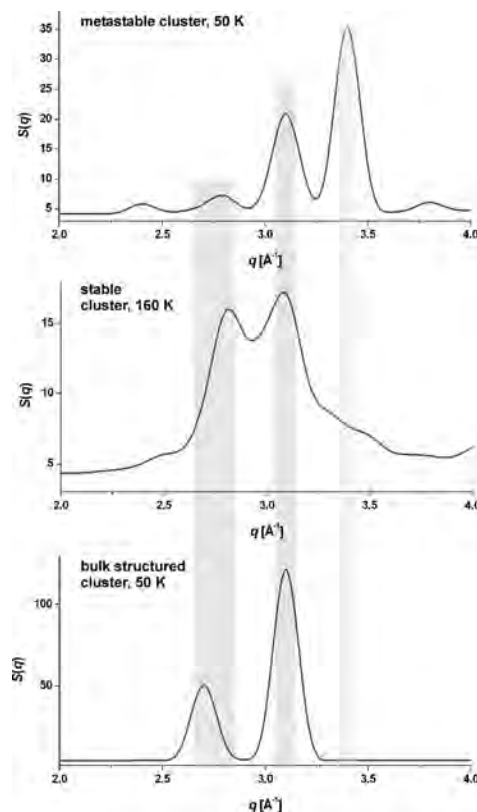
$\phi(t)$ has been calculated by molecular dynamics, and its Fourier transform is shown in Figure 18. In Figure 18 the generalized phonon density of states is given as a function of ν with $\omega = 2\pi\nu$. For the metastable state $f(\nu)$ at 50 K is quite different from that of the stable state at 160 K. In particular, the pronounced peak at 2 THz (metastable state) does not appear in the frequency spectrum of the stable state (and also not in the bulk). Thus, we may conclude that the appearance of the superstructure in the metastable state (Fig. 17) is accompanied with the appearance of the low frequency mode at 2 THz. This mode is completely missing


Figure 17. Structure factor $S(q)$ of a cubic Al$_{500}$ cluster with (001) surfaces which is in the metastable and stable state, compared with $S(q)$ for the bulk (also here 500 particles have been used but with periodic boundary conditions). The light blue bars indicate peaks which are common for all phases; they are typical for Al. The yellow bar emphasizes the well pronounced peak at 3.4 Å^{-1} that appears only in the metastable phase and could be a hint for a superstructure.

Figure 18. Generalized phonon density of states $f(\nu)$ of a cubic Al$_{500}$ cluster in the metastable and stable state. The well pronounced peak at 2 THz in the frequency spectrum of the metastable state is recognizable to some extent only in the stable state. This peak results from surface oscillations at the metastable cluster.

in the spectrum of the solid in the bulk as well as in the liquid bulk state. The low frequency mode is probably the cause for the transition from the metastable to the stable cluster state. Let us briefly discuss this.

The outer dimensions of the metastable cluster are smaller compared to the initial bulk-structured cluster. Therefore, during the equilibration phase the whole cluster passes through a "shrinking process," and due to the repulsion, this shrinking process should be followed by a "recoiling effect"; that is, there is an oscillation reflected in a temporal change of shrinking and recoiling leading to a "breathing" of the whole cluster.

In connection with Figure 16 we discussed that the potential energy V_{ms} of the metastable state must be larger than the potential energy V_s of the stable state. Since the transition takes place after a certain time and not at once, we can conclude that there is a certain potential barrier ΔV_{ms} which the cluster has to overcome. The "breathing" of the cluster can lead to the effect that the system has, at a certain time, the potential energy $V \geq V_{ms} + \Delta V_{ms}$, and then the transition from the metastable to the stable state can take place; it is only a question of time until a fitting configuration has established by chance which yields a potential energy high enough ($V \geq V_{ms} + \Delta V_{ms}$) to overcome the potential-energy barrier.

Analogies to Atomic Excitations There is a certain analogy between metastable states of clusters and of atoms in an excited electron state: (1) The potential energy in the excited (metastable) state is larger than in the ground (stable) state. (2) The systems (atoms, clusters) leave their excited (metastable) state without external influence after a certain time interval: the atoms by emiting photons, the clusters by increasing their temperature (see also Fig. 16).

The atoms are in an excited state for 10^{-8} s while the clusters are in a metastable state for approximately 10^{-12} s. The time interval of 10^{-12} s is much smaller than 10^{-8} s (excitation time of atoms). Nevertheless, the lifetime of 10^{-12} s of the metastable state is relatively large; it is distinctly larger than the time interval (0.4×10^{-12} s) that a sound wave needs for the propagation across the nanosystem. The lifetime of such metastable states is a function of the particle number and is also a function of the outer shape of the nanosystem [3].

6.2.3. Bifurcation Phenomena

In connection with metastable states of clusters the following effect is of particular interest: When a cluster transforms from the metastable to the stable state, there are several possibilities for that. In other words, the local minimum in the potential energy of the metastable state is surrounded by numerous deeper minima which correspond to numerous stable states. Which of these stable states the cluster will finally take cannot be predicted in principle. Due to the unavoidable fluctuations in the potential energy of such nanosystems it is completely a matter of chance (Section 6.2.2).

In other words, in connection with cluster state transitions there is a *bifurcation* in the sense of chaos theory (Fig. 19): At the bifurcation point nature plays dice to decide on which

Figure 19. Illustration of the bifurcation phenomenon: In principle it cannot be predicted in what stable state the metastable systems transits. At the bifurcation point nature plays dice in order to decide on which of the various branches the cluster will finally rest.

of the various branches (stable states) the cluster will finally rest.

Stable cluster configurations may differ in both the inner structure as well as the outer shape. In general, the inner structures show multicrystalline compositions (i.e., there are grain boundaries, dislocations, and other lattice defects). The outer shapes of the clusters strongly depend on the arrangement of these lattice defects.

This is an interesting phenomenon and there is no counterpart in micro- and macrotechnique. In macrotechnique, a system (for example, a machine) will always be destroyed after a certain time, if the mechanic does not keep the machine in good condition; this degradation of the system is due to its interaction with the systems surrounding. There are no other transitions in micro- and macrotechnique. As we have seen, the situation is different in connection with nanosystems: The transition at the bifurcation point is constructive; the system will not simply be destroyed but there emerge new forms, namely one of the possible stable states (see Fig. 19).

As said, in micro- and macrotechnique we do not observe such phenomena, and this is because there are no such metastable states. If there were, nevertheless, metastable states also established in the macroscopic realm, in principle a screwdriver could transform spontaneously into a hammer or a nippers; Nature plays dice; a screwdriver becomes either a hammer or a nippers, and such transitions would take place without any external influence. We know that such phenomena are not possible in micro- and macrotechniques but should be real phenomena in nanotechnology, in particular, within the frame of materials research at the nanolevel.

The bifurcation phenomenon is the behavior of single clusters. This specific behavior comes into play by the mutual influence of temperature and the interaction between the particles forming the cluster. There is a certain kind of independent creativity which does not come from outside; that is, it is not forced by the observer or by other factors of the

environment but is an inherent characteristic of the system itself. Such behavior is also known in connection with biological systems, which are, however, much more complex compared to the Al clusters studied here. Since this specific behavior (creativity) is essentially influenced by the temperature and the interaction potential between the particles, nanosystems at zero temperature have to be considered as "dead" systems without any creativity.

6.2.4. Final Remarks

Although the Al clusters represent *inorganic* systems there are certain analogies to biological systems:

(1) A nanosystem can be creative; that is, it can meet individual decisions which cannot be influenced from outside; the bifurcation phenomena (Fig. 18) can be interpreted in this way.
(2) A nanosystem is able to transform spontaneously; it can transform from a metastable state to a stable state without external influence. Spontaneous transformations are also typical phenomena within biology, in particular in connection with embryology.
(3) New forms, new shapes, which were not existent before, emerge without external influence. Also within biology (e.g., in embryology) new forms appear, which were not existent before.
(4) The shapes of such nanosystems transform to more complex forms. This behavior too is typical for biological systems and is a feature of biological evolution. The nanosystems transform, for example, from a cube to a cuboid, and a cuboid is more complex than a cube because one needs more description elements to characterize it.

6.3. Nanoengineering

6.3.1. Nanomodels

So far the general procedures and different elements for designing molecular dynamics models have been discussed. As long as there are just single and simple shaped objects of interest, like cubical nanoclusters, the setup of an appropriate molecular dynamics model is relatively easy. Since the initial positions are given by the perfect lattice structure such objects can be built by using any programming language to implement the according algorithms. Depending on the variety of materials, characterized by the lattice constant and structure (fcc, body-centered cubic, hexagonal, etc.), and depending on the possible orientations [(001), (011), (111), and so on] the software development is more or less extensive. For the generation of (semi-infinite) surface models the additional application of periodic boundary conditions (within two dimensions) is necessary.

But obviously such simple objects are only of minor interest within the field of nanoengineering, where either structures with complex shapes or interactions (cluster–cluster or surface–cluster) under various conditions play an important role. Especially for studies of nanomachines (but for others too) the molecular dynamics (MD) models have to contain moving parts in addition to objects of miscellaneous materials, and therefore, the software should be able to combine single structures, each with different initial values.

Quite clearly, the development of a computer program that can generate MD models for all the above-mentioned topics is rather extensive. While the setup of simple structures (cuboids, spheres, surfaces) and the setup of the initial values according to rotational or transitional movements and for the construction (positioning, centering, adjusting) of individual objects may be fixed by usual programming, the nanodesigning part of complex shapes has been accomplished by a common commercial software.

The idea arose from the fact that for metallic nanostructures—unlike covalent bonded materials—there are basically no restrictions concerning their initial shapes (i.e., in this case a molecular dynamics model can be built first by defining the outer shape and then by filling it up with atoms according to the crystal lattice). Since the design of three-dimensional shapes is a very common topic within mechanical engineering—the so-called computer aided design (CAD)—one can use a suitable CAD software with a programming interface to perform such a task.

Here the choice fell on the commercial software package Genius Desktop® (in combination with Mechanical Desktop®) that includes a LISP derivative as programmable interface. At first, two additional system functions have been developed, one to compute the outer limits of a three-dimensional CAD object, the other to determine whether a given spatial point lays within a selected object or not. Then, with the help of these functions the implementation of various filling, scaling, and storage algorithms for different lattice structures has been performed.

But in contrast to common mechanical engineering the nanodesign does not end here. The nanomodel with its initial atomic perfect lattice positions corresponds to a temperature of 0 K. So the next step is to accelerate the atoms until an equilibrium is reached according to a prescribed specific model temperature. Such an equilibration is performed during a sufficient number of MD calculation steps by rescaling the particle velocities:

$$\mathbf{v}_i(t) \leftarrow \sqrt{\frac{T_d}{T}}\mathbf{v}_i(t) \qquad i = 1, \ldots, N \qquad (141)$$

where T_d is the desired model temperature, and T and $\mathbf{v}_i$ are the current temperature value and velocity vectors. During such an isothermal equilibration phase, the rescaling needs to be applied after about each tenth time step only.

The rescaling of velocities is not only useful for the equilibration of nanomodels but can be applied during molecular dynamics calculations too, where varying T_d with time leads to artificial tempering or cooling processes.

6.3.2. Differences Between Nanoengineering and Common Mechanical Engineering

Most often the initial molecular dynamics model, according to the perfect lattice structure, is not a stable configuration. Figure 20 illustrates the typical design steps in the case of metallic nanostructures. First, a CAD model is established which defines the rough layout, known from common mechanical engineering. Then the molecular dynamics model is created by filling the CAD design with single atoms.
Figure 20. The three steps of nanodesign: First, a CAD model has to be established. Then, the molecular dynamics model is created by filling the CAD object with 1958 aluminum atoms. Finally, temperature is applied on the model during an equilibrium phase (in this case 300 K).

Finally, the realistic nanostructure results from the equilibration process which applies a prescribed temperature to the molecular dynamics model.

As can be seen quite clearly, the final shape differs significantly from the CAD model. How can this be explained?

The atomic positions of the molecular dynamics model are set according to the perfect lattice structure. While such a structure is a stable configuration in macroscopic realms this is no longer valid for nanometer-sized objects. Therefore, the atoms of the molecular dynamics model rearrange their positions during the equilibration phase until a stable configuration is reached. Most often this leads to quite different results compared to the initial design.

In conclusion, one has to recognize that, in comparison to common mechanical engineering nanodesign strongly depends on the outer shape of the considered structure.

Another difference is significant too: While in mechanical engineering sharp edges or plane surfaces or any shape and also continuous calibrations are common, nanodesign is limited to certain positions of single atoms (i.e., the shape of structures is restricted to certain measures dependent on the material). This becomes obvious, if one thinks about such trivial mechanical parts like fittings and bearings.

And in addition, the initial shape of a nanomodel which may have more or less pronounced edges can change considerably during the equilibration phase (as well as later on during the molecular dynamics calculation) and, therefore, the layout of the model would have to be redesigned. That is, building nanomodels or performing nanoengineering is an iterative process of nanodesign, molecular dynamics

calculation, and redesign, and there is almost nothing in common with common mechanical engineering.

6.3.3. Nanomachines

The synthesis of real nanomachines has not yet been performed, but it is a most interesting topic to perform molecular dynamics studies and, therefore, to determine how and under what conditions nanomachines could be working—regardless of the question of how to assemble them in reality.

An example of such a study is illustrated in Figure 21. This is a model of a simple nanoturbine that consists of a paddle wheel with an axle and two bearings resting on a substrate. The propulsion of the turbine could be established by a particle or laser beam.

When comparing Figure 21a with Figure 21b the differences between common mechanical engineering and nanodesign again become obvious. While mechanical engineering
Figure 21. Nanoengineering of a simple turbine. The turbine consists of a paddle wheel with an axle and two bearings. (a) Mechanical engineering model build with common CAD software. (b) Perspective view and cross-section of the MD model [the corresponding side view is shown in (c)]. The paddle wheel rotates with 5×10^{10} revolutions per second. (d) The paddle wheel ruptures, if the number of revolutions is increased to 10^{11} per second model [the side view of (d) is shown in (e)]. The bearings (blue) consist of 4592 silicon atoms, each with ideal shaped surfaces. Due to the strong covalent bonds of silicon the bearings have been treated as rigid objects within the MD calculations. The axle with the attached paddle wheel (yellow) has been assembled with 5226 aluminium atoms and the substrate (green) consists of krypton.

usually works with sharp edges and smooth surfaces, nano-design is restricted to the use of single atoms which leads to the typical grainy appearance of nanostructures. Moreover, tolerances may be kept very small with mechanical engineering, but nanodesign allows measures only in certain steps where the steps depend on the according material. Therefore, the fit of axle and bearing is rather loose as can be seen in the cross-sections of Figure 21. However, the MD studies have shown that such nanoturbines could be working stable for revolutions of up to about 5×10^{10} per second.

7. MONTE CARLO METHOD

In contrast to molecular dynamics calculations, where we have completely deterministic algebraic equations, the Monte Carlo method is a numerical approach in which specific stochastic elements are used. The Monte Carlo method was introduced by Metropolis et al. [936] in 1953. The method and results have been extensively reviewed in the literature (see, for example, [937]). Since we have concentrated in this chapter mainly on molecular dynamics, we only want to discuss here some basic characteristics.

Whereas the molecular dynamics method enables the investigation of *static* and *dynamic* properties, the Monte Carlo method only deals with *static* properties; these are configurational averages and thermodynamics quantities. The results produced by the two methods should be in agreement to order N^{-1} and, therefore, one can expect agreement of the two methods within statistical error. It should be emphasized that the Monte Carlo method may be easily extended to quantum mechanical systems.

The widespread applications of the Monte Carlo method made it to an important tool in science and technology. In connection with condensed matter physics typical applications are (see, for example, [937]): fluids and plasmas, thermal properties and scattering functions for solids, liquids, and dense gases; properties of metallic alloys (in particularly in connection with short- and long-range-order properties); relaxation phenomena and diffusion processes; kinetics of crystal growth; phase transitions; magnetic properties of surfaces; kinetics of adsorption on surfaces; structural and thermal properties of glasses and amorphous magnets and of other disordered systems; ground state properties of certain quantum systems; etc.

The Monte Carlo method has been used in a diverse number of ways. For example, in connection with molecular calculations five types have often been used: classical Monte Carlo, quantum Monte Carlo, path-integral quantum Monte Carlo, volumetric Monte Carlo, and simulation Monte Carlo. But there are still many variations of these five types in literature. Here we only want to give the main principles of the classical Monte Carlo method and those of the quantum Monte Carlo method.

7.1. Classical Many-Particle Problems

The Monte Carlo method enables the determination of *configurational averages*. Let us consider a quantity α which depends on the configuration $\Gamma = \Gamma(\mathbf{r}_1, \ldots, \mathbf{r}_N)$ of the N particles of the system: $\alpha = \alpha(\Gamma)$. The configurational average of α is given in a canonical ensemble by

$$\langle \alpha \rangle = \int d\Gamma\, \rho(\Gamma) \alpha(\Gamma) \tag{142}$$

where

$$\rho(\Gamma) = \frac{\exp\left\{-\frac{V(\Gamma)}{k_B T}\right\}}{\int d\Gamma\, \exp\left\{-\frac{V(\Gamma)}{k_B T}\right\}} \tag{143}$$

The Monte Carlo method enables the determination of integrals of type (142). Below we discuss the main points of this procedure.

Let us split the configurational space into k cells with sufficiently small elements $\Delta\Gamma$, and let Γ_m, $m = 1, \ldots, k$, be the corresponding configurational states. Then, the average (142) may be approximated by

$$\langle \alpha \rangle_{\text{MC}} = \frac{\sum_{m=1}^{k} \alpha(\Gamma_m) \exp\left\{-\frac{V(\Gamma_m)}{k_B T}\right\}}{\sum_{m=1}^{k} \exp\left\{-\frac{V(\Gamma_m)}{k_B T}\right\}} \tag{144}$$

We can estimate (144) by selecting at random a certain number $L\ (<k)$ of configurational states, average α over these configurations, and weigh each configuration with the appropriate Boltzman factor [938]:

$$\langle \alpha \rangle = \frac{\sum_{m=1}^{L} \alpha(\Gamma_m) \exp\left\{-\frac{V(\Gamma_m)}{k_B T}\right\}}{\sum_{m=1}^{L} \exp\left\{-\frac{V(\Gamma_m)}{k_B T}\right\}} \tag{145}$$

However, this method is only practicable if the occupation probabilities do not differ very much from each other, and this is not fulfilled in the case of

$$\frac{\exp\left\{-\frac{V(\Gamma_m)}{k_B T}\right\}}{\sum_{m=1}^{L} \exp\left\{-\frac{V(\Gamma_m)}{k_B T}\right\}} \tag{146}$$

Thus, this method is not practicable because in the case of (146) the number of configurations required for reasonable averaging would be enormous.

In the Monte Carlo approach, however, configurations are selected with a frequency proportional to (146), and one has to average over the selected configurations with equal weight and, instead of (145), we get

$$\langle \alpha \rangle_{\text{MC}} = \frac{1}{L} \sum_{m=1}^{L} \alpha(\Gamma_m) \tag{147}$$

In the Monte Carlo approach ensemble averages are estimated by taking a random walk in configuration space. A Markov chain is produced in which the individual Markov states are points in the usual configuration space of statistical mechanics. Without going in detail, the steps in a Monte Carlo calculation for a system consisting of N atoms at temperature T are the following:

(1) The initial position vectors of the N are given:

$$\mathbf{r}_1^a, \ldots, \mathbf{r}_N^a$$

(2) The potential energy

$$V^a = \frac{1}{2} \sum_{\substack{i,\,j=1 \\ i \neq j}}^{N} \upsilon\big(|\mathbf{r}_i^a - \mathbf{r}_j^a|\big) \qquad (148)$$

and the Boltzmann factor

$$b^a = \exp\left\{-\frac{V^a}{k_B T}\right\} \qquad (149)$$

are calculated on the basis of the initial coordinates.

(3) A particle (say 1) of the system is selected, either serially or at random, and random atomic displacements $\Delta x_1, \Delta y_1, \Delta z_1$ are selected, each uniformly distributed over the interval $(-\Delta/2, \Delta/2)$.

(4) On the basis of the new configuration the potential energy V^n is given by

$$V^n = V^a - \sum_{j=2}^{N} \big[\upsilon_{1j}^a - \upsilon_{1j}^n\big] \qquad (150)$$

and for the Boltzmann factor we have

$$b^n = \exp\left\{-\frac{V^n}{k_B T}\right\} \qquad (151)$$

(5) If

$$\Delta V = V^n - V^a \qquad (152)$$

is negative, the new configuration is accepted and the old configuration is replaced by the new one. It is evidently more probable than the former one.

(6) If ΔV is positive the move is accepted only with the probability

$$\exp\left\{-\frac{\Delta V(\Gamma)}{k_B T}\right\} \qquad (153)$$

The computer selects a uniformly distributed random number h from the interval $(0,1)$ and compares it to (153). If the exponential expression is greater, the new configuration and the new potential energy become the current properties of the system. Otherwise the old configuration is counted again.

In a sufficiently long chain produced by these rules, configurations Γ appear with a probability of

$$\exp\left\{-\frac{V(\Gamma)}{k_B T}\right\} \qquad (154)$$

as is required in a canonical ensemble.

7.1.1. Applications

Articles include: Decay of pyramidal nano-island formed on Si(100) studied by kinetic Monte Carlo simulation [939], Particle size distribution of nanospheres by Monte Carlo fitting of small angle X-ray scattering curves [940], The structure of frozen phases in slit nanopores: A grand canonical Monte Carlo study [941], Simulation of nanocolloid chemical potentials in a hard-sphere polymer solution: Expanded ensemble Monte Carlo [942], Study of molecular shape and non-ideality effects on mixture adsorption isotherms of small molecules in carbon nanotubes: A grand canonical Monte Carlo simulation study [943], and Nanodroplets on a solid plane: Wetting and spreading in a Monte Carlo simulation [944]. Further information can be found in [945–997]. An interesting Monte Carlo study is given in [998, 999]. It is a simulation of long, thin molecules in a periodic box. The system shows two phases: a nematic liquid crystal and an isotropic liquid (see also Fig. 22).

7.2. Quantum Many-Particle Problems

The expectation value of an operator is given by

$$\overline{F} = \frac{\int d\mathbf{r}_1 \cdots d\mathbf{r}_N \, \psi_T^*(\mathbf{r}_1, \ldots, \mathbf{r}_N) \widehat{F} \psi_T(\mathbf{r}_1, \ldots, \mathbf{r}_N)}{\int d\mathbf{r}_1 \cdots d\mathbf{r}_N |\psi_T(\mathbf{r}_1, \ldots, \mathbf{r}_N)|^2} \qquad (155)$$

where $\mathbf{r}_1, \ldots, \mathbf{r}_N$ are again the N position vectors of the N particles, and $\psi_T(\mathbf{r}_1, \ldots, \mathbf{r}_N)$ is a trial wave function which can be determined by means of the variational principle. The variational method enables the computation of the ground-state properties of many-particle systems. The variational energy is given by

$$E_T = \frac{\int d\Gamma \, \psi_T^*(\Gamma) \widehat{H} \psi_T(\Gamma)}{\int d\Gamma |\psi_T(\Gamma)|^2} \qquad (156)$$

Figure 22. The image shows a snapshot from a Monte Carlo simulation of long, thin molecules in an elongated periodic box. The molecules are color-coded by orientation. The system shows two phases at equilibrium: a nematic liquid crystal (in the center) and an isotropic liquid (on either side) separated by planar interfaces. These simulations allowed the first determination of the surface tension of the equilibrium nematic–isotropic interface and confirmed that the molecules in the nematic phase are preferentially aligned in the plane of the surface. Subsequent simulations, using the molecular dynamics method, investigated capillary-wave fluctuations of this interface as a function of cross-sectional area.

where $\widehat{H}$ is the Hamiltonian. E_T will be the minimum when $\psi_T(\Gamma)$ is the ground-state solution of Schrödinger's equation. $\psi_T(\Gamma)$ must be either symmetric or antisymmetric with respect to the coordinates depending on the statistics. The parameters of $\psi_T(\Gamma)$ are optimized so that the energy E_T is minimized.

The problem is to construct realistic trial wave functions $\psi_T(\Gamma)$ [1000]. For a Bose system at zero temperature Bijl [1001] proposed the form

$$\psi_T(\Gamma) = \prod_{i<j=1}^{N} f(r_{ij})$$
$$= \exp\left[-\frac{1}{2}\sum_{i<j=1}^{N} u(r_{ij})\right] \qquad r_{ij} = |\mathbf{r}_i - \mathbf{r}_j| \quad (157)$$

That is, the trial function $\psi_T(\Gamma)$ was chosen to be a product of pair functions, where $u(r)$ is an unknown function. Equation (157) has been generalized to Fermi systems [1002–1004],

$$\psi_T(\Gamma) = D(\Gamma)\exp\left[-\frac{1}{2}\sum_{i<j=1}^{N} u(r_{ij})\right] \qquad (158)$$

where $D(\Gamma)$ is the ideal Fermi gas wave function. Another form for the trial wave function is given by [937]

$$\psi_T(\Gamma) = \exp\left[-\frac{1}{2}\sum_{i<j=1}^{N} u(r_{ij})\right]$$
$$\times \sum_p (\pm 1)^p \phi(\mathbf{r}_i - \mathbf{s}_{p_i})\eta_{\sigma_i \sigma_{p_i}} \qquad (159)$$

η is a spinor, p is a permutation of the pairing of particles to lattice sites $\mathbf{s}$, $\phi(\mathbf{r})$ is a single-particle orbital about a lattice site, and the $\pm$ sign is for Bose or Fermi statistics.

The integrals required to evaluate expectation values [Eq. (155)] can be carried out by the Monte Carlo method (see, for example, [937]). The Monte Carlo simulation of quantum many-particle systems is very similar to that of classical systems (Section 7.1). For quantum systems an algorithm is needed for the production of configurations with the probability proportional to the square of the trial wave function $\psi_T(\Gamma)$. The probability distribution

$$\frac{\psi_T^*(\Gamma)\psi_T(\Gamma)}{\int d\Gamma \, |\psi_T(\Gamma)|^2} \qquad (160)$$

for quantum systems is completely equivalent to the probability for classical systems which is given for the canonical ensemble by (143).

7.2.1. Applications

Articles include: Quantum Monte Carlo methods [1005], A quantum Monte Carlo study of the Josephson effect in a quantum dot [1006], Benchmark quantum Monte Carlo calculations [1007], The behavior of correlation functions in trans-polyacetylen: Quantum Monte Carlo study [1008], and Various spin-polarization states beyond the maximum-density droplet: A quantum Monte Carlo study [1009]. More

information can be found in [1010–1028]. An interesting study, also in connection with density functional theory (Section 2.1.2), is given in [1029] for carbon clusters.

Carbon clusters are very difficult to model accurately due to the wide range of geometries and because there are single, double, and triple bonds. In [1029] the energetics of various clusters have been studied as, for example, C_{24} clusters. This study has been done on the basis of highly accurate diffusion quantum Monte Carlo calculations. To search for structural isomers it is proposed in [1029] to use a hierarchy of methods of increasing accuracy. The first step is to apply empirical methods based on bond counting and geometrical considerations. The second step is to refine the selection by quantum mechanics calculations using, for example, density-functional formalism. The final energetic ordering of different isomers can be obtained on the basis of highly accurate calculations; for this purpose in [1029] the diffusion quantum Monte Carlo method has been used. The results in connection with C_{24} are shown in Figure 23. There are five isomers: ring, sheet, bowl, O_h cage, and D_6 fullerene. Figure 23 shows that the results obtained from the density-functional methods scatter considerably about the curve resulting from the diffusion Monte Carlo method. It is stated in [1029] that an accurate treatment of electron correlations is critical for accurate results.

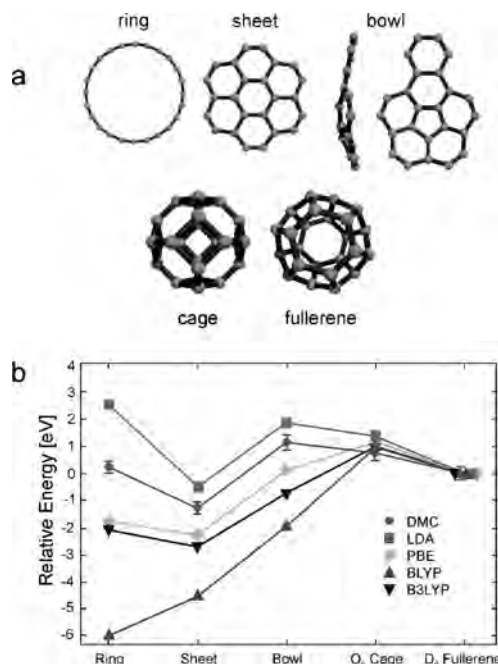

Figure 23. (a) C_{24} isomers: ring, sheet, bowl, O_h cage, D_6 fullerene. (b) The energies and structures of the C_{24} isomers given relative to the D_6 fullerene. It can be seen that the results obtained from the density functional methods (LDA, PBE, BLYP, B3LYP) scatter considerably about the curve resulting from the diffusion quantum Monte Carlo method (DMC). (LDA: local density approximation; PBE: Perdew, Burke, Enzerhof generalized gradient approximation for the exchange-correlation energy within the density functional formalism; BLYP: generalized gradient approximation density functional; B3LYP: hybrid density functional). 8. SUMMARY

Nanosystems behave in general very differently from macroscopic systems: Properties which are well defined and clearly fixed in the bulk are often no longer typical features in nanophysics and nanotechnology. New effects emerge which have no counterpart in other fields of physics, chemistry, and technology. For example, the melting temperature of a macroscopic system is usually well defined, and the system is thermally stable up to the melting point. In contrast to that, the melting temperature of a nanosystem is in general dependent on the particle number and can also be a function of the outer shape of the system. Moreover, the melting temperature of certain nanosystems is not defined and not clearly fixed, respectively. And there are other surprising effects in the nanometer-size realm, for example, bifurcation phenomena: Nanosystems (e.g., nanoclusters) can transform *spontaneously* from a metastable to a stable state, and the transformed state may differ from the metastable state in both the inner *atomic* structure as well as the outer shape. When such a nanosystem transforms from the metastable to the stable state there are several possibilities for that. Which of these stable states the system will finally take is completely a matter of chance (Section 6.2.2). This is an interesting phenomenon and has no counterpart in micro- and macrotechnique, but there is rather a certain vicinity to biological systems (Section 6.2.4).

This is a completely new situation, and the new nanophysical effects reflect a huge potential for technological applications. This process is just at the beginning but presupposes, on the other hand, a good theoretical understanding of the systems under investigation. Therefore, in nanophysics and nanotechnology not only do sophisticated experiments and methods have to be established, but also specific methods for the theoretical treatment of such systems have to be selected and refined.

What is the adequate theoretical treatment of typical atomic nanoeffects? How relevant in this context are the usual methods of solid state physics, which have been successfully applied to the bulk state? We discussed this question and came to the result that the standard model of solid-state physics (ordered structure, harmonic behavior) can be no basis for the treatment of nanosystems, which is due to the strong anharmonicities even at relatively low temperatures. These anharmonicities cannot be considered as small perturbation to the harmonic approximation and are caused by the atoms at the surface which are less bonded than in the bulk. Therefore, the mean-square amplitudes of the atoms at the surface are significantly larger than in the bulk leading to relatively strong anharmonicities. This phenomenon can be observed even at low temperatures. This behavior is also typical for nanosystems since a great fraction of atoms are more or less close to the surface region of the system. In small nanosystems (for example, clusters with a few hundred of atoms) even the innermost particles cannot be treated as bulk particles since the cutoff radius for the interaction potential is larger than its distance to the surface.

This phenomenon leads to complex situations, much more than in the case of macroscopic systems. For example, a typical feature of nanosystems is that their properties vary strongly with temperature which are moreover a sensitive function of particle number. For the theoretical treatment of such phenomena methods are needed which in general cannot be based on the standard model of solid-state physics (ordered structure, harmonic behavior).

In Section 3.1 we argued that for the theoretical treatment of nanosystems we have to recourse to the most general method in order to be able to analyze the diversity of structural and dynamical atomic effects which are typical for such systems. Therefore, the most important tool for the investigation of nanosystems is the molecular dynamics method. No other microscopic method in condensed matter physics allows one to treat anharmonicities without approximation. Thus, the molecular dynamics method should be considered as the *standard method* for the theoretical description of nanosystems. Not only can anharmonicities be treated without approximation within this method but also the temperature effects and their dependence on the particle number.

We started our considerations with the quantum-theoretical treatment of nanosystems, that is, with the methods of quantum chemistry. Here the discussion concentrated on the Hartree–Fock method and the density-functional formalism, and we restricted ourselves to a few brief statements. The reason is the following: Up to now, these methods only allow the determination of *zero-temperature* properties. However, as we have stated above, temperature effects are of considerable importance in connection with nanosystems. In particular, nanoproperties are in general very sensitive to small variations in temperature and, therefore, it should hardly be possible to conclude from *zero-temperature* data (Hartree–Fock method, density-functional formalism, etc.) to *non-zero-temperature* properties. It would be most fruitful to consider in future investigations also the non-zero-temperature density-functional formalism by Mermin. Also the embedded-atom method (Section 5.3.4) and quantum molecular dynamics introduced by Car and Parrinello (Section 5.3.5) can lead to misleading results since here too non-zero-temperature data are coupled with zero-temperature properties.

On the other hand, in order to be able to perform a molecular dynamics calculation the interaction potential between the particles is needed as input. For a reliable description of the properties of nanosystems the precise knowledge of the interaction potential is required. We showed in Section 5.2 that surface properties are in general sensitive to small potential variations—more than in the bulk of the crystal. Both the repulsive and the attractive part of the potential have to be determined carefully. However, the determination of accurate pair potentials for systems of interest (e.g., metals and materials with covalent bonding) is rather difficult even for the bulk, and the nanoproblem, where a great fraction of atoms belong to the surface region, is much harder because of the change in electronic states and other relevant properties near the surfaces of the nanosystem.

A lot of realistic molecular dynamics calculations have been performed for various systems, but the physical basis for the used interaction potentials is often not recognizable and serves merely as fitting functions which is unsatisfactory. Furthermore, often the potentials have not been tested carefully, in some cases even not at all. Serious research in

nanoscience requires just the opposite: Since the properties of nanosystems are particularly sensitive to potential variations, the potentials have to be determined as carefully as possible for such systems.

There exist many phenomenological approaches for the interaction, but we did not discuss these functions in detail because in most cases there is no or almost no physical background for their introduction—these potentials have often been chosen for purely pragmatic reasons. For example, the Morse potential has not been constructed on the basic interaction types (ionic interaction, van der Waals forces, metallic interaction, covalent binding) discussed in Section 5 but it is based on the spectroscopy of molecules. Nevertheless, the potential has been used extensively in the study of various many-particle properties, and there is obviously no physical justification for that.

The potential functions should be constructed on the basis of the physical features of the system under investigation. These potential functions will in most cases be dependent on certain model parameters which have to be fitted accurately. This has been done, for example, for Al by means of the pseudopotential method (Section 6.2), and the parameters were fitted by a wide range of experimental data.

In conclusion, for a realistic atomic description of nanosystems there is no alternative to the molecular dynamics method. However, the situation in connection with interaction potentials has to be improved. For the design of nanosystems and also in connection with nanoengineering reliable potential functions with an adequate physical background are needed, and they should not merely be used as fitting functions.

GLOSSARY

Correlation energy The modification of the Coulomb energy of a system that results from the tendency of electrons to stay apart from each other.

Coulomb blockade Current respectively tunneling suppression at low bias, caused by charging effects.

Deoxyribonucleic acid (DNA) A macromolecule consisting of one or two strands of linked deoxyribonucleotides.

Electronic band structure A quantum-theoretical approach of the dynamics of the electrons in solids that predicts certain restricted ranges (bands) for the electronic energies.

Electron X-ray absorption fine structure (EXAFS) A variation of the X-ray absorption of a material as a function of energy. The energies are just above those required for photons to bring core electrons into the continuum. The method is based on the interference between the outgoing photoelectrons waves and electron waves backscattered from atoms adjacent to the adsorbing atoms.

Exchange effects Effects which are due to an exchange of space and/or spin coordinates of the particles involved, for example, electrons.

Fullerene A form of carbon consisting of an empty cage of atoms. Fullerene derivatives can be created by adding endo- or exohedral substituents. This opens the possibility of obtaining a wide range of building blocks for developing new materials with unique properties.

Harmonic approximation The dynamics of a many-particle system can be formulated within the harmonic approximation if the displacements x of the atomic structure from its equilibrium geometry can be described with linear restoring forces $F(Fx)$. In this case the potential energy is proportional to x^2.

Law energy electron diffraction (LEED) An experimental scattering technique for the study of the atomic surface structure by electrons of uniform energy within a range of 5–500 eV.

Nanotube A one-dimensional fullerene (a convex cage of atoms with only hexagonal and/or pentagonal faces) with a cylindrical shape. Depending on the direction that the tubes appear to have been rolled (quantified by the "chiral vector"), they are known to act as conductors or semiconductors. Nanotubes are proving to be useful as molecular components for nanotechnology.

NMR The effect is due to a large number of nuclei in a static magnetic field which absorb energy from a radiofrequency field at certain characteristic frequencies.

Pair correlation function The pair correlation function $g(r)$ is the probability of finding an atom (or molecule) at r if there is another atom at the origin. $g(r)$ is normalized to unity at large r.

Screening The reduction of the electric field about a charge (for example, an ion of a metal) by the space charges of the surrounding electrons (e.g., conduction electrons).

Statistical ensemble A collection of systems of atoms (or molecules) which are used for the description of an individual system. Time averages for the individual system can be expressed by averaging over the systems of the collection (ensemble) at a fixed time.

Virial coefficients For a given temperature T, the virial coefficients are defined as constants in the expansion of P/RT in powers of the particle number density, where P is the pressure and R is the gas constant.

Conducting Polymer Nanostructures

Rupali Gangopadhyay

Hokkaido University, Sapporo, Japan

CONTENTS

1. INTRODUCTION

With the advancement of science and technology the world around us is shrinking and the importance of nanostructures is increasing. Attaining the nanoscale control over the spatial arrangement of the building blocks of materials has become an important objective of material scientists, because organization of materials on nanoscale very often leads to materials with physical properties distinctly different from the bulk counterpart. A new branch of science has been established for studying the preparation, properties, and application of such smaller objects of different size, shape, and origin. In view of this recently emerging field of nanoscience and nanotechnology, a nanomaterial is defined as one consisting of a substance or structure, at least one of the dimensions of which is less than 100 nm (0.1 μm). It has been repeatedly established that materials with such reduced dimension are especially important for showing fascinating electronic, optical, and magnetic properties. Science and technology of such micro- and nano-sized materials and objects are studied under different titles *viz.* micro- and nano-electronics, microelectromechanical systems (MEMS), micromolding in capillaries (MIMIC), etc. [1–4]. In parallel with the progress of nanotechnology, importance of multifunctional and lightweight materials, suitable for fabrication of smaller devices, is also increasing. Inherently conducting polymers (ICP) top the list of the smart and intelligent materials that can be successfully utilized for fabrication of different optical devices (LED and ECD), rectifying diodes, transistors, photovoltaic cells, rechargeable batteries, sensors for chemical and biochemical species, and so on [5–12]. However, some inherent difficulties in the nature of conducting polymers, such as their insolubility and infusibility, brittleness, poor mechanical property, etc. have primarily obstructed their successful and widespread application. For the same reason, to get conducting polymer-based nanomaterials in hand was not as easy as other polymers, at least up to the first 15 years after their discovery. These polymers are synthesized only in macroscopic precipitate form or in brittle and intractable film form, both which are highly disordered; but fabrication of nanodevices, particularly those relevant to micro- and/or nanoelectronics, demand some ultimate control over the synthesis leading to the defect-free and highly ordered form of the polymer. At the same time, the method of obtaining such defect-free materials with reduced dimension should be highly reproducible and controllable so that the synthesized materials are always identical. Therefore, the origin of synthesis of conducting polymer-based nanomaterials lies in the desire of attaining the nanoscale control over the structure and property of these polymers and to combine them with established nanotechnological systems. On the other hand, this attempt is also in pace with the attempt to overcome the intractability of the same.

Over the last 15 years, there have been a series of attempts to overcome the intractability of conducting polymers and to bring them in solution and/or in melt. Some of these attempts have directly launched some ICP-based nanomaterials. Depending upon the approach of synthesis, shape, size, and properties of the nanomaterials are varied. However, almost all possible forms of nanostructures *viz.* nanoparticle, nanotubule, nanofiber, nanowire, nanolayer (sometimes monolayer also), and patterned structures have thus far been prepared from ICPs. These materials were widely characterized from different aspects and were sometimes subjected to very interesting and sophisticated

applications. Principles and objectives of different techniques followed, for the development of such nanomaterials are the subject of discussion in this article. Structures of the synthesized materials, some of their fundamental properties, and interesting applications, as well as application potential have also been mentioned in this context. Investigations regarding synthesis, characterizations, and suitable applications of such materials encompass the field of chemistry, materials science, solid state physics, and even biological sciences. The subject is highly interdisciplinary and has rarely been reviewed thus far with such large purview. In the present context, versatility of this subject has been presented with careful selection and compilation of works.

2. OVERVIEW

Before entering a detailed discussion of the different techniques followed for obtaining ICP nanomaterials, the subject of discussion should be outlined so that it can be followed systematically. The quest for obtaining conducting polymers in microscopic/nanoscopic form has primarily given birth to the core-shell type nanoparticles with different size and morphology. Depending upon the synthesis techniques and other conditions, the ICP component could form either the core or the shell of the system. However, in such works, the prime achivement was prevention of the macroscopic precipitation of the ICP, thereby overcoming its lack of processability to some extent; the nanoparticles were mainly stabilized by the support polymers and were not separate entities. Different processable polymers like poly(vinyl alcohol) (PVA), polystyrene (PS), some surfactants, etc. were used as the stabilizers in these works. Later on, the synthesis of ICP nanoparticles have encountered multidirectional advancement and true nanoparticles—hollow or filled up, have been synthesized with different physical properties and applications. A broad spectrum of inorganic nanoparticles with versatile properties (colloidal stability, catalytic activity, magnetic susceptibility, etc.) were used for supported growth of the conducting polymers and also to combine their inherent properties. This section has been reviewed earlier in detail [13–15].

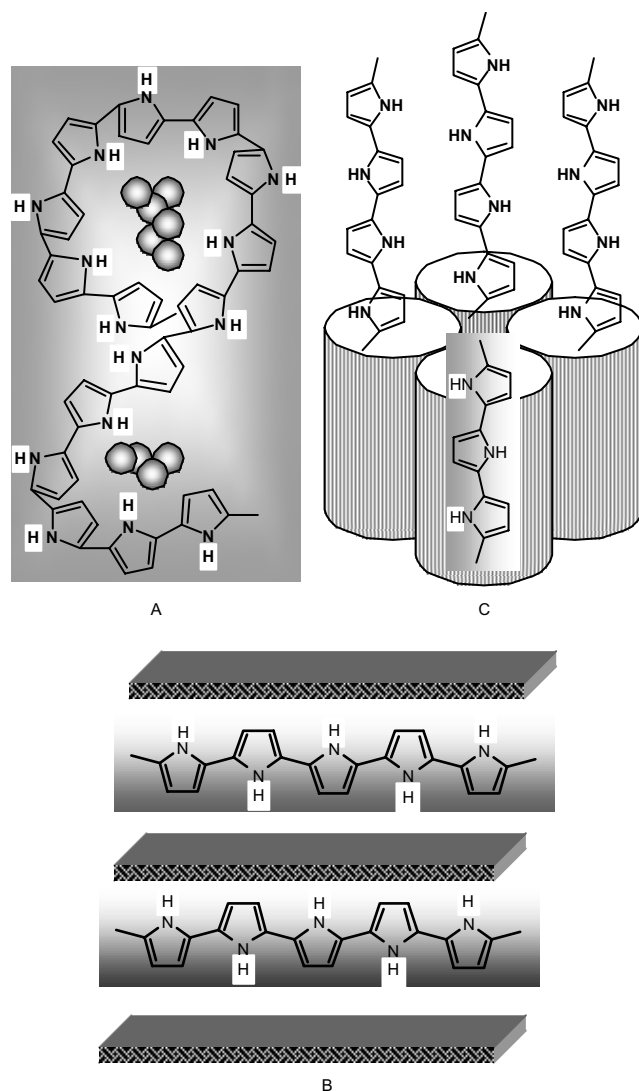
Channeled growth of conducting polymers within different inorganic/organic templates has given rise to ICP-based hybrid materials of some different types. Polymers could be grown chemically/electrochemically within three-dimensional templates like zeolite, porous glass, polymeric membrane, etc. in the form of nanotubules or nanowires. After removal of the host, the polymeric nanomaterials are set free in solution. If the host is a two-dimensional (layered) one like FeOCl, V_2O_5, etc., the polymer is in the form of a single chain or monolayer. Regardless, the template essentially introduces some control over the growth of the conducting polymer and brings it to nanoscopic form. All these inorganic-organic hybrid materials (nanoparticles and nanostructured materials) are collectively designated as "nanocomposites" which constitute a branch in advanced materials science. Various aspects of this particular class of ICP nanomaterials have also been peer-reviewed many times by different groups [16–20]. Formation of the three most widely investigated nanocomposites has been schematically shown in Figure 1.


Figure 1. Schematic presentation of formation of three major categories of nanocomposites: A. Nanoparticles incorporated; B. 2-D (layered) template guided; C. 3-D template guided.

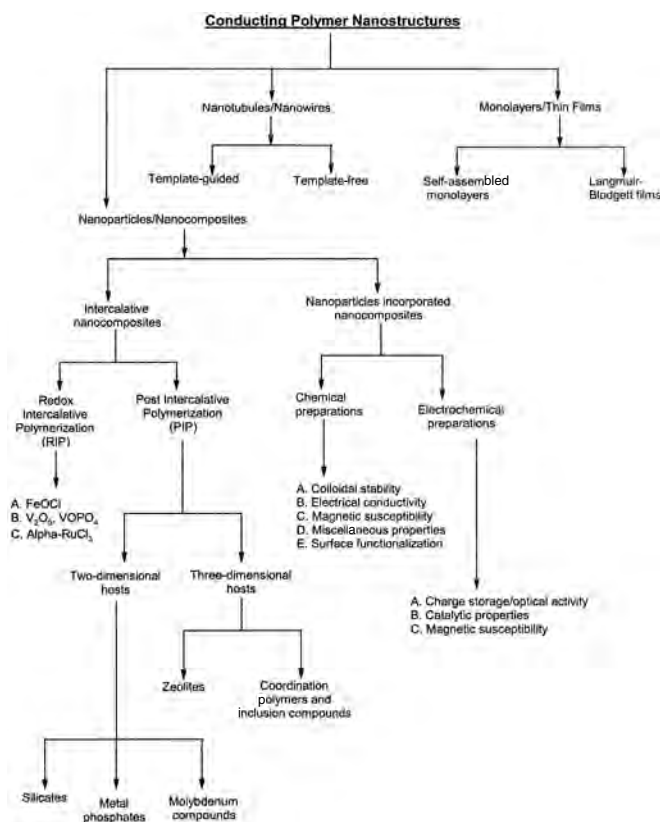
Template-guided methods are replaced later by more advanced template-free techniques of synthesis and materials with more advanced properties were obtained. Thin film and monolayer is another form of assemblence of conducting polymers in nanolevel; this has also been performed by both template-guided and template-free methods. Moscovite mica, some chemically designed surfaces, etc. have been used for templated monolayer growth. On the other hand, Langmuir–Boldgett (LB) technique is applied for template-free growth of monolayers. Fundamental electrical properties of such nanomaterials are different from their bulk counterparts to different extents which have been revealed by critical analyses. Nanomaterials of this type are a very recent addition to the list of advanced materials. At the same time, some very especial applications of such nanomaterials in electrically driven nanodevices like junctions, actuators, circuitry, etc. have been designed. An outline of the different materials synthesized and methodology followed has been presented in Table 1. However, these smaller objects are

Table 1. Conducting polymer nanostructures at a glance.


recent developments and have not been presented collectively thus far. In this article, these materials and devices are also introduced. It should be mentioned that this article is not solely decided to "nanoscale" materials only and addresses both micro- and nano-dimensional materials and devices under the title of "Nanostructures" because both are smaller materials and it is meaningless to draw a clear line of demarcation between them.

3. NANOPARTICLES

3.1. Colloidal Dispersions Guided by Steric Stabilization

The general feature, as well as the obvious problem with conducting polymers, is that during their chemical polymerization, they are precipitated out from the medium as intractable solid and cannot be turned to usable forms like films and coating. After discovery of these polymers and their promising properties and application potential, there has been a continuous effort to keep them in solution by controlling their particle size and morphology. The principles followed in this direction were steric stabilization or colloid formation. The former technique generally provides a bi-component or a tricomponent system, while the latter route may produce a bi-component and/or a tri-component system, depending upon the nature of components.

The most elementary approach is the bi-component steric stabilization which is nothing but to polymerize aniline

or pyrrole in presence of the solution (generally aqueous) of a suitable polymer so that the macroscopic precipitation of the former is prevented by the latter. This stream of investigation was started in the early 1980s and is still active. During these years, a number of low Tg polymers were utilized in this respect and colloidal dispersion having different extent of stability and versatile properties were introduced. Depending upon the nature of the reacting polymers, reaction conditions like temperature, solvent morphology, and size of the conducting polymer, etc. were varied. As revealed from the transmission electron microscopy (TEM) images, the conducting polymer was present in nanoparticle form and its dimension was within 300 nm. Water soluble polymers *viz.* methylcellulose (MC) [21], PVA [22], poly(ethylene oxide) (PEO) [23], poly(vinyl acetate) (PVAc) [24], poly(vinyl pyrrolidone) (PVP) [25], etc. were utilized elaborately and adsorption of these polymers onto the surface of the growing, conducting polymer particles was the key to their stabilizing property. This way, the conducting polymer nuclei were prevented from further aggregation, thereby giving rise to core-shell morphology where conducting polymer resides within the core.

The earliest report in this particular field of work was published in 1986; in this work MC (Mol. Wt. 95,000) was used as the steric stabilizer to the growing PPy particles in aqueous medium using $FeCl_3$ as the oxidant [21]. From scanning electron microscopy (SEM) images, globular PPy particles with $\sim$100–200 nm diameter were detected and maximum conductivity $\sim$0.2 S/cm was obtained. This work was followed by a series of works published by Vincent and Armes et al. [22–27], who could stabilize both PAn and PPy more efficiently using PVA, PVP, PEO, and some other polymers and copolymers. General synthesis technique was to add the monomer solution dropwise into the mixture of oxidizing agent and stabilizer under stirring. In few works the oxidant solution was added dropwise to the mixture of monomer and stabilizer. Depending upon the stabilizer, solvent, and other conditions (like the order of addition of reactants), size and morphology of PAn and PPy particles were varied. For example, using PVA as a stabilizer, spherical PPy particles of the size range 50–250 nm were obtained [22], while for PEO, the particle size changed to 390–490 nm [23]. Using $K_2S_2O_8$ as the oxidant much smaller particles $\sim$30 nm were detected. On the other hand, using polymer of 2- and 4-(vinyl pyridine-co-p-amino styrene) (VPAS) sterically stabilized PPy and PAn particles having rice grain shape and $\sim$120 nm length were obtained [24–26]. Electrical conductivity of these composites were nearby to each other; PPy-PVA : 1.5 S/cm, PPy-PEO : 1-2 S/cm, PPy-MC : 0.2 S/cm, PAn-VPAS : 0.5 S/cm. In a later publication [27], Aldissi and Armes have shown the effect of different stabilizers on the particle size of PPy; in this work PEO, PVA (two different molecular weight), PVP, P2VP-BM (butyl methacrylate), and P4VP-BM were used under similar reaction conditions. Spherical particles appeared in each case and it was observed that PVA resulted in smallest particles. Particle diameter varied from $\sim$60 nm to $\sim$350 nm and particles with larger diameter resulted in lower conductivity.

Since then, this field of investigation has been widely and elaborately cultivated and has produced a number of

fruitful results. PAn is the most exclusively studied polymer in this respect, and lot of composites with good processability and high electrical conductivity were obtained [28–31]. Vincent and Waterson and Stejskal et al. have published a series of works on synthesis and characterization of PAn nanoparticles under different chemical environment [32, 33]. Banerjee and Mandal [34] have introduced a novel method of obtaining PAn nanoparticles using ultrasonication, and subsequently used the nanoparticles to give rise to composites with extremely low percolation threshold. However, in all such works, although conducting polymer is present in nanoparticle form, it has no separate identity as nanoparticle. Its macroscopic form in combination with the support polymer is only considered and it is only studied as composites.

Recently, there have been a few publications reporting stabilization of PAn nanoparticles in the micelle of SDS and dodecylbenzene sulphonic acid (DBSA) [35, 36]. In such cases, aniline is polymerized in the presence of SDS or DBSA so that growing PAn chains are surrounded by the micelles and are prevented from macroscopic precipitation. Very recently, Ghosh et al. [37] have also published a novel technique for obtaining PAn nanoparticles in DMSO medium, which formed a stable solution without any stabilizer. These works are somewhat different from the core-shell type solutions.

There is a second stream of synthesis of core-shell type materials in which a conducting polymer component serves the outer layer or "shell." In other words, these works are analogous to coating some polymeric or inorganic nanoparticles with conducting polymers. As the polymeric latex particles are concerned (as the core materials), the objective of the work is to synthesize stable dispersion of conducting polymers with good film forming property and high electrical conductivity. The first report of this series of work was published by Yassar et al. [38] who could obtain aqueous dispersion of –COOH or –SO$_3$H functionalized polystyrene latex particles coated with PPy; this dispersion could be film-casted and maximum conductivity 0.25 S/cm was obtained. Similarly, styrene-butadiene rubber (SBR) with a small amount of methacrylic acid formed the latex pyrrole; aniline and methyl thiophene (MT) were polymerized on the latex particles using FeCl$_3$, CuSO$_4$, etc. different catalysts [39]. Conductivity of PPy and PAn containing blends were of the order of 10^{-1} S/cm, while PMT containing composites showed 10^{-4} S/cm. However, these two reports were not supported by successive investigators at least in the point of stability of dispersion.

Later on, the research group of Lascelles and Armes have carried out a widespread investigation on this stream of work aiming at successful synthesis of a stable core-shell type of composites having the shell of conducting polymers. In contrast to the earlier reports, they have started with sterically stabilized latexes *viz.* polystyrene (PS) stabilized by PVP or PEG [40, 41]. A simple chemical polymerization technique was followed in each case, and three important conducting polymers—PAn, PPy, and poly(3,4 ethylene dioxy thiophene, (PEDOT))—were utilized. Respective monomers were added to the PS dispersion having micron- and submicron-sized PS particles followed by the addition of oxidant solution. The reaction was carried

out for 24 h, and in each case a parallel reaction scheme was also followed in which the oxidant was taken in PS latex and monomer was added from the outside. The composites were obtained as a stable dispersion in which conducting polymer-coated PS latex particles more or less preserve the colloidal stability. In contrast, chlorinated copolymer latex (Haloflex EP 252) without any steric stabilizer resulted in macroscopic precipitation [42]. A detailed study on the synthesis-structure-property relationship has been carried out by this research group using different dimensions of PS latex, different experimental conditions, etc. and all these materials were studied from different aspects to build up a thorough understanding on this subject. The most interesting part of the work was the verification of core-shell morphology from SEM. Initially, the composite particles appeared in globular shape but after prolonged immersion in THF, the PS core was dissolved and "broken egg shell" like morphology of the composites was identified from the SEM image (Fig. 2). This confirms the real core-shell configuration of the composite particles where PS forms the core. All these composites were found to be highly conducting and classical percolation

Figure 2. SEM images of (a) PPy-coated PS latex, and (b) resulting PPy residues after extraction of the inner PS (core) particles by THF; a "broken egg-shell" morphology, a clear evidence of "core-shell" type orientation. Reproduced with permission from [41], S. F. Lascelles et al., *J. Mater. Chem.* 7, 1349 (1997). © 1997, RSC.

behavior was obtained in each case. The order of lowering in conductivity, as well as rising in percolation concentration, was as follows:

$$PPy\text{-}PS > PAn\text{-}PS > PEDOT\text{-}PS$$

There are a few other works in this direction that concern the coating of 60–100 μm polyurethane (PU) latex, stabilized by PEO and hydroxyethyl cellulose, with PPy; this presents a system with good film-forming capability and solid-state conductivity of 10^{-5} to 10 S/cm. In a recent work, stabilization of uniform, micron-sized PAn particles in a multicomponent system was reported, one of the components being porous PS particles. Colloidal stability at a higher PAn loading is an important achievement of this system although the other characterizations are forthcoming.

3.2. Combination with Inorganic Particles

The idea of synthesizing conducting polymer-based, core-shell type materials in which the polymer serves the shell has been most widely implemented on nanocomposites in which inorganic nanoparticles or nanoclusters (*viz.* metals, metallic oxides, sulphides, etc.) serve the core. These nanocomposites can be considered elegant hybrid materials, which play a bridging role between the world of conducting polymers with that of the inorganic nanoparticles, and which can successfully combine the physical properties of both. The work in this direction was started with the aim of combining the colloidal stability of a few inorganic colloids with optical and electrical properties of conducting polymers; later on, other characteristic properties like catalytic activity, magnetic susceptibility, etc. were also considered important for combination. Different inorganic particles used for the formation of nanocomposites, their dimensions, and important physical properties are tabulated in Table 2.

It was mentioned earlier that the insoluble and infusible nature of conducting polymers have kept them away from combining with foreign materials in a simple blending technique; *in-situ* polymerization was a more convenient way of combination. The same route was followed and is still being followed by the scientists as an efficient way of incorporating inorganic nanoparticles into conducting a polymer matrix. The pioneering work in this direction was reported by Armes et al. who were able to encapsulate silica particles of different dimension into the core of PPy and PAn [43]. Spherical silica particles of three different sizes—1 μm [43], ~38 nm [44], and 20 nm [45]—and "stringy" (elongated 40–300 nm long, 5–20 nm in diameter) silica particles [46] were utilized for this purpose. The general synthesis technique was to add the oxidant (or monomer) solution into the colloid containing the monomer (or oxidant) on stirring, and almost in all experiments the resulting composite was synthesized in the form of a stable colloid. The principle of synthesis in each case was to polymerize respective monomers (aniline or pyrrole) in the presence of the pre-formed inorganic colloid using some appropriate oxidant, generally ammonium peroxodisulphate (APS) (HCl) for aniline and FeCl$_3$ for pyrrole. Controlled polymerization of the monomer, preferably on the surface of the colloidal particles rather than in bulk, using low concentration of both

the monomer and the oxidant, was the key to the formation of a colloidal nanocomposite. Interestingly, a critical silica concentration was required for the formation of the nanocomposite colloid which was 2.0–2.3% (w/v) for larger silica (~38 nm) and ~1.0% for smaller (20 nm) silica particles. Composite particles were 1.5–3.0 μm in diameter and a maximum ~21% polymer loading was primarily obtained (with 38 nm silica). Gill et al. [45] were the first to reveal a unique "raspberry" morphology of the composites by high resolution TEM images that appeared reproducibly in other publications of the same group. This image apparently reveals that silica particles are connected or rather "glued" by the conducting polymer chain and such orientation accounts for the high silica loading in these materials (Fig. 3). Even on changing the morphology of silica colloid from spherical to elongated (stringy) silica the "raspberry"-like orientation of colloid has not changed much (Fig. 4). Later on, there was a thorough investigation [47–50] about the different reaction parameters like nature of oxidant, concentration of reactants, etc. and a colloid with 20 nm silica (1%) was used as an almost standard condition for succeeding works. Depending upon other conditions, polymer loading in these composites could be varied from ~37% to ~70%. Electrical conductivity of most of these samples fall within a broad range from 10^{-5}–1.0 S/cm and a maximum value 4.0 S/cm was obtained for the nanocomposites prepared with 20 nm silica and FeCl$_3$ oxidant in the presence of p-toluene sulphonate (PTS).

Later on, this field of investigation was extended to a series of other colloids, namely, SnO$_2$, TiO$_2$, Sb$_2$O$_3$, ZrO$_2$, and Y$_2$O$_3$, with the appearance of raspberry morphology in each case. But a nanocomposite in stable colloid form could be prepared only with two dispersants—SiO$_2$ and SnO$_2$—the reason of which was not very obvious [51, 52]. Extensive studies on different aspects of different pure colloids, as well as their respective nanocomposite colloids using inverse gas chromatography (XPS) and electrokinetic measurements, have revealed some unique surface features of SiO$_2$ and SnO$_2$ that can only account for the prolonged stability of the respective nanocomposites against precipitation. Brunauer–Emmet–Teller (BET) surface area measurements [53] have shown that a larger surface area of the supporting colloid is a necessary, but not sufficient condition, for the formation of colloidal nanocomposite. However, both these colloids possess significant porosity, as revealed from inverse gas chromatographic data [54] for which their specific surface area is always larger than expected. X-ray photoelectron spectroscopy (XPS) measurements and electrokinetic measurements have revealed that in both these nanocomposites, the Si/N or Sn/N ratio on the surface was found to be higher than that in bulk, which signifies that the surface of these composites is silica (or SnO$_2$)-rich rather than polymer-rich [55, 56]. Therefore, particles of the composites can be considered as associated particles of SiO$_2$ or SnO$_2$ connected by polymer chains, in which the surface feature of inorganic support materials is retained. The effect of other synthesis parameters like temperature, reagent concentration, nature of oxidant, effect of stirring, etc. were also studied in the succeeding articles and only the stirring was found to have any effect on particle size, polymer content, and conductivity of the composites [57]. A larger surface area

Table 2. An overview of the composition and properties of the nanoparticles incorporated nanocomposites.

Polymer used	Inorganic nanoparticles	Physical appearance	Significant characteristics/applications
PPy and PAn	SiO_2 (1 μm, 35 nm, and 20 nm), Stringy SiO_2 (40–300 nm long)	Stable colloid, can be spin-coated	Raspberry morphology (in TEM) showing inorganic particle-rich surface and monolayer of polymer
PPy and PAn	CeO_2 (0.52 μm), CuO (1.6 nm), α-Fe_2O_3 (spherical, polyhedral, and spindle-shaped), NiO (3.8 μm), SiO_2 (0.46 μm)	Stable colloid with core-shell type orientation	Oxidizing property of the core materials was exploited; no polymerization initiator was required. Nanocomposite with extremely low dc conductivity was obtained.
PPy and PAn	Colloidal gold (7–9 nm and 25 nm), silicon-titanium zeolite (TS-1,~100 nm) and $BaSO_4$ (20 nm)	Stable colloid or emulsion having core-shell morphology	Nanocomposite supported in membrane or in microemulsion. Variable thickness of the polymer coating; for 25 nm gold core, 10 nm thick shell was obtained.
PPy and PPV	ZrO_2 (20–30 nm), α-Fe_2O_3 (25–50 nm), SiO_2 (nm), n-TiO_2 (~10 nm), Al_2O_3 (35–50 nm), MgO (2–4 nm), carbon black	Macroscopic precipitation or colloid with limited stability	Improved thermal stability and dc electrical conductivity. Novel transport properties and applications
PPy and PAn	SiO_2 (20 nm)	Stable colloid with functional groups	Surface functionalized with –NH_2or–COOH group, important for immunodiagnostic assay
PPy and PAOABSA	MS (5–30 nm), Fe_xO_y (14 nm), Fe_2O_3 (15–50 nm), γ-Fe_2O_3(~85 nm)	Nanocomposite colloid or film (electro-chemical)	Nanocomposite powder or film, both having significant magnetic susceptibility.
PPy and PAn	Barium titanate (1 μm), Fe_2O_3 (4 nm, 40 nm), β-MnO_2, TiO_2, $LiMnO_2$, $LiMn_2O_4$, V_2O_5, WO_3, PMo_{12}, Ta_2O_5, prussian blue	Powdered solid (chemical) and/or film on electrode	Solids having appreciable electrical conductivity, improved charge storage, dielectric and optical properties; materials suitable for cathode and ECD.
PPy, PAn, and PEDOT	SiO_2 (20 nm), Pt (~4 nm), Pd, Cu, Pd, and a few other metals and bimetallic couples	Nanocomposite colloid/film	Nanocomposites with catalytically important metals; important for heterogeneous catalysis

of nanocomposites has offered them better performance as bio-adsorbent as compared to pure PPy. In one of the publications of these series [58], PPy and PPy-SnO_2 nanocomposites were both allowed to adsorb a model protein human serum albumin (HSA), and the spectrophotometric method has proven that colloidal nanocomposite possesses better adsorptive capacity compared to PPy itself.

When one group of scientists exploited the unique colloidal stability of a few nanoparticles toward synthesis of colloidal nanocomposite, the other group utilized the oxidative nature of some other particles for a similar purpose. In a series of publications, Matijevic et al. [59–61] have reported the formation of a colloidal nanocomposite by *in-situ* oxidative polymerization of pyrrole and aniline, where

Figure 3. TEM image of dried, diluted PPy-silica nanocomposite colloid using spherical silica particle (20 nm): typical "raspberry" morphology. Reproduced with permission from [48], S. Maeda and S. P. Armes, *J. Coll. Interface Sci.* 159, 257 (1993), © 1993, Elsevier Science.

nanoparticles of CeO_2, α-Fe_2O_3, CuO, NiO, and hematite-coated silica served the core materials as well as the oxidant. Aqueous suspensions of the inorganic particles containing pyrrole were heated up to $\sim$100 °C in a closed vessel to initiate polymerization leading to black colloidal suspension. Nanoparticles having no oxidative site (*e.g.*, SiO_2) cannot form such a colloidal composite, which indicates that the active participation of the oxidative centers of the inorganic colloid is the key to the formation of the colloid in these works. However, harshness of reaction condition is responsible for the extremely poor conductivity of these solids. CuO was also used to form colloid with PAn in insulating leucoemeraldine form. For experiments performed in air, aerial oxygen promotes polymerization of pyrrole to some extent even with silica particles with no catalytic property.

Works so far discussed present the "first generation nanocomposites" as the prime objective of synthesis of which was to encapsulate the inorganic particle and keep the composite in stable colloid form. Later on, diversity was brought to different aspects of the work; the synthesis technique as well as the objective of the work was varied. The synthesis technique was modified with the aim of enhancing microstrucrural homogeneity in composites. Emulsion polymerization and different types of template-guided polymerization replaced the simple reaction techniques. For example, *in-situ* formation and encapsulation of $BaSO_4$ nanoparticles within PAn shell and simultaneous stabilization of the whole in an oligo-ethylene oxide-based microemulsion was reported by Gan et al. [62]. Similarly, the *in-situ* formation of gold nanoparticles and their simultaneous stabilization within the core of a diblock copolymer was also reported by Selvan et al. [63, 64]. In contrast to two component composites in earlier publications, these systems present three component composites/nanocomposites in stable solution form.

Template-guided synthesis provides some control over the growth of the conducting polymer chain; two types of substrates were used as templates *viz.* inorganic nanoparticles embedded in polymeric/organic membranes and a self-assembled array of some modified inorganic hosts. In the former example, gold nanoparticles are arranged within the pores of an Al_2O_3 membrane and pyrrole is polymerized within the latter using the vapor phase polymerization technique [65]. The gold particles are acting as the nucleation center for polymerization and after slow removal of the membrane, the PPy-Au particles are set free in the solution. Further extending the work to filtration of KCN or $K_3[Fe(CN)_6]$ solution through the PPy-Au assembly, Au particles are removed and hollow capsules of PPy are obtained [66, 67]. The arrangement of Au nanoparticles coated with PPy and the hollow PPy capsule after removal of the Au core has been nicely shown in a TEM picture (Fig. 5). A conventional technique for synthesis can also be applied by adding oxidant solution into suspension of gold-containing pyrrole, but in that case some stabilizer (*e.g.*, PVP) should be added from outside. The PPy capsules obtained this way have potential application in entrapment of small and reactive molecules without hampering reactivity. The second example of a template utilizes self-assembly of pyrrole on some inorganic substrates like Al_2O_3 or synthetic zeolite,
Figure 5. TEM images of PPy-Au nanocomposite using Au particle of 30 nm diameter: (a) PPy-coated Au, (b) after removal of Au core by complexation. Reproduced with permission from [66], S. M. Marinakos et al. *Adv. Mater.* 11, 34 (1999). © 1999, Wiley-VCH.

desirably modified by some surface-active agents *viz.* hexanoic acid (HA) or cetyl pyridinium chloride (CPC) [68, 69]. These reagents themselves can form a self-assembled monolayer on the inorganic host by a semi-chemisorption mechanism; pyrrole molecules, on the other hand, have some affinity towards HA and CPC by which they can also form a monolayer (or a thin layer) on the modified substrate. With the addition of APS or $FeCl_3$, pyrrole is polymerized and the nanocomposite is grown. High electrical conductivity (of the order of 10^{-1} S/cm) indicates that PPy is present in highly ordered form. The synthesis of an optically active nanocomposite of PAn-silica was reported by a single publication following an electrochemical synthesis technique. The electropolymerization of aniline in the presence of colloidal silica (20 nm) and optically active camphor sulphonic acid in a flow through-electrochemical cell resulted in a desired nanocomposite in stable colloidal form with a characteristic "raspberry" morphology (TEM) and a core-shell type orientation [70].

The objective of synthesis of conducting polymer-based nanocomposites has been shifted to versatile directions other than simply obtaining the polymer in a stable colloid or in ordered structures. Colloids were designed having a wide range of characteristic physical and chemical properties, and the resulting nanocomposites could combine the desirable properties of the components in a single material. An apparently surprising result was obtained from the combination of ZrO_2 [71] and Fe_2O_3 [72] with PPy; these colloidal nanoparticles could enhance the electrical conductivity of PPy to an appreciable extent. The reason behind such an anomalous result was an improvement of compactness of the polymer after nanocomposite formation, the effect of which was reflected in improved thermal and environmental stability also. Nanodimensional TiO_2 [73, 74] was sometimes combined with PAn-DBSA (solution) to reduce the size of composite particles to as low as 35 nm; this combination, however, failed to improve the solid-state properties of the polymer. Very recently, Xia and Wang have published a novel approach

towards synthesis of spherical PAn-TiO$_2$ core shell type nanocomposites, using nanocrystalline TiO$_2$ having a diameter $\sim$27 nm [75]. Polymerization of aniline was performed chemically using APS (HCl) in the presence of TiO$_2$ particles and a surfactant solution. Ultrasonic irradiation was maintained during the polymerization and the nanocomposite was obtained as a dark green dispersion of particles with a dimension up to 200 nm. Electrical conductivity of the nanocomposite with 21.6% TiO$_2$ was 0.72, larger than that prepared without ultrasound assistance.

Carbon black (CB) is a very important material considering its filler properties to plastics and rubber. This material has been used as core of conducting nanocomposites in a series of works published by Wampler et al. [76, 77], using simple solution polymerization of pyrrole in the presence of CB. At a low concentration, CB hampers conductivity of PPy but after a critical CB loading, conductivity rises and saturation at $\sim$60% loading is observed. Deposition of PPy and PAn on other allotropes of carbon $viz.$ graphite and carbon nanotube (CNT) has also been reported in a number of publications [78–82].

Magnetic susceptibility of the well-known magnetic materials $viz.$ γ-Fe$_2$O$_3$, Fe$_3$O$_4$, etc. has been nicely combined with important physical properties of conducting polymers in a significant number of articles. Butterworth et al. [83, 84] have designed a novel technique by which silica-coated magnetite particles (prepared as described elsewhere [85]) were combined with PPy to give rise to magnetic nanocomposites. These ultrafine particles are expected to combine unique dispersing ability of silica with magnetic susceptibility of magnetite and the composite showed superparamagnetic behavior with an appreciable magnetic susceptibility of 6.5 emu/g. Higher silica loading enhanced the colloidal stability, although the conductivity and magnetic property were sincerely hampered. Superparamagnetic γ-Fe$_2$O$_3$ particles (9 nm) were included in a PPy-based composite by copolymerizing pyrrole and pyrrole-N-propylsulphonate with FeCl$_3$, and subsequently treating the materials by NH$_4$OH at 70 °C [86]. Incorporation of nanocrystalline Fe$_x$O$_y$ (14 nm) into a PAn matrix could be performed by mixing an aqueous solution of FeSO$_4$ with a NMP solution of PAn (EB) under N$_2$ atmosphere [87–89]. However, magnetic susceptibility of these materials could be observed only in high pH ($>$7) condition because of the appearance of Fe$_3$O$_4$ in such conditions. In a very recent publication, the in-$situ$ formation of a ferric oxide embedded nanocomposite of PPy was described following the sol–gel technique. Fe(NO$_3$)$_2$, 9H$_2$O was used as the precursor of ferric oxide, which (in 2-hydroxy ethanol medium) is converted to α- and γ-Fe$_2$O$_3$ (or Fe$_3$O$_4$) with simultaneous polymerization of pyrrole [90]. The resulting black powder shows electrical conductivity and magnetic property and both are enhanced on annealing to 250 °C and then diminishing. On changing the medium to 2-methoxy ethanol, a similar result is obtained although the conductivity and magnetic susceptibility is found to increase up to $\sim$350 °C.

A sophisticated method of obtaining superparamagnetic nanocomposite film with appreciable electrical conductivity was designed by Tang et al. [91]. γ-Fe$_2$O$_3$ particles (10 nm) were coated with anionic surfactant prior to mixing with solutions of PAn containing different anions ($e.g.$, DBSA, CSA, etc.) in different solvents. Highly conducting films (maximum conductivity 237 S/cm) with very high magnetic susceptibility (maximum saturation magnetization 40 emu/g) were thereby obtained. Another novel method of synthesis of magnetically susceptible nanocomposites was reported by Bidan et al. [92, 93] using electropolymerization principle. In this work, γ-Fe$_2$O$_3$ was surrounded by some anionic complexing agents so that core-shell type macro-anions are prepared with γ-Fe$_2$O$_3$ in core. As pyrrole is subjected to electropolymerization, in the presence of the dispersion of such macro-anions stabilized by some surfactant, the nanocomposite having good magnetic property is grown in-$situ$. An overall evaluation of the efforts of producing conducting polymer composites and nanocomposites has been done by Kryszewski and Jeszka in a contemporary review [94].

The quest for obtaining conducting composites with unique redox properties like conducting polymers and significant charge-discharge properties have led scientists to combine cathode-active materials like LiMn$_2$O$_4$, V$_2$O$_5$, etc. with PPy and PAn. Both chemical and electrochemical polymerization technique was followed and spectrums of different inorganic materials were combined in this respect. For combination with PPy, pyrrole was polymerized in the presence of V$_2$O$_5$, LiMn$_2$O$_4$, and β-MnO$_2$, etc., utilizing the oxidative power of the inorganic materials while PAn-NMP was solution blended with inorganic components. Interestingly, in such nanocomposites conducting polymers and the inorganic materials are participating as active components having complementary redox properties [95–102].

Catalytically important nanoparticles could be combined with conducting polymers to give rise to nanocomposites having catalytic activity. Pt [103] and PtO$_2$ [104, 105] are the two most important materials in this respect, and they were combined with PPy and PEDOT by the chemical polymerization technique. Later on, Au and Pd nanoparticles were also included into the PPy and PAn bed, sometimes using a solution-blending technique and sometimes by simultaneous oxidation-reduction reactions. Sometimes, even the PPy-SiO$_2$ nanocomposite (rather than only PPy or PAn) were also used to entrap Pd or Au nanoparticles with retention of catalytic activity and the nanocomposites having a larger surface area were found to be better adsorbents for catalytic particles. The electrochemical incorporation of other metallic and bimetallic elements in the ICP films and their subsequent application in chemical sensing ($e.g.$, glucose) and gas sensing, etc. are described in a few publications [106–111].

It was already mentioned that the surface of the first generation SiO$_2$-based nanocomposites containing PPy and PAn (introduced mainly by Armes et al.) was silica-rich rather than polymer-rich. These composites were considered as agglomerates of silica particles bound or a "glued" by polymer chains. Later on, there have been numerous efforts to synthesize nanocomposites with a PPy rich surface. In a very recent publication, large glass beads (diameter $\sim$550 μm) were coated with PPy by a chemically polymerizing pyrrole on the surface of beads treated with FeCl$_3$ [112]. The treatment was repeated to thicken the PPy coating, and coating thickness was found to increase from

6.2 μm to 20.2 μm after coating the beads twice. The surface is obviously PPy-rich, and thereby positively charged and capable of the removal of Humic acid from water. Chriswanto et al. [113, 114] and Perruchot et al. [115–117] have attempted to modify the composite surface by using porous silica particles but ended up with a silica-rich surface. The latter group has tried to functionalize silica particles with –COOH and –NH_2 groups so that adhesion of PPy to silica increased, and thereby a nanocomposite with PPy-rich surface is obtained. Different methodologies to introduce functionalized silica particles are grouped in Figure 6. Aminopropyl triethoxy silane (ATS) is a specific reagent for introducing –NH_2 groups to silica; silica particles were treated with ATS prior to deposition of PPy on them, which ultimately led to a PPy-rich surface of nanocomposites. PPy loading and electrical conductivity of the composite were found to be increased with ATS loading, and in the future the technique could be applied to form PPy coating (20–50 nm thick) on E-glass fibers as well [118, 119]. Functionalization of nanocomposite particles themselves with –NH_2 or –COOH groups (rather than only the core) could be performed with the objective of improving their performance in immunodiagnostic assay. Aminopropyl triethoxy silane was again used for this purpose, and stirring the preformed nanocomposites with an aqueous solution of ATS could add a –NH_2 functional group to them [120, 121]. In a modified technique, Goller et al. have described –NH_2 functionalization of PPy-SiO_2 nanocomposites through copolymerization of pyrrole and 1-(3-aminopropyl pyrrole) in the presence of silica; the amination was established from varying evidence [122]. On the other hand, in order to add a –COOH functional group to the composites, the reaction had to be started from copolymerization of pyrrole with 1-(2-carboxyethyl)-pyrrole or pyrrole-3-acetic acid, in the presence of ultrafine silica sol as described by Maeda et al. [124], the 3-substituted derivative presented better stability and other properties as compared to the other one [123–125]. The –COOH functionalized colloid proved itself to be an excellent candidate for immunodiagnostic
assays [126]. Amino-functionalized nanocomposites are also expected to show better performance in immobilization of biomolecules like hormones, antigens, antibodies, DNA, etc. [127].

4. NANOTUBULES AND NANOWIRES

Over the last one and a half decades, the world of conducting polymers has been enriched with a number of nanostructured objects in different forms like nanotubules, nanowires, nanorods, etc. The prime objective of synthesis in most of the cases, however, was to achieve the perfect control over the growth of polymers, which ultimately helps to reveal the unexplored fundamental properties of them. Inorganic and polymeric substrates having nanodimensional pores, channels, and gaps were used as a support for this purpose and conducting polymers were led to grow chemically or electrochemically within them. These ICP-loaded substrates are examples of a different kind of nanocomposite, in which the nanodimensional conducting polymer is the guest. After removal of the supporting matrix by selective dissolution, the nanomaterials are set free and can be collected in solid state and/or subjected to different studies. Depending upon the nature of the support and some other factors, these materials can be classified into two major classes *viz*. intercalative polymerization and template-guided polymerization.

There are two major differences between the intercalative nanocomposites, which depend on whether the supporting substrate itself is oxidative or not. In the former category, there are only a few layered materials possessing substantial oxidative property that is utilized for oxidative polymerization of the monomer within the substrate. The majority of the hosts are devoid of oxidative property and require oxidant (for the polymerization) to be applied from outside after incorporation of the monomer into the host. In each case, the reaction gives rise to solids with nanodimensional-conducting polymers confined in the host materials. The synthesis techniques are obviously named as redox intercalative polymerization (RIP) and post-intercalative polymerization (PIP), respectively. Template-guided polymerization should be discussed under a separate title because the related works very often present simultaneous polymerization and incorporation as will be clarified later. This classification, however, is not very applicable and very often, overlaps are observed.

4.1. Template-Guided Synthesis

Considering the simplicity of the system and the interesting properties of the resulting materials, the discussion should be started with template-guided polymerization. The underlying principle of this branch of synthesis is to allow chemical/electrochemical growth of conducting polymers within some chemically inert microporous/nanoporous membrane matrices. In most of the works, after the reaction is over the polymer-membrane hybrid is subjected to selective dissolution of the membrane (using appropriate solvent) in order to set the nanodimensional polymers free. Different synthesis techniques followed for template-guided polymerization

Figure 6. Schematic presentation of different routes of surface functionalization of PPy-silica nanocomposites by amino and carboxyl groups.

and properties of the polymeric nanomaterials have been presented collectively in Table 3. This stream of investigation was started in 1986 when Penner and Martin were able to polymerize pyrrole electrochemically within the pores of a polycarbonate (nucleopore) membrane having a thickness of 1 μm [128, 129]. This technique obviously controls the macroscopic growth of the polymer and leads the polymer to adopt fibrillar or microporous morphology. After dissolution of the matrix in chloroform, the fibrils or tubules are set free and could be separated. The availability of the support membranes in different pore sizes ranging 100 Å– 12 μM results in a variety of the dimension of the nanomaterials; at the same time, uniformity of the pore diameter leads to a uniform dimension of the conducting polymers synthesized under each confinement. The chemical polymerization technique has also been applied for the synthesis of these membrane-based polymeric nanomaterials; in that system, the membrane is placed as a separator of two compartments containing aqueous solutions of monomer and the oxidant. The solutions diffuse towards each other through the pores and react to form the polymer within. These techniques were applied for growth of a variety of conducting polymers, namely, PA [130], PPy [131, 132], PAn [133], and P3MT [134]. Tubular growth of PPy and N-methyl-PPy within a porous membrane under chemical and electrochemical synthesis conditions has been revealed by the respective SEM images (Fig. 7). In each case, however, nucleation of
Figure 7. SEM images of chemically synthesized PPy nanotubules (a & b) and electrochemically synthesized poly (n-methyl pyrrole) microtubules (c). Reproduced with permission from [132], C. R. Martin et al., *J. Am. Chem. Soc.* 112, 8976 (1990). © 1990, American Chemical Society.

Table 3. Synthesis techniques and important properties of template synthesized conducting polymer nanocomposites.

Polymer used	Template/host	Synthesis technique	Nature of isolated polymer	Important properties/applications
PPy, PTh, and PAn	Porous membranes: nucleopore, milipore, Gore-Tex, polycarbonate, Al$_2$O$_3$, stainless steel mesh	Both chemical and electrochemical polymerization	Nanotubules with diameter of the membrane pores, variable thickness, and very high conductivity (up to 3000 S/cm)	1. High conductivity of composites (up to 50 S/cm) 2. Excellent nanotubules with uniform size and thickness 3. Promising for application in biosensor
PAn	Al$_2$O$_3$	Two-step synthesis; Chemical polymerization followed by electro-deposition	PAn nanotubules loaded with Fe or Co nanowires	1. Polymer envelope protects the metallic core from environmental effects 2. Highly promising vertical recording materials
PPy	Porous PMMA membrane	Chemical polymerization	Interconnecting tubules	1. PPy-PMMA IPN-like structure 2. High conductivity (0.05–19.86 S/cm)
PPy, PAn, and PTh	Polystyrene colloid film	Electro-polymerization	Macroporous solid film	1. Conductivity similar to bulk polymer 2. Easy mass transport and rapid switching
PPy and PAn	Porous Vycor glass	Chemical polymerization	Uniform rod-like tubules	No macroscopic conductivity (10^{-7}S/cm) indicating no polymer on surface
PAn	SiO$_2$ network from TEOS	Electro-polymerization	Tubules (not isolated)	Electrochemically identical to bulk polymer
PA, PTh, PPy, and PAn	Zeolites (Z-Y, MOR, MCM, ZSM-5, etc).	Mainly chemical polymerization, little electropolymerization	Tubules and wires	Isolated polymers are chemically identical to bulk polymers but shorter in chain length and poorer in conductivity

polymerization starts at the wall of the pores and therefore hollow polymeric tubules are formed at each end. Controlling the duration of polymerization, the length as well as the thickness of the tubules can be controlled. For poly(3-methyl thiophene) (P3MT), prolonged polymerization resulted in the growth of polymer tubules out of the membrane in spiral form; for PPy, on increasing the duration of polymerization, the thickness of the tubule is increased, ultimately resulting in a closed polymeric wire, while for PAn only the tubules are obtained which does not close. Nanotubules of PPy can form stable colloidal dispersion if the dissolution of the substrate can be done in the presence of any stabilizer/surfactant; such a report is also available using dimethyl sulphosuccinate (DMSS) as dispersant [135].

Confined growth of polymers under such template-guided polymerization results in highly ordered/oriented form—the same as is revealed from their high solid-state electrical conductivity. Despite their large insulating fraction, the composites show conductivity as high as 50 S/cm and the isolated tubules show exceptionally high value as 3000 S/cm. The value is higher for tubules with a narrower dimension, all of which can be attributed to enhancement in ordering of the tubules [136–138]. Martin et al. have suggested that the nanotubules consist of a highly ordered, thin outer layer surrounding a disordered inner part or core. The outer layer or skin is highly conductive while the core is less conductive. Therefore, in the narrow tubules (diameter ∼50 nm), the highly conductive fraction is larger resulting in its high conductivity. The effect of different experimental parameters on the nature and morphology of the polymeric nanotubules were also studied and reported by another group; interestingly, they have even measured the elastic modulus of the nanotubules [139–141]. The mechanism of electrical transport in these materials was also studied and will be discussed in proper context.

Template-guided synthesis of a conducting polymer turned to a new direction with novel application potential recently when a two-step synthesis technique was designed for a three-component hybrid material [142–144]. This can be considered as an extension of the earlier methods followed by Martin et al. and others. Conducting polymer PAn, PPy, etc. are synthesized within microporous Al_2O_3 membrane using a chemical polymerization route similar to earlier ones. The array of conducting polymeric tubules in an Al_2O_3 matrix is subjected to electrodeposition of different metals *viz.* Fe, Co, Ni, etc. covering one side by silver and using the Al_2O_3-ICP array as the working electrode. As a result, the metallic nanowires are grown within the polymeric nanotubules confined in the inorganic membrane. After dissolution of the outer membrane, metallic nanowires encapsulated in a polymeric envelope are obtained; these materials are expected to bring revolution to vertical recording materials.

The templates discussed so far present systems with uniform cylindrical pores, which ultimately produce conducting polymers with fibriller morphology. Variation in the structure of the template, on the other hand, can obviously bring some change in the ultimate morphology of the nanomaterial. There are reports of producing templates with interconnected pores so that ultimately the interconnected, polymeric nanotubules are obtained. Such template

membranes made of PMMA and Vycor glass were reported from two different research groups. In the PMMA, two porogens—NaCl and PEG—were incorporated as foreign materials following solution bending technique; after leaching out the porogens in proper solvent, the required porous membrane with open pore structure [145] is obtained. Porous Vycor glass (PVG) is obtained by acid leaching of a phase-separated borosilicate glass; the soluble borate phase is dissolved in acid, leaving an open porous structure with narrow pore size distribution (∼80 Å) and made up of almost pure silica. Mainly, chemical polymerization of aniline and pyrrole were done within such open porous membranes, which in the former case produced composites with conductivity as high as 19.86 S/cm [146, 147]. For PVG, the redox polymerization (initiated by pre-exchanged Cu^{2+}) takes place mainly within the pores leaving the PVG surface highly resistive (10^{-7} S/cm). These interconnecting polymers were not isolated, however, from the matrix which seems to be difficult also, owing to the complexity of the system.

It is here relevant to mention the work that produced a conducting polymer in macroporous form. Polystyrene latex having PS spheres with a diameter 0.5 μm and 0.75 μm was used to coat the working electrode of a cell prior to electropolymerization of aniline, pyrrole, and bithiophene. Polymers grow on the electrode leaving the PS spheres free, and completion of polymerization followed by dissolution of the PS matrix leaves the polymer in macroporous form with large voids. Conductivity of the macroporous polymer is similar to the bulk one, although the high surface area provides them improved mass transport ability and rapid switching. Another very relevant work was published recently which describes the fabrication of "PAn inverse opals" via templating colloidal PS assemblies [148]. Wet colloidal sediment of PS spheres (which spontaneously self-organize into different crystal structures, *e.g.*, cubic, FCC, BCC, etc.) with a diameter of 640 nm was used as the host template, the interstices of which were used as the submicrometer-sized reactor array. Aniline hydrochloride and $K_2S_2O_8$ solutions were subsequently infiltrated through the PS array at a constant speed to initiate the oxidation polymerization of aniline within the voids. Afterwards, the host was dissolved in THF in order to get the self-supported, specially designed 3D network of PAn specifically termed as "inverse opals." This synthesis is a truly chemical technique and a successful step towards formation of photonic bandgap (PBG) crystals. Very recently, the same group has reported electrochemical synthesis of inverse opals from PPy or PTh [149]. The principle of synthesis is very similar to the chemical technique, only the polymerization of pyrrole or thiophene within PS assembly was performed electrochemically. Electro-entrapment of PAn in sol–gel derived porous silica films (prepared from tetraethyl ortho-silicate +1,1,3,3, tetramethyl-1,3, diethoxy-disiloxane + methanol + HCl) was recently reported [150].

4.2. Intercalative Polymerization

It was mentioned earlier that a second stream of template-guided polymerization consists of intercalative polymerization that describes the confined growth of conducting polymers (chemical/electrochemical) within the layers/networks of naturally occurring 2-D or 3-D inorganic

materials. Depending upon the chemical nature of the host (oxidative or neutral), such polymerization can be grouped as RIP and PIP. Different inorganic hosts used for intercalative polymerization and the few important observations on this system have been tabulated in Table 4. Redox intercalative polymerization of aniline and pyrrole has been performed with only a few layered hosts having substantial oxidizing power *viz.* FeOCl, V_2O_5, and α-RuCl$_3$. As mentioned earlier, the system is based on chemical polymerization by exploiting oxidative properties of the host matrix. The stream of investigation was started around 1987 when Kanatzidis et al. were able to guide RIP of pyrrole within the van Der Walls gaps of FeOCl layers [151]. FeOCl is a layered solid having an interlayer gap of 7.98 Å, and upon intercalating variety of chemical species, namely, amines, erathiafulvalene, pyridine, etc., the interlayer distance is found to be increased [152]. This particular research group was able to intercalate each of PPy, PAn, and PTh in FeOCl with the simultaneous reduction of a fraction of Fe (III) as evidenced by the Maussbauer spectroscopy, and in each case the interlayer spacing was also increased to different extents as an evidence of intercalation. The synthesis technique is as simple as stirring the respective monomers (Py, An, Th) with FeOCl crystals, although

the other conditions like reaction temperature, solvent, duration of reaction, etc. are varied for different monomers. For example, stirring FeOCl with neat pyrrole at 60 °C leads to the formation of $(PPy)_{0.34}$FeOCl [151–153] while synthesis of $(PAn)_{0.20}$FeOCl needs stirring with 10% aniline (in acetonitrile) in the air for 1 week [154, 155]. Intercalation of polythiophene could be done in a similar way by stirring 2–2′ bithiophene with FeOCl in acetonitrile [152, 153]. In each case, the interlayer distance of FeOCl increased by 6.54 Å (PAn), 5.23 Å (PPy), and 5.33 Å (PTh), respectively. The crystal structure of FeOCl and the possible arrangement of PAn chains within this host has been shown in Figure 8 (I & II). Intercalation of polyfuran in FeOCl was done by stirring 2,2′,5′,2″ tetrafuran with FeOCl at 100 °C in methanol, and in this instance, the interlayer distance is increased by 7.7 Å. The order of electrical conductivity of these materials follows:

$$PFu_{0.67-0.75}FeOCl < PAn_{0.20}FeOCl < PPy_{0.34}FeOCl < PTh_{0.27}FeOCl$$

$$0.001 \text{ S/cm} \qquad 0.007 \text{ S/cm} \qquad 0.15 \text{ S/cm} \qquad 5.0 \text{ S/cm}$$

In each of these works the polymers synthesized under the confinement could be separated by dissolution of the host

Table 4. Composition and important properties of a few intercalative nanocomposites involving laminar hosts.

Inorganic host	Polymer used	$\Delta d^{\#}$ (°A)	Conductivity (S/cm)	Important information/remarks
FeOCl (RIP)	PPy	5.23	0.150	1. Monolayer intercalation with monomer units oriented perpendicular to crystal plane
	PAn	6.54	0.007	
	PTh	5.33	5.000	2. Profound effect of aerial oxygen, appearance of α- and β-phases
	PFu	7.70	10^{-4}–10^{-3}	
	PNMP*	5.84		
V_2O_5 (RIP)	PAn	5.1	10^{-4}–10	1. Formation of polymer monolayer
	PTh	5.95	0.1	2. Influence of aerial oxygen detected
V_2O_5 Dried gel (RIP)	PAPSA	Not clearly mentioned	10^{-4}–10^{-3}	Both water soluble and insoluble parts of composites are available with good film-forming character
VOPO$_4$ (RIP)	PAn	4.9	Not	Aniline intercalates and polymerizes while Pyrrole does not.
	PPy	2.1	mentioned	
	P3MP*	8.7		Pyrrole derivatives intercalate.
	P 3, 4, DMP*	9.7		
α-RuCl$_3$ (RIP)	PAn	6.2	2.0	1. Effect of aerial oxygen was observed.
	PPy	6.0	—	2. PPy is formed in highly defective form.
MMT (PIP)	PAn	5.3	5×10^{-2} (Cu^{2+}) 10^{-6}–10^{-3} (APS)	1. Fixing An$^+$ followed by exposure to APS or fixing Cu^{2+} followed by exposure to An$^+$.
	PPY	4.5–5.0	2×10^{-5} (Cu^{2+}) 1.2×10^{-2} (I$_2$)	2. I$_2$ encourages surface polymerization to some extent.
Porous silicon (PIP)	PAn		20–30Ω (resistance)	Electroentrapment of PAn within host layers Lowering of resistance by $\sim$20–25 times
α-ZrP (PIP)	PAn	7.6, 13.6	10^{-4}–10^{-3}	Monolayer and bi-layer formation is possible.
MoS$_2$	PPy	4.5	$\sim10^{-1}$	Monolayer formation occurring, polymer chains are not perpendicular.
	PAn	4.2		
MoO$_3$	PAn	6.8	5×10^{-3}–3×10^{-3}	1. Monolayer formation with retention of high crystallinity of host.
	PPV	5.6	0.5	2. Formation of H$^+$-doped PPV (conducting).

*PNMP: poly(N-methyl pyrrole); P3MP: poly(3-methyl pyrrole); P 3, 4 DMP: poly(3,4 dimethyl pyrrole).

and were found to be chemically identical to that of the bulk polymers [156] synthesized conventionally.

V_2O_5, nH_2O xerogels present a group of layered materials that have been extensively used for the synthesis of hybrid materials by intercalation of PAn, PPy, and PTh. The investigation was started in 1989 when the interaction of aniline with water-swollen V_2O_5, nH_2O films changed color from dark red to bluish black indicating intercalation of PAn by oxidative polymerization of aniline [157]. Subsequent characterizations have proved that the conductive form of PAn

was generated with simultaneous reduction of the host frame but without disrupting the structural features of the latter. This work opened the way to a series of works highlighting the mechanism of polymerization, orientation of the polymer chains, and the effect of different external parameters like aerial oxygen, etc. In almost all these nanocomposites (including the FeOCl systems), the aniline and pyrrole units of polymer chains are oriented perpendicular to the layer. In the V_2O_5 system, an interlayer expansion of 5.14 Å was observed and a pronounced effect of aerial oxygen was also

found [158, 159]. The intercalation of PTh within V_2O_5 layers was possible on refluxing solution of thiophene (in acetonitrile) with the host for 24 h; in this case, interlayer expansion of 5.95 Å was observed. $PTh-V_2O_5$ composites are highly conducting (0.1 S/cm), while that of $PAn-V_2O_5$ composites vary over a wide range (10^{-4}–1 S/cm) [160].

$VOPO_4$, $2H_2O$ presents another system having substantial oxidizing power and intercalating capability. This layered system has been used up in the formation of intercalative nanocomposites in combination with PAn and PPy [161, 162]. For PAn, it requires stirring with neat aniline for 1–5 days in the dark at a temperature range over 1–35 °C; aniline is intercalated and subsequently polymerized to anilinium cation (An^+) with the simultaneous reduction of V(V) to V(IV). On exposure of this An^+-loaded $VOPO_4$ to oxidizing agents like $CuCl_2$, aniline polymerizes and the ultimate nanocomposite is formed. Instead of aniline, if ethanolic solution of An^+ is taken initially, then intercalation and subsequent polymerization of aniline takes place with simultaneous reduction of V(V) and the formation of the nanocomposite. Interlayer distance increases by 4.9 Å on the intercalation of PAn which also indicates monolayer formation. Pyrrole itself, under the similar conditions, gives polymerization only on the surfaces of the host while 3-methyl and 3,4-dimethyl derivatives of pyrrole give an intercalative nanocomposite formation with an interlayer expansion of 8.7 Å and 9.7 Å, respectively [163–165].

α-$RuCl_3$ offers another layered system having interesting catalytic, photochemical, and magnetic properties. This system was capable of undergoing RIP of aniline and forming $PAn/RuCl_3$ nanocomposite on stirring α-$RuCl_3$-aniline mixture in acetonitrile for 1 week in open air [166]. For PPy intercalation, to an aqueous suspension of pyrrole and Li_xRuCl_3, $FeCl_3$ solution is added dropwise to complete polymerization. Conductivity of PAn-α-$RuCl_3$ is 2.0 S/cm, while PPy formed under this condition is highly defective and almost insulating [167].

From the discussion on nanocomposite formation by the RIP method, it is obvious that the host material should possess sufficient redox activity to initiate the oxidative polymerization of the conducting polymer. Therefore, structured hosts not having oxidative property are incapable of taking part in nanocomposite formation in this technique. However, a large variety of such hosts including the oxides, silicates, phosphates, dichalcogenides, etc. has been utilized for nanocomposite formation by using suitable oxidants (for polymerization). This technique suggests intercalation of the monomer within interlayer spaces of the host by adsorption or ion exchange, etc. followed by exposure of the entire thing to oxidants: The total scheme is properly termed as PIP.

The inorganic host materials used for confinement of conducting polymers following the PIP method can be divided into two groups depending on whether it is two dimensional (2-D) or three dimensional (3-D). Two-dimensional hosts encompass a large variety of materials viz. the natural and synthetic silicates, phosphates, oxides, sulphides, etc. while 3-D hosts are mainly different zeolites and only a few coordination polymers and inclusion compounds. Among the layered silicates, the most extensively used are montmorillonite (MMT) and hectorite. All these clays contain a large number of hydrated cations in their interlayer space which are exchangeable with metal ion or organic cations, which is the key to the intercalation as well as polymerization of aniline, pyrrole, etc. This series of work was started with inclusion of PPy within MMT exchanged with Cu^{2+}. This report was published in the Ph.D. thesis of Van de Poel in 1975 when conducting polymers themselves were yet to be discovered properly [168]. This work was followed by a similar work describing the synthesis of $PAn-MMT-Cu^{2+}$ from aqueous aniline solution [169]. Polymerization of aniline or pyrrole in these materials is achieved at the cost of reduction of exchanged Cu^{2+} ions. Later on, there were numerous works regarding the synthesis and characterization of PAn or PPy intercalated, MMT-based nanocomposites [170–174]. The general synthesis technique of these materials can be described by a two-step process; at first, MMT containing metal ions like Na^+, Cs^+, etc. (having no oxidizing power) is exchanged with monomer cations in order to fix them onto the host, followed by their exposure to oxidants like APS or $FeCl_3$. Interlayer expansion of 5.3 Å for PAn-MMT and 4.5–5.0 Å for PPy-MMT were observed. As the conducting polymer fraction is mainly in the interlayer places, macroscopic conductivity of some of these composites is as low as 10^{-6} S/cm. All these composites are highly anisotropic in nature and maximum anisotropy as high as 10^5 was observed. The polymer confined in MMT layers is analytically identical to the bulk polymer, although few properties like molecular weight, dc conductivity, etc. are strongly dependent on different experimental parameters.

Montmorillonite is a layered silicate having very high swelling ability suitable for intercalation of polymers with bulky dopants. This capability has been utilized in intercalation of PAn having dopants like DBSA, camphor sulphonic acid (CSA), etc. following solution/emulsion polymerization of aniline in the presence of MMT [175–178]. On the other hand, some preformed colloids of PPy and PTh could also be intercalated into MMT simply by mixing the preformed latexes with the clay [179–185]. In a few experiments, electropolymerization of aniline has been followed for the synthesis of nanocomposite based on MMT or PS layers [186]. All these materials were explored from different aspects and important physical properties were observed.

Phosphates of different transition metals viz. Zr, Ti, Sn, U, etc. offer a large variety of layered materials which were extensively used for intercalative polymerization. Techniques of polymerization can be broadly classified into two main categories: either the monomer cation is fixed onto the host by cation exchange followed by exposure to oxidants or an oxidative cation (e.g., Fe^{3+}) is fixed by cation exchange followed by exposure to the monomer. α- and γ-zirconium phosphates (ZrP) [187, 188] and some of their organo derivatives (ZPS) [189] present layered systems with exchangeable hydrogen, which are first exchanged with NaOH or NaCl to form Na-derivatives of ZrP. The latter can then be exchanged with aniline to fix the same in ZrP. Then the aniline-loaded ZrP is exposed to APS or $FeCl_3$ in order to polymerize aniline within the matrix. It is interesting to note that aniline forms mono- and bi-layers in α-ZrP and after intercalation of the aniline interlayer, spacing increased by 6 Å. After dissolution of the host in HF, the PAn separated is similar to emeraldine salt and emeraldine base, respectively, within layers of ZrP(H) and

ZrP(Na) and electrical conductivity around 10^{-1} S/cm. The composites prepared with ZrP(H) are moderately conductive (10^{-4}–10^{-3} S/cm), but those with ZrP(Na) have poorer conductivity. Nanocomposites with ZPS (S indicates –SO$_3$H group) possess higher conductivity (0.1–4.2 S/cm) because of more efficient protonation with acidic H$^+$.

Tin (IV) phosphonates (SnP-C) also offer a layered host system with exchangeable acidic protons and have therefore been used for intercalation of aniline [190–192]. However, with this host, the fixation of Fe^{3+} prior to exposure to aniline was extensively followed and nanocomposites with poor conductivity (10^{-9} S/cm) were obtained, which indicates that PAn was formed only in the interlayer spaces. When α-tin bis (hydrogen phosphate monohydrate), Sn(HPO$_4$)$_2$, H$_2$O (α-SnP) is used as the host ($d = 7.89$ Å), the synthesis technique does not work well with prefixation of Fe^{3+} and fixation of aniline followed by exposure to APS+HCl gives a better result. α-SnP was also used to form a nanocomposite with PPy when it was exposed to pyrrole after being exchanged with Cu^{2+}. Electrical conductivity of these composites were not reported, although they were proven to have less branching/crosslinking as revealed by cyclic voltammetry (CV). In a parallel synthesis route, some layered hosts *viz.* α-Zr (HOPO$_3$)$_2$, α-Ti (HOPO$_3$)$_2$, H$_2$O and HUPO$_2$PO$_4$, 4H$_2$O (HUP) [193, 194] were combined with aniline using the help of aerial oxidation. The hosts were shaken with aniline and left in the air for the polymer to form. Composites formed in such a way are poorly conducting because of complete intercalation of polyaniline and the range of conductivity is within 10^{-5}–10^{-1} S/cm.

Molybdenum-based, layered compounds *viz.* MoS$_2$ and MoO$_3$ have been extensively used for intercalation of conducting polymers like PPy, PAn, and PPV. The interesting thing about MoS$_2$ was that it was earlier used for intercalation of only the highly reducing alkali metals and not the organic molecules. But it could be successfully used to intercalate PAn (from NMP solution) and PPy (by sequencial addition of pyrrole and FeCl$_3$ to the aqueous dispersion of MoS$_2$) to form single-phase hybrid materials [195, 196]. For PAn intercalation, an interlayer expansion of 4.2 Å is observed, while the same is 4.5 Å for PPy incorporation. Both these values are in pace with the dimension of the monolayer of PAn and PPy. Both these materials are highly conducting, the absolute value going to $\sim10^{-1}$ S/cm. The FTIR spectrum of the PPy-MoS$_2$ system shows a blue shift of ~10 cm^{-1}, which indicates that the molecular weight of PPy grown under such restricted conditions is lower than the bulk polymer.

MoO$_3$ presents a highly crystalline system having the potential application as an electrode in high-energy, density rechargeable Li batteries. This property has been successfully combined with electrical conductivity of PAn and PPV giving rise to a series of hybrid materials. The synthesis technique is the most conventional one as described earlier. MoO$_3$ solid was shaken with aniline and the An-MoO$_3$ was subsequently exposed to APS or FeCl$_3$ solution so that the aniline polymerizes and the dark green solid is formed [197, 198]. After dissolution of the host framework (in NaOH), the molecular weight of the PAn was found to be lower than the bulk. Conductivity of this system could be measured from polycrystalline thin films rather than pressed

pellets; the range of conductivity was found to be 10^{-4} to 10^{-3} S/cm. Formation of a PAn-MoO$_3$ nanocomposite and the arrangement of PAn chains within the MoO$_3$ layers is shown in Figure 9 (I & II). The interlayer expansion in PAn-MoO$_3$ is 6.8 Å, which is in agreement with the orientation of PAn rings perpendicular to MoO$_3$ layers. However, the PAn chains are lying parallel to each other in the troughs or valleys of the oxide sheets so that the incorporation of PAn does not hamper the crystallinity of MoO$_3$.

PPV is a highly conducting polymer that does not undergo oxidative polymerization. This polymer has been intercalated in MoO$_3$ framework using indirect technique, incorporation of the precursor poly (p-xylene-α-dimethyl sulphonium chloride), followed by the elimination of HCl and S(CH$_3$)$_2$ by heating. An interlayer expansion of 5.6 Å was observed and the sample shows a unique high conductivity ~0.5 S/cm,

Nazar, *Chem. Mater.* 8, 2005 (1996). © 1996, American Chemical Society.

which indicates that PPV is present in a highly doped form [199, 200].

All these examples discussed thus far relate to the confinement of conducting polymers within layered solids. But the synthesis of nanotubules or nanowires is most likely to take place within cylindrical or tubular pores which is available in some naturally occurring 3-D systems like zeolites. Zeolites are crystalline, aluminosilicate lattices formed from adjoining SiO_4 and AlO_4 tetrahedral building units which have given rise to open pores, voids, and channels in their structure. The pores and channels may have different shape and orientation and their size can vary from a few angstroms to ~20 Å. Versatile structural features are shown by the zeolites and depending upon their structure and chemical composition, physical properties are also varied [201, 202]. Zeolites are the only 3-D framework that have been extensively used as templates for growing conducting polymers, especially polyacetylene (PA) in nanoscopic form. The beginning of this stream of investigation dates back to 1978 when one research group reported the formation of PA within the channels of zeolite-X (Z-X) and studied the influence of exchangeable cations on the system [203]. Later on, different research groups have reported intercalation of PA in different zeolites *viz.* Y-, L-, A-, Ω-, ZSM-5, SAPO-5, Mordenite (M), etc.

The protonated form of ZSM-5, that is, H-ZSM-5 is a highly acidic zeolite capable of initiating cationic polymerization of acetylene. However, acetylene, being a gaseous one, the monomer loading in the host should be done at a high temperature (298 K to 550 K) under high pressure (10 torr to 1000 torr) [204]. Polyacetylene fills up the pores of zeolite and a color change from white or light gray to black or dark gray is observed. Methyl acetylene (MA) can be similarly polymerized within H-ZSM-5 and both the PA- and PMA-rich zeolite can show reversible change of color with exposure to NH_3. A comparative study on polymerization and spectroscopic properties of PA and its derivatives (methyl and ethyl) in H-ZSM-5 has been published by a contemporary research group [205]. Z-Y exchanged with Co and Ni has also been used for intercalative polymerization of acetylene [206].

This very attractive field of research has been very regularly cultivated by Bein and Enzel [207]. Over a period of few years, they have attempted polymerization of pyrrole, aniline, thiophene, and a few other monomers within different zeolite structures, producing a series of hybrid materials with versatile importance. The general technique followed for confining conducting polymers within zeolite spaces is a two-step one. At first, Na ions of the zeolite are exchanged with an oxidizing cation, for example, Cu^{2+}, Fe^{3+}, etc. followed by subsequent drying and exposure of the zeolite to monomer vapor or solution. Polymerization proceeds spontaneously and the nanocomposite is formed *in-situ*. Z-Y, Z-A, and M were the most widely used matrices for this purpose. Na^+ of these hosts are first exchanged with Cu^{2+} (from a $Cu(NO_3)_2$ solution) and subsequently equilibrated with pyrrole vapor (1 torr) for 1 h at 295 K and placed in a vacuum for 1 h. The yellowish or greenish color of zeolites gradually changes to different shades of green and black with the progress of polymerization. The Fe (III) form of zeolites could be used similarly but the monomer is to be

fed from solution instead of vapor. The polymer essentially forms in interstitial spaces rather than on the surfaces. That is why electrical conductivity values of these samples are as low as almost 10^{-9} S/cm, although the PPy isolated from these composites have conductivity around 10^{-4} S/cm. For the same reason, Z-A having a pore diameter less than a PPy chain cannot host the PPy. Isolated PPy is structurally similar to the bulk polymer, only the molecular weight is substantially lower which accounts for its poor conductivity. Later on, H-Fe-FAU was also used for PPy intercalation following an almost identical technique. L-Z is another form of zeolite that possesses parallel channels leading to one-dimensional growth of PPy [208–212]. Pd and SnO_2 were deposited randomly within the channels of the zeolite, which in the following step acted as an initiator for pyrrole polymerization [213]. Polymerization of thiophene and furfural could be done following similar techniques and almost similar results were obtained [210–211, 214–215]. The bulk conductivity of PTh-Z composite was too low to be reported, but the isolated PTh has shown a conductivity value of 0.01 S/cm. The effect of chain length played an important role in this respect also, and PTh confined in Pentasil-Z was found to vary from two to nine molecular units [215]. On the other hand, the pore size of Z-A was too low to allow PTh formation to take place inside.

Intercalation of PAn within zeolite is a bit different from that of PPy and PTh, because of the necessity of the presence of acidic medium during polymerization. However, it was possible to intercalate PAn in Z-Y, MOR, MCM-4, Halloysite, and a few other zeolites [216–220]. The synthesis technique is very similar to the PIP in nonoxidizing hosts; aniline or anilinium cation is adsorbed into the host followed by exposure to APS. The acid form of zeolite (Na^+ exchanged with H^+), however, is essential for the initiation of polymerization of aniline, and the acidic protons of zeolite can provide sufficient acidity for the formation of a green colored-emeraldine salt form of PAn. Other aspects of the synthesis of PAn-Z nanocomposite are similar to those of PPy-Z or PTh-Z; different properties of the isolated polymer are identical to bulk PAn although the chain length is much shorter. Bulk conductivity of the composite is as low as 10^{-8} S/cm and volume conductivity of the isolated PAn is as high as 10^{-2} S/cm, which indicates the formation of a polymer in interstitial spaces rather than on a surface. Interestingly, the chain length of PAn in Z-Y (six units) is shorter than that formed in interstitial spaces of MMT (15 units), which can be considered as limitation imposed by a 3-D network. In MCM-41 PAn chains with, several hundred units of length were obtained and around 20 PAn wires were found to exist together within a single pore [218].

There is a single report on electrochemical polymerization of aniline within Z-Y. This approach, is different from general electrochemical intercalation of PAn in a nonoxidizing host as described earlier. Here, the zeolite moiety is used as the solvent of the monomer rather than the host. Na-form of Z-Y was exchanged with aniline hydrochloride for 12 h to immobilize the aniline on the zeolite bed followed by filtration and washing. The working electrode (Pt) of the conventional electrochemical cell was then coated with aniline-loaded Z-Y from suspension in

THF using polystyrene as a binder [219]. Electropolymerization under a potentiodynamic condition was carried out in a 0.1 M HCl medium leading to an ordered growth of PAn within zeolite. Therefore, the monomer here is present only within the zeolite host, which is the novelty of the system. However, the amount of polymer synthesized under such conditions is too small to carry out further characterizations. In a recent report, intercalative polymerization of aniline in a Cu^{2+} exchanged natural zeolite named Halloysite has been published [220]. This host possesses a spiral cross-section and relatively thin walls, which did not affect the intercalation and polymerization, and a high resistance of composite again reveals complete intercalation of PAn.

Therefore, confinement of conducting polymers within different oxidizing/nonoxidizing 2-D and 3-D hosts has given birth to a variety of hybrid nanocomposites from which the polymer can be separated in nanostructured form. The stream of investigation is still alive and versatile modifications are in progress. It has already been mentioned that the quest for getting conducting polymers in nanostructured form has primarily led the scientists towards the nanostructured hybrid materials or nanocomposites. However, after the dissolution of the template, the chance of undesired aggregation remains, which very often disturbs the important characterizations of the nanodimensional polymer. Keeping this point in view, the nature of the template has gradually changed during this time and, recently, some molecular templates have become very popular providing very accurate nanoscale control over the conducting polymer. β-cyclodextrin (CD), having a basket-like structure, has been selected as a molecular template for both chemical and electrochemical growth of PAn and PPy nanowires [221, 222]. The template molecule provides some cavities for the pseudo, one-dimensional growth of the polymer ~10 nm in diameter and a few μm long. Electrical conductivity of the polymer is enhanced compared to the bulk polymer.

4.3. Template-Free Synthesis

Very recently, techniques for template-free synthesis of conducting polymers has also been published which describes direct-and single-step synthesis of ICP nanotubules, nanowires, etc. The stream was almost pioneered by Langer and Czajkowski, who have electrochemically synthesized PAn micro-and nano-rods following a novel technique [223, 224]. A movable Ir or Pt needle with a tip less than 10^{-2} mm was used as the working electrode in their work. After commencement of the polymerization, the electrode is slowly moved out of the reaction area so that the PAn is deposited on the PAn electrode only and the PAn microrod grows. Electrochemical synthesis of a single nanofibrillar and giant microfibrillar form of PAn, doped by fullerene derivatives, have been reported by Langer et al., which is one of the pioneering works in this direction [225, 226]. By suitable modification of the synthesis technique, a compact 3-D nano-network array could also be prepared. Later on, chemical synthesis of PAn nanotubules has been described by Dai et al. [227] and Wan et al. [228–230] who have used both fullerene derivatives and naphthalene sulphonic acid (NSA) derivatives for chemical synthesis of

PAn micro- and nanotubules (Fig. 10). The most conventional oxidizing agent, APS, was used for polymerizing aniline in these works. PPy microtubules were also prepared by the polymerization of pyrrole in the presence of β-NSA using APS as an oxidizing agent; controlling the concentration of NSA, the morphology of PPy could be altered from particles to fibers and tubules. Therefore, selection of a particular concentration of NSA was the key to synthesize PPy nanostructures in the present template-free method. Electrochemical synthesis of PPy microtubules (0.8–2.0 μm diameter and 15–30 μM length) could also be performed in the presence of β-NSA; electrical conductivity of chemically and electrochemically prepared microtubules are comparable (1–10 S/cm). Electrochemical deposition of PAn as concentric nanowire within multiwalled carbon nanotube (MWCNT) has been reported by Hassanien et al. [231]. However, the simplest self-formation of PPy microtubules has been published recently; electrochemical polymerization of pyrrole in the presence of Na-p-toluene sulphonate
(a)

(b)

(NaPTS) resulted in the formation of hollow tubules of PPy a few mm in length and several hundred μm in diameter [232]. These tubules are grown on the surface of simultaneously grown PPy film and are strong enough to tolerate free movement along Pt wire. These tubules are highly conducting (498 S/cm) and conductivity is extremely anisotropic (conductivity ratio 10^3 and 10^5 along two different planes). There is another report that describes spontaneous formation of tubular nanostructures of PAn through self-assembly in the presence of azobenzenesulphonic acid (ABSA) [233]. Therefore, synthesis of conducting polymer nanomaterials is easier and cheaper after the advent of template-free techniques; these technique are expected to bring revolution to the world of ICP nanomaterials.

5. MONOLAYERS AND THIN FILMS

Remembering the level of intractability of conducting polymers, it need not explain that it is highly difficult to obtain such polymers in thin film or monolayer form. However, considering the importance of highly organized and specifically arranged forms of conducting polymers in molecule-based electronic devices, there have been continuous efforts toward obtaining thin films of conducting polymers. Special interest was gathered on PAn owing to its low cost, easy preparation, environmental stability, and electronic properties. PTh has also been appreciably studied, while PPy is the least explored one in this respect. Two techniques are mainly applied here, one of which is the self-assembly and another is the Langmuir–Blodgett (LB) technique.

5.1. Langmuir–Blodgett Technique

Langmuir–Blodgett (LB) technique is a highly established technique for preparation of ultra-thin organic films as it offers unique control over the thickness and molecular orientation of the films. Fabrication of thin films following LB technique requires a very particular instrumental set-up and at the same time the polymer should have good solubility and amphiphilic nature. The principle is to dissolve the material of interest in a suitable solvent and to spread the solution onto the water surface as a monolayer [234, 235]. Owing to the lack of processability and amphiphilicity of conducting polymers, preparation of LB films from ICP has become highly restricted. Over the last few years, however, there were some successful molecular engineering approaches for obtaining the same. Such techniques include derivatization of the polymer with long alkyl chains, doping with an amphiphilic dopant, and co-LB deposition along with typical film forming materials [236–240]. This technique for thin film deposition has almost exclusively utilized PAn, while PTh was also used in a few examples but PPy is not used till now. In most of the works on LB film of PAn, the polymer is initially synthesized in a conventional technique, dedoped, and solvated in NMP [241] or NMP-CHCl$_3$ mixture [242, 243] (following its limited solubility in these solvents), the solution is then used for film formation following the established techniques. Few surface active amphiphilic molecules like stearic acid [237], cadmium stearate, cadmium arachidate, etc. [238, 240] were used as codeposition materials expected to improve the structural order of the polymeric film. In other streams of

work, PAn is derivatized with acid like camphor sulphonic acid (CSA), dodecylbenzene sulhonic acid (DBSA), toluene sulphonic acid (TSA), etc. [244] in order to improve the solubility of PAn in organic solvents like CHCl$_3$, and to use the solution for fabrication of LB film. For PTh, the work is easier because 3-alkyl detivatives of PTh have good solubility in CHCl$_3$ and some other organic solvents. Therefore the formation of PTh monolayers from CHCl$_3$ solutions by LB technique, sometimes using surface active agents like cadmium stearate, etc., is available in the literature [245–247]. All these monolayers were characterized from their structural and electrochemical aspects and their material properties were revealed. Spontaneous folding of an especially designed PTh monolayer to the corresponding nanowire was also reported in an excellent publication [248].

5.2. Self-Assembly Technique

The second method exploits the self-assembled monolayers (SAMs) of a support material as a template for the patterned growth of ICP thin films. This technique, in principle, is nothing but selective deposition of conducting polymers on some especially modified surfaces. For example, in related work, a glass surface was modified with patterned SAM of octadecyltrichlorosilane (OTS) following sophisticated techniques [249]. Afterwards, the surface was immersed in a solution of FeCl$_3$, followed by the addition of pyrrole, and PPy film grows on the modified surface with good adhesive property. For aniline, the addition of reactants was in reversed order—aniline followed by APS— although the result was the same. In another work published from the same group, PAn-NMP solution has been used for the formation of a patterned surface of PAn using a polymeric template [250]. The procedure is shown in Figure 11. In a related work, the glass surface was modified with a sulphonate group so that anilinium ions are selectively deposited on the surface followed by exposure to APS and the formation of a monolayer of polyaniline [251]. There is a single publication describing an sophisticated method for formation of PAn monolayers on the lattice-matched surface of Moscovite Mica, one special type of a phyllosilicate host matrix, having good lattice matching with the growth of PAn [252]. Although the synthesis technique is as simple as *in-situ* polymerization of aniline in the presence of a freshly cleaved mica sample, it provides the complete alignment of PAn chains relative to each other and also to the substrate. This work is similar to the intercalative polymerization of PAn within different oxidative/nonoxidative layered hosts discussed earlier; however, the complete alignment of PAn chains have given the work a new dimension. Overall, the synthesis of conducting a polymer-based monolayer or thin film is still confined in a few techniques and there is ample scope of exploring the stream of work in depth.

6. CONDUCTION MECHANISM IN INHERENTLY CONDUCTING POLYMER (ICP) NANOMATERIALS

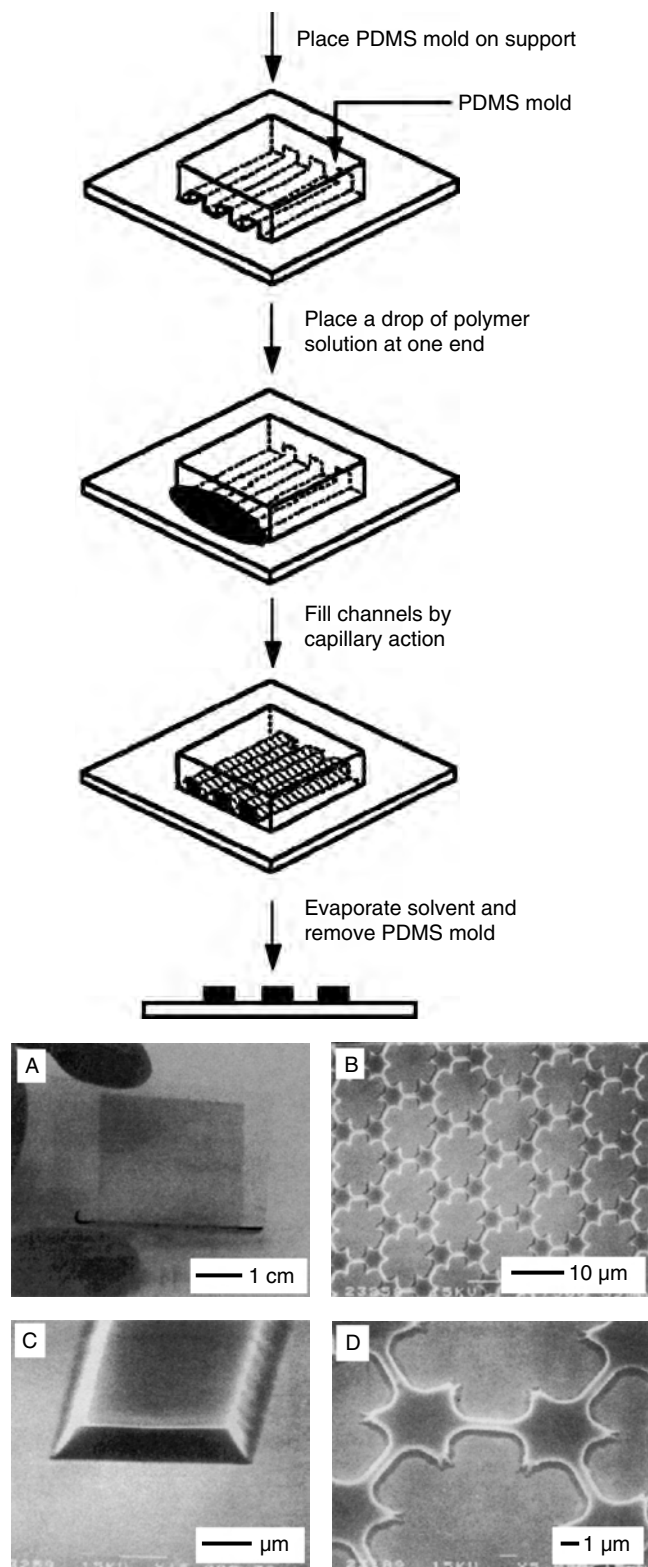
From the foregoing discussions about conducting polymer-based nanomaterials of versatile origin, it is now established that the conducting polymers present in the hybrid


Figure 11. (I) Schematic diagram for the formation of patterned microstructures of PAn (EB) by MIMIC (II) A. Photograph of parallel lines of PAn-ES formed on polyester film using MIMIC, B, C, D. SEM images of PAn-ES structures formed on Si-SiO$_2$ using MIMIC. Reproduced with permission from [250], W. S. Beh et al., *Adv. Mater.* 11, 1038 (1999). © 1999, Wiley-VCH.

nanocomposites or the polymers synthesized under a template-guided, synthesis technique possess some structural and physical differences from their bulk counterpart. These polymers, however, are analytically identical to the latter. Whether the confined growth has some effect on the electrical conduction mechanism of the nanodimensional polymers is a subject of very elaborate study. Thus for, this field has been cultivated only to a limited extent, results of which will be presented here briefly. For the sake of convenience of discussion of this part, ICP nanomaterials are grouped into two categories: the template-guided, nanodimensional polymers, separated from the template (nanotubules, nanowires, etc.) and the template-polymer assembly as a whole (ICP-inorganic nanoparticles, ICP-layered solids, etc.).

Before entering into categorized discussions it should be mentioned that the important model commonly applied for 1-D, 2-D, and 3-D conduction in solids is the Mott's variable range hopping (MVRH) theory [253]. According to this model temperature (T), dependence of electronic conductivity (σ) of a system is given by

$$\sigma = K_0 T^{-1/2} \exp[-(T_0/T)^{1/n}]$$

where K_0 and T_0 are constants and $n = 4, 3$, and 2 for 3-D, 2-D, and 1-D conduction, respectively. According to this theory, resistance (R) of a conducting polymer-based material can be analyzed from the plot of ln ($RT^{-1/2}$) vs $T^{-1/n}$. The value of "n" can be obtained from the fitting of the plot which indicates the dimensionality of the conduction. The Mott temperature parameter T_0 is directly proportional to the density of states at Fermi level and is inversely proportional to the localization length.

Carrying out the temperature-dependent conductivity measurements and analyzing the results with appropriate fitting with the MVRH model, it was found that for PPy and PAn tubules with a 400 nm diameter, 3-D electronic conduction is taking place (considering $T^{-1/4}$ dependence) [254]. Also for the bulk polymers synthesized under conventional chemical synthesis, the same conduction mechanism is prevailing. However, for the tubules with a 50 nm diameter, the conduction is predominantly 2-D because of the $T^{-1/3}$ dependence of the model equation [255]. Similar dimesnsionality of conduction was observed for the amorphous semiconductors also. For the semiconductors, the authors have suggested that when the film thickness becomes larger relative to the hopping distance, 3-D conduction takes place while film thickness being relatively smaller than the hopping distance, the conduction is constrained to two dimensions. An analogous argument is applied for the nanostructures. It can be recalled that nanotubules consist of a highly ordered, thinner outer layer (~5 nm) surrounding a relatively disordered core. For smaller diameter tubules, owing to the lager proportion of the ordered material, conduction is constrained to the layer and 2-D conduction is occurring; conversely, for larger diameter tubules, the conduction in a disordered phase predominates and the 3-D conduction takes place.

Intercalative nanocomposites in which PAn and PPy are confined within different 2-D and 3-D hosts like FeOCl, V$_2$O$_5$, MoO$_3$, etc. were widely investigated, with respect to their electrical transport properties using variable temperature electrical conductivity and thermoelectric power (TEP)

as probes. It can be recalled that these nanocomposites are two types: one containing FeOCl, V_2O_5, and α-RuCl$_3$ hosts that are synthesized by the RIP method and others that are synthesized by the PIP method using nonoxidizing hosts like MoO_3, MoS_2, ZrP, zeolites, etc. Normally, the electrical conductivity of the hybrid materials is poor and very often are completely insulating ($>10^{-7}$ S/cm) which can account for the lack of interpolymer contact in the composite or complete encapsulation of the polymer within the layers of the host. On the other hand, conductivity of the polymers extracted from the composite is generally lower than those synthesized by conventional technique; a smaller chain length of the polymers synthesized under confinement is the reason for that. All these hybrid materials are highly anisotropic which confirms their specific orientation. Conductivity measurements were done on PPy-FeOCl (which itself has relatively high conductivity, 10^{-1} S/cm) [151], α- and β- PAn-FeOCl (10^{-2}–10^{-3} S/cm), and PTh-FeOCl, all of which have shown thermally activated-type conductivity suggesting the materials to be semiconductors [151, 153–156]. However, all these materials possess grain boundary and, therefore, TEP is a more reliable probe to decide the nature of conduction. PPy-FeOCl and PTh-FeOCl along with bulk PPy and PAn (ES) show p-type metallic conduction. For PPy-FeOCl, the TEP is positive at 260 °C and falls steadily at lower temperatures and ultimately becomes negative below 340 K, indicating valence band to conduction-band carrier excitation within FeOCl framework becoming increasingly important. But TEP measurement on an α-(I) form of PAn-FeOCl both in single crystal and pressed pellet form shows p-type semiconducting nature with TEP ~ 7 μV/K at room temperature, increasing steadily with lowering temperatures reaching a value 100 μV/K at 140 K [153–155]. Therefore, in α-(I) PAn-FeOCl, the reduced FeOCl framework, rather than the PAn component, dominates the charge transport properties of the system. Short-chain PAn molecules in the interlayer space give rise to too many carrier-hopping barriers and lead the charge transport possibly through the FeOCl layers which accounts for this result. Thermoelectric power of β-PAn-FeOCl is dramatically changed and a change in the conduction mechanism from p-type to n-type is observed which is similar to bulk PAn. Therefore, the β-phase is considered a mixture of PAn and β-FeCOOH which is mainly owing to the higher chain length of PAn in β-phase.

Temperature-dependent (5–300 K) conductivity measurement on polyaniline-V_2O_5, H_2O suggests thermally activated behavior. A representative curve showing the variation of electrical conductivity (four probe) as a function of temperature is shown in Figure 12. Thermoelectric power data at the same temperature range is small and negative (~ -30 μV/K), which approaches 0 with an increasing temperature indicating (Fig. 13) the presence of a metallic density of states similar to PAn itself. PAn-V_2O_5 hybrid material is a combined system with two low-dimensional electrical conductors presenting two types of carriers—the small polarons (V^{4+}) and the large polarons (on PAn backbone). Films of PAn-V_2O_5 possess 100–1000 times higher conductivity than the pressed pellets [157–159]. On temperature-dependent conductivity measurement all samples show semiconducting nature and thermally activated
Figure 12. Four probe variable temperature electrical conductivity data of (A) (PAn)$_{0.48}$V$_2$O$_5$, nH$_2$O (film), and (B) (PAn)$_{0.48}$V$_2$O$_5$, nH$_2$O (pressed pellet) [n varies from 0.5 to 1.3]. Reproduced with permission from [159], C. G. Wu et al., *Chem. Mater.* 8, 1992 (1996). © 1996, American Chemical Society.

property. Thermoelectric power, is large and negative and very weak temperature dependence is shown. The freshly prepared samples reveal n-type semiconducting property similar to the reduced xerogel itself and a relatively weaker effect of PAn is observed which is strongly dependent on the extent of protonation, molecular weight, and the aging of polymer.

Composites of α-RuCl$_3$ with both PPy and PAn are highly conductive (23 S/cm and 1 S/cm, respectively) as compared to the host (α-RuCl$_3$ = 5×10^{-4} and its Li salt is 0.3 S/cm) [166, 167]. Therefore, electrical transport in these composites takes place through the ICP component, although some contribution from the [RuCl$_3$]$^{x-}$ may also occur. Variable temperature-conductivity measurements have shown a thermally activated-type transition, normal for the materials with

Figure 13. Variable temperature TEP data of (A) (PAn)$_{0.44}$V$_2$O$_5$, 1.3H$_2$O (film), and (B) (PAn)$_{0.44}$V$_2$O$_5$, 0.33 H$_2$O (pressed pellet). Reproduced with permission from [159], C. G. Wu et al., *Chem. Mater.* 8, 1992 (1996). © 1996, American Chemical Society.

a grain boundary. The activation energy is 0.3 eV and 0.35 eV for PAn and PPy samples. At a higher temperature (>100 K), the log (σ) versus $1/T$ curves fit to a straight line indicating the evidence of thermal activation, while at lower temperatures the deviation from a straight line indicated a more complicated transport process. Thermoelectric power is positive and increases steadily at a higher temperature indicating a metal-like transition in these materials; however, overall p-type behavior is observed, which is consistent with the behavior of the components. Thermally activated transport is commonly observed for Mo-compounds (MoS_2 and MoO_3) also containing nanocomposites. For MoS_2-PPy and MoS_2-PAn [195, 196], very similar behavior—p-type metallic nature—although the relatively large value of Seebeck coefficient (S) suggests a deviation from ideal metallic behavior. For MoO_3-based composites containing PAn and PPV [197–200], the activated transition is observed with activation energy 0.2 eV. There are a few other relevant studies on some other nanocomposites; however, considering the poor room temperature conductivity of the materials the lower temperature measurements do not seem to be convincing.

The mechanism of electrical transport has rarely been studied in nanoparticle-incorporated nanocomposites. Earlier on, there were a few reports on PPy-carbon black composites, which showed a deviation from existing models like MVRH or thermal fluctuation-induced tunneling of carriers (TFTC) [76, 77]. In another work, Gangopadhyay et al. [256] have studied variable temperature ac and dc conductivity and TEP measurements on PPy-Fe_2O_3 nanocomposites. Results have shown that dc conductivity fits the MVRH model satisfactorily, while ac conductivity TEP data shows complex behavior. At a lower temperature ($\leq$225 K), TEP varied linearly showing metal-like behavior while it deviates from linearity at a higher temperature. The results suggested that a single model is quite inadequate for explaining the overall behavior of the system; a heterogeneous model with a highly conducting island, connected by poorly conducting barriers, was suggested.

7. NANODEVICES

It has now been well established that conducting polymers, owing to their considerable technological potential, have occupied a very important position in the arena of materials science. Versatile applications of these polymers encompass electronics, sensors, actuators, optical bioanalytical devices, displays, etc. On the other hand, miniaturization of the optical, mechanical, and electronic devices has fueled the present revolution in information and biotechnology. This is because such microstructured devices are suitable for application in areas where an extremely small quantity is handled, and especially where many small simultaneous experiments are required. Therefore, it is very obvious that nanomaterials obtained from conducting polymers will possess rather enhanced application potential as compared to the bulk counterpart. As described earlier, these nanomaterials are synthesized in two general synthesis techniques—template-guided synthesis and self-assembly. Template-guided synthesis is easier although the self-assembly technique is more favored because it is free from the inconvenience of removing the template. Numerous applications of such

nanomaterials are possible, few examples of which will be discussed here. It should be mentioned here that very often nanodevices based on conducting polymers do not utilize the nanostructured forms of polymers described so far; rather the chemical/electrochemical deposit of the polymer, sometimes patterned suitably, are used as the active part of the devices. Few of these devices will also be mentioned here.

It has already been discussed that nanomaterials, obtained from conducting polymers, are generally of three types: nanoparticles, nanotubules/nanowires, and nanolayers. Immediately after the synthesis of the nanotubules, they were subjected to an excellent application as a bioanalytical device. The PPy nanotubules (within the membrane) were loaded with an enzyme (GOD) by simple immersion and one side of the membrane was coated by silver. This assembly was subjected to the successful measurement of glucose in the concentration range 1–25 mmol dm^{-3} [257]. In a modified version of this work, Parthasarathy and Martin have synthesized capped PPy nanotubules and have performed different bioanalyses after loading the nanotubules with enzymes like glucose oxidase, catalase, subtilisin, trypsin, and alcohol dehydrogenase by vacuum filtration [258]. This assembly works almost as an enzymatic bioreactor in both aqueous and nonaqueous medium as described by Figure 14. In a relatively recent publication, Sukeerthi and Contractor have demonstrated [259] the fabrication of biosensor arrays based on PAn microtubules grown within a microporous polycarbonate membrane. In this single device, three different enzymes were immobilized

Figure 14. Schematic diagram of methods used for synthesis and enzyme loading of microcapsule arrays: (a) Au-coated template membrane, (b) electropolymerization of pyrrole, (c) immersion into Fe^{3+} and pyrrole solution for formation of PPy tubules, (d) enzyme loading, (e) epoxy capping, and (f) dissolution of the template. so that in a single measurement, the array can recognize glucose, urea, and triglyceride from a mixture. In a different approach, a thin PAn film, electrochemically deposited on a nanometer-sized carbon fiber electrode, has been designed to form an ultra-micro pH sensor [260]. In another report, PPy containing hydrogel microelectrodes were proved to be interesting materials for neural communications [261].

There are different useful methods for the fabrication of conducting polymer junctions or nanoscale fibers/devices suitable for application in nanoelectronics, namely, electrospinning (electrostatic fabrication), etc. [262]. On the other hand, line-patterning is a method suitable for fabricating patterns from conducting polymers. The particular conducting polymers may either be electrodeposited or solution-casted on the specific regions. A very intelligent nonphotolithographic technique for the formation of patterned microstructures from conducting polymers (PAn) on a Si/SiO$_2$ wafer has been described by Beh et al. [263] and Krawice et al. [264]. The width of the smallest structure of PAn fabricated using this procedure was ∼350 nm. The schematic presentation of such a patterning technique and the different patterns fabricated are already shown in Figure 11. All these fibers, lines, patterns, etc. can play excellent electrodes for high quality optical displays and transistors. Earlier, Granstrom et al. have demonstrated the formation of micrometer- (10 μm) and nanometer-sized (100 μm) structures from a polythiophene derivative and their function as LED [265]. In a recent work, a movable electrochromic "pixel" was constructed from a microfabricated PPy deposited on an Au electrode. Depending upon the applied potential and thickness, the color of the PPy layer was changed from red to yellow. This particular device can have potential application in studying living cells or a single-cell organism [266]. Therefore, it is obvious that both electrical conductivity and potential, dependent light-emitting and color change properties of conducting polymers are exploited in the fabrication of such nanodevices. In a separate publication, Zhang et al. have reported the fabrication of nanowires and nanodots from PEDOT-PSS on a glass plate or silicon wafer. The fabrication was done by a soft lithographic method (MIMIC) and the nanowires (833 nm or 278 nm in width) are important for using in optoelectronic devices, where light propagation and electronic paths are defined by patterning [267].

Redox activity of conducting polymers and the relevant volume change has been successfully explored in the fabrication of miniaturized actuator devices from conducting polymers. Smela et al. have reported a series of works on the construction of microrobotic arms and microactuators for uplifting, gripping, and positioning of micrometer-sized objects. The conducting polymer (PPy-DBS$^-$) nanolayer (but not the monolayer) deposited on gold is the active material in such works. Through the series, the polymer is deposited and patterned following a standard micromachining technique. The PPy-Au bilayer actuator has a dimension of 30 μm to 100 μm, and it can execute very sharp but controlled folding of microsized plates by redox-induced, reversible oxidation and bending. This system is an excellent manipulation of a folding arm suitable for working with micrometer-sized objects [268]. Later on, this work was further modified and a complete arm including functions of
Figure 15. The system used for *in-situ* electrochemically induced stress measurements on the cantilever. Reversible electrochemical redox reaction of PAn and resulting lever deflection is shown in inset. Reproduced with permission from [272], M. Lahav et al., *Angew. Chem. Int. Ed.* 40, 4095 (2001). © 2001, Wiley-VCH.

elbow, wrist, and hand with fingers was constructed by a suitable modification of the earlier system [269–271]. This system works in micrometer dimension and can move with micrometer-sized objects within an area of about 250 μm × 100 μm, making the microrobot an excellent tool for single cell manipulation. The handling, transport, separation, and detection of cells and biomolecules, which should be essentially done in a very small volume of liquids, should be easier by these actuators. These microactuators, also termed as micromuscles, could be further modified so that they can be used to move plate, open and close boxes, and close microvials under complete control.

Very recently, the designing of an electrodriven cantilever has been reported [272] by the electrochemical deposition of PAn on one side as shown in Figure 15. On oxidation of the polymer, the micromachine is subjected to a stress generated by the electrostatic repulsion and the corresponding swelling of the polymer layer. As a result, the cantilever undergoes deflection and on reduction of the polymer the stress is released and the cantilever is retracted to the original position. This way, the micrometer-sized cantilever (length 160 μm, thickness 0.6 μm) can generate a stress of ∼2–∼4 Nm^{-1}. These examples can establish that conducting polymers in their nanoscopic forms are extremely intelligent candidates for versatile applications.

8. CONCLUSIONS

Keeping pace with the ongoing trend of miniaturization, a group of conducting polymer-based nanomaterials has also been launched—synthesis, characteristics, and a few

applications of which are described in this article. However, parallel with their application potential, ICP-based nanomaterials have raised excellent scientific interest favoring the true understanding of fundamental properties of themselves. At the same time, synthesis of these nanomaterials and successful designing of the nanodevices indicate the successful steps toward overcoming intractability of conducting polymers.

It is interesting to note that the attempt to obtain conducting polymers in different nanodimensional forms (nanoparticles, nanotubules, nanolayers) was started more or less at the same period by different research groups. Attempts to synthesize each of these materials were commenced with the template-guided polymerization route, which at a later stage, was replaced by more efficient, template-free routes. However, the template-free methods very often give rise to materials poorer in quality. Considering the scientific and technological aspects, the versatility of synthesis techniques and application aspects, the present status of research and development on these different branch nanomaterials is almost at the same stage. The conduction mechanism in these hybrid materials and/or nanostructured materials has not been properly explored until now.

The interesting point to observe is that the research on conducting polymer nanostructures was primarily centered on optimization of the synthesis techniques; the application aspect of the synthesized materials was explored later on. Therefore, the application potential of a large fraction of the earlier work on nanocomposites and nanotubules, etc. was not properly explored. But the recent trend in this respect is to synthesize the nanomaterial according to its specific use. This difference in the trend of work is very obvious from the present discussion on the ICP nanodevices. Recently, there has been wealth of research and development on the synthesis and application of such nanomaterials, and new polymers with novel application potential are also being introduced day by day [273, 274]. Nanostructures formed from inherently conducting polymers have recently been reviewed by Wallace and Innis [275]. It seems that conducting polymer nanomaterials are no longer difficult to get in hand: proper utilization of them should bring revolution to the world of lightweight, miniaturized devices.

GLOSSARY

Actuator   A device that performs through conversion of electrical energy into mechanical energy.

Ammonium peroxodisulphate (APS) $(NH_4)_2S_2O_8$, efficient oxidant for aniline polymerization.

Biosensor   An analytical device that detects biomolecules in the system or biologically produced signals.

Brunauer–Emmet–Teller (BET)   equation meant for multilayer adsorption of gases on solid surface. Total surface area of a granular solid can be derived from this equation.

Colloid   A stable dispersion of nanodimensional particles in a solvent. The dispersion can pass through ordinary filter paper.

Inherently conducting polymers (ICP)   Polymers with conjugated double-bonded backbone that can show significant electronic conductivity after doping with suitable dopants. ICPs are generally semiconductors (p-type) having versatile novel properties and important applications.

Microelectronics   Branch of electronics that deals with electronic junctions and devices smaller than 50 μm.

Nanocomposite   A composite that combines at least one nanodimensional component with a polymer or other material.

Nanoparticle   A particle with diameter $\leq$100 nm.

Nanotube/nanowire/nanorod   A tube/wire/rod having diameter $\leq$100 nm.

Percolation threshold   In an insulator-conductor, bi-component system, a critical fraction of conducting component is reached above which macroscopic conductivity of the system shows an inflexion. This particular limit is termed as percolation threshold.

Scanning electron microscopy (SEM)   that reveals the surface morphology of a solid by analyzing the electron beam reflected from the surface.

Steric stabilization   Prevention of macroscopic percipitation of a growing polymeric solid by using a soluble polymeric support. The precipitated polymer is supposed to be covered by the shell of the soluble polymer.

CONTENTS

1. INTRODUCTION

Because new structures and properties are obtained when dimensions are reduced to nanometric sizes, considerable effort is being devoted to produce nanomaterials and to exploit their special properties. Materials with nanoscopic dimensions not only have potential technological applications in various areas but also are of fundamental interest in that the properties of a material can change in this transition from bulk to molecular scale.

Polymeric systems are a field of increasing scientific and technical interest, offering the opportunity to obtain a broad variety of promising new materials, with a wide range of properties and potential applications. The properties of these polymers are strongly dependent on their microstructure and morphology, which are mainly determined by their synthesis conditions [1–23]. The most important consideration from a chemical viewpoint is that tailored properties are obtained when polymers are prepared with enhanced molecular and supermolecular order and, consequently, contain fewer conjugation-interrupting defects, such as sp^3-hybrid carbons or twists and kinks in the polymer chain [4–56].

Among the different strategies to synthesize ordered materials reported in the literature, template synthesis is a very promising and powerful tool [7]. This technique consists of including inorganic or organic constituents (guests) inside the void spaces of host materials. These void spaces act as a template, determining the shape, size, and in many cases the orientation of the compound produced. A composite is obtained when the host matrix maintains its integrity. Details and the most recent advances of this technology applied to obtain conducting polymers on the nanoscale are described in this chapter.

2. CONDUCTING POLYMERS

2.1. History and Applications

Since the first studies on the chemistry and production of synthetic polymers were related to saturated macromolecules, which are excellent electrical insulators, the technological applications of these materials with respect to their electrical properties are often directed to exploit their capacity as insulators. However, electronically conducting polymers possess different properties related to their redox behavior. In these materials, unsaturated chemical bonds contain unpaired electrons, which can be delocalized along the polymer chain. This characteristic provides interesting electronic properties, which can be exploited in several applications. In 2000 the world scientific community recognized the importance and the potential applications of

this class of materials when Shirakawa, Heeger, and Mac-Diarmid (prominent scientists in conducting polymer studies) were awarded the Nobel Prize in Chemistry for their research in this field [8].

Although conducting polymers are considered to be new materials within the most recent generation of polymeric materials [9], the first work describing the synthesis of what is now recognized as a conducting polymer was published in 1862 [10]. "Aniline black" was prepared from the anodic oxidation of aniline and, although its electronic properties were not established, a color change observed upon switching potential (later defined as electrochromism) was also reported [11]. Despite these initial works, the discovery of conducting polymers as materials which present reasonable electrical conductivity is attributed to Shirakawa et al. [12], who exposed freestanding films of polyacetylene to vapors of chlorine, bromine, iodine, arsenic pentafluoride, or sodium, obtaining an increase of 12 orders of magnitude in the electrical conductivity at room temperature. This amazing discovery was based on several studies initiated by Natta et al. [13] and Hatano et al. [14]. Natta's group described the synthesis of polyacetylene (PA) and Hatano et al. obtained the first results on the electrical conductivity of PA. Nowadays, the field of conducting polymerns is well established, and researchers are striving to arrive at materials with optimized properties so that all possible commercial applications can be fully exploited.

Conducting polymers are interesting materials because they present the electrical, electronic, magnetic, and optical properties inherent to metals or semiconductors, while retaining mechanical properties close to those observed for conventional polymers. These properties open new possibilities for technological applications. For example, the color change induced by the electrochemical doping–undoping enables the use of these materials in the manufacture of multichromic displays or electrochromic windows [15]. Taking the hole-injecting properties of these polymers under an applied potential or current, flexible light emitting diodes (LED) [16, 17] and light emitting photoelectrochemical cells have been developed [18, 19]. The photovoltaic effect observed in a conducting polymer|electrolyte interface, by irradiating it with energy higher than the polymer bandgap, has been a focus of attention due to the possibility of producing photoelectrochemical cells [20–23]. Other properties also suggest the use of conducting polymers as active components in batteries and capacitors [24–26], biosensors [27, 28], drug-releasing agents [29], gas separation membranes [30], electromagnetic radiation shielding [31], and conductive textiles [32].

Such unique properties are different from those that originate from a physical mixture of insulating polymers with conducting fillers. In intrinsic conducting polymers, the conductivity is related to the delocalization of π-bonded electrons over the polymeric backbone, coexisting with unusual electronic properties, such as low energy optical transitions, low ionization potentials, and high electron affinities [33]. This phenomenon is a consequence of the presence of the conjugated C=C double bonds in the polymer backbone,

as seen in the molecular structures of the repeating units of some conducting polymers (Fig. 1) [34].

2.2. Electrical Conductivity: Electron Delocalization, Oxidation, and Doping Processes

After the Nobel laureates' pioneering work on highly conductive polyacetylene [12], much effort has been devoted toward finding a satisfactory explanation for this phenomenon. Electronic conduction in conjugated C=C double bonds is achieved with electron delocalization, which only occurs if charge carriers have the mobility to carry the charge throughout the chains. Shirakawa et al. [12] showed that the electronic conductivity of polyacetylene changes dramatically when cations or anions are incorporated into the polymer. In analogy to inorganic semiconductors, where an external agent is also incorporated into the matrix to promote conductivity, the species that increased the electronic conductivity of conducting polymers were designated "dopants." Thus, by "doping" a semiconductor organic polymer, the conductivity changes from 10^{-15}–10^{-10} S cm^{-1} to values arriving at 10^4 S cm^{-1}. The doping process distinguishes conducting polymers from all other kinds of polymers. The controlled addition of known, small ($<10\%$) nonstoichiometric amounts of chemical species results in dramatic changes in the electronic, electrical, magnetic, optical, and structural properties of the polymer. The initial studies involving doping are now defined as chemical doping
Figure 1. Structure of the π-conjugated conducting polymers.

by charge transfer [9], and an example is the treatment of *trans*-polyacetylene with an oxidizing agent to produce the *p*-doped parent polymer [35].

The phenomenon of electronic conduction in polymers was based on early theories on the same phenomenon seen in studies of inorganic semiconductors, the band model. Basically, the electrical properties were related to the width of the energy gap (E_g) between the valence band and the conduction band. Based on these concepts, Su et al. [36] proposed a unidimensional model based on the existence of structural defects in the polymer backbone originating during polymerization, with the formation of radicals in the undoped state. This delocalized defect can move as a solitary wave in *trans*-polyacetylene and is called a neutral "soliton" in field theory and, by oxidation or reduction, it is possible to remove or add electrons, giving rise to positively or negatively charged solitons (Fig. 2). These species can move along the PA backbone carrying charge but no spin (spinless). If an electron is added to the cation or taken away from the anion, a neutral radical soliton is again established.

In a mechanism involving solitons, electron conduction involves only fully occupied bands in the ground state and leads to the formation of a half-occupied electronic level (one electron) within the gap. This model was initially challenged [37] as it did not explain the fact that the conductivity of PA, poly(*p*-phenylene), poly(*p*-phenylene vinylene), poly(*p*-phenylene sulfide), and polypyrrol (PPy) could be associated with charge carriers having zero spin (spinless) and not to unpaired electrons [38]. Furthermore, polyheterocyclic conducting polymers do not possess degenerate ground states, making conduction by solitons improbable in these materials.

The initial species formed by ionizing polyheterocycles is a radical ion that has both spin and charge, called a "polaron" [39–42]. A polaron is a positively charged hole site (radical cation) or a negatively charged electron site (radical anion), plus a lattice relaxation (distortion) around the charge producing electronic levels within the gap. Theoretical models demonstrate that two radical ions (polarons) react exothermically to produce a dication or a dianion (bipolaron). The former is thermodynamically more stable than two polarons, due to electronic repulsion exhibited by two charges confined in the same site, and causes strong lattice distortions.

Briefly, there are two models concerning the conductivity of conducting polymers. The first has a degenerate ground state and solitons as the most important phenomenon. The second model, used for polyheterocyles, has polarons and bipolarons as the charge carriers and the dominant charge-storage configurations.
Solitons and polarons–bipolarons explain the electronic motion along the same segments of a polymer chain, but Mateeva [43] proposed that charge transport also occurs by interchain hopping of charges, as seen in Figure 3. In this model, three elements contribute to the overall conducitvity: (A) single chain or intramolecular transport, (B) interchain transport, and (C) interparticle contact. These elements comprise a complicated resistive network, which determines the effective mobility of the carriers.

Thus, the mobility and the conductivity are determined on both microscopic (intra- and interchain) and macroscopic (interparticle) levels [44]. Experimental determinations of mobility of the charge carriers in PA films confirmed that interchain and interparticle transports are the limiting factors for conduction [45]. It can be seen that, although a particular molecular structure theory might predict a lower conductivity based on single-chain conjugation, the conductivity observed could occur due to morphologically controlled interparticle effects. Briefly, interchain interactions are the most important fact that contributes to the occurrence of charge transport in polymer films [46, 47].

As stated before, electron delocalization along the polymer chain requires the partial oxidation or reduction of the chain by introducing an external agent called a dopant. In the first work concerning electronic conductivity in polyacetylene, the polymer was submitted to oxidizing and reducing agents, as shown in the scheme

$$(\mathrm{CH})_n + ny\mathrm{X} \longrightarrow [(\mathrm{CH})^{+y}\mathrm{X}_{y-}]_n$$
$$(\mathrm{CH})_n + ny\mathrm{M} \longrightarrow [(\mathrm{CH})^{-y}\mathrm{M}_{y+}]_n$$
This process was called "chemical doping." Although this method produces highly conductive materials, one of the most interesting properties of conducting polymers is the possibility of modulating the electrical (and other) properties
Figure 3. Several mechanisms of charge transport in a conducting polymer: (A) single chain or intramolecular transport, (B) interchain transport, and (C) interparticle contact.

Figure 2. Schematic representation of solitons in *trans*-polyacetylene.

by controlling the doping process and the concentration of the dopant. Unfortunately, chemical doping generally leads to completely doped polymers.

To solve this problem, "electrochemical doping" is an alternative to be considered. In this method, the doping level is precisely controlled by an external potential applied though an electrode. It supplies the charge necessary to oxidize or reduce the polymer film conveniently deposited on a conductive substrate [9]. The first work concerning this concept was published by the same group who introduced the chemical doping as a way to achieve high conductivity in polymers [48]. In electrochemical doping processes, the charge generated in the polymer chain is compensated by ionic diffusion from the electrolyte to the polymer film and these ions play the role of dopants. Figure 4 shows both p- and n-electrochemical doping processes in a poly(3-methylthiophene) film.

In certain cases (e.g., in polyanilines), the doping processes can take place with no redox reactions. The degree of oxidation of polyaniline (PAni) and its derivatives can range from a fully reduced form to a completely oxidized one [49]. Figure 5 shows the oxidation degree of the polyanilines: leucoemeraldine (fully reduced), emeraldine (partially oxidized), and pernigraline (fully oxidized). In this case, all oxidation states are in the so-called "base form" and, although the oxidation degree was altered, the electronic conduction does not reach reasonable values.

The emeraldine base form reacts with dilute acids (e.g., HCl) to give rise to the corresponding salts, with protonation occurring mainly at the imine nitrogen atoms. This reaction is accompanied by an increase of approximately 9–10 orders of magnitude in conductivity of the polymer, reaching 5 S cm^{-1}. Thus, instead of redox reactions, electronic conductivity in polyanilines occurs only for the emeraldine form and is dependent on the protonation degree. This is interpreted on the basis of a p-type doping process and, in contrast to other polymers, does not induce changes in the number of electrons associated with the polymer chain. According to MacDiarmid and Espstein [49], the high conductivity of PAni emeraldine salt is mainly related to a highly symmetrical π-delocalized structure.

"Photodoping" in conducting polymers is achieved when the material is exposed to radiation with energy greater than its bandgap. This kind of doping does not involves dopant insertion into the backbone and the doped material quickly returns to the parent-undoped polymer if the incident radiation is discontinued [35]. The polymer chain is simultaneously oxidized and reduced, producing free electrons and holes. Recombination of the charge carriers can occur as
Figure 5. Polyaniline in different states of oxidation, ranging from leucoemeraldine to pernigraniline.

either radiative or nonradiative decay. When one of the photogenerated charge carriers (electron or hole) is collected by other species, the photodoping method finds application in several devices to convert light into electricity, such as photovoltaic devices and photoelectrochemical cells.

The basic processes to achieve efficient solar energy conversion in photoelectrochemical cells are well understood [50] and charge carriers generated in the photodoping processes can be conveniently converted into electricity if the electrolyte contains redox species to collect and transport the charge. The photodoping phenomenon in conducting polymers and the energy position of the bands govern the nature of the redox species to be used. Solution species are reduced at the surface of an irradiated p-doped polymer, while oxidation occurs at an irradiated n-doped polymer [51, 52]. Redox species are not incorporated into the polymer because the photodoping phenomenon is not accompanied by dopant insertion. Figure 6 shows an example of the charge generated (and collected by the external circuit) by photodoping of poly(4,4′-dipentoxy-2,2′-bithiophene) [53]. In this experiment, oxygen dissolved in the electrolytic medium plays the role of the redox species. Furthermore, if a potential is applied during irradiation, electrons and holes separate and photoconductivity is observed [35].

The doping process can occur by charge injection at the metal–semiconductor interface. In the case of the photodoping method, electron–hole pairs exist only while light is shining on the polymer. For charge injection at a metal|semiconductor interface, electron–hole pairs are separated while a bias voltage is applied across the heterojunction. By this method, the conducting polymer can be used as active material in field effect transistors and LEDs.

Doping processes in conducting polymers lead to a new material, with little or no degradation of the polymer chain, and reversibility of this phenomenon is one of the most important features of these materials. This ability to be cycled between charged and neutral states forms

Figure 4. Electrochemical (a) p- and (b) n-doping processes observed for poly(3-methylthiophene) in an electrolyte containing LiClO$_4$.
Figure 6. Photoresponse of a poly(4,4′-dipentoxy-2,2′-bithiophene) film submitted to −0.3 V (vs. Ag\AgCl) and polychromatic irradiation of 100 mW cm^{-2} using a 0.1 mol L^{-1} (C$_4$H$_9$)$_4$NClO$_4$ solution in CH$_3$CN as electrolyte.

the basis of the applications of conducting polymers in secondary (rechargeable) batteries and electrochromic displays. Indeed, the large spectrum of applications of conductive polymers using the variation of their properties upon "doping" has attracted the attention of many researchers. Recently, Heeger [9] associated the method used to dope conducting polymers with possible technological applications for these materials, as can be seen in Table 1.

2.3. Synthesis

Since the first reports on the conductivity in polymers, many alternatives have been proposed to produce these materials. Although polyacetylene was the first conducting polymer to be studied in detail, other polymers also have been extensively investigated because of the low environmental stability of polyacetylene. Thus, polyheterocycle polymers, such as polypyrrole, polyaniline, polythiophene, and their substituted derivatives, are nowadays materials in the spotlight. Indeed, much of the work relating the encapsulation of conducting polymers in hosts (which is the scope of this chapter) is devoted to composites based on these three families of polymers. Thus, we have limited this discussion only to the most used methods to prepare these conducting polymers.

Table 1. Doping mechanisms in conducting polymers and the related applications [9].

Doping mechanism	Applications
Chemical doping	transparent electrodes, antistatics
	EMI shielding
Photodoping	photoinduced electron transfer
	photovoltaic devices
	tunable NLO properties
Electrochemical doping	electrochemical batteries and capacitors
	electrochromic devices
	light-emitting electrochemical cells
Interfacial doping	FET
	tunneling injection in LED

There are two ways to synthesize conducting polymers: the "classical chemical synthesis" and the "electrochemical method." The polymerization process occurs by oxidation of the monomer and, for the chemical methods, an oxidizing agent is used. In electrochemical synthesis, an external potential or current is used to oxidize the monomer. When choosing one methodology instead of the other, one must take into account the final properties of the resulting products as well as the applications where the material will be used. For example, *in-situ* electrochemical polymerization is usually preferred in technological applications where a modified electrode is required. Otherwise, chemical synthesis of conducting polymers usually leads to larger quantities of material. As will be seen, a new approach to chemical synthesis also enables the preparation of regioregular polymers. Chemical synthesis of soluble polymers also permits the deposition of films by spin-coating, spraying, or casting.

Chemical methods consist of the direct oxidation of the monomer with an appropriate chemical oxidant. Anilines and pyrroles require a lower potential to be oxidized when compared to thiophenes. Pyrrole is one of the most easily oxidized monomers and there is a great variety of oxidizing agents that can be used in the polymer synthesis, such as the salts of Fe(III) and Cu(II). Polypyrrole powder with a conductivity of 200 S cm^{-1} has been prepared by oxidizing the monomer with FeCl$_3$ [54].

Polythiophenes can also be obtained by direct oxidation of the monomer by an oxidizing agent, such as Fe(III) or other transition metals. However, it is difficult to control the final properties of the first in direct oxidation of thiophenes, and other reactants have been explored for use in the preparation of polythiophenes by chemical polymerization. Organometallic coupling reactions have been used with success to produce polythiophenes, based on Ni or Pd catalyzed reactions. For example, in Ni-catalyzed reactions, dibromothiophenes react with Mg to produce the corresponding Grignard reagent, and the polymerization occurs by polycondensation catalyzed by Ni(bipyridine)$_2^{2+}$ [55]. For polythiophenes, regioregular structures have been obtained by chemical methods. Hoffmann et al. [56] synthesized a series of poly(3,3′-dialkyl-2,2′-bithiophenes) by chemical oxidation of regioregular alkylated thiophenes and verified that the length of the alkyl chain could be related to the solubility and the electrical conductivity of the product.

Chemical methods are also largely used to produce polyanilines by oxidizing the monomer with a great variety of agents, such as ammonium persulfate, manganese oxide, chromium oxide, and hydrogen peroxide. Unlike pyrroles and thiophenes, the oxidation of anilines is usually done in aqueous acid media [57]. The acid medium is necessary because, as mentioned, polyanilines are doped by nonredox processes and electrical conductivity only occurs if the polymer is protonated. The monomer/oxidant ratio has a strong influence on the electrical conductivity of the former and on the polymerization yield [58]. According to Geniès et al. [59], polymer degradation takes place if a high concentration of oxidant is used. The emeraldine salt obtained by chemical synthesis of polyaniline in a HCl medium presents electrical conductivity of 5 S cm^{-1} and treatment with a weak base, typically NH$_4$OH, leads to the emeraldine base with a conductivity of ca. 10^{-9} S cm^{-1}.

Electrochemical synthesis is convenient to produce polymer films deposited on electrodes. The electrochemical synthesis of a given conducting polymer can be achieved by galvanostatic or potentiostatic methods in three-electrode/one-compartment electrochemical cells. The synthesis solution, generally nonaqueous, contains the monomer and a supporting electrolyte. The latter provides the conductive medium and the dopant anions. An important feature of the oxidative electropolymerization reaction is that it proceeds with electrochemical stoichiometry, with values generally in the range of 2.1–2.6 F mol^{-1}, depending on the type of polymer and the electrosynthesis conditions. Polymer formation requires two electrons per monomer and the excess charge corresponds to p-doping of the polymer. By controlling the charge in the cell it is possible to monitor the thickness of the polymer film. Moreover, by changing the nature of the dopant ion (electrolyte salt) or the value of the electrodeposition current density or voltage the physicochemical properties and the morphology of the final polymer can also be controlled [60]. Electropolymerization is the preferential method for preparing conducting polymers because the resulting products are "clean" and generally do not require extraction from the initial monomer/oxidant/solvent mixtures. Besides, electrochemical synthesis offers the additional advantage of homogeneous incorporation of the dopant counterions into the polymer films.

PPy can be obtained by electrochemical synthesis on Pt substrates, producing a strongly adherent, durable film with good electronic and conductivity properties [61]. PAni can be easily prepared by electrodeposition of the film from highly acidic (e.g., H_2SO_4 or $HClO_4$) aqueous solutions, since its electroactivity is promoted by protons [62]. Depending on different solvent/acid media the films of PAni display significant variations in structure and properties [59]. Thiophene, benzene, phenol, and other aromatic hydrocarbons have also been electrochemically polymerized [63]. The use of functionalized acids as dopants in PAni and its derivatives has contributed to increase solubility, promoting a better compatibility between polymer and solvent [58].

Although chemical and electrochemical syntheses require different conditions for the production of high quality polymers, the mechanism accepted for polymerization is basically the same for both methods. Figure 7 shows a typical mechanism for the polymerization of pyrroles and thiophenes. The initial step in the process is monomer oxidation to form a radical cation. For polypyrroles and polythiophenes, ideal chain growth is obtained by 2,5-coupling of the pyrrolic or thiophenic rings (Fig. 7). In this case, the linear product has the highest conjugation in the chain and all properties are optimized. Although the 2,5-coupling is preferential, it is also possible that the reactions proceed at positions 3 and 4 of the rings. This alternative path can lead to branched polymers with undesirable properties. Basically, attaching substituent groups to the 3- and/or 4-positions minimizes the occurrence of α,β coupling during the polymer synthesis, resulting in more regular structures with enhanced properties [64]. Fewer α,β linkage defects in the final structures lead to more effective conjugation, which is an essential feature for more conductive final products. Furthermore, other effects derived specifically from the
Figure 7. Mechanism for the formation of polypyrroles and polythiophenes.

substituent group also contribute to increase the electrical conductivity.

A similar mechanism was proposed by Geniès et al. [65] for the polymerization of aniline. 1,4-Couplings are needed to produce linear polymers with this monomer. Figure 8 presents this mechanism, supposing that only 1,4-couplings occur in the polymerization. As mentioned, branched polymers are not desirable because electron delocalization is precluded in nonlinear chains.

The next section discusses the effect of the structure on the properties of the polymers.
Figure 8. Polymerization mechanism accepted for the synthesis of polyaniline.

2.4. Structure–Property Relationship

The close relationship between polymer properties and their structures is the most interesting characteristic of such materials because few variations in the polymer chains, such as the inclusion of pendant groups or the modification of the molar mass, lead to the preparation of materials with different characteristics. Among the several characteristics that make conducting polymers unique materials, electrical conductivity was the first property studied. This property is basically related to the presence of conjugated double bonds along the polymer backbone, as can be seen in Figure 1. These bonds can be aliphatic (as in PA) or aromatic (in PAni) and allow π-electron delocalization along the polymer structure. Electrical conductivity is strongly dependent on the doping agent and can be changed by several orders of magnitude as the dopant nature or concentration is altered [66].

The nature of the doping agent also affects the mechanical properties of conducting polymers. Self-standing films of polypyrrole are obtained using surfactant salts as doping agents [67]. Polyaniline is a nonmelting and nonprocessable material when doped with HCl; however, it shows elastomeric behavior when doped with sulfonic acids [68, 69] or phosphoric acid esthers [70, 71]. Changes in the mechanical behavior are associated with plastification effects induced by amphifilic dopants. Microcrystalline domains obtained by casting polyaniline solutions induce pseudo-cross-linking that permits the formation of flexible films [72].

The strongly conjugated π-electron system present in conducting polymers makes most of these materials insoluble in ordinary organic solvents. Changing their structures by introducing pendant groups is an alternative to make them more soluble. Qiao et al. [73] studied the influence of different alkyl substituents on the properties of polythiophenes and concluded that alkyl chain lengths up to about 10–12 carbons induce the formation of layered structures in the parent polythiophene. Alkyl side chains of appropriate length also contribute to making the polymer more soluble, in organic solvents, which broadens the possibility of using it in technological applications [73, 74].

As increases in the length of the polymer chain intensify electron delocalization, it could be supposed that the electrical conductivity is proportional to the chain length. However, Gruber and Utley [75] prepared several oligomers of p-phenylene-vinylene and showed that the electrical conductivity remains unchanged independent of the number of monomeric units. These results indicate that Matteva's proposition [43], about the conductivity occurring by intermolecular carrier mobility, is probably correct for this polymer. On the other hand, another article reported that increasing the molar mass of polyaniline from 15,000 to 174,000 g mol^{-1} changed the conductivity from 1.2 to 17 S cm^{-1}. However, there is no consensus on whether the enhanced conductivity is a function of the increased molar mass or is due to the crystallinity degree [76].

As stated, electrical conductivity is also proportional to the crystallinity degree because closer intermolecular distances occurring in the crystalline phase make it easier for the carriers to hop among the chains [76]. Thus, branched chains produced by α,β coupling during polymer synthesis induce lower conductivity values, because branched macromolecules are less crystalline. Besides, the presence of branching also generates traps that hamper the charge carrier mobility along the polymer backbone. Basically, attaching substituent groups to the 3- and/or 4-positions minimizes the occurrence of α,β coupling during polymer synthesis, producing more regular structures [64]. Fewer α,β linkage defects in the final structures lead to a more effective conjugation, which is an essential feature to arrive at more conductive final products. Furthermore, other effects derived specifically from the substituent group also contribute to increasing the electrical conductivity. Moreover, those functionalized polymers with longer alkyl chains have been used to produce more regioregular structures. Roncali et al. [77] verified that no irregular head-to-head or tail-to-tail couplings are observed in the product obtained from the electrochemical polymerization of 3-(3,6-dioxaheptyl)thiophene.

As discussed, the complex morphology of conducting polymers plays a crucial role in their physical properties. In general, conjugation length, interchain interactions, and the extent of disorder are significant parameters that govern the final characteristics of the resulting polymer [78].

Figures 7 and 8 show the mechanisms for the ideal growth of conducting polymer chains to obtain linear backbones. However, other kinds of coupling can occur during the polymerization. Although preferential couplings during polymerization of pyrroles and thiophenes occur in positions 2 and 5, secondary reactions are possible in positions 3 and/or 4, leading to branched products. Figure 9 shows possible structural defects that can occur in a polypyrrole chain [79]. A similar phenomenon is observed in polyaniline synthesis, where polymerization in position 2 leads to pendant groups that affect electron delocalization.

Electrical conductivity in solid-state systems is dependent on the number of charge carriers and on the mobility of these carriers. Inorganic semiconductors possess few charge carriers, but these carriers have high mobility, due to the high crystallinity degree and purity presented by these materials. Otherwise, conducting polymers have a high number of charge carriers with low mobility. The low mobility of
Figure 9. Scheme of structural defects presented by polypyrrole.

charge carriers is attributed to structural defects, as shown in Figure 9. For this reason, the production of polymers with optimized values of electrical conductivity is directly related to the increase of the mobility of the carriers. Indeed, the possibility of controlling the electronic and optical properties of a conducting polymer by tailoring the organic molecular structure (precluding structural defects) will open new possibilities of using these materials in technological applications.

One of the most promising alternatives to produce conducting polymers with fewer structural defects is the encapsulation of the polymer chains in the internal cavities of host structures. Among the possibilities of achieving encapsulated polymers, the "template synthesis" of the conducting polymers in cavities, pores, and lamellae has been explored to produce highly ordered polymer chains with optimized characteristics.

3. CONDUCTING POLYMERIC NANOMATERIALS

3.1. Preparing Conducting Polymers by Template Synthesis

Conjugated polymers have many potential applications, most of which are related to their conductivity. In these materials, the chemical bonding leads to one unpaired electron per carbon atom. Moreover, π-bonding, in which the carbon orbitals are in the $sp^2 p_z$ configuration and in which the orbitals of successive carbon atoms along the backbone overlap, leads to electron delocalization along the backbone of the polymer. This electronic delocalization provides the "highway" for charge mobility along the backbone of the polymer chain. Consequently, doped conjugated polymers are good conductors for two reasons [9]:

i. Doping introduces carriers into the electronic structure. Since every repeating unit is a potential redox site, conjugated polymers can be n-type (reduced) or p-type (oxidized) doped to a relatively high density of charge carriers [80].
ii. The attraction of an electron in one repeating unit to the nuclei in the neighboring unit leads to carrier delocalization along the polymer chain and to charge carrier mobility, which is extended into three dimensions through interchain electron transfer.

Disorder, however, limits carrier mobility and, in the metallic state, limits the electrical conductivity. In most of the cases, this disorder consists of the presence of conjugation-interrupting defects, such as sp^3-hybridized carbons or twists and kinks in the polymer chain [38, 81]. Ioffe and Regel [82] argued that, as the extent of disorder increased in a metallic system, there was a limit to metallic behavior; when the mean free path becomes equal to the interatomic spacing, coherent metallic transport would not be possible. Thus, the Ioffe–Regel criterion is defined in Eq. (1), where k_F is the Fermi wave number and l is the mean free path:

$$k_F \cdot l \approx 1 \qquad (1)$$

In Eq. (1), the metallic regime corresponds to $k_F \cdot l \gg 1$; however, this truly metallic regime has not yet been achieved with conducting polymers. Based on the Ioffe–Regel criterion, Mott and Davis [83] proposed that a metal–insulator transition must occur when the disorder is sufficiently large that $k_F \cdot l < 1$. In the limit, where $k_F \cdot l \ll 1$ (i.e., where the strengh of the random disorder potential is large compared to the bandwidth), all states become localized and the system is called a "Fermi glass." Fermi glass is an insulator with a continuous density of localized states occupied according to Fermi statistics. Although there is no energy gap, the behavior is that of an insulator because the states of the Fermi energy are spatially localized.

Generally, conjugation-interrupting defects are introduced during the synthesis that, as previously mentioned, involves in the first step the formation of cation radicals. The further fate of this highly reactive species depends on the experimental conditions. In favorable cases the next step is a dimerization reaction and stepwise chain growth proceeds via association of radical ions (RR route) or of a cation radical with a neutral monomer (RS route) [84, 85]. Even in these cases, parallel dimerization reactions might occur, leading to different products or to a polymer with a disordered structure. If the synthesis conditions are not carefully optimized, a mixed material is obtained, containing electrochemically active and conducting as well as inactive and insulating portions [86]. It has been demonstrated that, in the synthesis of polypyrrole, the current density is a crucial parameter. At low current densities its structure is dominated by one-dimensional chains, while at high current densities two-dimensional microscopic structures of the polymer are formed. The structure substantially affects the conductivity of the polymer phase. The conductivity of the two-dimensional (2D) form is higher and its temperature dependence is lower, which is of importance when this polymer is used for practical purposes. Detailed studies have shown that short 1D chain segments acting as tunneling barriers interconnect the higher conductive 2D islands [87, 88].

In the case of polyaniline, assuming that polymerization does occur via a radical intermediate, coupling is possible at all three positions on the ring (albeit with differing probabilities) and a number of alternative products to the emeraldine-based structure can be envisaged, including both head-to-head and head-to-tail coupling of the monomer units. The conductivity can be varied over 15 orders of magnitude under appropriate synthesis conditions, up to a maximum of 10^2 S cm^{-1}, typical values being 10^{-3}–10^{-2} S cm^{-1} when oxidized and 10^{-2}–10^{-1} when reduced, although material with predominantly meta-coupling has a very low conductivity (10^{-15}–10^{-14} S cm^{-1}) [84].

Indeed, research directed toward conjugated polymers with improved structural order and hence higher mobility is a focus of current activity in the field. In principle, disorder can be controlled. Experimental studies have established that, for conducting polymers, the electrical properties improve as the degree of chain extension and chain alignment are improved. In polymers with enhanced supermolecular order, the polymer chains are ordered via stretching and/or crystallization of the polymer. Using these approaches, conductivity values in excess of 100,000 S cm^{-1} have been achieved for highly ordered polyacetylene [89],

which is near that of copper. Unfortunately, the doped forms of polyacetylene are so reactive that it appears unlikely that this material will be useful for any of the proposed applications of conductive polymers [90, 91]. Conductivity values for more chemically stable materials (heterocyclic conjugated polymers) are many orders of magnitude lower. Hence, developing strategies for improving the conductivity of these polymers is an important research objective. In this context template synthesis appears to be an "elegant approach" for controlling the extent of molecular and supermolecular order in electronically conductive polymers.

The underlying principle of the template synthesis technique is akin to that of producing components through the use of replication (e.g., die-casting or mold casting, like making ice candies out of molds) [92]. The term "replica" polymerization was first used by Szwarc in 1954 [93]; this term was then displaced by "matrix" or "template" polymerization. In this technique, materials can be deposited within the void spaces of the host materials. These void spaces act as a template that determines the shape, size, and, in many cases, the orientation of the produced particle. Thus, by carrying out the synthesis of conducting polymers in a confined medium, the polymer chains are forced to align within the environment of the host matrix and an enhancement of the conductivity can be expected.

The strategy in using template synthesis involves the judicious selection of the host material and suitable precursors to the desired guest(s). There now exists a huge range of choice of hosts. They can be inorganic, organic, or organometallic compositional types, with 1D tunnels, 2D layers, or 3D framework structures [7, 94]. Hosts may be of insulating, semiconducting, metallic, or superconducting types or may attain these properties following inclusion of the chosen guest. On surveying known host structures, one finds that channel, interlamellar, and cavity dimensions vary widely in size, separation, and perfection, spanning the size range from barely being able to accommodate the smallest ionic or molecular guest all the way to having channel dimensions of about 5–10,000 Å, interlamellar spaces of 3–50 Å, and cavity diameters of 6–10,000 Å.

The template method has a number of interesting and useful features [95]. First, it is very general and can be used to prepare tubules and fibrils composed of electronically conductive polymers [96–104], metals [105–109], semiconductors [110, 111], carbons [112], and other materials. Furthermore, nanostructures with extraordinarily small diameters can be prepared. In addition, when membranes with monodisperse diameter pores are used as templates, monodisperse nanostructures are obtained. Finally, the tubules or fibrils synthesized within the pores can be freed from the template membrane and collected. Alternatively, an ensemble of micro- or nanostructures that protrude from a surface like the bristles of a brush can be obtained. When the host matrix is not dissolved, a nanocomposite is produced.

Nanocomposites can be defined as a combination of two or more phases containing different compositions or structures, where a least one of the phases is in the nanoscale regime [7, 113, 114]. Size effects in nanostructured materials are of great importance from both fundamental considerations and modern practice. It seems of interest to consider

the upper and lower limits of the nanosizes [115, 116]. By nanomaterials, materials are commonly meant to have the size of the grains or phases (D) composing their structure not exceeding 100 nm, in at least one direction. This upper limit is very arbitrary and its value is dictated by convenience considerations rather than by physical ones. However, simple estimations show that, starting from this size, the fraction of disordered interface regions becomes increasingly noticeable (this fraction is about $3s/D$, where s is the width of the grain-boundary region and D is the characteristic size); at reasonable values of $s \approx 0.5$–1 nm, this fraction reaches several percent. On the other hand, the upper limit of D should correspond to the size that is a characteristic length of a physical phenomenon (e.g., the free path of carriers for transport properties, the domain features for magnetic characteristics, etc.). It is clear that the limiting D values would differ for different physical–chemical properties and different materials.

The field of polymer nanocomposites has attracted considerable attention due to the small size of the structural unit and the high surface-to-volume ratio can result in properties not found in bulk materials [117–119]. In this way, new materials with new properties can be obtained and have wide ranging implications for a variety of areas, including chemistry, physics, electronics, optics, materials science, and biomedical science.

The research in polymer-intercalated composites is not exclusively directed toward obtaining high-conductivity materials. Other important properties could also be interesting for a variety of applications. All of these aspects will be discussed in the next sections.

3.2. Development of the Technique

There are several examples in the literature of depositing materials within the pores of microporous membranes. Bean [120] first demonstrated the art of filling the pores of a membrane with silver, followed by Possin [121], who used an electrodeposition technique in the fabrication of thin wires as small as 400 Å, using mica with etched pores as templates for the growth of elements of the microstructures. Williams and Giordano [122] claimed to have reduced the size to 80 Å after some refinements to this technique. Penner and Martin began their template-synthesis work in 1985 by electrochemically synthesizing the electronically conductive polymer polypyrrole within the pores of a nanoporous polycarbonate filtration membrane [96]. Martin et al. coined the term "template synthesis " to describe the process whereby electronically conductive polymers (or other material) are synthesized within the pores of microporous support membrane [98, 123–127]. Most of the initial work entailed the use of two types of membranes: "track-etch" polymeric membranes and porous aluminas.

Nowadays a wide variety of nanoporous solids have been used as template materials. Tonucci et al. [128] have described a nanochannel array glass with pore diameters as small as 33 nm and pore densities as high as 3×10^{10} pores per square centimeter. Douglas et al. [129] have shown that the nanoscopic pores in a protein derived from a bacterium can be used to transfer an image of these pores to an underlying substrate.

Recently, several papers have reported the use of the uniform and straight channels of anodic aluminum oxide (AAO) films as a template [130–133]. Conducting polymers and the copolymer nanofibrils obtained have uniform and well-aligned arrays and their diameters and lengths can be controlled by changing the aspect ratios of the AAO membrane.

3.3. Hosts

"[T]he possibility of assembling a conducting polymer chain within a non-polarizable porous channel is a fascinating one, not only because it would yield a true molecular nanowire, but also it would allow us to study selectively the charge transport mechanisms operating along the polymer chains. . . " [134].

When contemplating how to make template synthesis or "well-defined" host–guest inclusions systems, it is pivotal to really appreciate the effects of the topology and reactivity of the internal surface of the host on the occluded guest [7]. These factors will control, for instance, details of the chemistry between the host and the guest inside the host lattice. Representative examples of the hosts that have been used in template synthesis of conducting polymers are shown in Figure 10.

3.3.1. One-Dimensional Tunnel Hosts

The synthesis of nanoscale organic polymer fibers, cylinders, and wires has created a tremendous amount of excitement in several segments of the scientific community [95, 135, 136].

a)

1-D tunnel hosts:
– Graphite tubes
– Nuclepore membranes
– Inorganic tunnels
– Zeolites, molecular sieves
– Soft chemistry
– Aligned polymer channels

2-D layered hosts:
– Graphite
– Oxide, halide and halcogenide layers
– Organic, inorganic LB films
– Self-assembled mono- and multilayers
– Miscellaneous inorganic layers

b)

3-D framework hosts:
– Carbon sieves
– Porous glasses
– Polymer cavities
– Block-copolymer nanodomains
– Zeolites, molecular sieves
– Protein cages
– Inorganic insertion materials
– Buckyball endohedral complexes and
– insertion compounds

c)

Figure 10. Representative examples of (a) one-dimensional tunnel hosts, (b) two-dimensional layered hosts, and (c) three-dimensional framework hosts.

Such nanoscale sculptures are intrinsically interesting systems with a myriad of potential applications.

A variety of materials that contain one-dimensional pores are known (Fig. 10a) but most of the initial work in this area has entailed the use of two types of membranes: "track-etch" polymeric membranes and porous aluminas (Fig. 11).

Track-Etch Membranes A number of companies, such as Nuclepore and Poretics, sell microporous and nanoporous polymeric filtration membranes that have been prepared by the track-etch method [135, 137]. This method entails bombarding a nonporous sheet of the desired material with nuclear fission fragments, to create damage tracks in the material, and then chemically etching these tracks into pores. These membranes contain randomly distributed cylindrical pores of uniform diameter. Membranes with pore diameters as small as 10 nm are available commercially; pore densities approach 10^9 pores per square centimeter (Fig. 11a and b). The commercially available membranes are prepared from polycarbonate or polyester; however, a number of other materials are amenable to the track-etch process.

Porous Alumina Membranes of this type are prepared electrochemically from Al metal [138]. Pore densities as high as 10^{11} pores per square centimeter can be achieved [139]. Nanomaterials produced by the template method, membranes with high pore density, allow a greater number of nanostructures to be produced per unit area of template membrane (Fig. 11c and d). While such membranes are sold commercially, only a limited number of pore diameters are available. Foss et al. [106, 140] have, however, prepared membranes of this type with a broad range of pore diameters. Membranes with pores as small as 5 nm were made and smaller pores can be prepared.

Most of the work of Martin et al. has focused on polypyrrole, poly(3-methylthiophene), and polyaniline. These polymers can be synthesized by oxidative polymerization of the corresponding monomer. This may be accomplished either electrochemically or with a chemical oxidizing agent. Both of these methods can be used to do template synthesis of conductive polymers. The easiest way to do electrochemical templating is to coat one surface of the templating membrane with a metal film and then use this metal film as anode to electrochemically synthesize the polymer within the pores of the membrane [107, 141, 142]. Chemical template synthesis can be accomplished by simply immersing the membrane in a solution of the desired monomer and its oxidizing agent. This fabrication procedure is shown schematically in Figure 12. Other groups have since used such methods [109, 133].

In developing these template-synthetic methods, an interesting discovery was made. When these polymers are synthesized (either chemically or electrochemically) within the pores of the track-etched polycarbonate membranes, the polymer preferentially nucleates and grows on the pore walls [98–100, 123, 143]. As a result, polymeric tubules are obtained. By controlling the polymerization time, tubules with thin walls (short polymerization times) or thick walls (long polymerization times) can be produced. For polypyrrole, the tubules ultimately "close up" to form solid fibrils. In contrast, polyaniline tubules will not close up, even after long polymerization times [143].
Figure 11. Electron micrographies of polycarbonate (a and b) and alumina (c and d) template membranes. For each type of membrane, an image of a larger pore membrane is presented (a and c) so that the characteristics of the pores can be clearly seen. An image of a membrane with extremely small pores is also presented (b and d). (a) Scanning electron micrograph of the surface of a polycarbonate membrane with 1 μm diameter pores. (b) Transmission electron micrography (TEM) of a graphite replica of the surface of a polycarbonate membrane with 30 nm diameter pores. The pores appear "raged." This is an artifact of the graphite replica. (c and d) TEMs of microtomed section of alumina membranes with (c) 70 and (d) 10 nm diameter pores. Reprinted with permission from [136], C. R. Martin, *Chem. Mater.* 8, 1739 (1996). © 1996 American Chemical Society.

The reason that the polymer preferentially nucleates and grows on the pore walls is straightforward [99]. Although the monomers are soluble, the polycationic forms of these polymers are completely insoluble. Hence, there is a solvo-phobic component to the interaction between the polymer and the pore wall. There is also an electrostatic component because the polymers are cationic and there are anionic sites on the pore walls [99]. This illustrates an important
Figure 12. Schematic of the procedure for preparing fibers from anopore alumina membranes.

point: If a "molecular anchor" that interacts with the material being deposited is present on the pore wall, a hollow tubule (as opposed to a solid fibril) will be obtained. This concept of a molecular anchor provides a general route for template synthesis of tubular micro- and nanostructures [125]. A plot of conductivity versus diameter for template-synthesized polypyrrole fibrils is shown in Figure 13.

Whereas fibrils with large diameters have conductivities comparable to those of bulk samples of polypyrrole, the conductivities of the nanofibrils, which have the smallest diameters, are more than an order of magnitude greater. The template-synthesized materials have higher conductivities because the polymer chains on the outer surfaces of the tubules or fibrils are aligned. This can be proven with a technique called polarized infrared absorption spectroscopy (PIRAS) [98, 126, 144].

The PIRAS method entails measurement of the absorption by a polymeric sample of two orthogonally polarized beams of infrared radiation. One beam is polarized perpendicular to the axes of the fibrils, and the other has a
component that is parallel to the fibril axes. In general, if the integrated absorption intensities of the perpendicular and parallel polarizations are the same, the polymer chains show no preferred orientation. In contrast, if equal absorption is not observed, the polymer chains show some degree of alignment. The extent of this alignment can be assessed by calculating a parameter called the dichroic ratio, which is the ratio of the integrated absorption intensities of the parallel and perpendicular polarizations [126, 144]. In this case, the smaller the dichroic ratio, the greater the extent of polymer chain alignment.

By controlling the polymerization time it is possible to prepare tubules with very thin or very thick walls [145]. The PIRAS data were obtained as a function of polymerization time and the extent of polymer chain alignment in the layer of conductive polymer that was deposited directly onto the polycarbonate (short polymerization times) or on subsequently deposited layers (long polymerization times). Figure 14 shows the results of experiment. Parthasarathy and Martin found that the layer of polypyrrole that is deposited directly on the pore wall is ordered (low dichroic ratio) but that the extent of order decreases in subsequently deposited layers (dichroic ratio approaches unity). Analogous results were obtained with polyaniline tubules [143].

These data show that template-synthesized conductive polymer fibrils or tubules have a layer of ordered polymer chains at their outer surface and that the extent of this chain order decreases toward the center of the nanostructure. The chains on the outer surface of the conductive polymer tubules and fibrils are ordered because the polycarbonate chains that make up the pore walls in the template membranes are likewise ordered. Hence, the first layer of conductive polymer chains deposits in accordance with the

Figure 13. Conductivity versus diameter for polypyrrole fibrils. Data for two different synthesis temperatures are shown: lower curve, 0 °C; upper curve, −20 °C. Reprinted with permission from [135], C. R. Martin, *Science* 266, 1961 (1994). © 1994, American Chemical Society.
Figure 14. Dichroic ratio for polypyrrole tubules synthesized in a polycarbonate membrane with 400 nm diameter pores, as a function of polymerization time. Since polymerization time controls tubule wall thickness, the *x*-axis is also a wall thickness axis. The band at 1560 cm^{-1} was used to obtain the data. Reprinted with permission from [145], C. R. Martin, *Acc. Chem. Res.* 28, 61 (1995). © 1995, American Chemical Society.

polycarbonate chains on the pore wall. The central core of a fibril is disordered because the order-inducing influence of the pore wall is lost in subsequently deposited layers. The thinnest template-synthesized fibrils have the highest conductivity (Fig. 13) because they contain a relatively higher proportion of ordered material (and a smaller amount of disordered material) than the larger diameter fibrils.

Although particle track-etched membranes are commercially available, the technology has recently been improved in some laboratories [109, 146], in order to produce reliable and reproducible nanoporous particle track-etched membranes (nano-PTM). These lab-scale samples exhibit controlled properties: mean pore size in the range of 15–1000 nm, low pore size distribution, perfectly cylindrical pores with smooth walls, and a parallel arrangement across the membrane. With such optimized properties, nano-PTMs are considered excellent templates for the preparation of controlled nanoscale materials.

Scanning electron micrographs of the "as-prepared" polypyrrole nanostructures after dissolution of the PC membrane clearly show that nanotubules are obtained (Fig. 15) [147]. The nascent polymer is preferentially deposited as thin layers on the pore walls and thus produces hollow polymer tubules that run through the entire thickness of the membrane. It must be noted that the tubules form a continuum with the outer polypyrrole films (i.e., surface layers) and so are strongly fixed.

As shown in Figure 16, two kinds of morphology are observed in terms of the Ppy nanotubule outside diameter. For diameters higher than 100 nm, the tubules are rigid and form a brush supported by the surface layers. At the other extreme, for diameters below 100 nm, the polymer tubules become very flexible and are lying on the surface when the PC membrane is dissolved [147].

The marked difference in morphology between the alumina membrane-templated nanostructures and polycarbonate membrane-templated nanocylinders observed by Mativetsky and Datars [133] reflects a difference in the surface chemistry taking place at the pore walls. A scanning

electron micrograph providing an edge-on view of a filled alumina membrane is shown in Figure 17.

The basic shape of the nanostructures is that of a linear aggregate of irregular blobs. The blobs measured 290 ± 50 nm across, had an elongated shape, and were packed closely together. Few of the nanostructures extended from end-to-end of the template membrane. As no molecular anchor sites are present on the alumina pore walls, there is no preferential growth along the pore walls; instead, the nucleation appears to be at random positions within the pores. The polypyrrole subsequently grows radially outward from the nucleation site, until a pore wall or another polypyrrole mass is contacted. Once in close proximity, the blobs can grow together [133].

The Mott characteristic temperature T_0 was the same as that for similar diameter polycarbonate membrane-templated nanocylinders. This suggests that the two types of samples have similar charge carrier localization lengths, similar densities of states at the Fermi level, and similar conductivities. This supports the argument that there

is no conductivity-enhancing order in the polycarbonate membrane-templated nanocylinders [133].

Micro- and nanotubules of conducting polymers have been reported by several groups [130, 132, 148, 149]; however, few large-area, high-quality bilayer films have been reported in detail. In this sense, Fu et al. [150] used templates of microporous alumina membranes having a thickness of 60 μm and pore diameters of 20 and 200 nm. Flexible polythiophene micro- and nanotubules, and aligned tubule/gold bilayer films with an area of 1.8 cm^2, were obtained by direct oxidation of thiophene in freshly distilled boron trifluoride diethyl etherate solutions. Raman spectroscopic studies give evidence for polymer chain orientation in the skin of the nanotubules (20 nm). The micro- or nanotubule/gold bilayer film shows broad and strong redox responses and its charge/discharge capacity is about 30 times that of the usual polythiophene film. These results imply that such films are advanced materials for fabricating capacitors with high energy density.

Li et al. [131, 151] have recently used a template to prepare pyrrole/aniline and pyrrole/3-methylthiophene copolymer nanofibrils by the chemical copolymerization technique and have investigated the structure and morphology of the copolymer fibrils. The copolymerization has a high potential for modifying the physical properties because it provides materials with intermediate properties between two or more monomers. Copolymer nanofibrils were successfully synthesized in the pores of micropores of an AAO template by the chemical copolymerization technique [32]. Electron scanning microscopy results showed that the template technique could control the length, diameter, and thickness of copolymer nanofibrils, which had uniform and well-aligned arrays. A thermogravimetric study demonstrated that the copolymer was thermally stable, as compared to the homopolymers and mixtures. In addition, the conductivity of the copolymers is higher than that observed for homopolymers.

Among the huge range of hosts, many studies were performed using carbon nanotubes [104, 152, 153]. The formation of nanotube/polymer composites is considered a promising approach to an effective incorporation of carbon nanotubes into devices with possible synergetic effects.

Organic LEDs with lower current densities and better thermal stabilities than the corresponding pure polymer devices [154], and photovoltaic cells of a reasonably high quantum efficiency (1.8% at 2.9–3.2 eV) [155], have recently been fabricated. Chen et al. [104] obtained polypyrrole-coated carbon nanotube electrodes that showed significantly improved electrochemical redox performance. Specifically, when the formation charge is around 680 mC cm^{-2}, the redox charge improves 2.5 to 23 times, compared to the flat Ti and Pt substrates. In all these cases the coaxial nanowire structure and the ease with which several conducting polymers can be deposited onto the aligned carbon nanotubes suggest a wide range of potential applications for the conducting polymer–carbon nanotube nanowires, especially in optoelectronic devices and high-performance, lightweight rechargeable batteries.

There has been considerable technological interest in conducting polymers with tubular or fibrillar nanostructures. Areas of application that can be foreseen to benefit from the small size and organization of conducting polymers include electrochemistry, optoelectronics, microelectronics, sensors [156], and bioencapsulation (drug delivery systems involving microencapsulation) [135, 157].

3.3.2. Two-Dimensional Layered Hosts

The ability of nitrogenated bases to penetrate into the interlayer space of different layered solids is the basis for the so-called "intercalatation polymerization" of molecules like aniline and pyrrole [158]. It is a promising strategy to study the confinement of polymer chains in nanometer size inorganic galleries. As conjugated polymers have many potential applications, their insertion in the layered (two-dimensional) inorganic hosts has received extensive attention over the past few years and many conjugated polymer/inorganic host hybrid composites have been synthesized and studied. In intercalation polymerization the inorganic host serves as template within which a guest molecule of nanometer dimensions is assembled. Host lattices such as FeOCl [159], uranyl phosphates [160], transition-metal oxides [161–163], and aluminosilicates [164], with lamellar structures, have been successfully used. The constrained environment is expected to lead to a high degree of polymer ordering and to useful properties [165].

The protons of the carboxylic groups present in the interlayer space of tin (IV)-2-carboxyethylphosphonate (SnP-C) can be ionically exchanged by transition metals (e.g., Fe^{3+}) that act as oxidizing agents for the polymerization of aniline. This process made possible the synthesis of polyaniline in the interlayer spaces producing the composite Pani/SnP-C, which showed electroactive properties characteristic of polyaniline, although the amount of polymer does not exceed 4.0 wt%. The formation of the polymer in the interlayer space of the host material was confirmed by Fourier transform infrared and X-ray diffraction [166]. The photoelectrochemical behavior of the composite was investigated as a function of applied potential, polyaniline

concentration, and the direction of polychromatic radiation [167]. As shown in Figure 18, the photoelectrochemical response was observed as an anodic or cathodic photocurrent, depending on the applied potential [168].

The variation in the sign of the photocurrent with the potential indicates that not only does the bandgap energy change with the potential, but also there is a change of the position of the band edge in relation to the standard potential of the redox pair present in the solution. The photoelectrochemical response showed good stability to prolonged irradiation times and is comparable to the values reported in the literature for other materials, although only 4 wt% of active material was present in the composite.

An alternative route for preparation of PAni-phosphate intercalation materials was reported by Zarbin et al. [169], which consists of submitting the host to a saturated aniline atmosphere. Subsequently the sample was immersed into an oxidant solution and a dark green solid was isolated. The characterization results demonstrated strong evidence for the formation of nanocomposites, indicating that the polymeric chain had high linearity and negligible cross-linking or branching.

The polymerization of aniline in the interlayer space of hosts has also been induced electrochemically [170]. In this way, aniline-intercalated montmorillonite/Pt systems were used as electrodes for aniline anodic oxidation operating in an acid medium. Redox peaks observed in the cyclic voltammograms of the resulting intercalated PAni are associated with polymer protonation/deprotonation processes. This technique can also give information about the oxidation mechanisms occurring either in the interlayer region or on the external surface of the host. Furthermore, it is very important to extend the use of these electrochemical polymerization procedures to other systems, although the required acidic medium could be a limitation with regard to the structural stability of host lattices [158].

The unusual combination of polypyrrole, vanadium oxides, and bentonites has never been reported before the work of Fontes et al. [171]. This promising new ternary composite, formed by the redox/intercalative reaction of polypyrrol with the lamellar bentonite/V_2O_5 [172, 173],
Figure 18. Photoelectrochemical response of the PAni/SnP-C/Fe composite in 0.1 mol L^{-1} $HClO_4$/0.1 mol L^{-1} $LiClO_4$ electrolyte and 0.2 mmol L^{-1} KI/KI 0.02 I_2 mmol L^{-1} redox pair, at 5 mV s^{-1}.

exhibits a characteristic green color and keeps the lamellar structure and electrochemical/electronic properties of the starting materials. The main advantage is its good stability and conductivity as well as its poor solubility in water, in addition to its good adherence to most electrode surfaces. All of these properties ensure potential applications as electrode modifiers, for analytical and sensor purposes.

The research in polymer-intercalated nanocomposites is not exclusively directed toward obtaining stable, electroactive, and highly conductive materials. Intercalation polymerization is also a promising strategy to study the chain structure of conducting polymers and their polymerization mechanisms. According to Wu et al. [174], when polyaniline is inserted into inorganic galleries the strong intermolecular interaction of the polymer chains is eliminated by the host barriers and a polyaniline single chain can be obtained. This is nearly impossible in the classical chemical polymerization of aniline. In addition, the polymerization rate is much slower in the confined environment. Aniline polymerization is a somewhat complicated process; it is a typical precipitation polymerization with a high reaction rate. These features make it difficult to identify and characterize the reaction intermediates and monitor the reaction rate. Thus, in intercalation polymerization the slow kinetic diffusion retards the reaction rate and possibly allows a novel method to study the mechanism during the polymerization induction period, the formation of dimers, and the propagation of polymer chains.

3.3.3. Three-Dimensional Framework Hosts

The design and understanding of well-defined conducting structures of nanometer dimensions and developments along this line could ultimately reduce the size of electronic circuits to molecular dimensions. In this way, conducting polymers have been synthesized within several kinds of hosts.

A material that can be used as a three-dimensional host matrix to obtain conducting polymer nanocomposites is porous vycor glass (PVG—Corning 7930). PVG is a highly transparent porous glass obtained by acid leaching of phase-separated alkaline borosilicate glass [175]. The soluble borate phase is dissolved leaving an open porous structure of essentially pure silica. It has interconnecting pores with a narrow pore size distribution (approximately 80 Å), and a pore of nearly 26%. Si—O—H groups, with acid hydrogens that permit an ion-exchange reaction with Cu^{+2}, form the internal surface of the pores. When pyrrole is added to PVG/Cu^{+2}, the monomer diffuses through the pores, starting oxidative polymerization. Polymer formation is shown by the color change from light blue to black, after 30 min of immersion of PVG/Cu^{+2} in pyrrole solutions.

A PVG/polyaniline nanocomposite was obtained in an inverse way; the monomer was first introduced inside the PVG pores and, after that, the PVG containing the monomer was immersed in an acid oxidizing solution, to promote polymerization. The green color observed in the final product is evidence for polyaniline formation in its conducting state, the emeraldine salt.

In both cases, the polymers are obtained with linear chains, with a very low incidence of structural defects and cross-linking. The very narrow pore size distribution in the glass prevents the occurrence of intermolecular interactions, structural defects, and cross-linking, providing the formation

of molecularly isolated polymer chains. Therefore, these nanocomposites could be produced with high reproducibility, without modifying the chemical properties of polypyrrole or polyaniline. The reversible color change of PAni/PVG composite from dark green (emeraldine salt) to dark blue (emeraldine base) when the glass is immersed in an acid solution or a basic solution, respectively, indicates the usefulness of this material as a sensing phase for an optical pH sensor [176].

Sotomayor et al. [177] describe the use of PAni/PVG nanocomposite as a sensing phase in an optical fiber pH sensor. The optical sensor was constructed by fixing a PVG slide onto the distal end of bifurcated optical fiber bundle, with a cyanoacrylic resin. The sensor response was found to be reversible in the pH range from 5 to 12 and linear from 7.4 to 9.5. Response times of 4, 8, and 16 min were obtained for slide thicknesses of 0.5, 4, and 1.5 mm, respectively. Changes of temperature, ranging from 20 to 40 °C, showed only minor effects on the dynamic range. Similarly, the ionic strength and the nature of the ions showed only small effects on the sensor response. Leaching of PAni was not observed and the sensor lifetime was ca. 5 months. These results indicated that the PAni–PVG nanocomposite is really suitable for the construction of optical pH sensors, with good analytical performance, since the glass slides can be prepared with good reproducibility and durability.

Due to structural complementarity, zeolites have also been recognized to be suitable host compounds to stabilize conducting polymers on the nanoscale. They are a class of crystalline aluminosilicates based on rigid anionic frameworks with well-defined channels and cavities. These cavities contain exchangeable metal cations and can also hold removable and replaceable guest molecules [178]. The primary building units of zeolites are $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedra linked together by corner-sharing, forming bent oxygen bridges. It is possible for the tetrahedra to link by sharing two, three, or all four corners, thus forming a variety of different structures. The important structural feature of zeolites, which can be exploited for template matrices, is the network of linked cavities or pores forming a system of channels throughout the structure. These cavities are of molecular dimensions (approximately 300 to 1200 pm) and a controlling factor in whether molecules can be adsorbed in the cavities is the size of the window or pore opening into the channel.

Early reports on the encapsulation of conjugated polymers in zeolites relate to polypyrrole [179], polythiophenes [180], and polyaniline [181]. Polyacetylene is an interesting case, not only because the bulk polymer is particularly sensitive to atmospheric attack, but also because the doped material can have both the highest conductivity for an organic polymer, and the lowest weight per conducting chain. Bein [182] showed that polyacetylene could be obtained in a variety of microporous hosts, under a variety of conditions, and using different forms of zeolite, including protonated, alkali metal, and transition metal exchanged forms. Recently, Cardin et al. [183] have shown that, in zeolites exchanged with Ni^{2+} or Co^{2+}, ethyne polymerizes rapidly at low temperatures to give complete filling of the voids. The materials were characterized by several techniques (Raman, thermogravimetry and electronic spectra,

infrared and X-ray photoelectron spectroscopy) and shown to form polyacetylene that fully fills the voids of the host, so that the composites are stable to air indefinitely, presumably because oxygen cannot gain access to the polyene chain.

Heterogeneous materials, which have a wide range of void space sizes, can also be used as hosts in template synthesis. Neves et al. [184, 185] have explored the idea of using the heterogeneous porosity of inorganic (sol–gel silica) and organic [poly(vinylidine fluoride)] films as templates for preparation of polyaniline (nano)composites. The large size pore distribution (∼2.5–800 nm) in both template matrices results in a fraction of polyaniline growing more ordered than in films synthesized without spatial restriction. Small-angle X-ray scattering and scanning electron microscopy experiments were done to determine the pore diameters. Cyclic voltammetry experiments confirmed the electroactivity of the composites. In Figure 19 the voltammetric peaks correspond to the changes in the oxidation state of the polyaniline that can be related to the ratio between amine and imine content in the film. There are two characteristic redox couples: at the cathodic extreme the conversion leucoemeraldine to the emeraldine salt and at the anodic extreme from the emeraldine to the pernigraniline form. From analysis of the voltammograms it could be also observed that the redox charge is more intense in the order PAni < PAni/silica < PAni/PVDF. The film porosity increases in the same order, indicating that the swelling of composite bulk by the electrolyte solution should also be considered. The higher bulk interaction of the film with the electrolyte solution results in redox process intensification.

Diffuse reflectance spectra of PAni and the respective composites films (Fig. 20) show two distinct bands, one centered at ∼380 nm and other at ∼800 nm. According to Xia et al. [186] these bands can be ascribed to the π^*-polaron and π-polaron transitions. Note that the more significant differences between the spectra are an increasing absorption tail extending toward the near infrared region, observed only in the composites. This extended "free carrier tail" corresponds to a decrease in the bandgap, which is a direct consequence of an increase in the conjugation length [187]. Since no near-infrared (NIR) absorption tail is observed for
Figure 19. Steady-state cyclic voltammograms of polyaniline film and (nano)composites films in 1.0 mol L^{-1} HCl/1.0 mol L^{-1} NaCl electrolyte, at 5 mV s^{-1}.
Figure 20. Ultraviolet-visible NIR spectra for polyaniline film and (nano)composite films.

PAni films, the authors [185] concluded that polarons (dominant charge carriers in polyaniline) are more localized in the composite films.

The same authors [188] also investigated the charge/discharge performance of a lithium battery using PAni or PAni/silica as the cathode. For the PAni/silica film, the discharge in the first cycle was 352 mA h g^{-1} and reached a stable value of 223 mA h g^{-1} after the 25th cycle, when the Coulombic efficiency was 95%. In contrast, the initial discharge capacity for the PAni film was 94 mA h g^{-1} and then stabilized at 52 mA h g^{-1}, with the same Coulombic efficiency as the composite. The values are in good agreement with those reported by Venancio et al. [189] for electrochemical thin films with a discharge capacity of 107 mA h g^{-1} and a Coulombic efficiency of 97.5%.

Due to a larger pore size distribution in both template matrices, the polymer formed a continuous conducting network within the composite films but porous morphologies were still observed. The formation of a continuous conducting network within the porous silica matrix increases the electroactive surface area exposed to the electrolyte, thereby providing parallel ionic and electronic conduction pathways which improve the process of charge transfer and mass transport. The balance between these processes is responsible for the good performance of the composite as an electrochemical device.

4. CONCLUSIONS

The goal of this chapter was to present template synthesis as an elegant approach to obtain conducting polymers on the nanoscale. A wide variety of polymers and hosts can be combined to produce materials with the desired properties. This method provides a route for controlling the extent of molecular and supermolecular order in electronically conductive polymers. This allows predictable control not only of the magnitude of the conductivity but also of the conduction mechanism within the material. Hence, these template-synthesized nanostructures are proving to be useful materials for exploring the fundamentals of the conduction

processes in conductive polymers. On the other hand, this method also provides protection from atmospheric attacks to sensitive polymers.

Future research could focus on the preparation of new nanomaterials involving novel kinds of hosts as well as alternative polymeric guest species. Nevertheless, much work should also be devoted to optimizing the preparation by controlling the steps and parameters during template synthesis; increasing understanding of the intercalation mechanisms of monomers, the polymerization driving force, and the nature of host–guest interactions; providing a more profound characterization of the systems; and developing new applications for template-synthesized nanomaterials.

This promising technology could show practical utility early in this century, provided the huge challenge of rapidly and reproducibly moving matter at the atomic level can be surmounted. This interdisciplinary field of research needs creative imagination and should receive increasing attention in the exciting nanoscale world of the future.

This field is now growing rapidly and in just one chapter it is not possible to be entirely comprehensive. Thus, we apologize to those authors whose contributions have not been included.

GLOSSARY

Nanocomposite A combination of two or more phases containing different compositions or structures, where a least one of the phases is on the nanometer scale.

One-dimensional tunnel hosts Host materials that contain one-dimensional channels or pores with internal diameter on the nanometer scale.

Template synthesis Inclusion of inorganic or organic constituents (guests) inside the void spaces of a host material. These void spaces act as a template, determining the shape, size, and in many cases the orientation of the compound produced.

Three-dimensional framework hosts Crystalline or amorphous host materials with channels and/or cavities extending to the three dimensions. The internal diameter of the channels or cavities is on the nanometer scale.

Two-dimensional layered hosts Host materials with a bidimensional structure and an interlayer space on the nanometer scale.

Conducting Polymer Nanotubes

Meixiang Wan

Chinese Academy of Sciences, Beijing, China

CONTENTS

1. INTRODUCTION

Since the discovery of carbon nanotubes (CNTs) by Iijima in 1991 [1], nanotubes, nanofibers, and even molecular wires have received great attention because of their unique properties. First, the properties of the nanotubes differ from the analogous properties of their bulk materials due to size, surface, and quantum effects. Second, a nanotube is an excellent template or "nanoreactor" to prepare molecule wires or molecule rings, which are fundamental units of molecule devices. Third, coated or filled nanotubes with electrical, optical, and magnetic materials can be as multifunctionalized nanomaterials. As a result, tubular nanomaterials including carbon nanotubes have promising potential applications in electronic, optical, and mechanical devices [2–6], drug delivery [7], and bioencapsulation [8].

Meanwhile, since the invention of conducting polyacetylene (PA) doped with iodine by Shirakawa et al. [9] in 1977, which was awarded the Nobel in chemistry in 2000, conducting polymer as a new field has been established and developed. Compared with other materials, some advantages of conducting polymers are shown as follows [10]: (1) Their conductivity at room temperature can be changed from the insulating through the semiconducting to the metallic range (10^{-9}–10^5 S/cm) by a doping process resulting in covering the whole range from the insulator to metal range. (2) The metallic state can also be brought back to its insulating state

by a dedoping process, and the doping/dedoping process is reversible. (3) Changing the doping degree can control the structure and physical properties. (4) Besides these, conducting polymers remain lightweight and the processability of conventional polymers [10]. These unique properties result in extensive investigations for commercial applications in energy storage devices, electrochemical/chemical sensors, and electrochromic devices [10–12]. Nowadays conducting polymers are the forth generation of polymers.

Currently, conducting polymer nanotubes or nanowires as moleculer wires have attracted attention because of their highly conjugated length and metal-like conductivity (10^0–10^5 S/cm) [10]. However, some fundamental issues on conducting polymer nanotubes or nanowires, such as synthesis, characterization, and property of the nanotubes, need to be understood. So far, many research works dealing with these issues have been reported in the literature; especially their potential application in nanodevices has been developed.

In this chapter, the synthetic method, spectroscopic characterization, and physical properties of the conducting polymer nanotubes including nanofibers, multifunctionalized nanotubes, as well as nanotube dendrites are overviewed in detail. The formation mechanism of self-assembled nanotubes and their multifunctionalized nanotubes, especially nanotube dendrites, is discussed briefly.

2. CONDUCTING POLYMER NANOTUBES

2.1. Synthetic Methods

In principle, utilization of application of conducting polymer nanotubes in nanodevices is limited by development of the synthetic method for conducting polymer nanotubes. As a result, a template-synthesis method [13], an electrospinning method [14], a template-free method [15], and electrochemical polymerization with a scanning microelectrodes [16] have been used to synthesize or prepare conducting polymer nanotubes or nanofibers. In particular, a new approach to synthesize the nanostructures by using organized assemblies or self-assemblies of supramolecular system as nanoreactors or templates has been developed rapidly and demonstrated to be full of promise for preparing the nanostructures of materials [16, 17]. In this section, synthetic methods dealing

with the template-synthesis method and self-assembly process, characterization, and physical properties of the conducting polymer nanotubes are discussed.

2.1.1. Template-Synthesis Method

Among those synthetic methods described, the template-synthesis method is one effective and common route to synthesize or prepare conducting polymer nanotubes or nanowires. Martin and his co-workers have successfully obtained PA, polythiophene (PTH), polypyrrole (PPy), and polyaniline (PANI) nanotubes or nanofibers by using this method [13, 18–24]. Moreover, other papers dealing with template-synthesized conducting polymer nanotubes have also been reported in the literature [25–39]. The moleculer structure of some typical conducting polymer nanotubes obtained is shown in Figure 1.

In general, template-synthesized conducting polymer nanotubes can be prepared either electrochemically [55–58] or by using a chemical oxidizing agent [59–61]. The easiest way to do electrochemical template synthesis is to coat a metal film onto one surface of the membrane and then use this thin film to electrochemically synthesize the desired polymer within the membrane [59]. Chemical template synthesis can be accomplished by simply immersing the membrane into solution of the desired monomer and its oxidizing agent [44, 45]. This method has advantage of controlling diameter and length by porous diameter and thickness of the membranes respectively. Moreover, changing the polymerization time can control the wall thickness of the nanotubes. Especially, it is a powerful method to prepare oriented arrays of the conducting polymer nanotubes, which are fundamental conditions to fabricate nanodevices. On the other hand, a membrane as a template is required in this method. Sometime post-treatment for removal of the template is required after polymerization, resulting in disorder or destruction of the nanotubes.

In general, a porous membrane for the template-synthesis method is required as a template, which allows monomer polymerization inside the pore individually. A typical schematic of the template-synthesis method is shown in Figure 2. Usually, porous alumna prepared electrochemically from aluminum metal is used as the common template [47]. The pore in these membranes is arranged in a regular hexagonal lattice. Pore densities as high as 10^{11} pores/cm^2 can be achieved [48]. Although such membranes are sold commercially, only a limited number of pore diameters are available. Foss et al. [49–51] have made membranes with pores as small as 5 nm.
Track-etched membranes, such as polycarbonate (PC) [52], are also used as common templates to synthesize nanotubes or nanofibers of conducting polymers. Track-etched membranes present a significant advantage because they lead to the production of different kinds of nanotubes or nanowires with monodisperse diameter and length. Those track-etched membranes with a wide range of pore diameters (0.03 to 12 μm) and pore densities (10^5–10^9 pore/cm^2) can be achieved. Except for the previously described membranes, glass membranes have been reported. Tonic et al. [53], for instance, described a nanochannel array glass membrane which contains pores with diameters as small as 33 nm and densities as high as 3×10^{10} pore/cm^2. Beck et al. [54] prepared a new large pore diameter zeolite; Wu and Bein [55, 56] have used zeolite as a membrane to synthesize polyaniline and graphitic nanofibers. In addition, Ozin [57] discussed a wide variety of other nonporous solids that could be used as template materials.

Furthermore, synthesis or preparation of oriented nanotube arrays of conducting polymers is also one of the aspects in the field of conducting polymer nanotubes because it is a fundamental condition for fabricating nanodevices. The template-synthesis method is a powerful route to prepare nanotube arrays. Marinakos et al. [58] described two methods for assembling one-dimensional (1D) arrays of Au nanoparticles. Both methods involve aligning nanoparticles in the pores of Al$_2$O$_3$ or PC filtration membranes. The first strategy is to entrap and align particles in the pores by vacuum

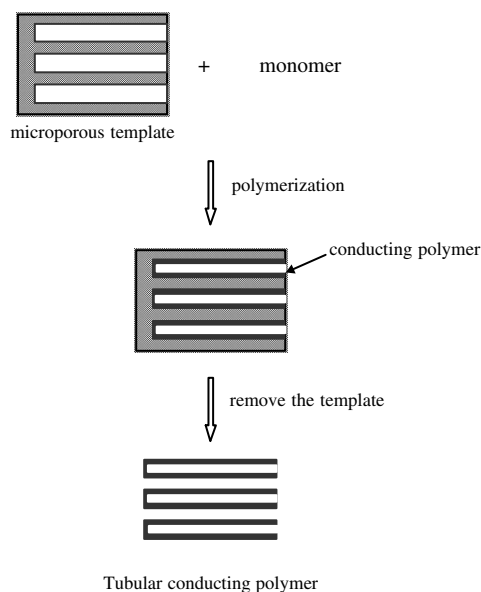
Figure 1. Molecule structure of some typical conducting polymer nanotubes.


Figure 2. Schematic of template-synthesized conducting polymer nanotubes.

filtration. Hornyak and co-workers [59] have also reported a similar method.

2.1.2. Self-Assembly Process

Recent advances in the control via self-assembly of synthetic molecules has generated numerous molecular architectures by applying principles such as hydrogen bonding, hydrophobic interaction, molecular recognition, and solvent–molecule interaction [73]. Research on self-assembled nanotubes or nanowires through hydrogen bonding, amphiliphilic block copolymer, and supermacromolecules as templates is discussed. The formation mechanism of the self-assembled nanotubes is also discussed briefly.

Hydrogen Bonding   As one knows, calyx[4]hydroquinone (CHQ) is a reducing form of calyx[4]quinine [31], which has four hydroquinone moieties with eight –OH groups. Four inner –OH groups form a circular proton-tunneling resonance of H-bond stabilized "cone" structures. The four free –OH groups can lead to self-assembled structures with intermolecular H-bonds. Hong et al. [62] investigated the assembling phenomena of CHQ with density functional calculations of various possible combinations of assembled structures derived from previously reported calixarene based dimers, trimers, tertramers, hexarence, and polymers by using the computer-aided molecular design approach based on intermolecular interaction forces. Their results suggest that in the presence of water molecules, a linear tubular polymeric structure be highly stabilized by the formation of H-binged bridges between repeating tubular actamer units. In particular, nanotubes arrays composed of electrochemically/photochemically active CHQ can be synthesized through a hydrogen bonding reaction. They also found that addition of water molecules into CHQ in acetone resulted in stable self-assembling thin needlelike nanotubes whose size depends on the evaporation rate and temperature.

Nanoscale conducting cylinders of polyaniline doped with camphoresulfonic acid (CSA), where 4-hexylresorcianol (Heres) (PANI $(CSA)_{0.5}(Heres)_y$, reported by Kosonen et al. [63]) is another typical sample of self-organization of the hydrogen-bonding reaction because Heres is hydrogen bonded to form supramolecules, which further undergo self-organization. Highly ordered hexagonal cylindrical structures were observed with a distance between the cylinders of 35 Å. This method would allow an easy preparation of nanoscale organic conducting wires, just by mixing the components together.

Amphiphilic Block Copolymer   Up to now, various morphologies including spheres, cylinders, vesicles, and layers that can be formed through self-assembly of amphiphilic block copolymers in block-selective solutions have been reported in the literature [64–69]. The reported results indicate that the self-assembly of block copolymers is clearly a potentially powerful route for the generation of nanostructured materials. However, virtually all the studies have focused on organic block polymers. Since the discovery of the living anionic-opening polymerization of strained silicon-bridged ferrocenophanes, it has become possible to access polyferrocene block copolymers, which combine organometallic segments with inorganic or organic co-blocks

[70, 71]. The incorporation of the polyferrocene block offers the opportunity to access self-assembled materials with redox-active, semiconducting, or preceramic nanodomains, or large periodic variation in the refractive index suitable for optical and phonic applications [72–74]. Manners [75], for example, has reported the self-assembly of poly-(ferrocenyldimethelsilane-*b*-dimethylsiloxane) cylinders. In particular, the first organometallic nanotubes using a different block ratio was reported by Raez et al. [76].

Supermacromolecules as Templates   In fact, surfactant [77–87], block copolymers [64–68], and colloidal particles [88, 89] have been successfully used as templates to obtain self-assembling nanostructural materials under adequate conditions. Langer et al. [90] reported that micro- and nano-fibril structures were obtained in PANI copolymers doped with fullerene derivatives prepared by electro-oxidative polymerization. The fibrils of 10 to 100 nm thickness are usually as long as 30,000 nm. Fibrils of PANI–C_{60} derivatives can also be obtained at the surface of the PANI nanolayer under controlled charge polymerization conditions, which can reach lengths from 1000 to 3000 to 15,000 nm and thickness of about 1000 nm. These complex structures support a fractal growth model and a modified diffusion-limited aggregation growth mechanism.

Wan and co-workers found that PANI and PPy micro/nanotubes could be synthesized electrochemically and chemically by *in-situ* doping polymerization in the presence of β-naphthalene sulfuric acid (β-NSA) as a dopant [91]. This method was called a template-free method because it did not use an external membrane as template. In fact, the essence of this method is a self-assembly process because of the dopant acting as a dopant and template function at the same time. Therefore, it is simple and cheap compared with the template–synthesis method. The schematic of the chemical and electrochemical self-assembly process to synthesize conducting polymer nanotubes or nanowires is shown in Figure 3. In a typical chemical self-assembly process, for example, aniline or pyrrole monomer was mixed in aqueous solution with ultrasonic stirring at room temperature. Then oxidant [e.g., $(NH_4)_2S_2O_8$ or $FeCl_3$] was added to this mixture by stirring at 0–5 °C for about 8–10 hours. Finally, the resulting precipitate was filtered and washed with deionized water, methanol, and ethyl ether several times, then dried in a dynamic vacuum at room temperature for 24 hours. Moreover, the reliability and practicality of this
Figure 3. Schematic of chemical and electrochemical self-assembly process to synthesize conducting polymer nanotubes.

method for synthesizing conducting polymer nanotubes by changing the polymer chain and dopant structure as well as the polymerization method have been demonstrated [92–111]. In their studies, PANI and PPy as well as their derivatives were used as the conducting polymers because of their high conductivity, stability in air, and easy preparation. Two kinds of dopant were used: one was inorganic acid, including HCl, H_2SO_4, H_3PO_4, and HBF_4 [108] without surfactant function; another was organic functionalized acid with surfactant function (e.g., $–SO_3H$ group). Naphthalene sulfuric acid and its derivatives [93–100, 105–107, 109, 111], hydrogen sulfated–fullerene [$C_{60}(OSO_3H)_6$] [102], 6-disulfo-nanpthyl-thiorea (PMMA4) [102], 4-{n-[4-(4-nitrophenylazo)phenyloxy]alkyl} aminobenzene sulfonic acid (represented by Cn–ABSA and n = 2, 3, 4, 6, 8, and 10) [103, 104], and p-toluenesulfonate acid (PTSA) [101] were used as organic functionalized acids. Chemical and electrochemical polymerization were used as polymerization methods because both methods are common and useful routes to synthesize conducting polymers. Scanning electron microscopy (SEM) images of some typical self-assembled nanotubes obtained by the author are shown in Figure 4. As one can see the resulting PANI and PPy are fibers and their average diameters are in the range of 50–1000 nm, depending on the polymer chain, dopant, polymerization method, and synthesis conditions [92–111]. Transmission electron microscopy (TEM) measurements showed that most of those nanofibers are hollow. For a given polymer chain and dopant, however, sometimes those fibers are solid depending on the synthesis conditions [92–111]. In addition, the formation yield, morphologies, and size strongly depend on the polymer chain, dopant structure, and synthesis conditions. In particular, the molar ratio of monomer to dopant and the concentration of dopant significantly affect the morphology and size of the resulting nanostructures [92–111].

Although without using external membrane as template, controlling the size of the self-assembled nanotubes is possible. In case of PANI–$C_{60}(OSO_3H)_6$ nanotubes, for example, changing the addition of water in the reaction system can control the diameter, and length of the nanotubes decreases with increasing the addition of water during the polymerization [102] as shown in Figure 5. Moreover, the diameter of PANI–H_3PO_4 nanotubes decreases with increase of the molar ratio of aniline to H_3PO_4 [108] as shown in Figure 6, which is a typical sample to show that the diameter of the self-assembled nanotubes is affected by the molar ratio of monomer to dopant. Of course, one can change the dopant structure and dopant concentration at the same time to control the size of the nanotubes. For instance the diameter of PANI nanotubes doped with different naphthalene sulfonic acids (e.g., α-NSA, β-NSA, and 1,5-DNSA, whose which position and number of $–SO_3H$ groups attached to the naphthalene ring are different) increases with increase of the concentration of dopant [109]. For a given concentration of dopant, however, the diameter of the nanotubes depends on the dopant structure, showing order PANI-(α-NSA) > PANI-(β-NSA) > PANI-(1,5-DNSA) [109] due to their different solubilities in aqueous solution [112]. Especially, PANI–Cn-(ABSA) reported by Qiu and Wan [103] provided another good example that the diameter of the

nanotubes is affected by the dopant structure, showing the diameter decreased from 275 to 200 nm when the n value of Cn–ABSA dopant changed from 2 to 10.

C_{60} or Carbon Nanotube Derivatives as Dopants In principle, C_{60} or CNT derivatives with $–OSO_3H$ groups can be used as the dopant for conducting polymers, especially PANI because of its proton-doping characteristic [112–123]. Obviously, self-assembly of conducting polymer nanotubes doped with C_{60} or CNT derivative as a dopant is a challenge in the field of nanomaterials. Up to now, only a few papers dealing with these issues have been reported in the literature [102, 114]. Qiu et al. [102], for example, reported that PANI
Figure 5. Effect of addition water on the diameter of self-assembled PANI–$C_{60}(OSO_3H)_6$ nanotubes. Reprinted with permission from [102], H. J. Qiu et al., *Macromolecules* 34, 675 (2001). © 2001, American Chemical Society.

nanotubes can be synthesized by *in-situ* doping polymerization in the presence of sulfated C_{60} [$C_{60}(OSO_3H)_6$] as a dopant. It was reported that the PANI–$C_{60}(OSO_3H)_6$ nanotubes are formed through a self-assembly process because of $C_{60}(OSO_3H)_6$ acting as template in the formation of PANI–$C_{60}(OSO_3H)_6$ nanotubes and as a dopant at the same time due to the hydrophilicity of $C_{60}(OSO_3H)_6$. When water is absent in the reaction system, however, only grains are obtained, indicating addition of water during polymerization is a necessary condition for self-assembly of PANI–$C_{60}(OSO_3)H_6$ nanotubes. Moreover, changing the addition of water during polymerization can control the size of the resulting PANI–$C_{60}(OSO_3H)_6$ nanotubes (see Fig. 5). Meanwhile, the flexibility of the nanotubes is enhanced slightly by increasing the addition of water during polymerization. The effect of water during the polymerization on the formation,
size, and flexibility of the nanotubes might be due to hydrogen bonding of water and polymer chains of PANI.

In particular, Wei and Wan [114] synthesized the PANI nanotubes doped with sulfated multiwall carbon nanotubes [MWNT–$(OSO_3H)_n$] as the dopant by *in-situ* doping polymerization without using any external template. It was noted that by changing only the molar ratio of aniline to MWNT–$(OSO_3H)_n$ one could obtain two kinds of PANI nanotubes. One is PANI coated MWNT–$(OSO_3H)_n$ [represented by PANI–*c*-MWNT–$(OSO_3H)_n$]; another is MWNT–$(OSO_3H)_n$ doped PANI nanotubes [represented by PANI–*d*-MWNT–$(OSO_3H)_n$]. When the molar ratio of aniline to MWCNT–$(OSO_3H)_n$ is less than or equal to 1 (e.g., 1/2 or 1/1), for instance, the polymerization of aniline occurs dominantly on the surface of MWNT–$(OSO_3H)_n$, resulting in formation of PANI coated MWNT–$(OSO_3H)_n$ [i.e., PANI–*c*-MWNT–$(OSO_3H)_n$]. The coaxial structures of the resulting PANI–*c*-MWNT–$(OSO_3H)_n$ nanotubes are conformed by TEM images and electronic diffraction. Moreover, TEM images clearly show a thin layer of PANI is coated on the surface of MWNT–$(OSO_3H)_n$ nanotubes, indicating MWNT–$(OSO_3H)_n$ nanotubes only act as templates for PANI polymerization to form PANI–*c*-MWNT–$(OSO_3H)_n$ nanotubes due to hydrophilicity of aniline. When the aniline/MWNT–$(OSO_3H)_n$ ratio became high (e.g., 2/1, 4/1, and 8/1), on the other hand, MWNT–$(OSO_3H)_n$ doped PANI nanotubes [i.e., PANI–*d*-MWCNT–$(OSO_3H)_n$] formed via a self-assembly process, which was proved by SEM and TEM measurements. Their outer diameter is 100–150 nm and inner diameter is several nanometers down to even zero, depending on the polymerization conditions. Compared with PANI–*c*-MWNT–$(OSO_3H)_n$, however, the surface of the PANI–*d*-MWNT–$(OSO_3H)_n$ nanotubes is very rough. Electronic diffraction revealed that either PANI–*c*-MWNT–$(OSO_3H)_n$ or PANI–*d*-MWNT–$(OSO_3H)_n$ nanotubes are amorphous, which differs from crystal MWNT–$(OSO_3H)_n$ nanotubes.

Formation Mechanism of Self-Assembled Nanostructures Wan et al. proposed a template-like model to interpret the formation of the self-assembled conducting polymer nanotubes without using external porous membranes as templates [102]. The schematic of the formation mechanism of self-assembled nanotubes or nanofibers is given in Figure 7a. The template-like model means that the micelles formed by dopant and/or monomer/dopant salt or supermolecules act as templates in the formation of the nanotubes. Based on this model, it is easy to understand that the essence of the method proposed by the author is a typical self-assembly process because of dopant providing counterions for doping and acting as a template in the formation of nanotubes at the same time. Now let us discuss the formation mechanism of the self-assembled nanotubes when dopant is with and without surfactant function in detail.

Dopant with surfactant function, such as NSA, $C_{60}(OSO_3H)_6$, PMMA4, PTSA, and Cn–ABSA, is easy to form micelles in an aqueous solution due to its hydrophilicity of –SO_3H group of the dopants. The micelles are expected to form spherical micelles through micellerization due to lower surface energies. Moreover, aniline monomer reacts with dopant to form an aniline/dopant salt through

Figure 6. Inference of [An]/[H_3PO_4] on the average diameter of self-assembled PANI–H_3PO_4 nanotubes. [SDBS] = 2.4×10^{-3} M, at 0–4 °C. Reprinted with permission from [167], Z. M. Zhang and M. X. Wan, *Synth. Met.* 175, 135 (2003). © 2003, Elsevier.

acid/base reaction at the same time. As a result, the anilinium cations coexist in the reaction solution. Those anilinium cations can diffuse into the surface of the spherical micelles by electrostatic interaction. Moreover, these spherical micelles are further aggregated to form cylindrical micelles through a self-assembly process. It is reasonable to believe that the self-assembled cylindrical micelles might act as templates in the formation of nanotubes. After adding oxidant [e.g., $(NH_4)_2S_2O_8$], the polymerization only takes place at the micelle/water interface due to the hydrophilicity of oxidant [115]. The growth of the nanotubes is accessed [116] or enlongated [117] by polymerization and aggregation. When the molar ratio of aniline to dopant is high, however, free aniline can diffuse into the micelles to form aniline filled micelles. Those aniline filled micelles might act as templates in forming nanofibers. That is why both nanotubes and nanofibers can be observed in the experiment, and their yield depends upon the synthesis conditions, especially the molar ratio of aniline to dopant. See Figure 7.

In the aniline/MWNT–$(OSO_3H)_n$ system, however, the H_2O-dispersed MWNT–$(OSO_3H)_n$ might play two roles. One

acts as the supramolecular template with anilinium cations [108] in the formation of the nanotubes. Another acts as a dopant, which in turn is generated by H^+ transfer form the –SO_3H groups to enhance the electrical conductivity of PANI. In fact, the doped PANI or its oligomer is a kind of cationic polyelectrolyte with a very rigid backbone structure, which has the tendency to form self-assembled cylindrical micelles induced by the anionic-type MWNT–$(OSO_3H)_n$ in the process of polymerization, leading to the formation of PANI–d-MWCNT–$(OSO_3H)_n$ nanotubes [118, 119].

2.2. Spectroscope Characterization

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are used to measure the morphology of the resulting materials. In particular, TEM is a powerful route to prove if the resulting nanofibers are hollow. Moreover, elemental analysis, the ultraviolet-visible (UV-vis) absorption spectrum, X-ray photoelectron spectroscopy (XPS), and Fourier transform infrared (FTIR) spectra as well as X-ray diffraction are used to characterize the molecular structure of the resulting nanotubes. It was found that the main chain of the nanotubes is identical to that of conventional conducting polymers (i.e., granular conducting polymers). However, it is expected that the polymer chain of nanotubes synthesized by the template method should be reined due to template pores. How can we prove it? Usually X-ray diffraction, Raman spectra, and polarized infrared absorption spectroscopy (PIRAS) are used to prove that the template-synthesized nanotubes show supermolecular order [120]. PIRAS entails measuring the absorbance by the sample of two orthogonal polarizations of IR radiation [121]. In PIRAS measurements, one polarization is perpendicular to the axes of the nanotubes ($I_\perp$) and the other has a component that is parallel to the nanotube axes ($I_\parallel$). In general, if $I_\perp$ and $I_\parallel$ are absorbed to the same extent, the polymer chain shows no preferred orientation. Unequal absorbance indicates that the polymer chains are preferentially aligned. PIRAS data can be quantified by calculating a parameter called the dichroic ratio (R). If the R value is equal to 1, meaning no preferential chain alignment, while an R value less than 1 means some degree of alignment, the lower the R, the greater the extent of alignment. Martin et al. [125] reported that the R value of PPy nanotubes reduced with decreasing temperature, indicating the alignment degree of polymer chain at lower temperature is higher than that at high temperature. Moreover, the Raman spectrum is also a powerful tool to prove the orientation of polymer chains. Fu et al. [123] proved that the polymer chain in the skin of polythiophene nanotubes (20–200 nm in diameter), which were synthesized electrochemically by a template-synthesis method (microporous alumna membranes as templates) in the presence of boron trifluoride dietetheate as a dopant, is oriented [123]. Wei and Wan [105] reported that the electronic structure of PANI–$C_{60}(OSO_3H)_6$ nanotubes is identical to that of either doped or dedoped PANI, depending on the solvent used. But influence of morphology on the electronic structure of PANI–$C_{60}(OSO_3H)_6$ nanotubes can be legible. In general, the crystallinity of the nanotubes depends on the polymer chain, dopant and polymerization method [92–111].

In most case, the nanotube is partially crystalline due to special tubular morphology. In particular, it was found that the crystallinity of the nanotubes is affected by the self-assembled micelles, which act as templates in the formation of the nanotubes. Yang and Wan [101] reported that PPy–PTSA nanotubes are partially crystalline and all sharp peaks observed in the PPy–PTSA nanotubes are in excellent agreement with that of pyrrole/PTSA supermacromolecular clusters, which act as templates in the formation of PPy–PTSA nanotubes. On the other hand, their grains are amorphous [101]. In addition, Wei and Wan [114] found that the Raman spectra of PANI–d-MWNT–$(OSO_3H)_n$ nanotubes differs from that of PANI–c-MWNT–$(OSO_3H)_n$ nanotubes, which might result from the different conformation of PANI in both of the nanotubes [124]. This is further confirmed by UV-vis spectra, showing more extended conformation of the PANI chain in the PANI–d-MWNT–$(OSO_3H)_n$ nanotubes due to its nanotubular structure [114].

2.3. Properties

2.3.1. Electrical Properties

Conductivity of conducting polymer nanotubes at room temperature is one of the important parameters to be understood. The four-probe method on pallet or freestanding film is usually used to measure the conductivity of the conducting polymers. However, the conductivity of nanotubes synthesized inside the pores is obtained by measuring bulk resistance across the filled membrane by the two-probe method. The surface layer of conducting polymers on the membrane can contribute to the resistance measurement but cannot be completely removed because it ensures contact between the tubes and the electrical wires [126] when the thickness of this surface layer is thin (∼100 nm) because such a thin layer did not contribute to the membrane resistance [13]. By measuring the bulk resistance across the filled membrane using the two-probe method, one can calculate the conductivity of a single nanofiber or nanotube when the diameter (d) and length (L) of the pores are known. Usually, one side of the membrane is held on a copper electrode, and two copper wires contact the other side of the membrane. Silver paste ensures a good contact and allows a well-defined cross section for calculating the conductivity. Therefore, the conductivity along a single fiber or tube can be calculated from the resistance measurement (R), which can be written as

$$1/R = 1/R_f + 1/R_m \qquad (1)$$

where R_f is the parallel sum of the resistance of the conductive polymer fibers or tubes, and R_m is the resistance of the membrane. In most cases, R_m can be neglected because $R_m \gg R_f$. As a result, Eq. (1) can be simplified into

$$1/R = 1/R_f = n/R_I \qquad (2)$$

where n is the number of nanotubes or nanofibers in the measurement area, and R_i is the resistance of an individual fiber or tube. Knowing the diameter (R) and length (L) of the pores, the conductivity (σ) of a single fiber or tube can be calculated according to the following equation:

$$\sigma = L/(R_i \pi d^2/4) \qquad (3)$$

Martin [13] reported that conductivity of PANI nanotubes measured by this method was enhanced by one or two orders of magnitude when the diameter decreased, showing a size effect on the electrical properties of the nanotubes or nanowires. Similar phenomena have also been observed from PPy nanotubes [125–127]. In principle, the electrical properties of conducting polymers are determined by their electronic structure. The charge transport occurs via mobility of charge carriers (polaron and bipolaron) along segments of the conjugated polymer chains and by hopping of these charges from chain to chain. The carrier mobility is the limiting parameter of the electrical conductivity and depends mainly on two factors: the interchain distance and the frequency of interchain hopping. The frequency of interchain hopping can be reduced either by increasing the conjugation length or by orienting the polymer chain. Thus, the polymer chains of the nanotubes synthesized inside of pores are forced to align within the environment of the host matrix and an enhancement of the conductivity can be expected. The enhancement of conductivity is attributed to the presence of a large ratio of polymer chain within narrow conducting polymer tubes.

Except for size effects on the conductivity of the nanotubes, the conductivity is also dependent upon the synthesis conditions, especially the molar ratio of monomer to dopant. Qui et al. [102] reported that changing the addition of water during polymerization can control the size of the resulting PANI–$C_{60}(OSO_3H)_6$ nanotubes (i.e., the diameter decreases with increase of the addition of water during polymerization). Moreover, it was found that room-temperature conductivity of self-assembled conducting polymer nanotubes depends on not only the doping degree but also the dopants used. For instance, the conductivity of PANI nanotubes (150–340 nm in diameter) doped with HCl, H_2SO_4, HBF_4, and H_3PO_4 is in the range of 0.49–6.38 S/cm, and an order of PANI–HCl > PANI–H_2SO_4 ≈ PANI–HBF_4 > PANI–H_3PO_4 is observed [108]. Moreover, the conductivity of PANI–H_3PO_4 nanotubes deceases with increase of the molar ratio of aniline to H_3PO_4 due to deceasing doping degree measured by XPS as shown in Figure 8. Obviously, the polymer also affects the conductivity of the nanotubes. Qiu [103] reported that the conductivity of PANI–Cn–ABSA ($n = 2, 4, 6, 8$, and 10) depends on the number of alkyl groups on the ABSA dopant, showing a maximum conductivity at $n = 6$. Moreover, Kosonen et al. [63] observed that the electrical conductivity of $(PANI–CSA)_{0.5}(Heres)_y$ increases two orders of magnitude upon formation of cylindrical structures potentially due to conformation of PANI chains within the cylinders. This is a good example of the effect of tubular morphology on the conductivity of conducting polymers.

Temperature dependence of conductivity measured by the four-probe method is an important route to understanding the conducting mechanism of conducting polymer nanotubes. It exhibits a metallic behavior if the conductivity increases with decrease of temperature ($\partial\sigma/\partial T < 0$), but it is semiconducting when conductivity increases with increase of temperature ($\partial\sigma/\partial T > 0$). Temperature dependence of conductivity for the self-assembled conducting polymer nanotubes always exhibits semiconducting behavior and obeys a
Figure 8. Effect of [An]/[H$_3$PO$_4$] on room temperature conductivity and doping degree of PANI–H$_3$PO$_4$ nanotubes, x room temperature, O doping degree. [An]/[H$_3$PO$_4$] = 2, [SDBS] = 2.4 × 10^{-3} M, at 0–4 °C. Reprinted with permission from [108], Z. M. Zhang et al., *Macromolecules* 35, 5937 (2002). © 2002, American Chemical Society.

variable range hopping (VRH) model proposed by Mott and Davis [128], which is expressed as

$$\sigma(T) = \sigma_0 \exp[(-T_0/T)^{1/n+1}] \qquad n = 1, \ 2, \ \text{and} \ 3 \quad (4)$$

where $T_0 = 8\alpha/ZN(E_F)K_B$, α^{-1} is the localization length, $N(E_F)$ is the density of state at the Fermi level, K_B is the Boltzmann constant, and Z is the number of nearest neighbor chains. The T_0 value corresponds to the hopping energy barriers of charge carriers, which can be obtained from the slope of the straight line of Log σ vs $T^{1/n+1}$. The T_0 value and n number (corresponding to 1D, 2D, and 3D at $n = 1, 2$, and 3 respectively) are affected by the polymer chain, dopant, and polymerization [93–97, 99–101, 108, 111]. It noted that PPy nanotubes obey the 3D-VRH model [99–101], while PANI nanotubes always show a 1D-VRH model [93, 108, 109]. The temperature dependence of conductivity of PANI self-assembled nanotubes doped with different inorganic acids is shown in Figure 9. As one can see, the data are best fit to the relationship of ln σ plotted vs $T^{-1/2}$, showing a 1D-VRH model [128]. The T_0 values follow the order PANI–H$_3$PO$_4$ > PANI–HBF$_4$ > PANI–H$_2$SO$_4$ > PANI–HCl. This is consistent with a trend of their room-temperature conductivity [108].

However, the room-temperature conductivity data, especially its temperature dependence, obtained based on this described method is not intrinsic due to large contact resistance between nanotubes. Therefore, direct measurement of single nanotube conductivity is necessary in order to obtain intrinsic conductivity of the nanotubes and its temperature dependence is required. Park [129] Recently reported that the conductivity of a single nanotube or nanowire can be measured by scanning tunneling microscopy technology, showing the conductivity of the single nanotube or nanowire is one or two orders of magnitude larger than that of bulk materials. However, modification of this method or development of new methods is required.

2.3.2. Other Properties

Fu et al. [123] reported that the aligned polythiophene nanotube/gold layered film shows broad and strong redox response and its charge/discharge capacity is about 30 times that of the usual polythiophene. These results present new opportunities for studying the electronic and optical properties of well-organized nanoparticle superstructures. Wan et al. found that PANI self-assembled micro/nanotubes exhibit an unusual magnetic loss at microwave frequency ($f = 1$–18 GHz) [92]. This is quite different from conventional conducting polymers that only have electrical loss without any magnetic loss at the same frequency. The unusual electromagnetic loss at the microwave frequency observed from nanotubes may be related to a special tubular morphology, arising from ordering caused by charge carrying polarons [92]. This result indicates that conducting polymer micro/nanotubes can be used as new stealth materials with advantages being lightweight with wide frequency band and high absorption, which are important in stealth technology. In addition, Zhang et al. [108] observed that PANI–H$_3$PO$_4$ nanotube films deposited on the glass substrate exhibited hydrophilic behavior, which was conformed by measuring contact angle with water ($O = 32°$), especially the hydrophilicity of PANI nanotubes is affected by the dopant used. For example, PANI–HCl, PANI–H$_2$SO$_4$, and PANI–HBF$_4$ films all are hydrophilic, and their contact angles with water are 40°, 38°, and 27°, respectively.

Hong et al., utilizing the redox reaction of CHQ nanotubes with novel metal ions, have made silver nanowires arrays which would be useful for molecular electronic devices [62]. Moreover, they have also reported that the organic nanotubes could also be used as a model for selective water/ion channels in biological systems and a nanohost to include size–specific guest molecules. Lui [70] and Ni et al. [71] reported that the incorporation of the polyferrocene block offers the opportunity to access self-assembled materials with redox-active, semiconducting, or preceramic

nanodomains, or large periodic variation in the refractive index suitable for optical and phonic applications [72–74].

3. CONDUCTING POLYMER NANOFIBERS

3.1. Synthetic Methods

In principle, the template-synthesis method can be used to prepare conducting polymer nanofibers. However, the length of the resulting nanofibers is limited by the thickness of the porous membrane as templates. As a result, it is difficult to prepare long conducting polymer nanofibers by using the template-synthesis method. On the other hand, the electrospinning method invented in the 1930s [130] is a route to prepare ultrafine fibers of conventional polymers. This technique has been recently rediscovered for applications such as high performance filters [131, 132] and for scaffolds in tissue engineering [133] that utilized the unique characteristic of the high surface area (10^3 m^2/g) provided by the fibers.

In the electrospinning method to prepare fibers, in general, a high electrical field is generated between a polymer fluid contained in a glass syringe with a capillary tip and a metallic collection screen. When the voltage reaches a critical value, the charge overcomes the surface tension of the deformed drop of the suspended polymer solution from on the tip of the syringe, and a jet is produced. The electrically charged jet resulting in the hyperstretching of the jet undergoes a series of electrically induced bending instabilities during its passage to the collection screen that results in the hyperstretching of the jet. These stretching processes accompanied by the rapid evaporation of the solvent molecules reduce the diameter of the jet. The dry fibers are accumulated on the surface of the collection screen, resulting in a nonwoven mesh of nano- to microdiameter fibers. The length of the nanofibers by the electro-spinning method is larger than that of the template-synthesis method.

It has been demonstrated that the fiber shape can be influenced by many parameters, such as the polymer, solvent, surface tension, solution viscosity, and solution conductivity. Changing the charge density and polymer solution concentration can control the fiber diameter [133]. For example, Norris et al. [134] reported the influence of solution viscosity on the formation of PANI–CSA fibers by the electrospinning method. They found that without the addition of PEO to PANI/CSA dissolved in chloroform no fiber formation occurred, as the viscosity and surface tension of the solution were not high enough to maintain a stable drop at the end of the capillary tip. Adding more doped PANI also could not increase the viscosity of the polymer solution, as the capillary tip had a very low solubility in chloroform. A stable drop at the end of the capillary tip was achieved once 2 wt% PEO was added to the solution.

Based on the electrospinning concept, Bognitzki et al. [135] have developed a straightforward and highly versatile template method for the production of polymer, metal, and hybrid nano- and mesotubes. The general concept is to take such extremely thin degradable template polymer fibers, which are prepared by the electrospinning method, and coat them with the desired wall materials using various types of deposition techniques. MacDiarmid et al. [136] have

recently reported polycrylonitrile and polyrene fiber can be easily and informally coated from aqueous solution with conducting polypyrrole or with Au by electrolyse deposition. In particular, polycrylonitrile fibers can be thermally converted to conducting carbon nanofibers, which may be a new route to prepare carbon nanofibers.

3.2. Characterization and Properties

Since only a few studies are on conducting polymer fibers prepared by an electrospinning method, structural characterization and physical properties of electrospun conducting polymer fibers have seldom been reported in the literature. However, MacDiarmid et al. [136] investigated the molecular structure and electrical properties of electrospun PANI/PEO blend ultrafine fibers. They reported that absorption spectra of PANI/PEO fibers were consistent with those of PANI in the emeraldine salt oxidation state and no other absorption bands were observed, indicating that the high voltage used in this electrostatic process did not result in any overoxidation of the PANI chains. Moreover, dedoping of the electrospun PANI/PEO fibers could not be achieved by suspending the nonwoven mat in 0.1 M ammonium hydroxide aqueous solutions since the water dissolved the PEO and caused the fibrous network in the nonwoven mat to break apart. Instead, dedoping of the electrospun mat PANI/PEO fibers was achieved by suspending the nonwoven mat in ammonia vapor.

In addition, they observed that the conductivity of electrospun PANI/PEO fibers was lower than that for a cast film at the same concentration of PANI, which was unexpected. There may be two reasons for that: one is that measuring the conductivity of the nonwoven mat was considerably more difficult than measuring the conductivity of the cast film due to the difficulty in obtaining an accurate thickness. Another is that the nonwoven mat is highly porous and therefore the "fill factor" of PANI filberts is less than that of a cast film. However, the dependence of conductivity of PANI/PEO filberts with the weight of PANI in blend is similar to that of a PANI/PEO blend film [137].

4. MULTIFUNCTIONALIZED NANOTUBES

Multifunctionalization of conducting polymer nanotubes with electrical, optical, and magnetic properties is another aspect of nanomaterials and nanotechnology because of the unique properties and promising potential applications in nanotechnology. Recently, some PANI multifunctionalized nanotubes with electrical, optical, and magnetic properties via the self-assembly process have been reported [138, 139]. In this section, the synthesis method, characterization, and physical properties are discussed, especially the formation mechanism of the self-assembled electrical, optical, and magnetic composite nanotubes containing inorganic nanoparticles.

4.1. Synthetic Methods

Two methods can fabricate multifunctionalized conducting polymer nanotubes with electrical, optical, and magnetic properties. The first method is to co-structure multifunctionalized nanotubes by using functionalized dopant. The second

method is self-assembly of composite nanotubes of conducting polymers in the presence of optic and magnetic inorganic nanoparticles.

4.1.1. Functionalized Dopant as a Template

As described, one can prepare multifunctionalized nanotubes with electrical, optical, and magnetic properties through a self-assembly process by using functionalized dopants as templates. In this method, the dopant acts as a doping and template function at the same time. That is to say, functionalized dopants not only contribute multifunction but also act as templates in the formation of the nanotube.

As one knows, azobenzene and its derivatives are generally characterized by reversible transformations from the more state *trans* to the less state *cis* form upon irradiation with UV light [140]. Moreover, the photoinduced isomerization of azobenzene moiety is always accompanied by a structural change as reflected in the changes of dipole moment and geometry [141]. In addition, azobenzene can be selectively attached to the side chains, main chain, cross–links, or chain ends of the polymers with photochromic characteristics. The photochromic characteristic may provide light control the chemical characteristic by an "on–off" light switch. Thus, it is expected that azobenzene derivatives with $-OSO_3H$ groups can be used to dope PANI, resulting in electro-optical PANI. Huang et al. [138] recently reported that conductive PANI nanotubes 110–130 nm in diameter can be synthesized via a self-assembly process in the presence of azobenzene sulfonic acid as a dopant for the fist time. They found that the formation probability and size of PANI–ABSA nanotubes depend on the molar ratio of aniline to ABSA and the concentration of ABSA.

Furthermore, chiral conducting polymers are of considerable interest because of their potential applications. Electrodes for electrochemical asymmetric synthesis [142, 143], modified electrodes capable of performing stereoselective analysis [143, 144], novel chiral stationary phases for chromatographic separation of enantiomers [145–147], microwave absorbents [148, 149], and electroactive chiral membranes for selective transport enantiomer chemicals [150] have been reported. Optically active conducting polymers, such as PPy [151], polythiophene [152], and polyaniline [153], have been reported in the literature. However, nanotubes of these chiral conducting polymers have seldom been investigated. Yang et al. [139] recently reported chiral nanotubes of PANI doped with (S)-$(-)$-2-pyrrolidone-5-carboxylic acid [(S)-PCA] or (R)-$(+)$-2-pyrrolidone-5-carboxylic acid (R)-PCA as a dopant via a self-assembly process for the first time. SEM and TEM images proved that most of the nanotubes with 80–220 nm outer diameter and 50–130 nm inner diameter are hollow along the whole length, and the aspect ratio of these nanotubes varies from 6 to 12. Those chiral nanotubes are independent upon the configuration of PCA dopant. However, morphology, size, and yield of PANI–(S)-PCA and PANI–(R)-PCA nanotubes are affected by the synthesis conditions, especially the aniline concentration and the molar ratio of aniline to PCA. When the concentration of aniline monomer was about 0.04 mol L^{-1}, for instance, the resulting PANI–(S)-PCA was

tubes, but as the concentration of aniline was higher (e.g., 0.1 or 0.35 mol L^{-1}), only granular PANI–(S)-PCA was obtained. Moreover, when the molar ratio of aniline to PCA was 2, the percentage of the nanotubes in both cases was decreased. If the molar ratio of aniline to PCA was higher or lower than 2, on the other hand, almost no tubes were observed.

4.1.2. Dopant Containing Inorganic Nanoparticles as a Template

Another easy way to costructure multifunctionalized conducting polymer nanotubes synthesis through a self-assembly process in the presence of optic and magnetic inorganic nanoparticles. Zhang and Wan [154] recently reported that PANI–NSA/TiO_2 nanotubes with average diameters of 90–130 nm were synthesized through the self-assembly process in the presence of β-NSA as the dopant. The morphologies and formation yield of the composite nanotubes were affected by the content of TiO_2 in the composites. In particular, the diameter of the composite nanotubes decreases with increasing the content of TiO_2 nanoparticles in the composites.

Obviously, preparation of conducting polymers containing magnetic nanoparticles has also attracted attention because of their unique electrical, optical, and magnetic properties, which result in many potential applications in electromagnetic interference shielding [155], electrochromic devices [157], and optical systems [158]. A lot of papers dealing with electromagnetic composites of conducting polymers have been reported [159–166]. Yaneyama et al. [159] and Partch et al. [160], for instance, reported an incorporation of metal oxide particles into PPy during electrochemical polymerization. In particular, Tang et al. [161] have developed a versatile process employing anionic surfactants to prepare processable freestanding films of PANI containing nanomagnets of γ-Fe_2O_3 as high as 50%. Moreover, Wan et al. [162–166] also reported a series of PANI and its derivative or PPy composites containing nanomagnetic particles (Fe_3O_4) prepared by a chemical method, showing high saturated magnetization ($Ms = 10$–40 emu/g) with a superparamagnetic behavior (i.e., $Mr = 0$ and $Hc = 0$), and high conductivity (10^{-1}–10^1 S/cm). However, nanotube or nanowire composites of conducting polymers containing magnetic nanoparticles have seldom been reported. Zhang and Wan [167] recently reported that composite nanowires of PANI–NSA containing Fe_3O_4 nanoparticles ($\sim$10 nm in diameter) with an average diameter of 80–100 nm were prepared by a self-assembly process in the presence of β-NSA as a dopant. However, TEM shows most of them are solid, but a small quantity is hollow. Here, it should be noted that the self-assembled composite nanotubes containing inorganic nanoparticles (e.g., PANI–NSA/TiO_2 or PANI–NSA/Fe_3O_4) described previously are quite different from the coated carbon nanotubes with other materials. In case of coated or filled carbon nanotube composites, carbon nanotubes only act as templates. In case of self-assembled composite nanotubes (e.g., PANI–NSA/TiO_2 or PANI–NSA/Fe_3O_4), however, conducting polymers and inorganic nanoparticles costructure to form composite nanotubes through a self-assembly process. There is evidence to

prove it. One is that some black dots ~10 nm in diameter embedded in the nanofibers or in the skin of PANI–NSA/Fe_3O_4 nanotubes are observed by means of TEM measurements [163]. Moreover, electronic diffraction patterns further proved that those black dots are Fe_3O_4 because those dots are not present in PANI–NSA nanotubes [163]. Further evidence is that the Ti element is only observed on the skin of PANI–NSA/TiO_2 composite nanotubes by an energy distribution spectrum [154].

4.1.3. Formation Mechanism

In Section 1, author proposed a template-like model to interpret the formation of the self-assembled conducting polymer nanostructures including nanotubes and nanowires without using external membranes as templates [102]. The template-like model means that the micelles formed by dopant and/or monomer/dopant salt or supermolecules act as templates in the formation of the nanostructures. Now it is easy to understand the formation mechanism of the self-assembled composite nanotubes or nanofibers containing inorganic nanoparticles. However, the substance of the templates in the composite nanotubes is quite different from that of the self-assembled nanotubes without inorganic nanoparticles.

In case of PANI–NSA/Fe_3O_4 [109] or PANI–NSA/TiO_2 nanostructures [154], Fe_3O_4 or TiO_2 nanoparticles are dispersed in NSA solution before polymerization. As a result, it is possible to form a "core–shell" structural mixture in which Fe_3O_4 or TiO_2 nanoparticles act as "core" and NSA dopant act as "shell." So aniline/NSA micelles containing Fe_3O_4 or TiO_2 nanoparticles might form due to the hydrophobility of aniline and hydrophilicity of –SO_3H group of NSA. If NSA is assigned as a "tail" and aniline containing Fe_3O_4 or TiO_2 nanoparticles as a "head," the micelles with "head–tail" structure can be formed. Therefore it is reasonable to believe that the resulting "head–tail" micelles might act as templates in forming composite nanostructures containing inorganic nanoparticles. The formation process of the composite nanotubes is as same as that of self-assembled nanostructures in the absence of inorganic nanoparticles, and a possible formation schematic of PANI–NSA/Fe_3O_4 or PANI–NSA/TiO_2 nanostructures is shown in Figure 7b.

4.2. Characterization

Elemental analysis, FTIR, UV-vis absorption, XPS, and X-ray diffraction are also used to characterize the molecular structure of multifunctionalized nanotubes of conducting polymers. The molecular structure of the multifunctionalized nanotubes of conducting polymer is identical to that of conventional conducting polymers. For instance, FTIR measurements indicated that the main chain of chiral PANI–(s)-PCA or PAN–(D)-PCA nanotubes [139] is similar to that of conventional doped PANI [112]. However, some differences in the FTIR spectrum between chiral and conventional PANI were observed [139]. Meanwhile, the electronic structure of chiral PANI nanotubes measured by UV-vis absorption spectra is identical to that of conventional PANI [112]. However, inference of the configuration of the chiral dopant (PCA) on its electronic structure is not observed. X-ray scattering patterns of the chiral nanotubes observed

a very sharp peak at $2\theta = 6.43$ ($d = 13.73$ Å), which is assigned to the periodicity distance between the dopant and N atom on the adjacent main chain of PANI. This results from tubular morphology because it is absent from its grains [139].

Similarly, the molecular structure of composite nanotubes containing inorganic nanoparticles is also identical to that doped conducting polymers. However, X-ray scattering peaks of those inorganic nanoparticles can always be observed from that of composite nanotubes. For instance, both characteristic peaks of PANI–NSA nanotubes and Fe_3SO_4 nanoparticles can be observed from that of PANI–NSA/Fe_3O_4 nanotubes [109]. This indicates that there is no chemical interaction between Fe_3O_4 and PANI–NSA in the composites. In addition, a sharp peak at $2\theta = 8.8$ assigned to the scattering along the orientation parallel to the PANI chain [168] can be observed in the composite nanotubes. Interestingly, it is absent from doped PANI by a common method [112], indicating the polymer chain in the nanotubes is partially oriented along the polymer chain due to tubular morphology.

4.3. Properties

In general, the room-temperature conductivity of multi-functionalized nanotubes depends on the polymer chain, dopant, synthesis method, and conditions, which are similar to those in the nanotubes described in Sections 1 and 2. In most cases, the conductivity of functionalized nanotubes containing inorganic nanoparticles is lower than that without inorganic nanoparticles due to the electrical insulating behavior of those inorganic nanoparticles. For example, the conductivity of PANI–NSA/Fe_3O_4 nanotubes decreases with increasing content of Fe_3O_4 in the composites [109]. In some cases, however, adding nanoparticles in the composites can enhance the conductivity of composite nanotubes containing inorganic nanoparticles. A typical sample is that the conductivity of PANI–NSA–TiO_2 nanotubes increases with increase of the content of TiO_2 nanoparticles in the composites [154], which is consistent with results reported by Su and Kurumoto [169]. The temperature dependence of the conductivity for those multifunctionalized nanotubes shows semiconducting behavior and obeys the VRH model [128], which is similar to that of nanotubes described in Sections 1 and 2.

It is expected that the multifunctionalized nanotubes exhibit some new interesting properties except for electrical properties. The resulting multifunctionalized nanotubes, such as chiral PANI–PCA [139], PANI–ABSA [138], PANI–NSA/Fe_3O_4 [167], and PANI–NSA/TiO_2 nanotubes [154], show very interesting optic and magnetic properties. For electro-optic nanotubes, for example, PANI–ABSA [138] nanotubes exhibited *trans–cis* photoisomerization, which is similar to that of azobenzene moiety, upon irradiation with UV light ($\lambda = 365$ nm). However, the rate of photoisomerization of PANI–ABSA is reduced in comparison to that of ABSA by measuring the kinetics of photoisomerization, indicating the doped *trans*-azobenzene moieties along the PANI backbone, probably owing to steric hindrance, are more resistant to the photoisomerization process in comparison with small molecular ABSA [138]. In addition, Yang

and Wan [139] recently reported chiral nanotubes of PANI–(S)-PCA and PANI–(D)-PCA nanotubes showing a positive and negative Cotton effect measured by circular diachroism, indicating helical screw of the polymer chain is observed in the chiral nanotubes. Moreover, Zhang and Wan [154] reported that the PANI–NSA/TiO_2 composite nanotubes are hydrophobic, proved by measuring water contact angle, but the PANI–NSA nanotubes are hydrophilic. Especially, the hydrophobility of the composite nanotubes increases with increase of the content of TiO_2 nanoparticles in the composites. This result suggests that adding TiO_2 nanoparticles can change the hydrophilicity of PANI. Moreover, Zhang and Wan [167] recently reported that PANI–NSA/Fe_3O_4 composite nanofibers exhibited a superparamagnetic behavior (i.e., no hysteretic loop), and their electrical and magnetic properties can be adjusted by changing the content of Fe_3O_4 in the composites.

5. CONDUCTING POLYMER COATED CARBON NANOTUBES

Coating or filling of nanotubes with other materials is a simple and effective method to prepare electrical, optical, and magnetic composite nanotubes. In most cases, carbon nanotubes have been used to impart electrical properties to insulating materials (e.g. polymers) for electronic applications [170, 171]. On the other hand, conducting polymer coated CNTs have recently received great attention because of their unique electrical, optic, and magnetic properties and potential applications in a wide range of devices, including nanoelectronic and biomedical devices [172, 173]. Due to the mass production of CNTs [174] and soluble derivatives [175] of the carbon nanotubes, composite CNTs containing other materials have been developed rapidly. Especially, conducting polymer coated CNTs are expected to be new way to prepare new types of nanotubes. In fact, a combination of CNTs with conducting polymers has been demonstrated to lead to composite materials processing of properties of each constituent component with a significant effect [175–178]. As a result, highly efficient photovoltaic cells [179, 180], light emitting diodes with low current density and good thermal stability [181], and aligned coaxial nanowires with high surface and interface [182] based on composites of CNTs with conducting polymers have been reported.

In this section, synthesis method, characterization, and properties of conducting polymer coated CNTs are introduced.

5.1. Synthesis

In principle, conducting polymer coated CNTs can be fabricated chemically or electrochemically by *in-situ* doping polymerization in the presence of CNTs. For example, Fan et al. [183] synthesized PPy coated carbon nanotubes using *in-situ* polymerization of pyrrole on carbon nanotubes in 0.1 M HCl solution containing $(NH4)_2S_2O_8$ as oxidant at 0–5 °C. A typical synthesis process was described as follows: 0.1 M HCl solution (150 ml) containing CNTs was ultrasonically stirred at room temperature for about 0.5 h to disperse CNTs. Pyrrole monomer (0.67 g) in 100 ml HCl (0.1 M)

solution was added to the CNT suspension system with ultrasonic stirring. Then 50 ml HCl (0.1 M) solution containing $(NH_4)_2S_2O_8$ was slowly added drop by drop into the suspension system with a constant sonication. The reaction mixture was sonicated for an additional 4 h at 0–5 °C, after which the CNT/PPy powder formed was filtered and rinsed with distilled water and methanol until the filtrate was colorless. The obtained black CNT/PPy powder was dried under vacuum for 24 h. In order to prepare uniform PPy coated CNTs, the following conditions are required: (1) The reaction solution should be dilute so that CNTs can be dispersed very well. (2) The oxidant (e.g., ammonium persulfate) must be dropped very slowly so that the polymerization of pyrrole on the surface of CNTs is not too rapid. (3) Supersonic stirring is easy to disperse CNTs in the reaction, which is much better than magnetic stirring due to its insoluble in any solvent. The diameter of PPy/CNT nanotubes is about 80–100 nm, and a uniform layer of PPy on the surface of CNTs was proved by TEM measurements, indicating CNTs only act as templates for polymerization of pyrrole monomer. Especially, Pamamurthy et al. [184] recently fabricated PANI/CNT composites for Schottky electronic device application. They described the preparation of Schottky diodes in detail as follows: the mixture of the emeraldine base form of PANI with different weights present of CNTs was procured onto ITO coated glass slides. Then the slides were placed in an oven under a vacuum of 20 mm Hg at 50 °C to remove the solvent. Vapor doping of the dried films was achieved by placing the films in a closed chamber with 1 M HCl solution for 48 hr. Aluminum was then evaporated onto the front side of the samples to form Schottky contacts. Moreover, Chen et al. [185] reported thin and very uniform PPy films are successfully coated on the surface of each carbon nanotube by electrochemical polymerization. They also synthesized uniformly PPy films coated over each carbon nanotube of the well–aligned carbon nanotubes arrays by electrochemical polymerization in the aligned arrays.

5.2. Characterization

SEM, TEM, elemental analysis, FTIR, and X-ray are used to characterize the molecular structure of the resulting conducting polymer coated CNTs. Especially the Raman spectrum is a powerful tool to characterize CNTs. Fan et al. [183] used FTIR and Raman spectra to characterize the structure of PPy–CNTs. They reported that the characteristic peaks of PPy could be observed in the CNT/PPy samples, which are similar to those of PPy using a chemical and electrochemical polymerization method. The Raman spectrum of CNTs has two significant peaks at 1348 and 1578 cm^{-1}, indicating the used CNTs are multiwall carbon nanotubes because 1601 cm^{-1}, corresponding to single wall carbon nanotubes, is absent. The Raman spectrum of PPy–CNT nanotubes is similar to that of CNTs, but the intensity of those peaks in PPy–CNT nanotubes is decreased. On the other hand, the Raman spectrum of PPy shows a broad band at 1300–1600 cm^{-1} in the C=C stretching vibration range. Moreover, X-ray scattering patterns of PPy–CNT nanotubes not only have characteristic peaks of CNTs (3.42, 2.13, 1.70 A), but also show PPy amorphous characteristics (broad peak). There is no

new peak in X-ray scattering patterns of PPy–CNT nanotubes, indicating no interactions between PPy and CNTs took place.

5.3. Properties

Pamamurthy et al. [184] also reported that the electrical characteristics of PANI/CNT Schottky diodes are nearly an order of magnitude higher than those of PANI devices. Chen et al. [185] reported that the growth current of PPy on the well-aligned carbon nanotubes is much larger than that on the flat Ti/Pt substrate. Moreover, PPy-coated carbon nanotube electrodes show significantly improved electrochemical redox performance, showing that the redox charge of PPy films is enhanced significantly by carbon nanotubes. These results may lead to the possibility of using the hybrid material in high-performance, lightweight, rechargeable batteries. This is very promising that the electrode developed in this study could be used as high performance electrode in rechargeable batteries [186]. Huges et al. [187] also reported that arrays of aligned MWNTs coated with conducting polymer composites (e.g., PPy) are not only well suited for energy applications such as super capacitors and secondary batteries but also for use in devices such as sensors that would benefit from this desirable combination of properties. Fan et al. [183] measured the electrical, magnetic, and thermal properties of PPy–CNT nanotubes, but no new physical properties were observed, indicating CNTs only act as templates for pyrrole polymerization. However, they found that homogeneous solution of CNTs dispersed in PPy dissolved in m-cresol with ethanol could be formed. Based on this result, Liu et al. [188] measured third-order optical nonlinearity ($\chi^{(3)}$) of CNTs by degenerate four-wave mixing for the first time. They reported that $\chi^{(3)}$ of CNTs is about 6.460×10^{-14} esu at 1064 nm, and considering the local field correction, the contribution of one carbon atom to third-order nonlinearity is about 5.921×10^{-36} esu, which is larger than that of C_{60} (5.000×10^{-36} esu).

6. SELF-ASSEMBLED NANOTUBE DENDRITES OF CONDUCTING POLYMERS

Dendrite tubes, such as the vessels in the bodies of animals and plants, are a very popular structure in the nature [189]. Although many metal, metal oxide, and polymer dendrites have been produced by fractal growth [190–192], they are all composed of solid particles, not tubes. Recently, dendrites of carbon nanotubes have been reported [193], in which a carbon nanotube grows up from the outer walls of another one, but it is not a popular phenomenon and cannot form complete dendrites with many branches. However, Wei and Wan [194] have recently found that nanotube dendrites of PANI doped with chiral D-camphor-10-sulfonate acid (D-CSA), α-NSA, β-NSA, 1,5-DNSA, and H_3PO_4 as the dopant can be synthesized in stationary state through a self-assembly process. Typical SEM and TEM images of PANI–CSA nanotube dendrites synthesized through a self-assembly process are shown in Figure 10. In the meantime, PPy nanotube dendrites doped with PTSA were also obtained by the same
Figure 10. Typical SEM and TEM images of PANI–(D)-CSA nanotube dendrites synthesized through a self-assembly process.

method. SEM images confirmed that all resulting PANI and PPy are of fibrous morphology, but these fibers are aggregated to form dendrite morphology. Those branches spread out from the boot and each big branch has thinner branches. The diameters of the branches are in the range of 230 to 540 nm, but they become thinner and thinner along the direction from the boot to the top. Interestingly, the TEM images revealed that these branches are hollow; especially their inner diameters decreased from the boot to the top and become zero at the end. Moreover, it was found that the diameter of the branches and the aggregated morphology of the nanotube dendrites are affected by the synthesis conditions, including dopant structure, the concentration of dopant and monomer, as well as their molar ratio. The diameter of PANI–D-CSA nanotubes decreases with increase of mole ratio of aniline to D-CSA, for instance, while the branch number increases with increase of the interaction along the polymer chain. They proposed that the nanotubes are derived from an *in-situ* polymerization on a micelle template consisting of dopant and/or dopant/monomer salt through a self-assembly process [127]. Dendrite morphologies are induced by the interactions among conducting polymer chains, including interaction of hydrogen bond and ionic bond through aggregation. This method shows a possibility to prepare nanotube dendrites of conducting polymers through a self-assembly process for the first time.

7. SUMMARY

In summary, the nanomaterials, especially nanostructures (e.g., nanotubes and nanofibers, even molecule wires), of conducting polymers have attracted attention due to their unique properties and promising potential applications in nanodevices especially molecule devices. However, this field is only at the beginning because many fundamental issues need to be studied in detail. First, synthesis or preparation of new materials with unique properties, including electrical, optic, and magnetic functions, thermal and air stability, as well as process ability, is required. Second, modification of old methods and development of new methods to synthesize or fabricate nanostructures are needed. Especially, controlling morphology and size of nanotubes or nanowires through the self-assembly process is a key issue. Meanwhile, development of methods for oriented arrays of nanotubes or nanowires is a key technology to fabricate nanodevices. Furthermore, searching for new characterization routes to measure molecular structure and physical properties of nanotubes or nanowires is also a fundamental scientific issue. In particular, measurements of physical properties of single nanotubes or nanowires are required in order to understand size, surface, and quantum effects on the physical properties of single nanotubes or nanowires. Utilization of nanodevices and molecule devices strongly depends on the development of these scientific issues.

GLOSSARY

Carbon nanotubes (CNTs) Essentially tiny strips of graphite sheet rolled into tubes and capped with half a fullerene at the each end. Their diameter is just a few billionths of a meter.

Conducting polymer Fourth generation of polymer that has semiconducting and metallic properties and retains polymer's lightweight and processability. In principle, the π-conjugated polymers can be converted to the semiconducting and even metallic state by using a chemical or electrochemical doping method. The characteristic of the molecule structure consists of π-conjugated polymer chains and counterions, depending on doping type (p- or n-type).

Doping In the conducting polymers this is an important route to convert the electrical insulating state to the conducting state of the conducting polymers. On the other hand, the doping concept in conducting polymers differs from that of inorganic semiconductors. For instance, the intrinsic conducting polymer doping is a chemical or electrochemical redox reaction, while it is atom replacement in inorganic semiconductors. Moreover, dedoping can be performed in the conducting polymers, and the doping/dedoping process for conducting polymers is reversible. Thus, the conducting polymers are called intrinsic conductive polymers, which quietly differ from the conducting plastic polymers containing inorganic conducting particles (Ag and Cu nanoparticles as well carbon powders) as conducting fillers.

External template Made of porous micromembrane, which allows monomer polymerization inside the pore individually. Porous alumna prepared electrochemically from aluminum metal or track-etched polycarbonate is widely applied as an external template to synthesize nanostructures by using the template-synthesis method.

Fullerene C_{60} is a pure carbon molecule composed of at least 60 atoms of carbon and contains only hexagonal and pentagonal faces. The name is a homage to R. Buckminster Fuller for his writing on geodesic domes. Also they are referred to as Buckyballs. Fullerenes are seen as promising components of future microelectromechanical systems and in nanotechnology. Current work on fullerenes is largely theoretical and experimental.

Hydrophilic/hydrophobic Describes a contact behavior of materials with water or oil, which can be determined by water or oil contact angle, depending on the surface energies and the surface roughness of the materials.

Nanostructures Material size is in the range of 1–100 nm, and the micromorphology is complex including tubes, fibers, hollow spheres, and even nanotube junctions.

Organic light-emitting diodes (OLEDs) One of the electronic devices which can electroluminesce from conjugated polymer or organic molecule layers sandwiched between metallic electrodes. Operation of a LED is achieved when the diode is biased sufficiently to achieve injection of positive and negative charge carriers from opposite electrodes. Capture of oppositely charged carriers within the region of the polymer layer can then result in the formation of the singlet excitation, which is generated by photoexcitation across the π–π^* gap, and this can then decay radioactively to produce the same emission spectrum as that produced by photoexcitation. Charge carrier injection, transportation, and recompilation are important processes in LEDs. Especially equilibrium injection of positive (hole) and negative (electron) charge is a key to enhance the electroluminescence efficacy and brightness.

Polyaniline PANI is an unusual member of π-conjugated conducting polymer in which nitrogen atoms are incorporated between phenyl (C_6H_4) rings. It consists of three different types, depending on the oxidation state (represented as y, and $0 < y < 1$), for instance, reduced lecucoemeradine base for $y = 1$, partially oxidized emeraldine base form for $y = 0.5$, and fully oxidized pernigraniline for $y = 0$, respectively. Moreover, the electrical properties of PANI are controlled by both oxidation and protonation states, which is different from many other conducting polymers (e.g., polyacetylene) whose electrical properties are well understood by simply considering the properties of conjugated backbones.

Self-assembly Molecules can self-construct nanostructures through intermolecular weak interaction, such as van der Waals force, hydrogen bond, hydrophilic/hydrophobic interface. Recently, the self-assembly process has been widely used to synthesize or prepare nanostructures including nanotubes, nanofibers, hollow spheres, and even nanotube junctions.

Superparamagnet A type of magnetic material in which both remnant magnetization (Mr) and coercive force (Hc) are very low, even equated to zero. Sometimes they are called soft magnets.

Template-synthesis method A common and effective route for synthesizing nanostructural materials. A porous membrane as a template is required, which allows nanostructural

materials to be synthesized inside porous micromembranes, resulting in controllable size of the nanostructural materials. Especially, it is a powerful route to prepare aligned nano-structural arrays, which are fundamental units for preparing nanodevices. However, post-treatment for removing template is required, which results in disorder or destruction of the resulting nanostructures.

Van der Waals force A weak intermolecular attractive force which cannot result from ionic charges.

Chiba University, Chiba, Japan

CONTENTS

1. PRINCIPLE OF DYNAMICS OF CONDENSED MOLECULES

The band shape analysis of vibrational spectra provides useful information about the dynamics of a molecule in liquids and solutions. Since the original works of Gordon [1] and Shimizu [2], in which vibrational line profiles of dense gases, liquids, and solutions are represented by Fourier transformation of a time correlation function, many studies on molecular motion in the condensed phase have been reported [3–14]. A molecule in a condensed phase changes its temporal equilibrium orientation and vibrational phase of transition moment, owing to frequent collisions with its surroundings. In this section, such a fluctuating rotational-vibrational transition moment is considered. Here, a relevant transition moment operator $\mu(t)$ can be developed into a series in terms of the atomic displacement coordinate Q (normal coordinate) of vibrational mode ν

$$\mu(t) = \mu_0(t) + \left[\frac{\partial \mu(t)}{\partial Q(t)}\right]_{Q=0} Q(t) + \cdots \quad (1)$$

For a rotational-vibrational transition, the relevant term is

$$\left[\frac{\partial \mu(t)}{\partial Q(t)}\right]_{Q=0} Q(t) \equiv \mathbf{m}(t) \quad (2)$$

The vector $\mathbf{m}(t)$ can be written as a product of its unit vector $\hat{\mathbf{m}}$ and its modulus m

$$\mathbf{m}(t) = \hat{\mathbf{m}}(t)m(t)$$
$$m(t) = |\mathbf{m}(t)| \quad (3)$$
$$\hat{\mathbf{m}}(t) = \mathbf{m}(t)/m(t)$$

Clearly $\hat{\mathbf{m}}$ and m denote, respectively, the angle-dependent and amplitude-dependent factors of the transition moment vector. Therefore, $\hat{\mathbf{m}}(t)$ can be assigned to the purely orientational coordinate and $m(t)$ to the purely vibrational coordinate of the fluctuating rotational-vibrational transition moment. When the reorientational (rotational) relaxation and the vibrational relaxation of the transition moment are independent of each other, the infrared absorption spectral intensity $I(\omega)$ can be written as [1–3]

$$I(\omega) = \int_{-\infty}^{\infty} dt \, \exp\{-i(\omega - \omega_0)t\}$$
$$\times \langle \hat{\mathbf{m}}(0)\hat{\mathbf{m}}(t)\rangle \langle m(0)m(t)\rangle \quad (4)$$

where ω is the angular frequency and ω_0 is the band center. The function $\langle \hat{\mathbf{m}}(0)\hat{\mathbf{m}}(t)\rangle$ corresponds to the reorientational correlation function, and $\langle m(0)m(t)\rangle$ to the vibrational correlation function. Here the reorientational and vibrational relaxation times, τ_r and τ_v, are defined as

$$\tau_r = \int_0^{\infty} dt \langle \hat{\mathbf{m}}(0)\hat{\mathbf{m}}(t)\rangle \qquad \text{and}$$
$$\tau_v = \int_0^{\infty} dt \langle m(0)m(t)\rangle \quad (5)$$

If we assume that the reorientational and vibrational relaxation do not depend on each other and the reorientational and vibrational correlation functions have an exponential form, $I(\omega)$ has a Lorentzian shape, and thus the measured half-band width $\Delta\nu_{1/2}$ (cm^{-1}) of $I(\omega)$ is expressed as a sum

$$\Delta\nu_{1/2} = \Delta\nu_r + \Delta\nu_v \quad (6)$$

where

$$\Delta\nu_r = (2\pi c\tau_r)^{-1} \qquad \text{and} \qquad \Delta\nu_v = (2\pi c\tau_v)^{-1} \qquad (7)$$

Then the half-band width of the infrared band for a single vibrational transition has information about the reorientational and vibrational relaxation of a condensed molecule. Although the infrared measurement cannot divide spectroscopically the reorientational and vibrational relaxation processes, the vibrational relaxation time obtained from the isotropic part of Raman scattering can be diverted to evaluate the reorientational relaxation time [3]. These principles should also be applied to study the dynamics of molecules confined in nanoscale pores.

2. THEORETICAL DESCRIPTION OF CONFINED MOLECULES

Confined fluids in nanopores have received considerable attention in recent decades. The molecule-nanopore interaction should induce interesting phenomena, such as micropore filing and capillary condensation. Modern methods, such as grand canonical Monte Carlo (GCMC) simulation [15–17], molecular dynamics (MD) [18], and density functional theory (DFT) [19, 20], have led to substantial progress in understanding adsorption phenomena. In particular, the DFT method is quite effective for the study of adsorption in nanopores. In this section, we introduce DFT and discuss the capillary condensation of fluids in mesopores.

2.1. Density Functional Theory

DFT is a useful tool for the description of inhomogeneous classical fluids. Such systems are characterized by spatial variation of the average single particle density $\rho(\mathbf{r})$. DFT methods are based on the idea that the free energy of an inhomogeneous fluid can be reproduced by a functional of the local density $\rho(\mathbf{r})$. The basic formulations of DFT can be found in [21], and [22] provides the review. The simplest version of DFT using the local density approximation (LDA), which does not take into account short-range correlations in the repulsive part of the free energy functional, has been used successively in the study of wetting phenomena [23], liquid-gas interfaces [24], and capillary condensation [25–27]. However, it has been recognized that LDA fails to predict the strong oscillations that are present in the density profile of a fluid in contact with a solid substrate [28]. These oscillations are a reflection of short-range correlations in a fluid. Tarazona and co-workers [29, 30] developed a nonlocal version of DFT, which is based on the weighted-density approximation (WDA) including such correlations. The basis of WDA is that hard-sphere Helmholtz free energy can be expressed as a function of a smoothed density $\rho_s(\mathbf{r})$, which is a nonlocal functional of the true density profile $\rho(\mathbf{r})$. WDA yields realistic oscillatory density profiles, which reflect packing constraints on the arrangements of particles in the case of a fluid in simple confining geometries. Moreover, it was shown that WDA generally yields results comparable to those obtained by GCMC simulations [28], which are regarded as reference computer experiments. Tarazona's version of DFT has recently been

employed for theoretical predictions of adsorption isotherms in porous materials and phase transitions, such as micropore filling, capillary condensation in pores, layering, and wetting transitions on solid substrates [20, 31–39]. The nonlocal density functional theory has also been used to study the high-pressure adsorption of supercritical gases [40–42] and to calculate the pore size distribution (PSD) of porous materials, such as activated carbons, mesoporous silica, and pillared interlayered clays [19, 43–47]. In particular, DFT-based methods for the pore size characterization of activated carbons from nitrogen adsorption isotherms have become a standard characterization method in recent years.

Different versions of WDA have been introduced by several authors (e.g., Rosenfeld [48], Denton and Ashcroft [49], and Kierlik and Rosinberg [50]). The WDA method of Rosenfeld-Kierlik-Rosinberg has been employed for the theoretical study of adsorption, mainly for the adsorption of mixtures [51–58]. The WDA method of Tarazona has also been applied for the adsorption of mixtures [59–61], although it should require more computation time than that for Rosenfeld-Kierlik-Rosinberg.

In this section, the nonlocal DFT based on WDA, which was developed by Tarazona, is treated. In the conventional DFT approach, it is assumed that the pore has a fixed geometry and is open and in contact with bulk fluid. For this system, a grand canonical ensemble provides an appropriate description of the thermodynamics. In this ensemble, system volume V, temperature T, and chemical potential μ are specified. For a fluid in the presence of a spatially varying external potential $V_{ext}(\mathbf{r})$, the grand potential functional Ω can be expressed as

$$\Omega[\rho(\mathbf{r})] = F[\rho(\mathbf{r})] + \int d\mathbf{r}\, \rho(\mathbf{r})[V_{ext}(\mathbf{r}) - \mu] \qquad (8)$$

where $F[\rho(\mathbf{r})]$ is the intrinsic Helmholtz free energy functional. At thermodynamic equilibrium, $\Omega[\rho(\mathbf{r})]$ is a global minimum with respect to variations in $\rho(\mathbf{r})$. The minimum value is equal to the thermodynamic grand potential of the system. It is customary to divide $F[\rho(\mathbf{r})]$ into two parts, which are due to repulsive and attractive interactions. The repulsive interaction is modeled by a hard sphere of diameter d, and the attractive interaction is treated in a mean-field fashion

$$F[\rho(\mathbf{r})] = F_{hs}[\rho(\mathbf{r}); d]$$
$$+ \tfrac{1}{2} \iint d\mathbf{r}\, d\mathbf{r}'\, \rho(\mathbf{r})\rho(\mathbf{r}')\Phi_{att}(|\mathbf{r} - \mathbf{r}'|) \qquad (9)$$

Here $\Phi_{att}(|\mathbf{r}|)$ is the attractive part of the pairwise potential between two fluid molecules. The attractive part of the fluid-fluid potential is represented by the WCA form of the Lennard-Jones (LJ) potential [62]

$$\Phi_{att}(r) = \begin{cases} -\varepsilon, & r < r_m \\ \Phi_{LJ}(r), & r_m < r < r_c \\ 0, & r_c < r \end{cases} \qquad (10)$$

$$\Phi_{LJ}(r) = 4\varepsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right] \qquad (11)$$

where $r_{\mathrm{m}} = 2^{1/6}\sigma$ is the location of the minimum of the LJ potential and r_{c} is the cutoff distance. The hard-sphere free energy functional $F_{\mathrm{hs}}[\rho(\mathbf{r})]$ is not known exactly for the three-dimensional fluid. Therefore, further approximations must be made with respect to the free energy functional. The hard-sphere term is often divided into an ideal gas component and an excess (configurational) component

$$F_{\mathrm{hs}}[\rho(\mathbf{r}); d] = F_{\mathrm{id}}[\rho(\mathbf{r})] + F_{\mathrm{ex}}[\rho(\mathbf{r}); d] \qquad (12)$$

The ideal contribution $F_{\mathrm{id}}[\rho(\mathbf{r})]$ is given exactly by the local density expression

$$F_{\mathrm{id}}[\rho(\mathbf{r})] = kT \int d\mathbf{r}\, \rho(\mathbf{r})[\ln(\Lambda^3 \rho(\mathbf{r})) - 1] \qquad (13)$$

where $\Lambda = h/(2\pi m kT)^{1/2}$ is the thermal de Broglie wavelength of a molecule of mass m, h is the Planck constant, and k is the Boltzmann constant. The excess component is expressed as

$$F_{\mathrm{ex}}[\rho(\mathbf{r}); d] = \int d\mathbf{r}\, \rho(\mathbf{r}) f_{\mathrm{ex}}[\rho_{\mathrm{s}}(\mathbf{r}); d] \qquad (14)$$

where $f_{\mathrm{ex}}[\rho_{\mathrm{s}}(\mathbf{r}); d]$ is the excess free energy per molecule in the hard-sphere fluid, which is calculated from the Carnahan-Starling equation of state [63]

$$f_{\mathrm{ex}}[\rho_{\mathrm{s}}(\mathbf{r}); d] = kT \frac{\eta(4 - 3\eta)}{(1 - \eta)^2} \qquad (15)$$

with $\eta = \pi \rho_{\mathrm{s}} d/6$. The smoothed density $\rho_{\mathrm{s}}(\mathbf{r})$ is given by an average of $\rho(\mathbf{r})$ weighted by a suitable function w, which is allowed to depend on $\rho_{\mathrm{s}}(\mathbf{r})$ [29]

$$\rho_{\mathrm{s}}(\mathbf{r}) = \int d\mathbf{r}'\, \rho(\mathbf{r}') w[|\mathbf{r} - \mathbf{r}'|; \rho_{\mathrm{s}}(\mathbf{r})] \qquad (16)$$

The weight function w is specified by requiring the direct correlation function of a uniform hard-sphere fluid (which is calculated from functional differentiation of Eq. (12) with Eq. (16)) to be close to the corresponding Percus-Yevick result. The Tarazona prescription for the weight function uses a (truncated) power series expansion in the smoothed density

$$w[|\mathbf{r} - \mathbf{r}'|; \rho_{\mathrm{s}}(\mathbf{r})] = w_0(|\mathbf{r} - \mathbf{r}'|) + w_1(|\mathbf{r} - \mathbf{r}'|)\rho_{\mathrm{s}}(\mathbf{r})$$
$$+ w_2(|\mathbf{r} - \mathbf{r}'|)[\rho_{\mathrm{s}}(\mathbf{r})]^2 \qquad (17)$$

The expansion coefficients w_i ($i = 0, 1, 2$) are given in [29, 30]. Then Eq. (16) reduces to a quadratic equation for $\rho_{\mathrm{s}}(\mathbf{r})$

$$\rho_{\mathrm{s}}(\mathbf{r}) = \rho_{\mathrm{s}0}(\mathbf{r}) + \rho_{\mathrm{s}1}(\mathbf{r})\rho_{\mathrm{s}}(\mathbf{r}) + \rho_{\mathrm{s}2}(\mathbf{r})[\rho_{\mathrm{s}}(\mathbf{r})]^2 \qquad (18)$$

with coefficients

$$\rho_{\mathrm{s}i}(\mathbf{r}) = \int d\mathbf{r}'\, \rho(\mathbf{r}') w_i(|\mathbf{r} - \mathbf{r}'|) \qquad (19)$$

for $i = 0, 1, 2$. The physical root of Eq. (18) is

$$\rho_{\mathrm{s}}(\mathbf{r}) = \frac{1 - \rho_{\mathrm{s}1}(\mathbf{r}) - \left[(1 - \rho_{\mathrm{s}1}(\mathbf{r}))^2 - 4\rho_{\mathrm{s}0}(\mathbf{r})\rho_{\mathrm{s}2}(\mathbf{r})\right]^{1/2}}{2\rho_{\mathrm{s}2}(\mathbf{r})}$$

$$= \frac{2\rho_{\mathrm{s}2}(\mathbf{r})}{1 - \rho_{\mathrm{s}1}(\mathbf{r}) - \left[(1 - \rho_{\mathrm{s}1}(\mathbf{r}))^2 - 4\rho_{\mathrm{s}0}(\mathbf{r})\rho_{\mathrm{s}2}(\mathbf{r})\right]^{1/2}}$$
$$(20)$$

where the second form is more convenient for calculations when $\rho_{\mathrm{s}1}(\mathbf{r})$ and $\rho_{\mathrm{s}2}(\mathbf{r})$ approach zero. Here the normalization condition for Eq. (17)

$$\int d\mathbf{r}\, w[|\mathbf{r} - \mathbf{r}'|; \rho_{\mathrm{s}}(\mathbf{r})] = 1 \qquad (21)$$

implies that

$$\int d\mathbf{r}\, w_i(|\mathbf{r} - \mathbf{r}'|) = \begin{cases} 1, & i = 0 \\ 0, & i = 1, 2 \end{cases} \qquad (22)$$

Therefore, in the limit of a uniform fluid, $\rho_{\mathrm{s}i}(\mathbf{r})$ becomes $\rho_{\mathrm{s}0}(\mathbf{r}) = \rho$ (bulk fluid density) and $\rho_{\mathrm{s}1}(\mathbf{r}) = \rho_{\mathrm{s}1}(\mathbf{r}) = 0$.

The problem of finding an equilibrium density distribution $\rho(\mathbf{r})$ can be solved by minimizing the grand potential functional (Eq. (8)) with respect to $\rho(\mathbf{r})$. The standard method employed first by Tarazona [29] is based on the Euler–Lagrange equation; the minimization requirement is satisfied by differentiating the grand potential functional with respect to density and equating to zero. The resulting Euler–Lagrange equation is

$$\mu = V_{\mathrm{ext}}(\mathbf{r}) + kT \ln(\Lambda^3 \rho(\mathbf{r})) + f_{\mathrm{ex}}(\rho_{\mathrm{s}}(\mathbf{r}))$$
$$+ \int d\mathbf{r}'\, \rho(\mathbf{r}') f_{\mathrm{ex}}'(\rho_{\mathrm{s}}(\mathbf{r}')) \frac{\delta \rho_{\mathrm{s}}(\mathbf{r}')}{\delta \rho(\mathbf{r})}$$
$$+ \int d\mathbf{r}'\, \rho(\mathbf{r}') \Phi_{\mathrm{att}}(|\mathbf{r} - \mathbf{r}'|) \qquad (23)$$

where the functional derivative of $\rho_{\mathrm{s}}(\mathbf{r})$ with regard to $\rho(\mathbf{r})$ can be represented as

$$\frac{\delta \rho_{\mathrm{s}}(\mathbf{r}')}{\delta \rho(\mathbf{r})} = \frac{w[|\mathbf{r} - \mathbf{r}'|; \rho_{\mathrm{s}}(\mathbf{r}')]}{1 - \rho_{\mathrm{s}1}(\mathbf{r}') - 2\rho_{\mathrm{s}2}(\mathbf{r}')\rho_{\mathrm{s}}(\mathbf{r}')} \qquad (24)$$

The terms on the right-hand side of Eq. (23) must be imposed to the chemical potential of the bulk fluid at all points in the system. For the homogeneous system, the chemical potential of the bulk fluid of a uniform density ρ_{b} is

$$\mu = \mu_{\mathrm{hs}}(\rho_{\mathrm{b}}) + \rho_{\mathrm{b}} \int d\mathbf{r}\, \Phi_{\mathrm{att}}(|\mathbf{r}|) \qquad (25)$$

Here, $\mu_{\mathrm{hs}}(\rho_{\mathrm{b}})$ is the chemical potential of the hard-sphere fluid calculated from the Carnahan-Starling equation of state

$$\mu_{\mathrm{hs}}(\rho_{\mathrm{b}}) = kT \ln\left(\Lambda^3 \rho_{\mathrm{b}}\right) + f_{\mathrm{ex}}(\rho_{\mathrm{b}}, d) + \rho_{\mathrm{b}} f_{\mathrm{ex}}'(\rho_{\mathrm{b}}, d)$$

$$= kT \left[\ln\left(\Lambda^3 \rho_{\mathrm{b}}\right) + \frac{8\eta - 9\eta^2 + 3\eta^3}{(1 - \eta)^3}\right] \qquad (26)$$

with $\eta = \pi \rho_{\rm b} d / 6$. The integral over r of attractive interactions (which is the second term on the right-hand side of Eq. (25)) can be performed analytically as follows

$$\int_{|\mathbf{r}| < r_{\rm c}} d\mathbf{r}\, \Phi_{\rm att}(|\mathbf{r}|)$$

$$= -\frac{32}{9}\pi\varepsilon(r_{\rm m})^3 + \frac{16}{9}\pi\varepsilon\sigma^3 \left[3\left(\frac{\sigma}{r_{\rm c}}\right)^3 - \left(\frac{\sigma}{r_{\rm c}}\right)^9 \right]$$

$$= -\alpha \qquad (27)$$

For numerical calculations, Eq. (23) with Eq. (25) can be rearranged as

$$kT \ln\left(\frac{\rho(\mathbf{r})}{\rho_{\rm b}}\right)$$

$$= f_{\rm ex}(\rho_{\rm b}) + \rho_{\rm b} f'_{\rm ex}(\rho_{\rm b}) - \rho_{\rm b}\alpha - V_{\rm ext}(\mathbf{r}) - f_{\rm ex}(\rho_{\rm s}(\mathbf{r}))$$

$$- \int d\mathbf{r}'\, \rho(\mathbf{r}') f'_{\rm ex}(\rho_{\rm s}(\mathbf{r}')) \frac{\delta\rho_{\rm s}(\mathbf{r}')}{\delta\rho(\mathbf{r})}$$

$$- \int d\mathbf{r}'\, \rho(\mathbf{r}') \Phi_{\rm att}(|\mathbf{r} - \mathbf{r}'|) \qquad (28)$$

or, denoting the right-hand side of Eq. (28) as Ψ

$$\rho(\mathbf{r}) = \rho_{\rm b} \exp(\Psi/kT) \qquad (29)$$

This equation can be solved by iterations of substituting the initial or current density in the right-hand side and getting a better estimate on the left-hand side. This calculation is repeated until the required accuracy is attained. However, this iteration process is not efficient, because it usually diverges in a few steps if the full new density obtained from Eq. (29) is used for the next step. To avoid this, the weighted iteration method can be employed for a better convergence as follows [29]

$$\rho_{(i)} = \omega \rho_{(i)}^{\rm out} + (1 - \omega)\rho_{(i-1)} \qquad (30)$$

where $\rho_{(i)}^{\rm out}$ is the quantity calculated by substituting the initial guess $\rho_{(i-1)}$ into Eq. (29) without employing weights ω. The density $\rho_{(i)}$ is used for the next step iteration. The weight ω can be optimized to reduce the time of computations. Then, for the successive iterations, it may be better to change the value of ω depending on the changing rate: $|\rho_{(i)}^{\rm out}(\mathbf{r}) - \rho_{(i-1)}(\mathbf{r})|/\rho_{(i-1)}(\mathbf{r})$. Another method for minimizing the grand potential functional in the nonlocal DFT has recently been developed by Neimark [64]. The method is based on the implementation of indeterminate Lagrange multipliers (ILMs). The ILM method gives a substantial advantage when the functional derivative $\delta\rho_{\rm s}(\mathbf{r}')/\delta\rho(\mathbf{r})$ cannot be expressed explicitly.

The pressure of a bulk fluid is described by the following equation of state

$$P = P_{\rm hs}(\rho_{\rm b}) + \tfrac{1}{2}\rho_{\rm b}^2 \int d\mathbf{r}\, \Phi_{\rm att}(|\mathbf{r}|)$$

$$= P_{\rm hs}(\rho_{\rm b}) - \tfrac{1}{2}\rho_{\rm b}^2 \alpha \qquad (31)$$

with

$$P_{\rm hs}(\rho_{\rm b}) = \rho_{\rm b} kT \frac{1 + \eta + \eta^2 - \eta^3}{(1 - \eta)^3} \qquad (32)$$

Here $P_{\rm hs}(\rho_{\rm b})$ is the pressure of the hard-sphere fluid, which is calculated from the Carnahan-Starling equation of state, and $\eta = \pi \rho_{\rm b} d / 6$. The chemical potential of the bulk fluid is represented by Eq. (26). The equation of state given by Eqs. (26) and (31) is essentially a two-parameter equation that depends on the hard-sphere diameter d and the product $\varepsilon\sigma^3$ (see Eq. (27)). In this mean-field approximation, the hard-sphere fluid serves as the reference system. That is, the fluid-fluid potential is split at the minimum $r_{\rm m} = 2^{1/6}\sigma$ in the WCA fashion, and the repulsive part of the potential is modeled by an equivalent hard-sphere potential with an appropriate hard-sphere diameter. Then the equivalent hard-sphere diameter should be temperature and density dependent according to WCA. Three prescriptions for the choice of the hard-sphere diameter are usually considered. The first choice is made such that d equals σ. The first choice of the hard-sphere diameter (d_1) has been used in nonlocal DFT by several authors [28, 31]. The second one is given by the well-known Barker-Henderson (BH) [65] expression

$$d_2 = \int_0^{r_m} dr\, \{1 - \exp[-\Phi_{\rm rep}(r)/kT]\} \qquad (33)$$

where $\Phi_{\rm rep}(r)$ is the repulsive part of the LJ potential

$$\Phi_{\rm rep}(r) = \Phi_{\rm LJ}(r) - \Phi_{\rm att}(r) \qquad (34)$$

The second choice (d_2) is only temperature dependent. However, the hard-sphere diameter d_2 from the BH expression may be overestimated when one deals with the nonuniform situations, that is, fluid in confining geometries, which shows high-density oscillation in contact with a solid substrate. The third one (d_3) originates from the works of Lu et al. [24] and Verlet and Weis [66]. The form of d_3 approximates the BH diameter

$$\frac{d_3}{\sigma} = \frac{\xi_1 kT/\varepsilon + \xi_2}{\xi_3 kT/\varepsilon + \xi_4} \qquad (35)$$

where the coefficients ξ_i ($i = 1$–4) are parameters chosen such that the theory yields a good fit for the liquid density along the coexistence curve. The coefficients $\xi_1 = 0.3837$, $\xi_2 = 1.035$, $\xi_3 = 0.4249$, and $\xi_4 = 1$, which fit the liquid branch simulated by use of the LJ fluid, are reported in [19].

The liquid-vapor equilibrium conditions are determined from the equality of pressures and chemical potentials in the two phases. Simultaneous solution of Eqs. (25) and (31) gives the equilibrium gas and liquid densities, chemical potential, and saturated vapor pressure. Thus, the chemical potential of Eq. (25) must adequately describe the behavior of the bulk fluid at different temperatures and satisfy the Maxwell relation. Ravikovitch et al. have determined the fluid-fluid interaction parameters of the LJ potential ($\sigma_{\rm ff}$ and $\varepsilon_{\rm ff}$) and the hard-sphere diameter d suitable for nitrogen fluid [20]. First, they determined the parameters so that the theory could reproduce the experimental liquid-gas coexisting densities, saturation pressure, and surface tension of the free liquid-gas interface at the normal boiling point of 77.347 K. The fitted parameters $\sigma_{\rm ff}$, $\varepsilon_{\rm ff}$, and hard-sphere diameter d are listed in Table 1. Then parameters of the LJ potential were fixed and a subsequent optimization was

Table 1. Parameters of the fluid-fluid interaction potentials.

Fluid	$\varepsilon_{\mathrm{ff}}/k_B$ (K)	σ_{ff} (nm)	d (nm)	Ref.
N_2	94.45	0.3575	0.3575	[20, 42]
Ar	118.05	0.305	0.338	[42]

Note: The cutoff distance for the fluid-fluid interaction is $5\sigma_{\mathrm{ff}}$. d is the equivalent hard-sphere diameter.

Table 2. Parameters of the solid-fluid interaction potentials.

Solid-fluid	$\rho_v \varepsilon_{\mathrm{ff}}/k_B$ (K/nm^2)	σ_{sf} (nm)	Ref.
O-N$_2$	0.2253	0.317	[20, 42]
O-Ar	0.262	0.30	[42]

Note: The effective diameter of oxygen atoms in the wall is $\sigma_{\mathrm{ss}} = 0.276$ nm.

made only with respect to the hard-sphere diameter d as a function of temperature. The thermal dependence of the equivalent hard-sphere diameter was calculated with the use of Eq. (35) with the coefficients $\xi_1 = 0.3837$, $\xi_3 = 0.4249$, and $\xi_4 = 1$. The fitted parameter ξ_2 has been found to be 1.034. Ravikovitch et al. have reported that the theory describes the liquid-vapor densities and saturation pressure of nitrogen within 5% accuracy in the temperature range 63–90 K [44].

2.2. Adsorption on Cylindrical Mesopores

Recently, new families of mesoporous materials have been synthesized. Mesoporous molecular sieves, known as M41S, exhibit uniform pore structures and can be synthesized to consist of a regular array of hexagonal and unidimentional mesopores (MCM-41) [67, 68] or cubic structures (MCM-48) [69]. The mesopores of MCM-41 materials can be systematically varied in size from around 2 nm to 10 nm [68]. The siliceous mesoporous material SBA-15 also possesses a regular two-dimensional array of cylindrical channels [70, 71]. SBA-15 can have larger pores (up to 30 nm), which are larger than those of MCM-41 materials.

Recently Neimark et al. have studied capillary condensation in mesopores of MCM-41 and calculated pore size distributions, using nonlocal DFT [20, 36, 43, 44]. They approximated the mesopore of MCM-41 with a cylindrical pore composed of oxygen [20, 44], although its pores actually have a hexagonal cross section [67, 68].

The adsorbent-adsorbate interactions, V_{ext}, for the cylindrical pore geometry can be modeled with the use of the LJ potential integrated over an infinitely long cylinder [72, 73]

$$V_{\mathrm{ext}}(r, R) = \pi^2 \rho_s \varepsilon_{\mathrm{sf}} \sigma_{\mathrm{sf}}^2$$

$$\times \left[\frac{63}{32} \frac{F(-4.5, -4.5, 1.0; \beta^2)}{[R^*(1-\beta^2)]^{10}} - 3 \frac{F(-1.5, -1.5, 1.0; \beta^2)}{[R^*(1-\beta^2)]^4} \right] \quad (36)$$

where $\beta = r/R$ and $R^* = R/\sigma_{\mathrm{sf}}$, and then r, R, and $F(\alpha, \beta, \gamma; \chi)$ are the distance from the center, radius of the cylinder, and a hypergeometric function, respectively. Here the excess adsorption per unit pore volume is calculated as

$$\Gamma_v = \frac{2}{(R - \sigma_{\mathrm{ss}}/2)^2} \int_0^{R-\sigma_{\mathrm{ss}}/2} r \, dr [\rho(r) - \rho_b] \quad (37)$$

where $\sigma_{\mathrm{ss}} = 0.276$ nm is the effective diameter of oxygen atoms in the pore wall.

Ravikovitch et al. have determined the solid-fluid interaction parameters so that the theory could provide the best fit to nitrogen and argon standard isotherms on nonporous siliceous materials [20, 44] (see Table 2). They also

calculated fluid-fluid interaction parameters for nitrogen and argon such that the theory fit the experimental liquid-gas coexistence densities, saturation pressure, and surface tension of the free liquid-gas interface (see Table 1). Figure 1 shows the nitrogen adsorption isotherm in the cylindrical pore (diameter: $D^* = D/\sigma_{\mathrm{ff}} = 16.8$) at 77 K, calculated by the nonlocal DFT, using the interaction parameters reported in [20] (see Tables 1 and 2). In Figure 1, the grand potential changes along the adsorption and desorption are also shown. According to Neimark et al. [36], the DFT isotherm in a mesopore allows one to determine three characteristic points on adsorption-desorption isotherms: the pressure (P_{eq}) of the equilibrium capillary condensation transition; the starting point (P_{sc}) of spontaneous capillary condensation (vapor-like spinodal); and the starting point (P_{sd}) of spontaneous desorption (liquid-like spinodal) (see Fig. 1). For MCM-41 materials with pores wider than $\sim$5 nm, it has been reported that the experimental adsorption-desorption hysteresis loop is in agreement with the branches at P_{sc} and P_{eq} from the theoretical prediction [36].

3. ROTATIONAL AND VIBRATIONAL RELAXATION OF CONFINED MOLECULES

Although a capillary condensation theory has been devoted to the determination of pore size distribution of mesopores, adsorption studies of regular mesoporous silica such as MCM-41 or FSM [74, 75] demonstrated that classical capillary condensation theory could not explain the dependence of adsorption hysteresis on the pore width [76]. It has also been assumed that condensates in mesopores have the same
Figure 1. DFT isotherm for nitrogen in a cylindrical pore of diameter $D^* = 16.8$ (6.01 nm) at 77 K.

structure and density as bulk liquid. In the case of molecules adsorbed in micropores it was found that they formed a molecular assembly whose structure is different from that of liquid [77–79]. Hence, there is a possibility that molecular states of molecules adsorbed even in small mesopores are different from those of bulk liquid. Therefore, we should get microscopic information on adsorbed molecules in mesopores with the use of spectroscopic methods. In this section, nitrogen adsorption and argon adsorption on MCM-41 at 77 K are treated by means of DFT to gain an understanding the capillary condensation of fluids in small mesopores, and then the motional state of acetonitrile (CH_3CN) in mesopores of MCM-41 at 303 K is assessed by infrared band shape analysis. Acetonitrile is a symmetrical top molecule and has a very large dipole moment (3.92 D), which plays a key role in the reorientational relaxation [11].

3.1. Nitrogen and Argon Adsorption

The MCM-41 sample was prepared by Johannes Gutenberg University. The detailed preparation procedure of MCM-41 has been given elsewhere [80]. Nitrogen and argon adsorption isotherms at 77 K were measured with a conventional volumetric apparatus, manufactured by Quantachrome Corp. (Autosorb-1). Figure 2 displays the nitrogen adsorption isotherm on MCM-41 at 77 K. A distinct step in the isotherm occurs at a relative pressure of about 0.3 with no adsorption hysteresis. The slight inclination of the condensation step is due to a narrow pore size distribution. The total surface area S_t, external surface area S_{ex}, and primary mesopore volume V_p of MCM-41 were calculated with the α_s-plot method [81]. The α_s-plot method is based on a comparison of the adsorption isotherm for a given porous material with adsorption data for a reference nonporous solid. In the α_s-plot calculation, the nitrogen adsorption isotherm on macroporous silica gel LiChrospher Si-1000 (BET surface area: $S_{BET} = 26$ m^2/g) at 77 K was used as a standard isotherm [82]. The primary mesopore volume V_p and external surface area S_{ex} were calculated from the slope of a linear portion of the α_s-plot above the pressure of nitrogen condensation (α_s above 1.2) in primary mesopores (Fig. 3).
Figure 3. α_s plot for nitrogen adsorption on MCM-41.

The total surface area S_t was calculated from the slope of the initial part of the α_s-plot, that is, for α_s below 0.8. The mean pore diameter d_p was evaluated from the relations between the surface area, pore diameter, and pore volume for circular pores ($d_p = 4V_p/(S_t - S_{ex})$). The calculated total surface area S_t, external surface area S_{ex}, mesopore volume V_p, and mean pore diameter d_p are listed in Table 3.

In Figure 2, we also present the DFT isotherm of nitrogen at 77 K in the cylindrical pore of 3.92 nm (internal diameter: $d = 2R - \sigma_{ss}$) in comparison with the experimental isotherm on MCM-41. The theoretical isotherm exhibits metastable adsorption (P_{sc}) and desorption (P_{sd}) branches of the hysteresis loop and equilibrium transition (P_{eq}). Comparison with the experimental isotherm shows that the inflection point of the reversible experimental condensation branch does not coincide with the theoretical vapor-like spinodal line, but agrees satisfactorily with the equilibrium transition. Thus, this suggests that the capillary condensation and evaporation of nitrogen in the MCM-41 mesopore occur in a thermodynamic equilibrium state. However, the diameter of the model cylindrical pore used in the DFT calculation ($d = 3.92$ nm) is a little larger than that experimentally determined from the α_s-plot method ($d = 3.2$ nm, see Table 3). This may be attributed to an overestimation of the internal surface area ($S_t - S_{ex}$) obtained from the α_s-plot method. The correlation between theoretical and experimental isotherms of argon on the same MCM-41 sample at 77 K is shown in Figure 4. The theoretical isotherm was calculated from the same DFT model with a pore diameter of 3.92 nm, using the interaction parameters listed in Tables 1 and 2. The experimental adsorption branch is placed within the loop formed by the theoretical equilibrium transition and vapor-like spinodal, and then the

experimental desorption branch is close to the theoretical equilibrium capillary condensation. This suggests that the metastable state on adsorption cannot be easily achieved for small mesopores, and the deviations between theoretical and experimental isotherms for the small mesopores are likely caused by neglect of the intrinsic energetic and geometrical heterogeneities of the pore walls in the theory. Local density profiles for nitrogen and argon adsorption in the cylindrical pore are shown in Figures 5 and 6. At $P/P_0 = 0.2$, nitrogen and argon molecules form a two-layer structure on the pore wall. Then, at $P/P_0 = 0.6$, the two fluids condense in the pore and the density profiles have six highly pronounced layers. The oscillations suggest that the condensates are more structured in the pore compared with bulk fluids. On the other hand, the structureless feature of the condensed phase can be seen for the case of the capillary condensation of a fluid in a fairly large mesopore. In Figure 7 we present the density profile of condensed nitrogen in a slit pore (internal width = 6.81 nm or $\sim 19\sigma_{\text{ff}}$) composed of two graphitic substrates at 77 K. The density profile has a weaker fluid

structure in the center of the slit pore, and the local density is consistent with the average density of bulk liquid nitrogen. This indicates that the structure of the condensed phase in the pore center is similar to that of the bulk liquid. However, it is possible that the molecular motion of the condensed molecules in the mesopore (smaller than $\sim 10\sigma_{\text{ff}}$ in diameter) is more restricted or hindered than that of liquid molecules because of the highly ordered structure as mentioned before.

3.2. Acetonitrile Adsorption

The adsorption isotherm of acetonitrile on MCM-41 (Fig. 8) was measured at 303 K with a computer-aided volumetric apparatus. The adsorption isotherm had a sharp jump at $P/P_0 = 0.3$ without adsorption hysteresis, indicating capillary condensation in regular mesopores. Moreover, the adsorption isotherm had a well-defined plateau, which provides clear evidence for the upper limit of capillary condensation. The value of the BET monolayer capacity, n_{m},

for acetonitrile was 4.5 mmol g^{-1}. By assuming the surface area ($S_t - S_{ex}$; see Section 3.1) determined from the nitrogen adsorption isotherm to be available for the adsorption of acetonitrile, the apparent molecular area, a_m, of adsorbed acetonitrile can be calculated from the value of n_m. The value of a_m for adsorbed acetonitrile (0.37 nm^2) was quite different from the value 0.22 nm^2, which was calculated from the liquid density by assuming close packing as in a bulk liquid. This result indicates that the BET monolayer cannot be regarded as a perfect close-packed monolayer, and a specific adsorption of acetonitrile takes place. The later infrared (IR) data will show that acetonitrile molecules are adsorbed on the surface hydroxyls in the monolayer adsorption stage.

3.3. Infrared Spectra of Confined Acetonitrile

The infrared spectra of acetonitrile adsorbed on MCM-41 were measured at 303 K with an *in-situ* IR cell with KRS-5 windows, with the aid of an Fourier transform IR spectrometer (Jasco FT/IR-550). The IR spectra were measured with the summation of 256 consecutive scans and a resolution of 1 cm^{-1}. The MCM-41 powder was uniformly coated on the KBr disk under a pressure of 5 MPa for the IR measurement, which does not induce the destruction of the pore structure of MCM-41 [83]. Acetonitrile of spectroscopic grade reagent from Wako Pure Chemicals was used. Figure 9 shows the IR spectra of adsorbed acetonitrile in the C≡N stretching ν_2 region over the range of $P/P_0 = 0.05–0.33$. The adsorbed amounts at $P/P_0 = 0.05$ and 0.15 are 70% and 98% of the monolayer capacity. Hence the absorption bands at $P/P_0 = 0.05$ and 0.15 are assigned to acetonitrile molecules in the monolayer. The band at 2265 cm^{-1} can be associated with the C≡N stretching ν_2 band of acetonitrile molecules interacting with surface hydroxyls of MCM-41, because the growth of the 2265 cm^{-1} band coincides with the disappearance of the absorption band of free surface hydroxyls at 3744 cm^{-1}. According to Purcell and Drago [84], the C≡N frequency increases when acetonitrile forms a coordination complex with an electron acceptor molecule,
that is, overlapping of the N_{2S} orbital with the C_{2s} and $C_{2p\sigma}$ orbitals is responsible for the observed strengthening of the C≡N bond upon coordination of an acetonitrile molecule to Lewis acids. The C≡N stretching ν_2 band (2265 cm^{-1}) of acetonitrile adsorbed on MCM-41 shifts upward by 11 cm^{-1} from the bulk liquid phase value (see Fig. 9). Therefore, the upward shift should be due to the increase in the C≡N force constant of the acetonitrile molecule hydrogen-bonded to surface hydroxyls. In the case of a decationized zeolite sample with OH groups, similar spectral features were reported [85]. Above $P/P_0 = 0.3$, a new band is explicitly observed at a low-frequency side of the 2265 cm^{-1} band. This band becomes predominant above the adsorption jump (after capillary condensation). Furthermore, the band position of the lower frequency band agrees with that of the bulk liquid acetonitrile (2254 cm^{-1}). This suggests that the band at 2254 cm^{-1} can be assigned to the vibrational transition of the physisorbed molecule with nonspecific interactions.

The observed spectra in the C≡N stretching ν_2 region were carefully analyzed to assign the absorption bands of adsorbed acetonitrile exactly. As a first step of the analysis of the ν_2 band, the second-derivative curves were calculated from the observed spectra in the 2320–2220 cm^{-1} range (Fig. 10). At $P/P_0 = 0.05$, the second-derivative curve has minima at 2298 and 2265 cm^{-1} that correspond to the band positions. The curve around 2298 cm^{-1}, which originates from the band of the combination $\nu_3 + \nu_4$ transition, is very symmetrical, whereas the curve around 2265 cm^{-1} (ν_2 transition of the hydrogen-bonded acetonitrile) is slightly asymmetrical, owing to another component of the low-frequency side. At $P/P_0 = 0.15$, the minimum at 2254 cm^{-1} becomes quite apparent, indicating the presence of physisorbed acetonitrile (Fig. 10b). Nevertheless the 2254 cm^{-1} band is smeared out in the case of the infrared spectrum at $P/P_0 = 0.15$ (see Fig. 9); it is clear that there are at least two kinds of molecular states of hydrogen-bonded and physisorbed acetonitrile above $P/P_0 = 0.15$. In this section the ν_2 band of hydrogen-bonded acetonitrile is designated as the $\nu_2\alpha$ band, and that of physisorbed acetonitrile as the $\nu_2\beta$ band. Although the low-frequency component of
Figure 10. Second-derivative curves from the observed spectra of adsorbed acetonitrile in the 2220–2320 cm^{-1} range at (a) $P/P_0 = 0.05$, (b) 0.15.

the 2265 cm^{-1} band at $P/P_0 = 0.05$ cannot be attributed to physisorbed molecules, there is another possibility, to be described later.

3.4. Band Shape of the ν_2 Band of Liquid Acetonitrile

It is well known that the ν_2 band of liquid acetonitrile is significantly asymmetrical because of overlap of hot band transitions on the low-frequency side (Fig. 11). From a study of the gas phase rotation-vibration spectrum [86], the hot band transition from the first excited state of the degenerate C—C≡N bending ν_8 mode, $\nu_2^{h1} = \nu_2 + \nu_8 - \nu_8$, has its center 4.944 cm^{-1} lower than that of the fundamental transition, ν_2^f. Also the existence of a $\nu_2^{h2} = \nu_2 + 2\nu_8 - 2\nu_8$ transition is expected. Hashimoto et al. studied the ν_2 band of liquid acetonitrile [11] to determine the reorientational and vibrational relaxation times of liquid acetonitrile. They showed
Figure 11. Infrared spectra of liquid acetonitrile in the C≡N stretching ν_2 region at 298 K, and the deconvolution using four Lorentzian curves. ∘, Observed intensity; —, calculated total intensity; —, calculated component intensity.

that the peak position and bandwidth of the hot band transitions were not the same as those of the fundamental transition, but those contributions to the fundamental transition could be corrected by using the Boltzmann distribution; they succeeded in separating the component bands. In this section, their method was applied to analyze the ν_2 band of adsorbed acetonitrile in the MCM-41 mesopores.

3.5. Band Shape Analysis of the ν_2 Band of Confined Acetonitrile

As the hot band transitions should exist in both of the ν_2 bands of hydrogen-bonded and physisorbed acetonitrile, it is actually required to separate the fundamental ν_2 bands from the hot band transitions. Therefore, the analytical functions for fundamental transitions of $\nu_2^f \alpha$ and $\nu_2^f \beta$ and for hot band transitions should be determined upon the least-squares procedure. Here, it is assumed that the reorientational-vibrational relaxation processes of physisorbed acetonitrile can be described as a diffusion process similar to that of the bulk liquid molecule, whose spectral density has a Lorentzian form. Accordingly it is supposed that the $\nu_2 \beta$ band can be reproduced as a sum of three Lorentzian curves of the $\nu_2^f \beta$, $\nu_2^{h1} \beta$, and $\nu_2^{h2} \beta$ bands. Then, it is also assumed that the $\nu_2 \alpha$ band shapes over the range of $P/P_0 = 0.15$–0.37 are represented by the band profile measured at $P/P_0 = 0.05$. The band at $P/P_0 = 0.05$ should include both $\nu_2^{h1} \alpha$ and $\nu_2^{h2} \alpha$ bands, and the bands that come from a few kinds of α-species because of the surface heterogeneity. Then, the observed spectra in the 2320–2220 cm^{-1} range were deconvoluted with the use of the observed band profile at $P/P_0 = 0.05$ for the $\nu_2 \alpha$ band; three Lorentzian curves for $\nu_2^f \beta$, $\nu_2^{h1} \beta$, and $\nu_2^{h2} \beta$ bands; one Lorentzian curve for the $\nu_3 + \nu_4$ band of physisorbed acetonitrile, and a horizontal base line. The least-squares fitting was carried out under the following assumptions to reduce adjustable parameters: only the intensity and peak frequency of the $\nu_2 \alpha$ band, which are measured at $P/P_0 = 0.05$, are variable; the intensity ratios of the $\nu_2^f \beta$, $\nu_2^{h1} \beta$, and $\nu_2^{h2} \beta$ bands are 1:0.332:0.083 (the calculation of the relative intensities will be described in detail in Section 4); and the bandwidth of $\nu_2^{h1} \beta$ is equal to that of $\nu_2^{h2} \beta$. Examples of the resolved spectra are shown in Figure 12. The calculated composite curves shown by a bold solid line reproduce well the observed spectra. The band shape of the ν_2 band at $P/P_0 = 0.15$ is nearly similar to that at $P/P_0 = 0.05$ (Fig. 12a), as expected. However, we should regard with caution the change in the $\nu_2 \beta$ band in the low P/P_0 region, because the $\nu_2 \beta$ band below $P/P_0 = 0.24$ may have inevitable uncertainties.

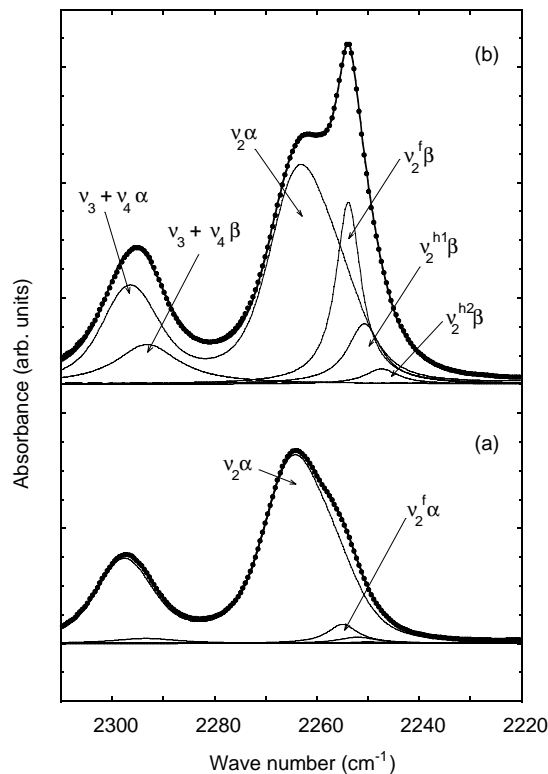
The absorbance of the $\nu_2^f \beta$ and $\nu_2 \alpha$ bands obtained by the least-squares fitting was plotted against P/P_0 in Figure 13. The relation between the absorbance of the $\nu_2^f \beta$ band and P/P_0 undergoes a steep upward jump at $P/P_0 = 0.3$. This steep jump stems from the capillary condensation, whereas other gradual increases in the absorbance below $P/P_0 = 0.3$ correspond qualitatively to the multilayer adsorption. On the other hand, the absorbance curve of the $\nu_2 \alpha$ band gradually increases above $P/P_0 = 0.15$, suggesting that the effect of adsorbate-adsorbate interaction increases the dipole moment of the C≡N bond of the molecule concerned.


Figure 12. Resolved infrared absorption spectra of adsorbed acetonitrile on MCM-41 in the C≡N stretching ν_2 region at (a) $P/P_0 = 0.15$ and (b) 0.37 (after capillary condensation). ○, Observed intensity; —, calculated total intensity; —, calculated component intensity.

3.6. Motional States of Confined Acetonitrile

The relationship between the half-band width (half width at half-maximum heights) of the $\nu_2^f\beta$ band and P/P_0 is plotted in Figure 14. The half-band width of the $\nu_2^f\beta$ band drops steeply at $P/P_0 = 0.3$. This sudden decrease is in beautiful agreement with the adsorption isotherm. Hence, the change
Figure 13. Changes in absorbance of the $\nu_2^f\beta$ band with adsorption. Open and solid symbols denote the $\nu_2\alpha$ and $\nu_2^f\beta$ bands, respectively.
Figure 14. Changes in half-band width of the $\nu_2^f\beta$ band with adsorption. A dashed horizontal line denotes the half-band width of the ν_2 band of liquid acetonitrile at 298 K.

in half-band width of the $\nu_2^f\beta$ band suggests that the relaxation process of an acetonitrile molecule transforms with capillary condensation. If the reorientational and vibrational time correlation functions of the single vibrational transition have an exponential form and thus the infrared band profile is given by a Lorentzian, the relaxation time is expressed by

$$\tau = (2\pi c\Delta\nu_{1/2})^{-1} \qquad (38)$$

$$\tau^{-1} = \tau_r^{-1} + \tau_v^{-1} \qquad (39)$$

where $\Delta\nu_{1/2}$ is the half-band width (cm^{-1}), and τ_r and τ_v are the reorientational relaxation and vibrational relaxation times, respectively. The measured half-band width is represented as a sum: $\Delta\nu_r + \Delta\nu_v$ (see Eqs. (6) and (7)). Therefore, the half-band width of the $\nu_2^f\beta$ band has information about the reorientational-vibrational relaxation of the physisorbed acetonitrile. The τ values for the $\nu_2^f\beta$ bands calculated by Eq. (38) are summarized in Table 4. It is expected that the physisorbed acetonitrile just below the steep rising of the adsorption isotherm prior to the capillary condensation undergoes fewer collisions with its surroundings than in the liquid state. However, the τ values of the physisorbed acetonitrile in the range of $P/P_0 = 0.15$–0.27 are smaller than that of the bulk liquid. In this relative pressure range, it is unlikely that the vibrational relaxation of the physisorbed acetonitrile is faster than that of the liquid acetonitrile, because the vibrational phase should be retained because

Table 4. Relaxation time of acetonitrile molecule adsorbed on mesopores of MCM-41.

State	Temp. (K)	τ (ps)
Adsorbed state over the range $P/P_0 = 0.15$–0.27	303	1.5
Adsorbed state over the range $P/P_0 = 0.32$–0.37	303	1.7–1.8
Liquid	298	1.7

there are fewer collisions between adsorbates. Therefore, the $\Delta\nu_v$ value of the physisorbed acetonitrile in the relative pressure range should be smaller than that of the liquid acetonitrile. Hence, this result suggests that the reorientational motion of acetonitrile molecules in this state is comparatively fast (larger $\Delta\nu_r$) because of the small intermolecular torque. Above $P/P_0 = 0.3$, the half-band widths of the $\nu_2^f\beta$ band tend to be narrower than that of the bulk liquid (Fig. 14). That is, the τ values are slightly longer than that of the bulk liquid at the same temperature. In this condensed state, it is supposed that intermolecular collisions of adsorbates in small mesopores cannot be more frequent than that of liquid molecules. If only collisions between acetonitrile molecules confined in small mesopores are restricted, the vibrational phase relaxation may be slow (smaller $\Delta\nu_v$), and the reorientational relaxation should be fast (larger $\Delta\nu_r$), owing to the free rotation of adsorbates. That is, the orientation of adsorbed acetonitrile should be retained more than that of liquid molecules in terms of the longer reorientational-vibrational relaxation time. Therefore, it is concluded that the reorientational motion of acetonitrile molecules condensed in mesopores is prevented more than that of the bulk liquid because of the large intermolecular torque, which comes from the confinement in small mesopores.

4. VIBRATIONAL DEPHASING OF CONFINED FLUIDS

Vibrational phase relaxations in condensed phases have received considerable attention in recent decades, because they are recognized as a powerful probe of intermolecular interaction dynamics [2, 87]. In Kubo-Rothschild theory a given stochastic process is defined by the rms magnitude of the Bohr frequency modulation Δ and its correlation time τ_c. The accurate determination of these Kubo parameters yields interesting information on molecular dynamics. Vibrational dephasing is especially suited to describing the dynamics of a hydrogen bonding. In the H-bonded systems, such as O—H$\cdots$Y and C≡N$\cdots$Y in solution, the modulation of the O—H and C≡N frequency (vibrational dephasing) occurs though the coupling to hydrogen bridge stretching ν_σ (H$\cdots$Y and N$\cdots$Y) modes, which undergoes energy exchange with the bath. In these cases, the τ_c-value reflects the lifetime of the hydrogen bond [2]. The simple dephasing model of Kubo-Rothschild theory can also be extended to describe an adsorbed molecule, which interacts with the solid surface [2]. The vibrational dephasing of translationally immobilized adsorbates can be simple, because there is no influence of the fluctuating bath. Therefore, pure vibrational dephasing should be observed in such a system. On the other hand, the concentration, reactivity, and accessibility of internal surface hydroxyl groups (SiOH) of MCM-41 or FSM-16 [88] are responsible for ion exchange and post-modification, such as silylation and chemical deposition. It is consequently indispensable to elucidate the molecule–SiOH group interactions at the molecular level.

It is well known that acetonitrile forms a coordination complex with an electron acceptor molecule [84], such as Brønsted sites and surface hydroxyls in zeolites [85, 89].

The C≡N group can also form a hydrogen bond of the ≡N$\cdots$HO type with SiOH groups of MCM-41, as discussed in Section 3. Hydrogen bonding affects the C≡N stretching mode significantly. The infrared band width of the C≡N stretching ν_2 mode of hydrogen-bonded acetonitrile is larger than that of unassociated acetonitrile by a factor of about 2. This indicates that the vibrational dephasing rate of the ν_2 mode is strongly influenced by hydrogen-bond formation.

In this section, the infrared adsorption bands of the ν_2 mode of hydrogen-bonded acetonitrile on SiOH groups of MCM-41 are treated.

4.1. Theoretical Methodology

The normalized spectral function of an infrared absorption band $\widehat{I}(\nu)$ is a Fourier transform of a dipole correlation function [2]

$$\widehat{I}(\nu) = c \int_{-\infty}^{\infty} \exp(-i2\pi c\nu t)\Phi(t)\,dt \qquad (40)$$

where c is light velocity and ν is the wave number. The following product is assumed as for $\Phi(t)$

$$\Phi(t) = \Phi_r(t) \cdot \Phi_{res}(t) \cdot \Phi_{ph}(t) \qquad (41)$$

where $\Phi_r(t)$, $\Phi_{res}(t)$, and $\Phi_{ph}(t)$ are the reorientational, resonance energy transfer, and vibrational dephasing correlation functions, respectively. It seems that it is difficult for the hydrogen-bonded acetonitrile on the SiOH group of MCM-41 to undergo a free reorientational motion around the main C_{3V} symmetry axis because of the hydrogen bonding. The resonant vibrational energy transfer process can also be negligible because the hydrogen-bonded acetonitrile may be isolated. Therefore, it is expected that the vibrational relaxation process of the hydrogen-bonded acetonitrile mainly shows aspects of pure vibrational dephasing. Hence, relaxation processes other than vibrational phase relaxation can be neglected. Therefore, the correlation function is rewritten as

$$\Phi(t) = \Phi_{ph}(t) \qquad (42)$$

Vibrational dephasing is expressed by the following Kubo relaxation function [2]

$$\Phi_{ph}(t) = \exp\{-\Delta^2[\tau_c^2(\exp(t/\tau_c) - 1) + \tau_c t]\} \qquad (43)$$

Here Δ and τ_c are the Kubo parameters. The correlation time τ_c determines the average time between perturbative events (such as "collisions" and "librations"). Here, the factor $\Delta h/2\pi$ can be looked upon as a root mean square intermolecular energy, reflecting the static distribution of the interaction. Then the spectral function $I(\nu)$ is

$$I(\nu) = \Gamma \int_0^{\infty} \cos 2\pi c t(\nu - \nu_0)\Phi_{ph}(t)\,dt \qquad (44)$$

where ν_0 is the band center and Γ is associated with the absolute intensity of the band. The observed spectral function is given by the convolution integrals of Eq. (44) as follows

$$I(\nu')_{obs} = \int_{-\infty}^{\infty} I(\nu)\text{ILS}(\nu' - \nu)\,d\nu \qquad (45)$$

Here $ILS(\nu)$ is the instrumental line shape function, which is the Fourier transform of the apodization function used. In this study, the Hamming function $[f(x) = a + b\cos(\pi x/L),$ where $a = 0.54$, $b = 0.46$, and L is the maximum retardation] was adopted for the apodization function. The ILS function is represented by

$$ILS(\nu) = 2L\frac{\sin(2\pi\nu L)}{(2\pi\nu L)}\left[a - \frac{b(2\pi\nu L)^2}{\{(2\pi\nu L)^2 - \pi^2\}}\right] \quad (46)$$

On the other hand, the observed spectral function of an infrared absorption band $I(\nu)_{\text{obs}}$ is measured by

$$I(\nu)_{\text{obs}} = \sigma(\nu)/\nu[1 - \exp(-hc\nu/kT)] \quad (47)$$

where $\sigma(\nu)$ is the absorption coefficient and $I(\nu)$ is called the "spectral density." Therefore, the Kubo parameters in Eq. (43) can be determined by curve fitting of Eq. (45) to the measured band profile represented by Eq. (47).

4.2. Band Shape Analysis

The observed spectra in the 2230–2305 cm^{-1} ranges were resolved into fundamental (ν_2^{f}), hot band ($\nu_2^{\text{h1}} = \nu_2 + \nu_8 - \nu_8$, $\nu_2^{\text{h2}} = \nu_2 + 2\nu_8 - 2\nu_8$), and combination band ($\nu_3 + \nu_4$) transitions (see Section 3 and [11]) of the form of Eq. (45). The least-squares fitting (DLS method) was carried out under restrictions from the following assumptions:

(1) The relative intensities I_{f}, I_{h1}, and I_{h2} of the ν_2^{f}, ν_2^{h1}, and ν_2^{h2} transitions are represented by

$$
\begin{aligned}
I_{\text{f}} &= 1 \\
I_{\text{h1}} &= 2\exp[-(\nu_8 \times 1.9865)/kT] \quad (48) \\
I_{\text{h2}} &= 3\exp[-(2\nu_8 \times 1.9865)/kT]
\end{aligned}
$$

The fundamental frequency of the ν_8 mode is estimated as

$$\nu_8 + x_{28} = (\nu_2 + \nu_8) + \nu_2 \quad (49)$$

where x_{28} is a constant that is associated with the nonharmonic term. In the case of bulk liquid ($\nu_8 = 378$ cm^{-1}, $\nu_2 + \nu_8 = 2628$ cm^{-1}, and $\nu_2 = 2254$ cm^{-1}), the constant x_{28} is -4 cm^{-1}. Then the fundamental frequency of the ν_8 mode of hydrogen-bonded acetonitrile can be calculated as

$$
\begin{aligned}
\nu_8 &= (\nu_2 + \nu_8) + \nu_2 - x_{28} \\
&= 2640 - 2263 - x_{28} \quad (50) \\
&\approx 381 \text{ cm}^{-1}
\end{aligned}
$$

(2) The peak frequency of ν_2^{h2} is given by $\nu_2^{\text{h2}} = 2\nu_2^{\text{h1}} - \nu_2^{\text{f}}$.
(3) The correlation time τ_{c} and Bohr frequency modulation Δ of ν_2^{h2} are equal to that of ν_2^{h1}. The example of the resolved spectra of hydrogen-bonded acetonitrile is shown in Figure 15. The calculated composite curve shown by a bold solid line reproduces well the observed spectra.
Figure 15. Resolved infrared absorption spectra of hydrogen-bonded acetonitrile on MCM-41 in the C≡N stretching ν_2 region at $P/P_0 = 0.001$ and $T = 283$ K. ∘, Observed intensity; —, calculated total intensity; —, calculated component intensity.

4.3. Vibrational Dephasing of Confined Acetonitrile

Figure 16 shows difference spectra for MCM-41 between the acetonitrile-adsorbed and adsorption-free samples in the O—H stretching (ν_{OH}) region at 303 K, as a function of relative pressure. The ν_{OH} bands of the free SiOH (3738 cm^{-1}) and terminal SiOH (3715 cm^{-1}) groups of MCM-41 were shifted downward by about 300 cm^{-1}, when they formed hydrogen bonds with acetonitrile molecules. Then the difference spectra between the acetonitrile-adsorbed sample and the outgassed one (background spectra) gave negative bands at 3738 cm^{-1} and 3715 cm^{-1}. Figure 17 shows infrared spectra of hydrogen-bonded acetonitrile in the C≡N stretching ν_2 region at 303 K as a function of relative pressure. As the negative ν_{OH} bands grow, the ν_2 band of the hydrogen-bonded acetonitrile (2264 cm^{-1}) increases. The integrated absorbance of the negative ν_{OH} bands has a linear correlation with that of the ν_2 band in the range of $P/P_0 = 0.001$–0.004 (surface coverage $\theta = 0.15$–0.32). This indicates that
Figure 16. Difference spectra of MCM-41 between acetonitrile adsorbed and adsorption free samples at 303 K (ν_{OH} region).
Figure 17. Infrared spectra of hydrogen-bonded acetonitrile on surface hydroxyls of MCM-41 in the C≡N stretching ν_2 region at 303 K.

Figure 19. Temperature effect on frequency shift of the ν_2 band of hydrogen-bonded acetonitrile.

a 1:1 hydrogen-bonded complex is formed in this pressure range. The correlation between the integrated absorbance of the ν_2 and negative ν_{OH} bands in the temperature range between 283 K and 333 K is shown in Figure 18. When the temperature was lowered (from 333 K to 283 K), a linear correlation was observed, although the surface coverage should be increased. Therefore, this indicates the formation of a 1:1 hydrogen-bonded complex in these temperature and pressure ranges.

The $\tau_c \Delta$ value, which is the product of τ_c and Δ, denotes the modulation regime of the system. If $\tau_c \Delta \ll 1$, the system is in a fast modulation limit; the perturbation of a vibrating molecule over a very short time does not intensively vary the phase, so its phase is retained for a long time. In this case $I(\nu)$ (Eq. (44)) is a Lorentzian curve. If $\tau_c \Delta \gg 1$, it is in a slow modulation limit; the phase is rapidly lost and $I(\nu)$ is a Gaussian form [2, 87]. As calculated $\tau_c \Delta$ values at 303 K are approximately 1.0, the system is in an intermediate modulation regime. The correlation time τ_c for the ν_2 band of hydrogen-bonded acetonitrile at 303 K is about 0.6 ps and is

independent of the surface coverage. The independence of τ_c of the surface coverage suggests that adsorbed molecules are highly isolated and the correlation time, τ_c, should be associated with the interaction with the SiOH group. The observed τ_c agrees with typical lifetimes of hydrogen bonds in liquid systems including solvent water [90]. Furthermore, in the case of a pyridine (C$_5$H$_5$N)—water system [91], the 988 cm^{-1} band of C$_6$H$_5$N is sensitive to hydrogen bonding of the N···HO type, the τ_c value of the mode is about 1.2 ps, and $\tau_c \Delta$ is approximately 0.8 over the whole concentration range. Accordingly, the observed vibrational dephasing must be ascribed to hydrogen bonding with the surface SiOH group. The ν_0 value decreases linearly with increasing temperature, as shown in Figure 19. When acetonitrile forms a coordination complex with an electron acceptor molecule, the C≡N bond force constant of acetonitrile is strengthened and the stretching frequency always increases, according to Purcell and Drago [84]. Therefore, in the case of hydrogen-bonded acetonitrile on the surface hydroxyl of MCM-41, the upward shift of the C≡N stretching frequency depends

Figure 18. Correlation between the integrated absorbance of the ν_2 and negative ν_{OH} band.
Figure 20. Temperature dependence of the modulation time τ_c.
Figure 21. Temperature dependence of average magnitude of the frequency modulation Δ.

on the electron transfer interaction of the nitrogen atom of the acetonitrile with the surface hydroxyl due to hydrogen bonding. The ν_2 band of hydrogen-bonded acetonitrile shifts upward by 12 cm^{-1} at 283 K and 10 cm^{-1} at 332 K from the bulk liquid phase value. Therefore, the downward frequency shift shows that the hydrogen bond becomes weaker with increasing temperature.

Figures 20 and 21 show the temperature dependence of τ_c and the Δ value, respectively. The τ_c value decreases with increasing temperature, while the Δ value increases. τ_c is the modulation time, which is related to the time scale of the molecular fluctuations (in this system, it should be the lifetime of the hydrogen bond), and the Δ is the average magnitude of the frequency modulation, that is, the frequency distribution of the CN stretching mode due to the coupling to the hydrogen bridge stretching ν_σ mode. Therefore, these results suggest that the lifetime of the hydrogen bond becomes shorter with increasing temperature. This is clearly consistent with the fact that the hydrogen bond becomes weaker with increasing temperature (see Fig. 19).

5. CONCLUSIONS

We found, through DFT, that condensates were highly structured in small cylindrical mesopores (diameter: $d = 3.9$ nm) compared with bulk fluids. This suggests that the molecular motion of the condensed molecules in such a small mesopore is more restricted or hindered than that of the bulk liquid because of the tightly ordered structure formation induced by the strong solid-fluid interaction. Then we explored the dynamics of adsorbed acetonitrile in the small mesopore of MCM-41 ($d = 3.9$ nm) by use of IR spectroscopy.

The IR spectra of adsorbed acetonitrile on MCM-41 were measured at 303 K. In the CN stretching ν_2 region, two bands were observed at 2265 cm^{-1} and 2254 cm^{-1}, assigned to hydrogen-bonded molecules on surface hydroxyls of MCM-41 and physisorbed molecules in mesopores, respectively. In this study, the 2265 cm^{-1} band was denoted as the $\nu_2\alpha$ band and the 2254 cm^{-1} band as the $\nu_2\beta$ band. The band width of the fundamental transition $\nu_2^f\beta$ was

obtained by removing the overlap with hot band transitions of the same mode, $\nu_2\alpha$ band, and other modes by least-squares fitting. Before the capillary condensation, the relaxation time τ obtained from the band width of the $\nu_2^f\beta$ band was smaller than that of the bulk liquid, indicating the presence of weakly hindered rotation. After the capillary condensation, the τ value was slightly longer than that of the bulk liquid, suggesting that the motion of acetonitrile molecules condensed in mesopores is prohibited in comparison with that of liquid acetonitrile at the same temperature.

The IR-band shapes of the ν_2 mode of the hydrogen-bonded acetonitrile on the surface hydroxyls (SiOH) of MCM-41 were analyzed with the Kubo-Rothschild theory to understand the vibrational dephasing dynamics. The rms magnitude of the Bohr frequency modulation Δ and its correlation time τ_c were determined for the vibrational dephasing of the ν_2 mode. The correlation time τ_c for the ν_2 band of hydrogen-bonded acetonitrile at 303 K was about 0.8 ps, which was independent of the surface coverage. The independence of τ_c of the surface coverage suggests that adsorbed molecules are highly isolated and the correlation time, τ_c, should be associated with the interaction with the SiOH group. The observed τ_c agrees with typical lifetimes of hydrogen bonds in liquid systems including solvent water. The τ_c value decreases with increasing temperature, whereas the Δ value increases. The τ_c is the modulation time, related to the time scale of the molecular fluctuations, and it should be the lifetime of the hydrogen bond in this system; the Δ is the average magnitude of the frequency modulation, that is, the frequency distribution of the CN stretching due to the coupling to the hydrogen-bond stretching mode. Therefore, these results suggest that the τ_c values obtained by this analysis reflect the pure vibrational dephasing of the CN stretching mode induced by the coupling to the stretching mode of the hydrogen bond with no influence of a fluctuating bath, and then the lifetime of the hydrogen bond becomes shorter with increasing temperature.

Although there are active studies on adsorption in nanopore systems such as MCM-41, one still cannot understand the molecular states of molecules adsorbed in mesopores. This article shows one aspect of molecular motional states of molecules adsorbed in mesopores. This type of research should be planned in the future.

GLOSSARY

Capillary condensation A phenomenon that liquid-like dense sate is formed in a pore (the pore size is larger than 2 nm) when a porous solid is exposed to a vapor. This occurs at a gas pressure smaller than the saturated vapor pressure at the given temperature.

MCM-41 One of the molecular sieves that have been discovered by Mobil scientists. It is composed of amorphous silica walls and possesses an array of uniform channels arranged in a two-dimensional hexagonal lattice. The diameter of the channel can be controlled in the range of 2–10 nm.

Mesopore A pore that has the size in the range of 2–50 nm by IUPAC classification.

Reorientational relaxation A diffusion of the direction of rotational-vibrational transition moment of adense molecule that is caused by intermolecular collisional steps.

Rotational-vibrational transition A change in rotational energy of a polyatomic molecule accompanying a vibrational transition ($v = 0$ to $v = 1$) induced by infrared irradiation.

Vibrational dephasing One of the different vibrational relaxation processes. A phase loss of the initial coherence of the autocorrelation of the vibrational amplitude.

Vibrational relaxation A coherence decay of fluctuations of a rotational-vibrational transition moment of a molecule in a dense phase.

Copper Chloride Quantum Dots

Keiichi Edamatsu, Tadashi Itoh

Osaka University, Osaka, Japan

CONTENTS

1. INTRODUCTION

Copper chloride (CuCl) crystal is one of the best-investigated materials from the early days of the optical study of semiconductors, because of its rich optical properties produced by excitons and exciton complexes such as biexcitons [1]. The exciton spectrum of CuCl and its assignment to the electronic band structure was first reported by Cardona [2]. He assigned the lowest exciton absorption band appearing at $\sim$3.20 eV ($T = 4$ K) to the singlet (Z_3) exciton band split by the spin–orbit coupling from the doublet band (Z_{12}) at $\sim$3.27 eV. Thus, unlike other semiconductor materials in which the doublet excitons are the lowest, the singlet lowest exciton in CuCl has the simplest configuration. Also, since the binding energy of the exciton ($\sim$200 meV) [3] in CuCl is one of the largest in semiconductor materials, the exciton is very stable even at room temperature. The stability as well as the simplicity of the lowest exciton state in CuCl makes the material very unique and important in the study of excitons and exciton complexes. These interesting features of CuCl also invited us to investigate the properties of excitons confined in nanometer-sized crystals, that is, quantum dots (QDs) of this material. In QDs, since the exciton wavefunction is confined three-dimensionally, distinct quantum confinement effects are expected. Again, due

to the small excitonic Bohr radius in CuCl, the confinement of excitons in CuCl QDs is much different from that in other semiconductor materials [4, 5]. Thus, it is worthwhile to explore the optical properties of CuCl QDs not only for a deep understanding of this characteristic material, but also from the general point of view of the study of semiconductor QDs.

In this chapter, we review a number of important works on the optical study of CuCl quantum dots and see how this material provides unique and important information in the study of semiconductor quantum dots. In Section 2, we introduce and discuss the quantum confinement effects on the lowest exciton states and its radiative decay process. In Section 3, we review the experimental and theoretical studies on the higher excited states of the confined exciton. In Section 4, we consider the enhancement of the optical nonlinearity and its mechanisms including its size dependence. In Section 5, we see the confinement of lattice vibrations (phonons) in the QDs and discuss their influence on the confined exciton states (exciton–phonon coupling). In relation to the exciton–phonon coupling, in Section 6, we discuss the phase relaxation or decoherence mechanisms of the confined exciton states. In Section 7, we see some extraordinary effects caused by the interfaces between the QDs and matrices. Finally, in Section 8, we summarize the current status of the study on CuCl QDs and give some perspectives.

2. EXCITON CONFINEMENT IN COPPER CHLORIDE (CuCl) QUANTUM DOTS

CuCl-like exciton spectra appearing in NaCl heavily doped with Cu^+ ions were first reported by Gross and Kaplyanski [6] in 1957, followed by Ueta et al. [7] and Kishishita [8]. The spectra were explained by the formation of CuCl microcrystals in NaCl matrix by the coagulation of Cu^+ ions. However, no clear explanation was given for high-energy shift of the spectra compared to the bulk one. The first experimental manifestation of the quantum size effect on the confined excitons in CuCl nanocrystals, or QDs, was performed by Ekimov et al. in glass matrix [9–12] in the 1980s and later on by Itoh et al. in NaCl matrix [13–15]. The effect was theoretically explained by Efros and Efros [16] in 1982. Exciton confinement of II–VI semiconductor colloidal nanocrystals was also reported by Brus [17] in 1984. Quantum confinement for the lowest 1S exciton state in a CuCl QDs affects

essentially the exciton translational motion with less influence on the internal motion because of the very small exciton Bohr radius $a_B^* = 0.7$ nm [9, 13]. This situation is called the "weak confinement" regime and quite different from the "strong confinement" regime applicable to II–VI or III–V nanocrystals where the exciton radius easily exceeds the particle size and the exciton internal motion is much modified by the confinement [16].

In the weak confinement regime, the energy of the lowest exciton, $E(a)$, is approximately given by

$$E(a) = E_g - Ry^* + \frac{\hbar^2}{2M}\left(\frac{\pi}{a}\right)^2 \tag{1}$$

where E_g is the bandgap energy, Ry^* is the effective Rydberg energy of the exciton, M is the translational mass of the exciton, and a is the radius of the QD [16]. Ekimov et al. [9, 11, 12] experimentally studied the absorption and luminescence spectra of CuCl QDs embedded in silicate glass matrices and discussed for the first time the exciton confinement of this material. Later, Itoh et al. [13–15] studied the optical spectra of CuCl QDs embedded in NaCl matrices. As shown in Figure 1, they measured the blueshifts of the Z_3 exciton luminescence and compared them with the mean radii of the QDs, which are estimated by means of the small-angle X-ray scattering method. Although they found that the QDs become somewhat oblate for larger sizes, they estimated the mean radii assuming that the QDs have spherical shapes. The observed blueshift $\Delta E = E(a) - E(\infty)$ of the confined exciton was well reproduced by Eq. (1), if the QD's radius a is replaced by an "effective radius" [14]

$$a^* = a - \eta a_{\mathrm{ex}} \tag{2}$$

where a_{ex} is the Bohr radius of the exciton, and η is a constant of order of unity. The qualitative explanation of the effective radius is that the exciton cannot reach the surface because of the finite size (i.e., internal motion of the exciton). This "dead layer" effect was explained theoretically by Kayanuma [18, 19] in a more quantitative way. This finding indicates that even in the weak confinement regime such as realized in CuCl QDs, the internal motion of the exciton must be taken into account. Kayanuma and Momiji extended their variational calculation to the cases of incomplete potential barriers [20], cylindrical shaped QDs [21], and quantum microsphere shells [22].

The three-dimensional confinement of the exciton wavefunction causes not only the blueshift of the exciton energy, but also the drastic modification of the radiative decay of the exciton. In bulk CuCl crystal, it is well known that the exciton strongly couples with radiation fields, thus forming exciton polaritons [1]. The oscillator strength of the exciton was distributed over the polariton states, and the radiative decay of the exciton must be treated in a framework of the polariton picture. In the QD, however, the polariton effect is not important because the size of the QD is much smaller than the wavelength of light. Consequently, the QD acts as a mesoscopic atom, in which the exciton exists as a coherent superposition of the electronic excitation over the QD's volume. In this situation, the oscillator strength of the exciton should be proportional to the QD's volume [23, 24]. Hanamura [24] showed that the radiative lifetime τ_r for the spherical QD is expressed by

$$\tau_r = \frac{3}{64\pi\varepsilon}\left(\frac{\lambda}{a}\right)^3 \frac{\hbar}{\Delta E_{\mathrm{LT}}} \tag{3}$$

where ΔE_{LT} is the longitudinal-transverse splitting of the exciton, ε is the background dielectric constant, and λ is the luminescent wavelength. This size-dependent radiative lifetime, which is sometimes referred to as "exciton superradiance" in QDs, has been confirmed by experiments [25–27]. Itoh et al. [26, 27] measured the radiative lifetimes of the confined excitons for various sizes between $a^* = 1.6$ and 15 nm, by means of selective excitation using a picosecond pulsed laser. They found that the observed radiative lifetime was in good agreement with Eq. (3), for smaller ($a^* \leq 4$ nm) QDs. For larger QDs, however, the observed radiative lifetime deviated from the theoretical value, approaching the constant value around $\tau_r \sim 50$ (130) ps at 10 (77) K. Although the reason for the deviation from the theoretical value was not fully understood, it was suggested that the deviation is attributable to the decoherence of the lowest exciton state originating from the admixture of the higher confinement states via thermal excitation and/or exciton–phonon scattering, which is expected to be more frequent for larger sizes because the splitting between the confined sublevels becomes smaller [24, 26, 27]. However, it is also worth considering that, in the range of the QD sizes concerned, the excitonic polarization is strongly coupled with electromagnetic fields. The exciton-field coupling in spherical QDs was theoretically examined by Ekimov et al. [28], and later on by Ajiki et al. [29, 30]. They pointed out that the oscillator strength, which is concentrated at the lowest confined exciton state for smaller ($a^* \leq 5$ nm) QDs, is transferred to higher confined states that become energetically resonant with a "surface mode" with the increase of QD size. From this point of view, it is natural that the radiative lifetime of the lowest confined exciton deviates from the simple theory, Eq. (3), in which the strong exciton-field coupling is not taken into account. It is suggestive that the size at which the observed lifetime started to deviate from the theory corresponds to the expected size at which the oscillator strength
Figure 1. Luminescence spectra of CuCl quantum dots (a) mean dot radius, embedded in NaCl matrices measured at 77 K. Dotted curve is the luminescence spectrum of bulk CuCl crystal.

begins to transfer from the lowest exciton state to other states. Recently, Cho and Ajiki [31, 32] have shown an unified picture in which the coupled modes between the exciton polarization and the radiation field are smoothly connected to those in microsphere cavities for larger sizes, and also to the exciton polariton picture in bulk crystal. In connection to the "exciton superradiance" or "giant oscillator strength" of the confined exciton, it is very interesting that the giant oscillator strength was recently predicted [33] and observed [34–36] in larger QDs based on III–V materials.

3. HIGHER EXCITED STATES OF THE CONFINED EXCITON

In the recent decade a lot of works on CuCl QDs mainly concentrated on the investigation of the optical properties of the lowest $1S$ exciton state as a typical example of the weak confinement. As far as the weak confinement regime in spherical QDs is concerned, the notation of the quantum number such as "$1S$" has two different meanings. One is for the Rydberg states of the internal motion of the exciton, and the other is for the confinement states of the translational motion of the exciton. Hereafter, we denote the former as small capital letters N, L as $1S$, $2S$, $2P$, $\ldots$, and the latter as lowercase letters n, l as $1s$, $1p$, $1d$, $2s$, $\ldots$, where N and n are the main quantum number, and L and l denote the angular momentum. In the limit of the weak confinement of spherical QDs with infinite potential barrier, the exciton energy ΔE_{NLnl} of the confined state ($NLnl$) is given as an extension of Eq. (1) by [16]

$$\Delta E_{(NLnl)} = E_g - \frac{Ry^*}{N^2} + \frac{\hbar^2}{2M}\left(\frac{\phi_{nl}}{a}\right)^2 \qquad (4)$$

where ϕ_{nl} gives the nth zero of the spherical Bessel function $j_l(x)$, satisfying

$$j_l(\phi_{nl}) = 0 \qquad (5)$$

From Eq. (4), one can see that the exciton internal motion (second term) is independent of its translational motion (third term), as in the bulk crystal. This approximation works well, as long as the exciton Bohr radius is much smaller than that of the dot size, or, in other words, the absolute value of the second term of Eq. (4) is much larger than the third term. This condition is fulfilled for the lowest $1S$ exciton in the QD with the size of a few nm. However, if the dot size is sufficiently small, or if the exciton is in the higher Rydberg state, the condition would not be satisfied. In these cases, the internal motion and the translational motion of the confined exciton are not separable, and thus the total angular momentum $J = L + l$ will be a good quantum number. Kayanuma [19] performed the variational calculation that includes both internal and translational motion of the excitons in spherical QDs and showed for the first time how the well-separated quantum states of Rydberg and confinement states in the weak confinement regime mix with each other when the dot size decreases toward the strong confinement regime. More recently, Uozumi et al. [37, 38] calculated the ground and excited states of the confined excitons with a much larger set of basis functions and examined their optical properties.

From the experimental side to observe the higher excited states of the confined exciton, since measurements of standard optical absorption and luminescence excitation spectra are strongly influenced by the inhomogeneous broadening of the exciton bands due to the wide size distribution [13], one must achieve more sophisticated experiments to reveal the optical responses originating from higher excited states. Itoh et al. [14, 15] performed the size-selective excitation of CuCl QDs using monochromated ultraviolet (UV) light. They observed several peaks in the excitation spectra depending on the detection photon energy of the inhomogeneously broadened photoluminescence. By selecting the detection photon energy, one can select the size of QDs for the detection, as expressed by Eq. (1). From the relationship between the energy position of the peaks in the excitation spectra and the detection energy of the photoluminescence, they found that these peaks originate from the confined states of the Z_{12} excitons, which split into three (including two heavy-hole and one light-hole) components. Also, they found the components that converge to the higher energy position for larger sizes. As described later, from comparison with other experimental results, they were attributed to the confined states of the Coulombic $2S$ states of the Z_3 and Z_{12} excitons. Later on, by means of the size-selective luminescence spectra, Itoh et al. [39] revealed the luminescence structure that is attributed to the excitons that are initially excited to the $1p$ confinement states. As described in Section 5, it is interesting that this confinement state strongly couples with the optical phonons in the QD.

Another useful technique to investigate higher excited states of the confined exciton is the two-photon excitation technique. Generally, the two-photon excitation has a different selection rule from that of one-photon excitation. For instance, exciton states with S type symmetry are optically allowed under one-photon excitation, whereas those with P type symmetry are allowed under two-photon excitation. Thus, individual structures associated with the exciton excited states are expected to be more distinctly observed without the disturbance from the contribution of the lowest strong exciton states with S type symmetry. Also, with two-photon excitation, one can spectrally eliminate the strong scattering of the excitation light, which sometimes causes difficulties in resolving the small signal close to the excitation photon energy. Fröhlich et al. [40] measured the two-photon excitation spectra of the confined exciton luminescence and found that the $1S$ exciton states are weakly two-photon active for the linear polarized light parallel to [110] axes but forbidden for [100] axes of the NaCl matrix. Considering that the $1S$ exciton of the bulk CuCl crystal is weakly two-photon active for the polarized light parallel to [110] but not to the [100], this finding indicates that the crystalline axes [100] of the CuCl QDs are parallel to that of the NaCl host crystal. Edamatsu et al. [41] observed the two-photon excitation spectra for CuCl QDs with different mean radii and found a steep increase of the two-photon excitation efficiency at a few hundreds mV higher than the lowest $1S$ exciton energy. Furthermore, the energy positions of the steep rise depended on the mean dot size of the samples. From the energy separation between the steep rise and the lowest $1S$ exciton, and from the comparison with the results of excited-state absorption described later, they

concluded that this steep rise of two-photon excitation originates from the nP Rydberg-like states of the confined exciton. This attribution was also in good agreement with the theory [19, 38, 42]. The confinement effect on the higher Rydberg-like states will be discussed later in this section. Edamatsu et al. [43] also studied the luminescence spectra of CuCl QDs in NaCl matrices under size-selective one- and two-photon excitation. As in the excitation spectra reported by Itoh et al. [14, 15], several structures, the positions of which were dependent on the excitation photon energies, were observed in the luminescence spectra. These structures were likely to originate from the confined exciton that was initially excited to higher confinement states. However, the energy positions of the observed structures did not follow the theoretical ones that assumed the spherical shape of the QDs. Instead, the experimental result might indicate that the shape of CuCl QDs in NaCl matrices would be more oblate, as previously suggested by Itoh et al. [13–15]. On the contrary, the luminescence structure that is attributable to the excitons that are initially excited to the $1p$ confinement states of the spherical QD in glass matrices was observed in size-selective one-photon [39] and two-photon [44] excitation. From these results, it is likely that CuCl QDs embedded in glass matrices have mostly spherical shapes. It is also noteworthy that, in the two-photon excitation, the size-selective luminescence spectra of the QDs in both NaCl and glass matrices exhibited an unknown structure, whose Stokes shift is nearly half that originates from the $1p$ confinement state [41, 44]. Baranov et al. [44] attributed the structure to the confined longitudinal excitons in the QDs. However, this attribution is inconsistent with the recent theory [29, 30] that dealt with the coupling between the polarization of confined exciton states and electromagnetic fields, as described in Section 2. Thus, the origin of this unidentified luminescence structure appearing in two-photon excitation is still a open question to be clarified in the future.

As well as the two-photon excitation, transient two-step excitation is a powerful method to investigate the higher excited states of the confined exciton. In this method, a strong UV pump pulse excites the confined excitons at their lowest states, and a succeeding weak pulse probes the transient absorption arising from the transition from the lowest to higher states of the confined excitons. Mimura et al. [45] found the infrared transient absorption attributable to the transition from Rydberg $1S$ to $2P$ states of the confined excitons in CuCl QDs embedded in NaCl matrices. The absorption spectra depended on the mean size of the QDs: the peak position of the absorption for QDs with mean radius $a^* = 3.5$ nm was located at 0.28 eV, while that for $a^* = 1.3$ nm QDs was at 0.39 eV. Yamanaka et al. [46, 47] studied the size dependence of the transient absorption by means of size-selective excitation, and the result was compared with the theory [37, 38]. In general, the agreement between the experiment and theory is very good: the observed blueshift of the transient absorption with the decrease of dot size is reproduced by the theory. The change of the Rydberg $1S$–$2P$ absorption with the dot size indicates that the effective Rydberg energy of the confined exciton depends on the dot size. In other words, the $2P$ state of the confined exciton in CuCl QDs in the size region under study (a few nm) is no more classified into the ideal weak confinement regime,

in which the internal motion of the exciton is assumed not to be affected by the confinement. Instead, since the effective exciton radius of the $2P$ exciton state is much larger than that of the $1S$ state, the confinement effect on the $2P$ state deviates from the weak confinement toward the strong confinement regime. The theoretical calculation [37, 38] presented the optical properties including two-photon and transient absorption spectra and predicted the drastic change of the optical spectra between the two extreme regimes. In addition to the transient absorption of the confined excitons in the QDs, transient absorption originating from the confined biexcitons in CuCl QDs was recently observed [48]. The excited state of the biexciton is not stable in bulk crystal because the excess energy of the excited states (a few hundred meV) is larger than the binding energy of the biexciton (32 meV). However, in the QDs, the excited biexciton can exist because the two excitons in one QD are never dissociated from each other. Since the observed transient absorption spectra of the confined biexcitons was very similar to those of the confined excitons, it was suggested that the excited states of the confined biexciton is approximately composed of one excited and one lowest excitons [48].

4. NONLINEAR OPTICAL RESPONSE AND CONFINED BIEXCITON

Control of nonlinear optical response is one of the most important aspects of semiconductor QDs for the application to optically functional devices. It is expected that multiply created excitons in a QD strongly interact with each other, because the two excitons are confined in a tiny space. The spatial closeness and strong interaction between the two excitons breaks the bosonic nature of the confined excitons, thus generating large optical nonlinearity even in the "weak confinement" regime [49–55].

Experimentally, the nonlinear optical response of CuCl QDs was first reported by Gilliot et al. [56, 57], and soon followed by other groups [58–64]. In these early experiments, strong nanosecond lasers were used as pump sources to examine the nonlinear response. The main features of these experiments are bleaching and blueshift of the exciton absorption bands. Since the exciton binding energy in CuCl is very large, these nonlinear effects were believed to be caused by many-body effects (i.e., creation of two or more excitons in a QD), rather than the formation of electron–hole plasma. In fact, the saturation intensity, from which the saturation of the exciton absorption takes place, was almost inversely proportional to $(a^*)^3$ [58, 62], indicating that the number of excitons per QD is an essential parameter to govern the optical nonlinearity of the QD. Edamatsu et al. [64] investigated the temporal evolution of the nonlinear optical response by means of subpicosecond pump-probe spectroscopy. They revealed that the nonlinear optical response was composed of saturation, blueshift, and broadening of the exciton absorption band. The saturation and broadening components almost disappeared within several picoseconds after the pump pulse, indicating that these components arise from hot carriers, or higher excited states of the exciton, which are initially generated in the QD by the pump that had considerably higher photon energy than the lowest Z_3 exciton energy. In contrast, the time evolution of blueshift had

longer decay times (60 and 380 ps), which are identical to the lifetimes of a biexciton (excitonic molecule) and an exciton, respectively. This finding is the first clear evidence that the blueshift component of the optical nonlinearity is mainly caused by the existence of a biexciton and an exciton in the QD. Furthermore, they observed that the exciton luminescence grows with a rise time that is consistent with the decay time of the biexciton, indicating a cascade radiative decay process of the biexciton via the exciton. In bulk CuCl crystal, the luminescence decay time of the biexciton was usually measured to be about half that of the excitons, reflecting the population equilibrium between the excitons and biexcitons brought by frequent exciton–exciton collisions [65]. In QDs, however, such collisions never occur between excitons isolated in different QDs, and thus the observed decay time represents the real lifetime of the excitonic molecule confined in a QD, which is of the same order as those in bulk crystal [66, 67]. Thus, the cascade radiative decay of the biexciton via the exciton is characteristic of the confined exciton and biexciton system in the QD. Similar results on the temporal evolution of the blueshift and the cascade decay of the biexciton were also obtained by Ikezawa and Masumoto [68]. By these experiments, it was clarified that the main origin of the optical nonlinearity of CuCl QDs is the blueshift of the exciton energy caused by the presence of another exciton in the same QD. However, the agreement of the observed amount of blueshift with existing theories had not been satisfactory [64] until Nair and Takagahara [54, 55] proposed the concept of "weakly correlated exciton pair states" in the QD, as will be discussed.

It is expected that the two excitons created in a QD interact with each other and form exciton pair states that are somewhat different from the ideal uncorrelated two exciton state. Especially, the existence of a biexciton (or excitonic molecule: a bound state of the two excitons) in a QD and the size dependence of the biexciton binding energy have been intensively discussed in several theoretical works [50, 69–75]. Since it is well known that the biexciton is very stable in bulk CuCl crystal, one can also expect the existence of biexcitons in CuCl QDs. In fact, the luminescence originating from the radiative decay from the biexciton to the exciton was observed in CuCl QDs under strong excitation using a pulsed laser [27, 76, 77]. Provided that the weak confinement regime is also applicable to the biexciton, one would expect that the blueshift of the biexciton energy is almost half that of the exciton, because the translational mass of the biexciton is approximately twice the exciton mass [see Eq. (1)]. As a result, the luminescence photon energy would decrease with the increase of dot size, because the luminescence is caused by the radiative decay from the biexciton to the exciton states [75]. Itoh [27] measured the peak position of the biexciton luminescence as a function of the dot size and found that the biexciton luminescence exhibits the redshift from the bulk value with the decrease of the dot size in the range $a \geq 3$ nm, whereas it shows blueshift for smaller sizes. The redshift for larger sizes is consistent with the consideration described previously. However, this size-dependent redshift was not clearly observed in other reports [76, 77]. Interestingly, the energy position of the biexciton luminescence for larger sizes did not converge to that of the

biexciton luminescence in the bulk crystal leaving a transverse exciton, but even closer to that leaving a longitudinal exciton [27, 77]. This phenomenon is likely to be explained by the previously mentioned consideration that the oscillator strength of larger QDs concentrates at the surface mode, which is located between the transverse and longitudinal excitons in the bulk crystal [28–30]. As a result, the biexciton luminescence of the QDs with larger sizes ($a \geq 10$ nm) is energetically closer to that of the bulk crystal leaving a longitudinal exciton. The blueshift for smaller sizes is attributable to the deviation from the weak confinement regime of the biexciton for the QDs of such small sizes. This consideration is consistent with the fact that the size at which the redshift turns to blueshift almost coincides with the Bohr radius of the biexciton (3.5 nm [78]). The binding energy of the biexciton is defined by

$$\Delta E_{BX} = 2E_X - E_{BX} = E_X - (E_{BX} - E_X)$$
$$= E_X - h\nu_{BX} \qquad (6)$$

where E_X, E_{BX}, and $h\nu_{BX}$ are the energies of exciton, biexciton, and biexciton luminescence, respectively. Even though the biexciton luminescence exhibits the blueshift, larger blueshift of exciton energy results in the increase of the binding energy with the decrease of dot size, as predicted by the theoretical calculations [69–75]. Concerning the biexciton state in CuCl QDs, it is also noteworthy that the optical gain and lasing associated with the transitions from the biexciton to the exciton states were observed [63, 64].

In addition to the lowest bound state of the biexciton, since the two excitons in a QD cannot separate entirely from each other, one may consider the excited states of the biexciton. These excited states correspond to a kind of antibonding state and thus are not stable in the bulk crystal. Nair and Takagahara [54, 55] pointed out that this "weakly correlated exciton pair state" plays an crucial role in the optical nonlinearity of the QDs. Ikezawa et al. [79, 80] observed the excited-state absorption from the exciton state to these excited biexciton states by means of a size-selective pump-probe technique. They found the absorption signals to the excited biexciton states ($J = 2$), as well as to the bound biexciton ($J = 0$). The blueshift of the excited biexciton was approximately twice as large as that of the exciton, indicating that each exciton constituting the excited biexciton effectively occupies half the volume of the QD [80]. Furthermore, they observed the absorption from the biexciton state to a triexciton states consisting of three excitons in a QD. In relation to the excited states of the biexcitons, it is also interesting that another kind of excited state of the biexciton composed of one Rydberg excited and one lowest exciton was observed in the infrared transient absorption, as described in Section 3.

To consider the size dependence of the optical nonlinearity, one must take account of two contradictory effects. One is the anharmonicity or nonbosonic nature of the exciton states, and the other is the superradiant oscillator strength of the confined exciton that is discussed in Section 2. The former decreases with the increase of dot size because the correlation between the two excitons in a QD decreases [54, 55]. On the other hand, the latter increases with increasing dot size because the oscillator strength of the confined exciton

increases with the dot size. Kataoka et al. [60] measured the third order optical susceptibility $\chi^{(3)}$ of CuCl QDs and its size dependence by means of the degenerate four-wave mixing method. The observed values of $\chi^{(3)}/\alpha$, where α is the linear absorption coefficient, increased with the increase of dot size until $\chi^{(3)}/\alpha = 3.4 \times 10^{-9}$ esu cm at $a \sim 5$ nm and decreased for larger sizes. They also discussed the size dependence of the oscillator strength of the confined exciton, which is derived from the observed $\chi^{(3)}$, and showed that the size dependence of $\chi^{(3)}$ mainly depends on that of the oscillator strength. The size (4–5 nm) at which the obtained values of $\chi^{(3)}/\alpha$ and oscillator strength exhibited the maximum value was in good agreement with the size where the luminescence lifetime started to deviate from the theoretical value [26, 27], as discussed in Section 2. Also, Yano et al. studied the size dependence of the absorption saturation and obtained a similar size dependence [61]. Thus, the saturation of the oscillator strength is likely to be one reason for the suppression of the optical nonlinearity in larger dots. For the other reason, Nair and Takagahara [54, 55] pointed out that when the energy difference $E_{XX} - 2E_X$ (where E_X and E_{XX} are the energies of confined exciton and correlated exciton pair state, respectively) is comparable or smaller than the homogeneous width of the states concerned, strong cancellation of the two terms (via the ground state and via the exciton pair state) on $\chi^{(3)}$ takes place and causes the suppression of the optical nonlinearity.

5. PHONON CONFINEMENT AND EXCITON–PHONON COUPLING

In addition to the exciton confinement, it has also been reported that lattice vibrations, of both acoustic [81–83] and optical [39, 43, 84–87] phonons, are confined and quantized in the CuCl quantum dots. Masumoto et al. [81, 82] investigated the confined acoustic phonons by means of the persistent spectral hole-burning spectroscopy. They found that the energy separation of the phonon sidebands from the zero-phonon bands to be inversely proportional to the radius of the quantum dots that were excited resonantly by a narrow-line laser. Similar results were also obtained by resonant luminescence spectroscopy, in which it was confirmed that the phonon sidebands originate from the confined acoustic phonons by means of the temperature dependence of the Stokes and anti-Stokes sideband intensities [83]. The inverse proportion of the confined phonon energy to the dot size is explained by the theoretical works on the confinement of acoustic phonons in isolated elastic spheres [88–92]. For the simplest case, the vibrational frequencies $\omega_{n,l}^S$ and $\omega_{n,l}^T$ of an elastic sphere in a free boundary condition are given by

$$\omega_{n,l}^S = \frac{\eta_{n,l}^S}{a} v_t \tag{7}$$

$$\omega_{n,l}^T = \frac{\eta_{n,l}^T}{a} v_t \tag{8}$$

where the superscripts S and T indicate the spheroidal and torsional modes, respectively, l is the angular momentum index, n is the branch number, a is the sphere radius, v_t

is the transverse sound velocity of the elastic medium, and $\eta_{n,l}^S$ and $\eta_{n,l}^T$ are the eigenvalues satisfying appropriate equations [88–92]. These lowest frequency modes with $n = 0$ are called surface modes, since these modes have a large amplitude at the surface. The amount of the observed Stokes shift for the QDs in glass matrices was in good agreement with the calculated value of $\hbar\omega_{0,0}^S$, or even with $\hbar\omega_{0,2}^T$ or $\hbar\omega_{0,2}^S$. Since only the spheroidal modes with $l = 0$ contribute to the resonant Raman scattering via the Z_3 exciton state [93], the observed phonon sideband was assigned as the lowest spheroidal mode $\omega_{0,0}^S$ [83]. For the QDs embedded in NaCl matrices, however, the observed energy shift is not explained by vibrational modes assuming simple boundary conditions [81–83]. Given that the sound velocities of the NaCl and CuCl are similar, the vibrational mode of the CuCl QD in the NaCl matrix might be extended further into the matrix, which would explain why the energy estimation is more complicated than that in glass matrix. Such matrix effects that might cause the disappearance of the lowest surface modes ($n = 0$) and the softening of the torsional modes were discussed by Tamura et al. [90].

In the case of the confinement of optical phonons, the situation is somewhat different. Since the optical phonon frequency depends less on its wave number, its dependence on dot size is also quite small. Ekimov obtained slight but positive dot-size dependence of the longitudinal optical (LO) phonon frequency in Raman spectra and interpret it as quantization along the dispersion curves of the LO phonon [86, 87]. As described later in this section, the confined LO phonon and the exciton strongly interact with each other, forming exciton–phonon complexes [39, 43, 84]. The strong exciton–phonon interaction also results in the renormalization of the LO phonon energy associated with the exciton [84, 85].

It is valuable to discuss the exciton–phonon coupling in the QD. For several QD materials, there are a number of works on the enhancement of exciton–acoustic–phonon coupling [92–96] and exciton–optical–phonon coupling [97–103]. Because of the different origins of the coupling— deformation potential for exciton–acoustic–phonon coupling and Fröhlich interaction for exciton–optical–phonon coupling—the mechanisms of the enhancement are also different. Since the confined excitonic state in CuCl QDs is much different from those in other materials, it is very interesting to examine the exciton–phonon coupling in CuCl QDs. In bulk CuCl crystal, the coupling between phonons and excitons is relatively week so that the exciton absorption and emission spectra are mainly composed of the zero-phonon line of the free exciton. The value of the exciton–acoustic–phonon coupling constant g defined by Toyozawa [104] for bulk CuCl was estimated to be the order of 0.001 [105]. Itoh and Furumiya [105] evaluated the exciton–phonon coupling constant for CuCl QDs (effective radius $a^* = 1.5$ nm) in NaCl matrix to be $g = 0.35$ from linear temperature dependence of homogeneous broadening of the resonant exciton luminescence. Kuroda et al. [106] obtained the approximately doubled value of g for CuCl QDs ($a^* = 2.3$ nm) in glass matrix by two-photon excitation. Edamatsu et al. [83] evaluated the Huang–Rhys parameter S [107] of the phonon sidebands originating from the confined acoustic phonons in resonant luminescence spectra.

The estimated values of S at $T = 0$ K are 0.24 and 0.30 for glass ($a^* = 2.4$ nm) and NaCl ($a^* = 3.2$ nm) matrices, respectively. In the case of deformation potential coupling, the Huang–Rhys parameter is related to the exciton–lattice coupling constant g [104]. The resulting values were $g = 0.07$ and 0.08 for the QDs in glass and NaCl matrices, respectively. Although these obtained values of g are slightly different from each other, they are all much larger than that estimated for the bulk CuCl crystal. This result indicates the strong enhancement of the coupling between the confined excitons and acoustic phonons in the QD. Although such enhancement of the exciton–acoustic–phonon coupling is intensively discussed for various QDs [92–96], it seems that there are not consentaneous conclusions at present. Further theoretical and experimental investigations will be necessary to clarify the mechanism of the enhancement of exciton–acoustic–phonon coupling in semiconductor QDs.

In the case of exciton–optical–phonon coupling, drastic effects have been observed in CuCl QDs as noted above previously. Itoh et al. [39] found that the confined excitons and LO phonons form exciton–phonon complexes; they observed in resonant luminescence spectra the anticrossing between the LO phonon sideband and the sideband arising from the excitation to higher confined states of the exciton. This anticrossing was also observed in two-photon excitation [43] and persistent hole-burning [84] spectra. The strong exciton–optical–phonon interaction in the QD also results in the renormalization of the LO phonon energy [84, 85], which means that the confined LO phonon associated with an exciton suffers considerable ($\sim$10%) [84] softening. In fact, the LO phonon sidebands observed in persistent hole burning [84], resonant luminescence [43, 84], and the beat frequency in four-wave mixing experiment [85] exhibited reduced LO phonon energies from that observed in off-resonant Raman spectra [87]. This is one of the unique phenomena originating from the strong exciton–optical–phonon interaction in CuCl QDs.

6. PHASE RELAXATION OF THE CONFINED EXCITON

The excitonic states confined in semiconductor QDs are sometimes referred to as artificial atoms or mesoscopic atoms, since they have discrete energy spectra and their wavefunctions are coherent superposition of the electronic excitation over the QD's volume. It is also expected that those states are more or less isolated from environment because of the three-dimensional confinement. If the excitonic states are well isolated form environment, it is expected that the phase relaxation, or decoherence, of the confined excitonic states will be very slow compared with that in bulk crystals. In fact, there are a number of experimental works reporting very long phase relaxation time in CuCl and other QDs [108–111]. The amount of phase relaxation time is crucial for the application of confined excitonic states to quantum information processing, because the phase relaxation essentially destroys quantum information held in excitonic wavefunctions. Thus, it is very important to study the phase relaxation mechanisms of the confined excitons.

To measure the phase relaxation time of the confined exciton, there two methods: frequency-domain and time-domain measurements. The former includes resonant luminescence and persistent hole-burning spectroscopy, and the latter does four-wave mixing and photon echo spectroscopy. Masumoto et al. [112] reported for the first time the homogeneous width of the Z_3 exciton in CuCl QDs embedded in NaCl crystal. They measured the homogeneous width by means of laser saturation spectroscopy of the exciton absorption and reported that the homogeneous width of the QD (mean dot radius = 6.1 nm) was 0.18 meV at 77 K. Itoh and Furumiya [105] measured the homogeneous width and its temperature and size dependence of the resonant luminescence of CuCl QDs in NaCl crystal. The homogeneous width Γ_0 extrapolated to 0 K was 0.32 meV for the QD (effective dot radius $a^* = 4.0$ nm), and Γ_0 increased with the decrease of dot size. Wamura et al. [113] measured the homogeneous width of CuCl QDs in NaCl crystal by means of persistent hole-burning spectroscopy. The obtained Γ_0 for the QD with $a^* = 4.1$ nm was 0.30 meV and increased with decreasing dot size, in accordance with that obtained from the resonant luminescence spectra described previously. Later on, Masumoto et al. [114] reexamined the persistent hole-burning experiment with high spectral resolution and obtained $\Gamma_0 = 0.07$ meV for the QDs ($a^* = 3.5$ nm) in NaCl. In addition, Kuroda et al. [106] measured the homogeneous width of CuCl QDs in a glass matrix by means of two-photon-excited resonant luminescence. The obtained Γ_0 was 2.1 meV for $a^* = 2.3$ nm. Since the homogeneous widths obtained from these frequency-domain experiments do not show good consistency, the corresponding phase relaxation time (T_2) ranges from subpicoseconds to over 10 picoseconds. This discrepancy is probably caused by the difference in experimental conditions, most probably in excitation intensity, which might affect the homogeneous width. In fact, Edamatsu et al. [83] recently reported that the homogeneous widths of the resonant luminescence of CuCl QDs in both glass and NaCl matrices were less than 30 μeV, which is limited by the experimental spectral resolution, at sufficiently weak excitation power. Meanwhile, the phase relaxation time of CuCl QD was measured by time-domain experiments: four-wave mixing or accumulated photon echo (see Section 7). Kuribayashi et al. [108] measured the phase relaxation time of a CuCl QD (mean dot radius = 5.4 nm) in a glass matrix and obtained $T_2 = 130$ ps at 2 K. Ikezawa and Masumoto [109] measured the phase relaxation time of CuCl QDs in NaCl and glass matrices. The obtained T_2 was very long: T_2 reached 1.3 and 2.6 ns at low temperature below 1 K (i.e., $\Gamma_0 = 1$ and 2 μeV) for the QDs in NaCl and glass matrices, respectively. Following to the finding of the very long T_2 in CuCl QDs, it has recently been reported that QDs of III–V materials also exhibit very long phase relaxation times of several hundred picoseconds [110, 111].

It is an very interesting subject to observe the mechanism of the very long phase relaxation of the confined excitons in relation to the exciton–phonon interaction. In a low excitation regime, where at most one exciton is to be created in a QD, it is expected that the phase relaxation mainly originates from interaction with phonons. At low temperature,

the main origin of the phase relaxation would be exciton–acoustic–phonon coupling while the coupling with optical phonons may be important at high temperature. In bulk semiconductors, the contribution of the acoustic phonon on the temperature dependence of the homogeneous width $\Gamma(t)$ is often expressed by

$$\Gamma(T) = \Gamma_0 + AT \qquad (9)$$

where A is a constant, and Γ_0 is the temperature-independent width that remains even at $T = 0$ K. The temperature-linear term originates from the contribution of the acoustic phonons that have continuous density of states from zero energy. On the contrary, the phase relaxation in CuCl QD is characteristic because, as described in Section 5, not only the excitonic states but the acoustic phonons are also quantized so as to have discrete energy spectra. Once both are quantized, the usual phase-relaxation mechanism via one-phonon emission or absorption can occur only when the energy separation between the lowest and higher excitonic states happens to coincide with one of the discrete phonon energies. As a result, the two-phonon process which involves almost simultaneous emission and absorption of the confined acoustic phonons becomes dominant in the phase-relaxation mechanism in this system. In a temperature region where the two-phonon process is a dominant mechanism, the homogeneous width of the zero-phonon line of the confined exciton is expressed by

$$\Gamma(T) = \Gamma_0 + A\sinh^{-2}\left(\frac{\hbar\omega}{2kT}\right) \qquad (10)$$

where $\hbar\omega$ is the energy of the confined acoustic phonon concerned, A is a constant, and Γ_0 is the temperature-independent width. The contribution of the two-phonon process on the homogeneous width in the CuCl QD system has been reported by recent photon echo [109] and resonant luminescence [83] studies. This contribution is characteristic of the QD system in which the electronic system is confined and the vibrational energies are actually quantized. The nature of the phase-relaxation process of CuCl quantum dots is much different from that of III–V compounds, in which the dot size is so large that the true zero-phonon line is not resolvable from the sidebands of the confined acoustic phonons.

In a higher temperature region, the zero-phonon band merges with the confined-acoustic-phonon sidebands, and the total homogeneous width is governed by the contribution of the phonon sidebands and is thus expressed by the one-phonon process of the acoustic phonons. When the spectral resolution is not good enough, this one-phonon contribution would be the dominant part of the homogeneous width measured in earlier experiments. In a lower temperature region, another mechanism of the phase relaxation with lower energy excitation might take place. Ikezawa and Masumoto [109] suggested the phase relaxation due to the coupling to a two-level system (TLS), which had been often used to explain the anomalous temperature dependences of the homogeneous widths of impurity atoms or molecules in glassy or polymer matrices [115]. With the contributions from the TLS and two-phonon process (10) taken together,

the low-temperature homogeneous width of the exciton confined in the CuCl QD system is expressed by [109]

$$\Gamma(T) = \Gamma_0 + A\sinh^{-2}\left(\frac{\hbar\omega}{2kT}\right) + B\cosh^{-2}\left(\frac{\hbar\omega'}{2kT}\right) \qquad (11)$$

where $\hbar\omega'$ is the excitation energy of the TLS, and B is a constant. The contribution of the TLS indicates that the interaction between the excited electron/hole and the surrounding matrices plays an important role in phase relaxation in the low-temperature region, as described in the next section.

7. INTERACTION WITH MATRICES

In the previous section, we described that the electronic states in semiconductor QDs are more or less isolated from environment and thus the phase relaxation time of the electronic excitation becomes very long. However, in general, real semiconductor QDs are not fully isolated from environment. In many cases, the QDs are suspended in surrounding matrix substances. As a result, the electronic excitation of the QDs sometimes interacts with matrices. For instance, it is known that colloidal QDs of II–VI materials exhibit intermittent ("random telegraph") photoluminescence [116] or spectral diffusion [117]. These phenomena are caused by Auger ionization of the QDs and succeeding carrier trapping in the matrix site near the QD [118]. In CuCl QDs, such phenomena as photofatigue [119] and persistent hole burning [120] also suggest the efficient ionization and trapping of the carriers in the matrices. Also, Kuroda et al. [121] found that CuBr QDs in glass matrices exhibit an extraordinary strong photon echo signal that originates from the accumulation effect due to the presence of long-lived excited states. The accumulated photon echo was also observed for CuCl QDs [108, 109], as stated in the previous section. Another strong indication of the interaction with the matrices is the contribution of the TLS on the low-temperature phase relaxation of the confined exciton described in the previous section.

Recent progress of the microspectroscopy technique has enabled us to observe and analyze photoluminescence signals from a single QD. The single QD spectroscopy has allowed the opportunity to study the electronic states of individual QDs interacting with the matrices and environment. Thus far, photoluminescence signals from single QDs of various kinds of materials were widely studied. Generally speaking, the stability of the photoluminescence signal from single QDs depends on many factors, such as material, environment, interface, temperature, excitation power, and so on. For instance, as described, colloidal QDs of II–VI materials exhibit intermittent photoluminescence [116] or spectral diffusion [117], depending strongly on the excitation power and on the surface treatment of the QDs. Adequately passivated colloidal QDs have very high quantum yields and low intermittent frequencies. It is worth studying such optical properties of single QDs for further understanding of the role of interaction with matrices. However, unfortunately, stable photoluminescence from single CuCl QDs has not been reported so far. In this context, Edamatsu et al. [122] observed frequently intermittent photoluminescence from a single QD, or a small number of QDs, of CuCl embedded

in NaCl crystal. The frequent intermittency suggested that the excited electrons or holes of this material easily escape from the QD and then are captured by some traps in the matrix, even at low temperature.

More important progress in the recent study of CuCl QDs is the sample preparation and characterization methods. The traditional methods to grow the CuCl QDs are thermal treatments of the supersaturated solid solution of CuCl in silicate glass [9, 10] or NaCl [13, 14] matrices. Haselhoff et al. [123, 124] studied the growth condition and size distribution of CuCl QDs in NaCl crystals. It is also noteworthy that the topographical investigations of CuCl clusters at the surface of NaCl crystal were made by near-field optical microscopy and atomic force microscopy observations [125]. However, the sizes of the observed clusters were rather large compared to the typical size of the QDs, and there are no optical or topographical observations of the individual QDs that have sufficiently small sizes. The serious disadvantage of the traditional growth methods is their poor controllability in size and concentration of the QDs. For instance, so as to observe single QD luminescence, we need sufficiently low concentration of the QDs. However, the concentration of the CuCl QDs thermally grown in glass or NaCl matrices is usually too high. As described, Edamatsu et al. [122] prepared CuCl QDs contained in thin films of NaCl crystals grown between two silica plates. However, the result indicated that we need QDs that have lower concentrations and are stable against autoionization of the photoinduced carriers to prevent the frequent luminescence intermittency. Up to now, there are a limited number of trials that intend to obtain well-characterized samples of the CuCl QD. Kurisu et al. [126] reported the growth of CuCl QDs embedded in SiO_2 film by means of a sputtering method. Kawamori et al. [127] reported the formation of CuCl island structures on CaF_2 substrates by means of molecular beam epitaxy. We hope that these efforts will succeed in growing well-characterized and well-controlled samples of CuCl QDs in the future.

8. CONCLUSION

In this chapter we have reviewed the optical properties of CuCl quantum dots associated with quantum confinement effects and related phenomena. Due to the confinement of exciton translational motion which is peculiar to this material, many kinds of intrinsic natures of coherent excitons, such as blueshift and splitting of exciton states, rapid radiative decay of exciton, size-dependent optical nonlinearity, etc., only appear in the quantum dots because of their small sizes similar to or smaller than the exciton coherence length. The exciton coherence is pronounced not only because of very small size and small number of impurities or crystal imperfections but also the dramatic decrease of exciton–phonon interaction. Those are the main reasons coherent control of confined excitons becomes practical [128]. The quantum control of photons in quantum dots will also be practical due to long coherence time of excitons. The aforementioned quantum size effects are all caused by the wave natures of confined excitons inside the quantum dots. The quantum dots are essentially typical open systems which

are easily affected by the physical properties of the surroundings, such as matrices. The shape of the quantum dot itself depends critically on the matrices: cubic in crystalline matrix and/or spherical in amorphouses. The confined excitons can interact with outer optical phonons by the Frölich interaction. The exciton energy and/or photogenerated carriers can be transferred through the interface between the quantum dots and their surroundings that cause the ionization of quantum dots, blinking, and the photofatigue effect on exciton luminescence. The charge transfer through the interface is nothing but the function of photocatalysis, and the energy transfer is similar to that on a reaction center.

In the near future, one can surely expect that the research fields of the quantum dots will be further expanded into many kinds of new fields not only in physics but also towards chemistry, biology, and information technology.

GLOSSARY

Biexciton A quasiparticle consisting of two excitons, or two electrons and two holes, combined together. It is also called an "excitonic molecule".

Exciton An elementary excitation (quasiparticle) of electronic states in semiconductors. An exciton consists of an electron and a hole combined by Coulomb interaction. As in the general treatment of two-particle systems, the exciton wave function can be separated into two parts: the internal (relative) motion of the electron and hole, and the translational motion as a combined particle. In most semiconductors, the internal motion of an exciton causes a series of discrete absorption bands similar to that of a hydrogen atom. This type of exciton is called Wannier exciton, and the series of absorption bands is called Wannier (or Rydberg) series of the exciton.

Quantum dot A nanometer-sized particle of semiconductor material in which the quantum nature of electronic behavior becomes dominant. In a quantum dot, the electronic wave function is confined in all dimensions. As a result, electronic and optical properties of quantum dots deviate from those of bulk crystal as a function of dot size. "Nanocrystal" is a synonym of "quantum dot".

Weak confinement The quantum confinement effect of the Wannier exciton in a quantum dot is characterized by the relationship between the exciton Bohr radius and the dot size. When the dot size is sufficiently larger than the exciton Bohr radius, it is a good approximation to treat the exciton as a particle whose translational motion is confined in the dot, with much less influence on its internal motion. This situation is called the "weak confinement" regime.

CONTENTS

1. INTRODUCTION

Core-shell nanoparticles have recently been the focus of a lot of scientific efforts because of the combination of different properties in one particle based on different compositions of the core and the shell. Furthermore, many interesting technological applications can be foreseen for this kind of material, in addition to others in analytical chemistry (chromatography), separation technology (ion exchange), catalysis, biochemistry and medicine, etc. [1, 2]. These types of particles can be defined by their different core and shell compositions. The core often (though not always, as will be discussed below) shows the relevant property (e.g. semiconductors, metals, magnetic oxides, encapsulated molecules), while the shell can stabilize the core; create compatibility between the core and the environment; or can change the charge, functionality, or reactivity of the surface. This is especially important if the shell is a polymer and the final core-shell particle can be homogeneously dispersed in a polymer on the nanoscale [3]. In recent years, especially for medical purposes, the shell has become more and more important (e.g., for drug delivery applications).

Core-shell nanoparticles are classified within this chapter according to their chemical composition, as follows:

- *Inorganic–Inorganic Nanoparticles*: This category mainly comprises metallic, magnetic, or semiconductor core particles surrounded by a semiconductor, insulating, or metal shell.
- *Inorganic–Organic Nanoparticles*: Hybrid systems that contain an inorganic core such as a metal or a metal oxide and an organic shell of a polymer or layers of molecules on the surface of the core.
- *Organic–Organic Nanoparticles*: Most of these systems contain cross-linked polymers as the core and a different polymer or functional molecule as the shell.
- *Organic–Inorganic Nanoparticles*: Entities with an organic cross-linked polymeric core surrounded by an inorganic shell.
- *Inorganic–Biomolecule:* The inorganic core is covered by biorelated molecules such as DNA sequences.

Core-shell architectures are the result of either a two-step approach, consisting of preparation of nanoparticles and then modification of their surface, or an *in-situ* approach during particle formation. The shell can be formed by surface chemical reactions, by simple adsorption of molecules or small nanoparticles or the whole core-shell nanoparticle can be formed by subsequent self-assembly and crosslinking of macro molecules.

This chapter provides an overview of the synthetic procedures and some selected properties that make core-shell nanoparticles a very interesting class of nanomaterials. Because of the many different possible ways to prepare such particles, we shall limit the description to the most common synthetic techniques, which in most cases will make use of solution chemistry.

For simplicity, in some occasions we shall make use of the terminology core@shell to represent the composition of the composite particles.

2. INORGANIC–INORGANIC CORE-SHELL NANOPARTICLES

2.1. Core-Shell Semiconductor Quantum Dots

One very important class within these all-inorganic nanoparticles is constituted by core-shell quantum dots. Quantum dots are semiconductor particles in which quantum size effects can be observed [4]. Such quantum size effects arise from the size-dependent separation between the valence and conduction bands characteristic of the semiconductor, which gives rise to very interesting optical properties, especially with respect to luminescence at well-defined and narrow spectral ranges, which depend on particle size. Although the luminescent properties are characteristic of neat quantum dots, it has been observed that the formation of core-shell structures leads to an enhancement of the luminescent properties of the core [5–9]. Coating of II–VI nanoparticles with a different semiconducting material has a profound impact on the photophysics of the nanocrystalline cores [4, 10–17]. A broad range of intensities and spectral emission characteristics can be obtained by varying the thickness and the bandgap of the overlayer. Deposition of a semiconductor with a larger bandgap than that of the core typically results in luminescence enhancement due to the suppression of radiationless recombination mediated by surface states [4, 10–18], while the degree of charge carrier confinement does not change. The absorption bands redshift only slightly, even for quite thick layers of ZnS on CdSe [10], ZnSe on CdSe [11], and CdS on CdSe [12], as expected for a minimum variation of the confinement. Conversely, a layer of a small bandgap semiconductor provides an additional area of delocalization for both the electron and the hole [14–20]. The relaxation of the confinement regime results in a red-shift of spectral features. These studies have been carried out with PbS and HgS layers deposited on CdS and CdSe nanoparticles. Recently, CdS nanoparticles with a monomolecular coating of MoS_4 have been investigated, which demonstrated both enhancement of the excitonic emission and a noticeable red-shift of absorption features [21].

Several methods have been developed for the synthesis of core-shell II–VI nanoparticles. Successive reactions within microemulsions were used by Hoener et al. [22] to prepare ZnSe-coated CdSe nanoparticles. The microemulsion method was used again by Han et al. [19] for the coating of CdS with Ag_2S, and by Tian et al. [20] for the synthesis of CdS@CdSe and CdSe@CdS. More recently, Hao et al. [23] also used microemulsions to prepare CdSe and CdSe@CdS nanoparticles, attaining a notable enhancement of the excitonic luminescence upon coating.

The most popular method for synthesis and coating of quantum dots was initially developed by Murray et al. [24]. This procedure also makes use of surfactants (trioctylphosphine (-TOP-) and trioctylphosphine oxide (-TOPO)), which act as solvents during the nanoparticle formation, making it possible to use high temperatures (on the order of 300 °C), which are necessary to yield highly crystalline materials, but also bind to the nanoparticle surface, limiting its growth [24]. Variations of this technology were subsequently devised to prepare core-shell nanoclusters [10–12].

One example would be the addition of preformed CdS particles in pyridine to a dispersion of CdSe in TOP/TOPO at 100 °C, which leads to a core-shell CdSe@CdS structure accompanied by a large increase in the photoluminescence quantum yield (see Fig. 1). A similar procedure was used for the synthesis of CdSe@ZnS with a very high luminescence quantum yield [10].

The group of O'Brien [25] simplified the quantum dot synthesis with the use of single-molecule precursors for each semiconductor material, and they prepared, for instance, highly monodispersed CdSe@CdS through the successive thermolysis of $[Cd\{Se_2CNMe(Hex)\}_2]$ and $[Cd\{S_2CNMe-(Hex)\}_2]$ in TOPO. Other core-shell combinations followed, such as CdSe@ZnS, CdSe@ZnSe, through the use of the corresponding single-molecule compounds [26].

Apart from the II–VI semiconductors, core-shell quantum dots were also made with InAs cores, with bandgaps tunable in the near-IR, which can be useful as IR biological luminescent markers. Cao and Banin [27, 28] explored the coating of these quantum dots with InP and CdSe, using pyridine or benzylamine as solvents at a high temperature. A drop in luminescence quantum yield was found after coating with InP, but an enhancement was found with CdSe, which was reasoned to be due to the quality of the outer surface.

2.2. Bimetallic Nanoparticles

The main properties of metal nanoparticles reside in their optical and catalytic properties. Therefore, within this section we separate the discussion of bimetallic core-shell nanoparticles according to the type of properties that have been investigated during their study.

2.2.1. Optical Properties

Metal nanoparticles display very interesting optical and electronic properties, which are mainly due to the collective oscillation of conduction electrons, when interacting with an electromagnetic radiation of certain frequency [29]. Since this is mainly a surface phenomenon, it is affected by the medium surrounding the nanoparticles, which can be a solvent, a solid matrix, or adsorbed molecules/coating shells [30]. Each metal is characterized by a particular, wavelength-dependent, dielectric function, which determines the frequency at which the plasmon resonance takes place. The whole optical picture is altered when one metal is deposited on the surface of nanoparticles made of a different metal, and plenty of deposition methods and optical studies can be found in the literature.

Morriss and Collins [31] pioneered this field with the synthesis of Au@Ag nanospheres of constant gold core diameter and epitaxially grown silver shells with varying thickness. The initial plasmon absorption band (pure gold, 518 nm) progressively blue-shifted and broadened until a single broad peak around 400 nm was observed for sufficiently thick silver shells. These experimental results were in reasonable agreement with the theory, with some discrepancy, which was likely due to simplifications in the theory. Kreibig and co-workers carried out more refined calculations on the Au-Ag system [32], which yielded a much closer agreement with the experimentally measured spectra.

Synthesis of Au@Ag and Ag@Au was also carried out recently by various chemical methods in solution, such as that of Rivas et al. [33], who achieved both structures by citrate reduction. Silver shells were also deposited on citrate-stabilized 12-nm gold nanoparticles in aqueous solution, with ascorbic acid as a reductant and cetyltrimethylammonium chloride as an additional stabilizer during the growth [34], which yielded quite monodisperse core-shell particles with controlled shell thickness.

The opposite structure (Ag@Au) is harder to achieve, since Au^{3+} ions can completely oxidize 10-nm colloidal silver, forming colloidal gold [35]. To avoid this problem, Cao et al. [36] have shown that by simple reduction of gold salts by sodium borohydride, in the presence of preformed silver nanoparticles passivated with bis(p-sulfonatophenyl) phenylphosphine, Ag@Au nanoparticles were formed. Such core-shell particles proved useful for DNA diagnosis. An interesting recent report on the Au/Ag system was made by Xia et al. [37], who observed that the addition of Au^{3+} ions to colloid dispersions of larger Ag nanoparticles leads to oxidation of the silver cores and reduction of gold on the surface, so that hollow gold particles are obtained that retain the shape of the original silver cores. Another interesting design for the synthesis of Au/Ag colloids was realized by Schierhorn and Liz-Marzán [38], who deposited an insulating silica shell on uniform gold cores and then applied an electroless plating procedure [39] to deposit silver on the outer silica surface, so that the spectral features of both metals can be preserved if the silica interlayer is thick enough, as shown in Figure 2.

Very extensive work on noble metal and core-shell bimetallic nanoparticles was carried out by Henglein and co-workers, who used γ-radiolysis to generate free radicals in aqueous solution, leading to a very well-controlled reduction of metal salts, normally in the presence of a suitable stabilizer. Examples of bimetallic coated particles include Au@Cd [40], Au@Pb [40, 41], Au@Sn [42], Au@Tl [40], Ag@Pb [43, 44], Ag@Cd [45], and Ag@In [43]. They observed a variety of optical and chemical properties of the particles in dilute aqueous solutions. As each of the less noble metals (Cd, Pb, Sn, Tl, and In) was deposited as shells on either of the noble core particles (Au and Ag), the absorption band of the core particles blue-shifted toward that of a pure colloid of the shell material because of the donation of electron density from atoms to the core metal particle [43, 45].

In a later study, Henglein et al. [46] used silver particles as a template to deposit mercury by γ-radiolysis. However, only a couple of layers of mercury can be deposited on the silver particles before mercury precipitates. A similar experiment was later performed in the presence of gold nanoparticles [47], with a limited penetration of mercury and again formation of a thin mercury layer on the surface. Henglein has also demonstrated the generation of Au@Pt and Pt@Au nanoparticles [48]. Although a gold layer on platinum clusters could be deposited radiolitically, the deposition of platinum on gold had to be performed by hydrogen reduction of aged $PtCl_4^-$, and the resulting core-shell structures seem to be formed by Pt islands that join together if a sufficient amount of the metal is deposited. Successive

Schierhorn and L. M. Liz-Marzán, *NanoLetters* 2, 13 (2002). © 2002, American Chemical Society.

radiolytic reduction has also led to trimetallic Pd@Au@Ag nanoparticles with interesting optical features [49].

2.2.2. Catalytic Properties

Toshima and co-workers have been very active in this field [50]. Apart from intensive research on the catalytic activity of several metal nanoparticles, they also studied the influence of various bimetallic geometries on catalytic activity [51]. For the synthesis of metal nanoparticles, they developed a reduction method based on the use of an alcohol as a solvent and reducing agent (at reflux) and a polymer (typically polyvinylpyrrolidone, PVP) as a ligand. In the case of bimetallic structures, they typically worked through simultaneous reduction of the two metals. The mechanism for the formation of core-shell structures by simultaneous reaction was proposed [52], based on two principal factors: redox potential (the metal more easily reduced would form the core), and a coordination ability of the ligand polymer upon the metal (the metal more strongly coordinated by the ligand polymer would form the shell). Pd-Pt bimetallic nanoparticles with various Pd/Pt ratios were produced in the presence of PVP [53, 54], resulting in similar sizes, but with quite different catalytic activities for selective partial hydrogenation of 1,3-cyclooctadiene to cyclooctene. The highest catalytic activity was achieved by the bimetallic nanoparticles with Pd/Pt = 4/1. This is the nanoparticle with the perfect core-shell structure. The catalytic activity decreases with decreasing Pd/Pt ratio, in other words, with decreasing number of Pd atoms. If the total catalytic activity is divided by the number of Pd atoms in a bimetallic nanoparticle, the catalytic activities of the Pd atoms are nearly equal to each other. This means that all Pd atoms are located in the surface layer of the Pd-Pt bimetallic nanoparticles. In addition, the Pd atom in the bimetallic nanoparticles has a much higher catalytic activity than the surface Pd atom in Pd monometallic nanoparticles. This fact demonstrates that the Pt atom, located in the core of bimetallic nanoparticles and adjacent to the surface Pd atom, affects the catalytic activity of the surface Pd atoms. This cannot be an ensemble effect but should be a ligand effect. The inner Pt atom should change the electronic density and/or structure of the surface Pd atoms, resulting in the higher catalytic activity of Pd-Pt bimetallic nanoparticles than Pd monometallic ones.

Studies have also been performed by Lee et al. [55], who deposited a very thin palladium shell on 5-nm gold colloids, to prepare bimetallic particles which should be more effective catalysts. The palladium shell was structurally different from its bulk counterpart, because of the electronic perturbation of the shell by the gold core, leading to a very large increase in the catalytic performance for the cyclization of acetylene to form various isomers of butane, *n*-hexane, and benzene, at room temperature.

2.3. Metallic Shells

We describe in this section the synthesis and some properties of encapsulated colloids composed of dielectric cores and metal shells. The interest in such particles is basically due to their optical properties, which differ from those of standard nanoparticles. Early work by Barnickel and co-workers [56] showed that particles made of silver layers on polystyrene

(PS) and polymethacrylate (PMA) displayed strongly red-shifted and broader absorption bands than those of standard 10-nm colloidal silver in solution. However, the coating was not homogeneous enough to provide a good model system for testing optical theories.

A much more consistent study was performed by Oldenburg et al. [57, 58], who managed to coat SiO_2 particles of various diameters with continuous gold shells. They found that the plasmon bands depend on the core-to-shell thickness ratio as well as on absolute core size. Their observation was reported to agree quantitatively with Mie theory [59]; for the calculation of this it was necessary to take into account the quadrupolar components, because of the large sizes. Later studies by the same group showed that the plasmon resonances in the shells can be tuned across the IR region, up to 2.2 μm [60], which was useful for demonstrating surface-enhanced Raman scattering (SERS) with these systems [61]. An example of the spectacular plasmon band shifts that can be obtained by varying the core-to-shell ratio is shown in Figure 3. Later studies on the formation of Au shells on silica were performed by Graf and van Blaaderen, who reported a higher colloid stability, which allowed their use for the assembly as colloid crystals [62].

The Halas group also reported the deposition of silver shells on silica spheres, with optical behavior in agreement with Mie theory [63]. Another method that has recently been designed [39] for the deposition of metal nanoparticles on silica spheres is electroless plating [64]. This method comprises as a first step the adsorption of a sensitizer (Sn^{2+} ions) on the silica surface, followed by the addition of Ag^+. Oxidation of Sn(II) to Sn(IV) takes place at the surface, while Ag^+ is reduced to Ag^0 in the form of small nanoparticles that remain attached to the surface. No full contact between adjacent metallic particles has been observed in this case, and therefore no spectacular optical shift was produced.

2.4. Coated Magnetic Nanoparticles

Magnetic nanoparticles are interesting for a number of different applications, both in the form of ferrofluids (new refrigerators that employ the magneto caloric effect [65], new inks for inkjet printers [66], novel spin valves [67], or for new cancer therapies, such as hyperthermia [68]
Figure 3. Example of the red shift in the plasmon resonance of Au nanoshells with increasing core-to-shell ratio. Reprinted with permission from [58], S. J. Oldenburg et al., *Chem. Phys. Lett.* 288, 243 (1998). © 1998, Elsevier.

and apheresis [69]) or in thin films [70–73], basically for magnetic storage. Most of these possible applications of ferrofluids require high remanent magnetization and high anisotropy at room temperature. High remanent magnetization is a characteristic feature of soft ferromagnetic materials with diameters above a critical minimum dependent on the material (>10 nm for Co). On the other hand, hard ferromagnetic materials, which often exist as alloys, exhibit high anisotropies. Soft ferromagnetic materials embedded in a noble metallic matrix show a technologically important effect called giant magnetoresistance (GMR). The ability to prepare air-stable ferromagnetic/noble metal bimetallic particles is therefore a challenge. Well-known ferromagnetic alloys consist of ferromagnetic 3d and noble metal elements of the platinum group. They are known to have large magnetic moments and large magnetic anisotropies [74]. Accordingly, the synthesis of monodisperse ferromagnetic/noble metal bimetallic particle alloys (especially Fe/Pt) or core-shell particles and their assembly into ordered arrays have been investigated intensely in recent years.

Rivas et al. [75] reported the synthesis of cobalt nanoparticles coated with silver, based on the successive reduction of Fe^{2+} or Co^{2+} and Ag^+ within the aqueous microdroplets of inverse microemulsions. A similar approach was later used by Seip and O'Connor [76, 77] for the synthesis of Fe@Au using cationic surfactants, with magnetic measurements showing superparamagnetic behavior.

Klabunde and co-workers [78] reported the formation of core-shell structures upon heat treatment of metastable alloy nanoparticles of immiscible metals prepared through the so-called solvated metal-atom dispersion (SMAD) method. For the case of Fe-In and Fe-Nd, but with Fe-Au, Fe-Bi, Fe-Ca, Co-Mg, and Ni-Mg, either stable alloys or segregated particles were formed. Magnetic studies of the Fe@In and Fe@Nd samples showed low coercivities and Fe crystallite size-dependent saturation magnetization, though apparently there was always an increase in stability against core oxidation.

More recently, the synthesis of well-defined, core-shell Co-Pt nanoparticles was reported by Park and Cheon [79]. The formation of these alloys is driven by redox transmetalation reactions between the reagents without the need for any additional reductants. While the reaction between $Co_2(CO)_8$ and Pt hexafluoroacetylacetonate results in the formation of alloy nanoparticles such as $CoPt_3$, the reaction of Co nanoparticles with Pt hexafluoroacetylacetonate in solution results in Co@Pt morphologies, which is schematically shown in Figure 4.

Core-shell nanoparticles with an *inverted* morphology were prepared by Sobal et al. [80], with Ag cores coated with uniform Co shells. These authors report an unexpected stabilization of the Co shell against oxidation, which can be due to electron transfer from the core. In this case, the higher electron density of the core allows a sufficient contrast in TEM to distinguish the core-shell morphology (Fig. 5).

2.5. Silica-Coated Nanoparticles

We have decided to discuss silica-coated nanoparticles separately because of their special interest, which is also the reason for the extensive work that has been performed on
Figure 4. Synthetic routes of core-shell and alloy nanoparticle formation via transmetallation reactions. Reprinted with permission from [79], J.-I. Park and J. Cheon, *J. Am. Chem. Soc.* 123, 5743 (2001). © 2001, American Chemical Society.

these systems. One of the major reasons for silica coating is the anomalously high stability of silica colloids, especially in aqueous media, but other reasons are the easy control on the deposition process (and therefore on the shell thickness) and its processibility, chemical inertness, controllable porosity, and optical transparency. All of these properties make silica an ideal and costless material for tailoring surface properties, while maintaining the physical properties of the underlying cores.

This technique was pioneered in the late 1950s by Iler [81], who described a method for coating with silica "particles with at least one dimension which is less than about 5 microns," and the nature of which is typically metal oxides and silicates. Silicate solutions with suitable concentration, pH, and temperature were termed *active silica*, which easily sticks to the surface of oxide colloids in suspension. The slow reaction ensured deposition of thin silica shells, thus retaining the surface shape of the core particles. An alternative to Iler's silica coating procedure was developed by Ohmori and Matijevic [82], following the already classical Stöber method [83] (base catalyzed hydrolysis and condensation of tetraethoxysilane (TES)) to coat hematite (Fe_2O_3) spindles in ethanol. This procedure was later modified by Thies-Weesie [84]. Later work by Philipse et al. used a combination
Figure 5. TEM image at low magnification of a monolayer of Ag@Co nanoparticles deposited on a carbon-coated copper grid by drying of a drop of solution. The core-shell structure is visible at higher magnification (see inset). Reprinted with permission from [80], N. S. Sobal et al., *NanoLetters* 2, 621 (2002). © 2002, American Chemical Society.

of the previously described procedures for coating magnetite (Fe_3O_4) superparamagnetic nanoparticles [85] and boehmite (AlOOH) rods [86]. Following Philipse's work, the silica coating of magnetite was later modified independently by Liu et al. [87] and by Correa-Duarte et al. [88], both achieving more homogeneous and well-defined shells. The control of magnetic interactions is an important consequence of the coating of magnetic particles, which was demonstrated by Donselaar et al. for particles in solution [89] and by Aliev et al. in close-packed thin films [72].

A different approach was followed by Schmidt and co-workers, who used various organosilanes as building blocks and spacers to introduce functionalities within the nanoparticle structure, which can be subsequently employed for preparing more complex materials [90, 91].

Silica coating of metal colloids was also studied in detail, specially during the last decade. This type of core-shell particle presents as an additional difficulty the chemical mismatch between the core and the shell materials. Thus, a procedure must be devised to link the core and shell materials with each other. Several routes have been followed with better or worse results. Ohmori and Matijevic [92] prepared $Fe@SiO_2$ particles by an indirect path comprising the initial coating of hematite spindles [82], followed by reduction of the core within a furnace in the presence of hydrogen. The high temperature promoted sealing of the pores of the silica shell, thus avoiding further oxidation of the metallic core. Liz-Marzán and Philipse [93] first approached the synthesis of $Au@SiO_2$ particles through the formation of nanosized gold particles on the surface of small silica spheres, followed by extensive growth in ethanol, so that Au was embedded as a core. However, a large proportion of pure silica spheres was also produced, which were difficult to separate.

A method that has provided substantially better results was later designed by Liz-Marzán et al. [94, 95], with the use of bifunctional molecules to anchor silanol groups on the nanoparticle surface, followed by a slow deposition of a thin silica layer in water, and subsequent growth in ethanol, resulting in monodisperse colloids with one Au core at their center and an outer silica shell of controlled thickness. An example of the concentric geometry achieved is shown in Figure 6. This system proved ideal for a systematic study of optical properties [95, 96]. The same method was later extended to $Ag@SiO_2$ by Ung et al. [35], though dissolution of the Ag cores was observed when concentrated ammonia was added to increase the thickness of the silica shell. The same team [35, 97–98] demonstrated that dissolution by ammonia is due to the possibility of chemical reactions taking place on the cores because of the porosity of the shells.
Figure 6. TEM micrographs of $Au@SiO_2$ nanoparticles with constant core size and increasing shell thickness, grown by TES hydrolysis.

Another advantage of this method is that the first deposition in water is so slow that the shape of the original core is preserved in the initial stages, which was shown first by Chang et al. [99] and then by Obare et al. [100] by coating gold nanorods with the same procedure. The method was also modified by Hall et al. [101], who used silane coupling agents during the growth of the shell to obtain particles with amino groups on the outer surface. Hardikar and Matijevic [102] demonstrated that for larger silver particles (60 ± 5 nm) stabilized with a complicated compound (Daxad 19), no coupling agent is necessary for silica coating through TES hydrolysis in 2-propanol, and this was also recently shown by Xia and co-workers for PVP-stabilized Ag nanorods [103]. Mine et al. have also recently found [104] that standard, citrate-stabilized Au nanoparticles can be homogeneously coated with relatively thick shells without the use of a silane coupling agent, through careful tailoring of the concentrations of ammonia and TES, as well as choosing the proper addition sequence. This leads to a cleaner system (no chemical alteration of the metal surface), but almost invariably implies the formation of some core-free silica particles in addition, which is undesirable for some applications. Ostafin and co-workers have recently devised a procedure to create mesoporous silica shells on Au nanoparticles coated with a thin silica layer by using surfactants during shell formation [105].

The same method was also applied [106] to coat CdS nanoparticles, observing that the silica shell not only enhanced the colloidal stability of the quantum dots, but also the photostability, so that no photodegradation took place, even under light and in the presence of oxygen. A similar procedure was used by the Alivisatos group [107, 108] with the aim of using highly luminescent quantum dots coated with silica for biological labeling. A new variation of the same method was used by Rogach et al. [109] for the coating of CdTe and $CdSe@CdS$ nanocrystals, which resulted in the inclusion of multiple cores within every silica sphere, as well as a dramatic drop in luminescence intensity upon coating.

Other methods were later designed for the preparation of $Ag@SiO_2$. The group of Adair [110] reported the coating through consecutive reactions within microemulsion droplets. The problem with this technique is that removal of surfactants is expensive, tedious, and time consuming. Pastoriza-Santos and Liz-Marzán prepared $Ag@SiO_2$ particles through reduction of Ag^+ by N,N-dimethylformamide (DMF) [111] in the presence of an amino-silane. High temperatures were needed to achieve fast reduction of the silver salt, prior to condensation of the organo-silica shell, but rather monodisperse silver cores were obtained, and the particles could be extracted into water or ethanol.

2.6. Semiconductor Shells on Metal Cores

Research has also been carried out to deposit other oxide shells on nanoparticles, particularly on metal nanoparticles. In this way, it is intended to make use of semiconducting properties of some oxides, such as TiO_2 or SnO_2, in combination with the conducting properties of the core. This can be exploited for biological and electronic applications, as detailed below.

One example is the synthesis of Ag@TiO$_2$ by Pastoriza-Santos et al. [112] through the reduction of AgNO$_3$ in DMF/ethanol mixtures, in the presence of titanium tetrabutoxide, which condensed on the surface of the silver cores. Layer-by-layer assembly of the resulting core-shell nanoparticles, followed by dissolution of the silver cores with ammonia, subsequently led to the development of ion-selective and biocompatible titania nanoshell films [113], which were found to be useful for monitoring the diffusion of dopamine, an important compound for neurochemical processes.

Coating of gold nanoparticles with titania was also achieved by Mayya et al. [114], who used a different TiO$_2$ precursor (titanium(IV) bis(ammonium lactato) dihydroxide), which is negatively charged and readily complexes with a positively charged polyelectrolyte, poly(dimethyldiallyl ammonium chloride), previously assembled on the nanoparticle surface, and can then be hydrolyzed, providing a good control on the morphology of the shell. The same authors applied this procedure to coat Ni nanorods with titania [115], and upon dissolution of the Ni cores they were able to obtain uniform TiO$_2$ nanotubes. Typical electron micrographs of the core-shell nanorods and titania nanotubes are shown in Figure 7.

Another interesting application of metal nanoparticles surrounded by semiconductor shells is the fabrication of composite nanoparticles with a large electronic capacitance. The idea is that there is a large difference between the Fermi level of the core and the conduction band energy of the shell, so that electrons diffusing through the shell can be trapped in the core for a long time. Mulvaney et al. [116] explored this possibility with Au nanoparticles encapsulated in a polycrystalline SnO$_2$ shell. These authors demonstrated that charge can be injected by cathodic polarization through γ-radiolysis, which resulted in a blue-shift of the plasmon band (as predicted by theory), which remained blue-shifted in the absence of oxygen, but red-shifted back when open to air because of oxygen reduction by the electrons stored in the core.
We finally include in this subsection metals surrounded by semiconductor shells which are not composed of oxides, but rather of chalcogenides. Kamat and Shanghavi [117] prepared Au@CdS nanoparticles by surface modification of Au colloids with mercaptonicotinic acid followed by the addition of Cd^{2+} and exposure to H$_2$S. The result was the formation of very small CdS particles attached to the surface of the Au cores, but also free in solution. To prepare particles with novel optical properties due to both local field effects of the metal and further enhancing nonlinear optics of quantum dots, Nayak et al. [118] generated Au@CdSe particles in TOP/TOPO organic solvents, though a large proportion of particles were a mixture of individual Au and CdSe particles, as detected by TEM. Hirano et al. [119] encapsulated nanosized gold with boron nitride at extremely high temperatures and proposed that these particles would have potential applications for single-electron transistors.

3. INORGANIC–ORGANIC CORE-SHELL NANOPARTICLES

Principally inorganic-organic nanoparticles can be divided into systems with an organic core and an inorganic shell or vice versa. Although this differentiation seems to be necessary for the specific properties of the prepared materials, similar methodologies are often used for their synthesis. A prominent technique for the preparation of such cores is the use of microemulsions [2, 120]. In this approach, in which the dispersed stabilized phase can be considered as a nanoreactor, the size, shape, and curvature of the surfactant-stabilized phase determine the shape of the nano-objects obtained. With this technique the core and the shell are formed with the use of the same microemulsion by simply subsequently building up the two moieties in the micelles. In a different approach the core is formed first, isolated, and modified with the shell in a separate step by covalent anchoring or adsorption of organic groups on the surface. For the synthesis of defined core-shell systems it is crucial to obtain in a first step well-defined cores. Water-in-oil microemulsions, sometimes also called reversed micelles, are probably the most widely investigated emulsion systems for the preparation of spherical inorganic nanoparticles. The metal precursor is usually dissolved inside the water droplets and reacts in this confined arrangement to the final particle. Two different methods were used for the formation of the nanoparticles: either all chemicals for the nanoparticle formation are already included in the water phase and the metal precursor is added, or two water-in-oil microemulsions, both containing precursors for the nanoparticle formation, are mixed. In the latter case, the exchange of substances occurs in the united microemulsion by diffusion and droplet collision. With the microemulsion method a variety of nanoparticles were synthesized, such as SiO$_2$ [121–124], TiO$_2$ [125–128], ZrO$_2$ [129], CdS [130], magnetite [131], or mixed metal oxide systems [132].

Surfactants are crucial for the stabilization of the microemulsions; they produce compatibility between the two

Figure 7. TEM images of (A) a nickel nanorod coated with titania, (B) titania-based nanotubes obtained by dissolution of coated nickel nanorods, (C) a higher magnification image of a nanotube. (D) A high-resolution image showing the presence of titania nanoparticles. Reprinted with permission from [115], K. S. Mayya et al., *Chem. Mater.* 13, 3833 (2001). © 2000, American Chemical Society.

phases and act as barriers against the agglomeration of the final particles. These molecules cover the surface of the particles formed and often interact with it, which can directly affect the local structure of the surface [133]. If the particles have diameters in the lower nanometer range, this interaction can result in a significant change of the particle properties. The capping of the surface with the surfactant is frequently used for the stabilization of the particles formed. With this methodology, for example, surface-capped Pd [134], Fe_2O_3 [135, 136], and CeO [137] particles were formed.

Emulsion polymerization has the potential to produce a stable and compact polymer layer, completely enclosing the particle and improving its chemical resistance. This is particularly important for pure metal particles that have a tendency to undergo oxidation reactions. Changing the concentration of monomers can readily control the thickness of the layer, which usually protects the core very efficiently. With this method, for example, Ag nanoparticles were encapsulated in styrene and copolymers of styrene and methacrylate. Encapsulated particles retain their optical properties and display a remarkable chemical stability [138].

Dense silica nanoparticles can be prepared by the Stöber process, as already mentioned [83]. The size of the nanoparticles formed can be controlled over a wide range with a narrow size distribution. Therefore, this method is often the source for dense silica nanoparticles, which can be subsequently surface modified after isolation. Additionally, the formed alcosol can also be used as a reaction medium for the direct surface modification of the particles, for example, with trialkoxy-substituted silane coupling agents (Fig. 8) [139]. Depending on the coupling agent, a change of the particles' properties, such as their solubility, coagulation behavior, or their reactivity, can be observed. Furthermore, the use of organically modified trialkoxysilanes in the synthesis of the silica core provides a method for decreasing the cross-linking density and/or to incorporating additional functionalities, such as dyes, into the core [90, 140]. For example, the use of $MeSi(OR)_3$ and $Me_2Si(OR)_2$ instead of $Si(OR)_4$ can subsequently decrease the cross-linking density of the particle core; therefore these particles can mimic a behavior, for example, with respect to solvent uptake that is between those of pure silica and cross-linked polymers [90]. Polymer chains were grafted to organosilicon nanoparticles that carried a Si-H surface modification [141]. PS with a terminal unsaturated bond was reacted with these particles by the application of a hydrosilation reaction. With this method particles with a radius of 10 nm were reacted with PS chains with gram molecular weights up to 20,000 g/mol. The resulting core-shell particles reveal a high compatibility with linear PS polymers if the molecular weight of the free polymer is equal to or smaller than that of the grafted polymers. In these cases, an optical transparent film
is obtained, while the pure organosilicon particles are totally incompatible.

3.1. Metal Nanoparticles with Capping Ligands

Probably the oldest nanoparticle system known is that of gold colloids, which were already used hundreds of years ago for the coloring of window glass. Because of their relatively simple preparation and exceptional stability, gold nanoparticles have also become an important research issue in the present time. In addition, gold nanoparticles are particularly easy to modify because they are often stabilized with weakly binding layers of charged ligands (e.g., citrate) that can be replaced with molecules with chemical functionalities that bind more strongly (e.g., thiols, amines, and disulfides) to their surfaces than these ligands. A two-phase synthesis approach results in monodisperse, stable, and soluble gold nanoparticles with a core size of a few nanometers [142]. The synthesis is based on the transfer of $AuCl_4^-$ from an aqueous phase into an organic phase under phase transfer conditions followed by reduction in the presence of thiols. This methodology produces thiol-capped gold nanoparticles. If the thiol employed has additional reactive functionalities attached, the surface-modified nanoparticles can undergo chemical reactions [142]. Another advantage of thiol-capped gold nanoparticles is that the ligands can undergo ligand-exchange reactions with other thiols [143]. The thiol-stabilized Au nanoparticles showed spontaneous self-assembly phenomena depending on the surface modification [144]. Mixtures of different thiol-capped metal cores (i.e., Ag and Au) were used for the formation of ordered two-dimensional arrays, so-called nanoalloys [145]. More information on aspects of the self-assembly of nanoparticles can be found in some recent reviews [146, 147].

Similar to the gold nanoparticles, other metals and semiconductors can serve as cores and bind organic molecules with anchor groups, allowing a strong interaction with the metal surface. Among others, platinum nanoparticles were prepared with the use of alkyl isocyanides as capping ligands, or the self-assembly of films of CdS nanoparticles was enhanced by dithiol ligands [148, 149].

A very interesting property of thiol-encapsulated gold nanoparticles is their activity in catalytic reactions [150]. From a chemical point of view, the attached thiol molecules should passivate the active gold surface. However, the thiolate encapsulation did not block the catalytic sites in a significant way, as proved by electrooxidation experiments. An explanation for this unusual behavior is the encapsulation of gold oxides formed in the organic layer. The uptake of oxygen and the subsequent expansion of the microstructure of the gold oxides led to an increase in particle size and the formation of nanoporosity in the shell.

3.2. Surface Modification of Metal Oxide Nanoparticles with Monomolecular Layers

Often the surface atoms of metal oxide nanoparticles carry terminal or bridging O^- or OH groups, less often Cl, OR, or carboxylate and other complexing groups. These surface

Figure 8. Silane coupling agents often used in the surface modification of silica particles.

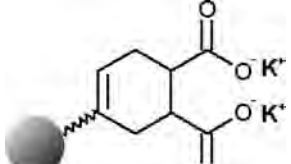
groups are typical reactive sites for the attachment of suitable organic groups. Coordinative bonds are less favorable because the interactions are too weak and because the metal atoms at the surface usually have no pronounced Lewis-acidic properties, that is, no empty coordination sites.

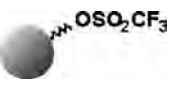
Many metal oxide nanoparticles contain chemical reactive hydroxy groups on their surface. These can easily react with organically substituted silane molecules of the principal formula R_nSiX_{4-n}, where X is a hydrolyzable group, such as a halogen, alkoxy, or amine group. The rest R is connected by a hydrolytically stable bond, for example, a Si—C bond. The OH groups on the surface of the nanoparticles react via hydrolysis and condensation reactions with these so-called silane coupling agents. A plethora of functional groups can be deposited on the particle surface with this approach, and it is beyond the scope of this chapter to mention all possible combinations. Depending on the functional group, specific surface properties can be introduced which are often important for further modifications, for example, to enhance the interfacial interaction between the inorganic particle and a polymer shell. Most of the work done with these compounds was on the modification of silica systems; however, in principal reactions with other nanoparticles that contain hydroxy groups on their surface can also be imagined, such as alumina [151].

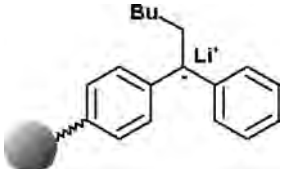
The work on organic surface modification of metal oxide nanoparticles by approaches other than those previously mentioned is limited. However, the chemical and structural principles behind the various surface modification methods can be discussed for clusters in which the overall geometry and surface structure are well defined. Because most of the modification methods of clusters can also be transferred to particles, and, based on the fact that there is a fluent transition between clusters and nanoparticles, a clear distinction between these two systems cannot be made. Therefore, we will also present here possibilities of surface modification of clusters with organic molecules to form core-shell-type architectures.

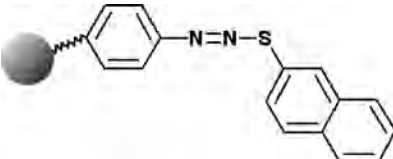
In the postsynthesis modification approach, the functionalized cluster or particle is formed in two steps that are distinctly separate from each other: the cluster/particle core is formed first, and the functional organic groups are introduced later in a different reaction. The alternative method is synthesis of the oxo clusters or particles in the presence of functional organic molecules (i.e., the functionalization of the clusters/particles occurs *in-situ*). The assembly of the cluster occurs in such a way that the organic groups are exclusively bonded to the surface atoms. The advantage of this method is that the process is based on a self-limiting organization of the inorganic and organic building blocks as the formation of the cluster core and the capping of the cluster surface by the organic groups mutually influence each other. The growth of the core is controlled and limited by the organic groups, and, vice versa, the incorporation of the organic groups on the cluster surface is controlled by the chemical reactions by which the cluster is formed. This technique is especially valuable for transition metal oxo systems formed in sol–gel reactions. For example, the surface-modified clusters $Zr_6(OH)_4O_4(OMc)_{12}$ (OMc = methacrylate) are formed when $Zr(O^nPr)_4$ is reacted with

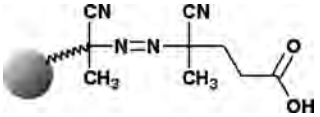
4 molar equivalents of methacrylic acid. The molecular structure reveals the existence of chelating and bridging methacrylate ligands which cover the cluster surface [152]. Clusters of different sizes and shapes and a different degree of substitution by organic ligands can be obtained by modifying the reaction conditions. The main parameters appear to be the nature of the metal alkoxide, the metal alkoxide/carboxylic acid ratio, and the type of carboxylate groups [153–161]. The results obtained for isolated and structurally characterized metal oxide clusters are models for the chemistry leading to the functionalization of larger metal oxide particles. An example of the use of bidendate ligands in the synthesis of surface-modified nanoparticles is the hydrolysis of different metal alkoxides in the presence of acetylacetone and a noncomplexing organic acid, which, after aging, led to nanoparticles with tunable sizes in the range of 2 to 4 nm [162–164].

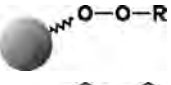
3.3. Polymer Shells


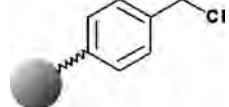


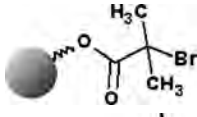


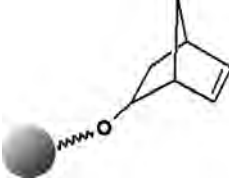












The attachment of polymers to the surface of nanoparticles is obtained by the initiation of the polymerization via a surface-immobilized initiator "grafting-from" approach, by the attachment of the polymer via active sites to the particle surface "grafting-to" approach, or by encapsulation techniques in dispersions. The "grafting-from" method has advantages over the "grafting to" method particularly because the latter has limits in the surface coverage due to diffusion restrictions caused by already immobilized macromolecules. Ionic and radical polymerizations were performed from the surfaces of nanoparticles. In general, these polymerization techniques can be divided into controlled and free radical polymerizations. The controlled polymerizations have the advantage that they possess the possibility to grow polymer shells with the desired thickness and composition. In contrast, free radical polymerizations usually show a very fast kinetics with many termination reactions occurring that do not allow a distinct control over the shell morphology.

3.3.1. Grafting-From Approach

Several polymerization techniques were used for the grafting-from approach (Table 1). Generally this method allows the highest density of polymer chains on the surface of a particle. For this technique the initiator molecules are usually attached to the particle surface in a first step, and afterward the polymerization is promoted.

Ionic Polymerizations Polyesters were grafted from various ultrafine inorganic particles such as silica, titania, and ferrite by anionic ring-opening copolymerization of epoxides and cyclic acid anhydrides [165]. The silica, titania, and ferrite particles had sizes of 16, 120, and 15 nm, respectively, and surface hydroxy group concentrations of 1.37, 0.77, and 0.55 mmol/g. The initiating group was a potassium carboxylate, which was attached to the surface by a series of modifications. The amount of initiating groups on the surface of the silica, titanium oxide, and ferrite particles was 1.92, 0.94, and 0.62 mmol/g, respectively. The organic monomers used were styrene oxide, chloromethyloxirane, gylcidyl methacrylate, gylcidyl phenyl ether, phthalic anhydride, succinic anhydride, and maleic anhydride.

Table 1. Examples of polymerization reaction initiated from inorganic particles.

Initiator	Inorganic particle	Polymerization method	Monomer	Ref.
	SiO$_2$, TiO$_2$, Ferrite	Anionic Ring Opening	Styrene oxide, chloromethyloxirane, gylcidyl methacrylate, gylcidyl phenyl ether, phthalic anhydride, succinic anhydride, maleic anhydride	[166]
	Au	Living cationic	2-Ethyl-2-oxazoline, 2-Phenyl-2-oxazoline	[167]
	SiO$_2$	Living anionic	Styrene	[168]
	SiO$_2$	Free radical	Styrene	[169]
	SiO$_2$	Free radical	MMA	[170]
	SiO$_2$	Free radical	MMA	[173]
	SiO$_2$	Controlled radical	Styrene	[174]
	SiO$_2$, Au	Controlled radical	N-Butyl acrylate	[176, 178]
	Au	Ring-opening metathesis polymerization	Different norbornenyl-containing monomers	[181]

Surface-modified gold nanoparticles were used to initiate the living cationic ring-opening polymerization of 2-ethyl-2-oxazoline and 2-phenyl-2-oxazoline [166]. The grafting-from polymerization was initiated by 11-hydroxyundecane-1-thiol attached to the surface, which was activated by triflate. In this manner, dense polymer brushes were prepared in a so-called one-pot multistep reaction. *Ex situ* kinetic studies of the polymerization of 2-phenyl-2-oxazoline using Fourier transform infrared spectroscopy and matrix-assisted laser desorption ionization time-of-flight mass spectrometry resulted in a linear relation between the reaction time and degree of polymerization of the grafted polymer. The

polymers were successfully end-functionalized by termination with secondary amines.

Living anionic polymerization was initiated from 12–20-nm 1,1-diphenylethylene (DPE) surface-modified silica nanoparticles [167]. *N*-BuLi was used to activate the DPE, which allowed the anionic polymerization of styrene in benzene. A high-vacuum reactor was used to allow polymerization from the surface of silica particles under anhydrous solution conditions.

Free Radical Polymerizations Diazo groups capable of initiating free radical polymerization were attached to the surface of pyrogenic amorphous silica (Aerosil) by a

multistep synthesis [168]. PS was grafted from the thus modified surface. It should be noted that in free radical polymerizations with the described macroinitiators, polymerization also occurs in the solution because the surface-attached initiator decomposes into two radicals from which one initiates polymerization in solution. Therefore, with this technique a purification step is necessary to separate the core-shell systems from the homopolymer. A linear dependence between the monomer and initiator concentration and the polymer coverage was observed.

In several studies, silane coupling agents such as alkoxysilanes [169] or chlorosilanes [170] have been used to modify the surface of silica particles. For example, 4,4'-azobis(4-cyanopentanoic acid) was immobilized on the surface of pyrogenic silica via amide bonds through attached aminophenyltrimethoxysilane. The concentration of diazo groups at the surface reached 0.2 mmol/g. DSC measurements proved that the stability of the initiator decreased upon immobilization. Poly(methyl methacrylate) (PMMA) with a molecular weight of up to 8.7×10^5 was grafted from the particle surface. The polymerization was highly affected by the Trommsdorff effect [171], which was also thought to be responsible for the higher molecular weights of the grafted polymer compared with the homopolymer formed in solution.

Surface-anchored peroxide initiators were used for the grafting of MMA [172]. This type of initiator was attached to the surface by treatment of silica particles with thionyl chloride to obtain surface Si-Cl groups, which were then reacted with tert-butylhydroperoxide or diisopropylbenzene hydroperoxide to form the initiating groups. Depending on the type of peroxide, the concentration of initiators on the surface was 0.08 mmol/g for tert-butylperoxide and 0.29 mmol/g for diisopropylbenzene peroxide. Both peroxide groups were able to initiate the polymerization and led to the grafting of PMMA.

The study of the kinetics and mechanism of an azo-initiated free radical styrene polymerization from modified silica particles was part of more detailed studies for the grafting of polymers from surfaces [170]. In these studies initiators with a cleavable ester group were attached to the surface.

Atom Transfer Radical Polymerizations In contrast to free radical polymerizations, in which, polymerization also occurs in the solution, this is not the case for controlled radical polymerization, such as transition metal-mediated atom transfer radical polymerization (ATRP). Dense silica spheres with a diameter of 70 nm were produced with the Stöber process and modified by reaction with the silane coupling agent [2-(4-chloromethylphenyl)ethyl]dimethylethoxysilane [173]. A surface concentration of the initiator of 0.14 mmol/g was thus achieved. The particles obtained were used as macroinitiators for ATRP of styrene. In a similar approach (11'-chlorodimethylsilylundecyl)-2-chloro-2-phenylacetate was covalently attached to the surface of commercially available silica particles, and ATRP grafting of styrene from the surface was achieved. The grafted polymers were detached from the solid particles for analysis. After polymerization of a first generation of grafts

and work-up of the hybrid particles, the chain ends of the grafts were still active in initiating a second monomer feed [174]. A soft polymer shell around 12-nm silica particles was formed with the use of a chlorodimethylsilyl-functionalized 2-bromo-2-methylpropionate derivative and n-butylacrylate as the monomer [175]. Hyperbranched polymer-silica hybrid nanoparticles were synthesized by surface-initiated self-condensing ATRP of an acrylic AB* inimer from 16-nm silica nanoparticles [176]. About 0.13 mmol initiator/g of silica particles and 0.4 initiator molecules/nm^2 were immobilized on the silica particles, corresponding to about 320 initiator molecules per silica particle. 2-(2-Bromopropionyloxy)ethylacrylate and tert-butylacrylate were used as monomers. Gold nanoparticles were modified with thiole-functionalized initiators for ATRP, and n-butylacrylate was polymerized from the surface [177]. Furthermore, CdS/SiO$_2$ core-shell nanoparticles were prepared and modified with an ATRP initiator, followed by the polymerization of MMA [178]. These hybrid inorganic polymer nanoparticles could be cast into films that retained the photoluminescence of the precursor CdS particles and showed an even distribution of the CdS/SiO$_2$ cores throughout the PMMA matrix. An alternative controlled/"living" radical polymerization technique that was used in the grafting of polymers from silica surfaces is the alkoxyamine-based method that also allowed the controlled synthesis of polymer brushes with variable sizes on the surface of the inorganic core [179].

Ring-Opening Metathesis Polymerizations Transition-metal-catalyzed ring-opening metathesis polymerization (ROMP) was used to graft different norbornenyl-containing monomers from the surface of colloidal gold particles [180]. The two-step preparation of metathesis-ready gold nanoparticles includes the preparation of 1-mercapto-10-(exo-5-norbornen-2-oxy)decane and its immobilization on the metal particles. Metathesis of the norbornene rings on the particles with catalyst Cl$_2$Ru(PCy$_3$)$_2$CHPh was achieved in less than 10 min in CDCl$_3$; subsequent addition of a redox-active ferrocenyl norbornene complex led to copolymerization. ROMP was also carried out from the surface of cadmium selenide nanoparticles stabilized by functional phosphine oxides [181]. These phosphine oxides bear a vinyl group that allows a carbene exchange with the metathesis catalyst and the subsequent polymerization of a variety of cyclic olefins.

3.3.2. Grafting-to Approach

The grafting-to approach is based on the reaction of preformed functional polymers containing reactive groups with the surface of inorganic particles. This includes the reaction with the bare surface, for example, in the case of silica with silanol groups at the surface, or the reaction of chemically modified surfaces that have already been treated with silane coupling agents. Either weak (hydrogen bonds, van der Waals) or strong (covalent, coordinative) chemical interactions are feasible.

The reaction of colloidal silica of 10-, 45-, and 120-nm diameter with trimethoxysilyl-terminated poly(maleic anhydride-co-styrene) and poly(maleic anhydride-co-MMA) in THF resulted in surface modification. The maximum

graft densities of 5 and 3.5 chains/nm^2 were obtained in the reaction of the silica colloids of 10- and 45-nm diameter [182].

Citrate-capped gold nanoparticles can be efficiently grafted with a covalently attached polymer monolayer a few nanometers thick, by simple contact of the metal surface with diluted aqueous solutions of hydrophilic polymers that are end-capped with disulfide moieties [183]. The end-functionalized polymers were synthesized with the use of disulfide-functionalized diazo initiators and *N*-[tris-(hydroxymethyl)methyl]acrylamide as well as *N*-(isopropryl)acrylamide as monomers. The hydrophilic polymer-coated gold colloids can be freeze-dried and stored as powders that can be subsequently dissolved to yield stable aqueous dispersions, even at very large concentration.

Another interesting approach to polymer-capped nanoparticles is the use of end-functionalized polymers, which can interact with the metal species as so-called macroligands, control the final particle size, and stabilize the particles in solution. Nanoscopic CdS entities were produced with this approach, with a thiol-modified poly(caprolactone) as the macroligand [184]. The clusters were grown through the reaction of thiourea with cadmium acetate, and the macroligands were in competition with this reaction by the surface stabilization of the formed particles.

There are a variety of other methods that allow the grafting of polymers to particle surfaces; the interested reader is referred to reviews on this topic [185–188].

3.3.3. Polymer Encapsulation

One of the major problems in the formation of polymer shells on the surfaces of inorganic particles is the chemical incompatibility of the surface and the monomers (Fig. 9). To overcome this difficulty, coupling agents with functional groups, as specified previously, are allowed to react with the surface functional groups. These groups either participate in the polymerization process or simply change the hydrophobicity of the surface. Another possibility for enhancing the polymerization on the particle surface in a heterophase polymerization is the growth of the macromolecules on the surface by the adsorption of required components, namely, surfactants, monomers, or initiator molecules. Interactions that typically take place with the compounds are charge-charge attractions, hydrogen bonding, or hydrophobic interactions.

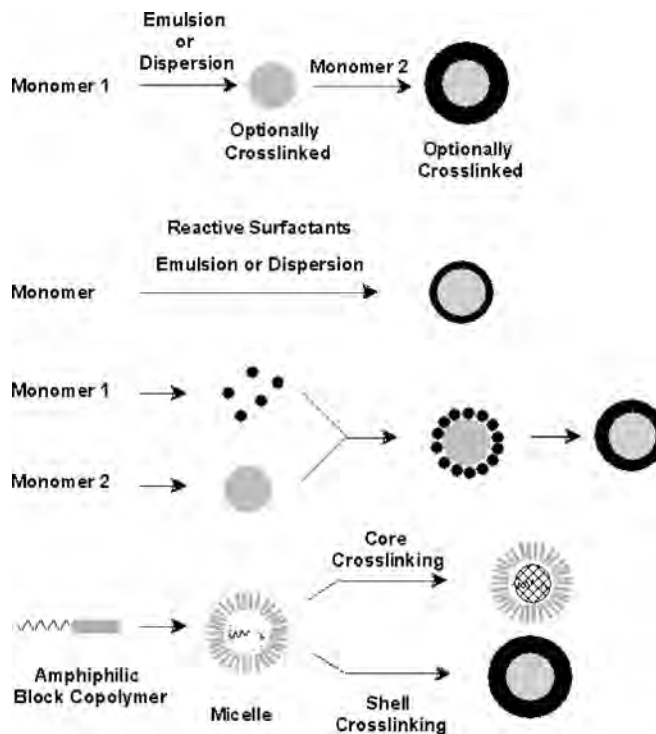
Polymerization occurs primarily at the surface of unmodified particles because of the adsorption of the monomer on the surface, followed by polymerization in the adsorbed layer [189–191]. The formation of an initial hydrophobic layer on the surface of the particles seems to be crucial for the formation of the polymer shell. Methods for the introduction of such a layer include the use of nonionic surfactants, amphiphilic block copolymers, etc. Furthermore, these surface-active molecules fulfill another task: they avoid agglomeration of the particles. The concentration of such compatibilizing molecules in solution must be carefully tuned because a latex formation in free micelles in the emulsion can be observed at higher concentrations. Moreover, these molecules are usually only weakly bonded to the surface and can therefore desorb easily. Hence, the covalent attachment of organic groups, which


Figure 9. Common approaches to core-shell particles. Adapted with permission from [216], J.-E. Jönsson et al., *Macromolecules* 27, 1932 (1994). © 1994, American Chemical Society.

potentially can interact in the polymerization reaction, is used for surface modification. Silane coupling agents are ideal for this purpose, especially in the case of oxidic inorganic particles containing reactive groups on their surface [192–199]. With a one-pot process Nanosized surface-modified silica particles encapsulated with a polymeric layer have been formed (Fig. 10). Depending on the reaction conditions like stabilizer concentration, different products were obtained, for example, those in which a few particles were encapsulated in a polymer shell and those where only single-shell particles were formed. Additionally, pure polymer latex particles can also be formed in an emulsion. Spherical CaCO$_3$-PS composite nanoparticles were obtained by pretreating CaCO$_3$ particles with stearic acid or γ-methacryloxypropyltrimethoxysilane to make them more hydrophobic and using these precursors in different emulsion polymerizations [200, 201].

Polymerization in microemulsions is probably the most promising versatile technique for the synthesis of a wide variety of nanoparticles with polymeric shells because this
Figure 10. Principle of the formation of 3D networks by site-specific interactions in the shell of nanoparticles.

technique offers the possibility of controlling precisely both the size of the core and that of the polymeric shell formed. This is especially important if the properties of the core-shell particles are dependent on both parameters. One example is magnetite particles, which are employed in biology and medicine for the magnetic separation of biochemical products and cells as well as the magnetic guidance of particle systems for site-specific drug delivery. Because the size, charge, and surface chemistry of magnetic particles could strongly influence their biodistribution, it is important to have good control over all of these parameters. In a recent study it was proved that magnetite nanoparticles with a core radius as small as 15 nm and a PMA-poly(hydroxyethyl methacrylate) random copolymer shell size between 80 and 320 nm can be synthesized in a single microemulsion [202].

An interesting unconventional technique used for the formation of organic shells is sonochemistry [203, 204]. This method was used for the quantitative coating of γ-Fe_2O_3 nanoparticles with octadecyltrihydrosilane and the formation of titania nanoparticles with a polyaniline shell. The advantage of this approach is that the aggregation of nanoparticles can be broken down under ultrasonic irradiation, and through the formation of a shell a new aggregation is avoided.

Armes et al. reported the synthesis of colloidal silica-conducting polymer core-shell nanocomposites by the oxidative polymerization of either aniline or pyrrole via dispersion polymerization in aqueous media on spherical or "stringy" silica nanoparticles [205–210]. The authors found that both the particle size and the chemical composition depend markedly on the type of chemical oxidant selected for the *in-situ* polymerization of the monomers. In addition, other functional cores were also used for the surface pyrrole polymerization, such as silica-coated magnetite particles [211] or tin oxide particles [212]. The resulting colloidal poly(pyrrole)-silica-magnetite nanocomposites have a conducting polymer content of 75 mass% and exhibit superparamagnetism. Furthermore, it was shown that a strong acid-base interaction between vinyl monomers such as 2-vinylpyridine, 4-vinylpyridine, and 2-(diethylamino)ethyl methacrylate and the silica surface promotes the formation of nanocomposites in the aqueous media [213]. In addition to studies on silica cores trapped in conducting polymers, other inorganic cores were also used. For example, $HAuCl_4$ was used as an oxidizing agent for the polymerization of pyrrole and the simultaneous formation of Au nanoparticles within the core [214].

4. ORGANIC–ORGANIC CORE-SHELL NANOPARTICLES

4.1. Polymer–Polymer Core-Shell Systems

In recent years spherical polymer cross-linked particles (microgels) have attracted attention in the production of micro- and nanostructured materials. In addition to their specific properties, such as the swelling behavior in certain solvents, a variety of functionalizations can be attached to the surface of these particles for further modifications. The major advantage of the microgel systems compared with other colloids is their stabilization by the solution. If the

appropriate solvent is used the particles are filled and surrounded by the solvent and therefore are practically dissolved within the molecular medium on a nanoscopic scale. The cross-link density can easily control the volume swelling behavior.

One of the most commonly used polymer cores consists of cross-linked PS, but other monomers for latex particles are also in use, which are typically formed by applying free radical emulsion polymerization in combination with selected quantities of cross-linking agents. An overview of different routes towards core-shell polymer nanoparticles is given in Figure 9. The methodologies used are (i) two-stage seeded emulsion polymerization; (ii) emulsion polymerization using reactive surfactants; (iv) stepwise heterocoagulation of smaller particles onto larger ones, followed by heat treatment at a temperature above the T_g of the shells; and (v) the use of reactive block copolymers that allow polymerization [215]. These routes are generally employed for micrometer-sized particles but can also be employed for nanoparticles. Because of the plethora of different systems already investigated, we will limit the description here to some principal modifications of the latex particles.

Some recent examples of different core-shell nanoparticles that were prepared by various types of emulsion polymerizations are PMMA-PS [216], polypyrrole-PS [217], PS-poly(*p*-vinylphenol) [218], poly(dimethylsiloxane)-poly(butadiene) [219], and cross-linked PS-poly-(*tert*-butyl acrylate) [220].

Some of these polymer–polymer core-shell architectures have potential applications for biomaterials. For example, PS-poly(glycidyl methacrylate) core-shell nanoparticles with mean diameters of about 85 nm were modified with a number of different ligands, including diamines of increasing chain length, amino acids and corresponding amines, and higher molecular weight ligands like polymyxin B [221]. The modified particles were tested for their endotoxin (ET) binding capacity in water and physiological sodium chloride solution with the *Limulus amebocyte lysate* assay. It was found that the ET binding properties of the different surface modifications depend on the ability of the ligand to form Coulomb and van der Waals interactions with the ET molecule influenced by the nature of the suspension medium. Therefore, the choice of ligands for particle modification has to consider minutely the conditions under which ET has to be removed, for example, removal from pure water, dialysis fluids, plasma, or blood.

PS latexes were functionalized with halogen-containing groups at their surface capable for initiating ATRP and applied as macroinitiators in this polymerization technique. With this method hydrophobic core-hydrophilic shell nanoparticles were prepared with the use of hydroxyethyl acrylate, 2-(methacryloxy)ethyl trimethylammonium chloride, or methacrylic acid as monomers [222, 223].

A technologically important issue for the application of conducting polymers is to increase their processibility by attaching them to latex particles. Because many of the conducting polymers are water-soluble the surface of the microgel needs at least to be partially polar. To reach this property latex particles were, for example, synthesized from carboxylic or sulfonic derivatized PS. These particles (120 nm)

are soluble in aqueous solutions and were used as a seed in a second stage for the synthesis of the core-shell particles. Polypyrrole, for example, can be polymerized around the core in an oxidative chemical *in-situ* polymerization [224]. In a similar approach styrene-butadiene-methacrylate latex (200 nm) was covered with polyaniline, polypyrrole, and poly(3-methoxythiophene) [225]. Polypyrrole was deposited from aqueous media on a poly(ethylene oxide)-stabilized PS latex with a mean diameter of 129 nm. The polypyrrole loading was varied systematically. The resulting polypyrrole-PS composites did not possess the expected "core-shell" morphology previously observed for other polypyrrole-coated PS particles. Instead, TEM studies indicated that the conducting polymer component was present as discrete 20–30-nm nanoparticles, which were adsorbed to the PS latex [217].

An example of core-crosslinked micelles is the use of amphiphilic poly(ethylene glycol)-*b*-polylactide (PEG/PLA) copolymers with an aldehyde group at one chain end and a methacryloyl group at the other terminal end. The methacryloyl groups located in the core of the micelle were polymerized to form core-shell-type nanoparticles with diameters between 20 and 30 nm and reactive aldehyde groups on the surface [226].

Microgels composed of environmentally responsive polymers continue to attract attention because of their potential applications in numerous fields, including drug delivery, chemical separations, catalysis, and sensors. Perhaps the most studied class of responsive polymers is thermoresponsive poly(alkylacrylamides). Hence, these polymers were also used in the synthesis of stimuli-responsive core-shell latexes [227]. Many of the synthesized systems contain a responsive and a nonresponsive component. Furthermore, multiresponsive systems were also investigated that are composed of two or more environmentally sensitive polymers [228]. For example, core particles composed of cross-linked poly(*N*-isopropylacrylamide) or mixtures of the latter with acrylic acid were synthesized via precipitation polymerization and then used as nuclei for subsequent polymerization for the formation of a shell. These hydrogel particles display both a strong temperature and pH dependence on swelling. Through a change of the composition of the core and the shell, for example, by copolymerizing other monomers, the response of these hydrogels is made tunable [229].

As already mentioned, the sol–gel process is a versatile tool if an oxidic shell should be formed around a particle. The advantage of this process is its applicability for a lot of different metals (e.g., Si, Ti, Zr, Sn, etc.) and the mild reaction conditions that allow the incorporation of organic groups into the networks formed. An interesting aspect of these coated polymer particles is the removal of their core by calcination and the production of hollow spheres.

4.2. Cross-Linked Micelles

Amphiphilic block copolymers can aggregate in solutions into spherical micelles depending on the solvents and concentrations between solvent and block copolymers. If the copolymers contain functional groups that are able to undergo cross-linking reactions, stable spherical core-shell nanostructures can be formed with either a cross-linked core

or shell and with differing physical and chemical properties of the core and the shell that can be tailored over a wide range.

Wooley et al. prepared several examples of so-called shell cross-linked knedel-like (SCK) polymer assemblies with diameters between 5 and 100 nm [230]. Based on the cross-linked shell, these nanostructures have a robust character and surface stability under changing environmental conditions. In addition, the shell serves as a membrane that has a permeability that can be tailored to control the transport of guests to and from the core. Furthermore, the lack of cross-links in the core region maintains chain mobility and access to the core volume. Hence these systems are nanoscale scaffolds that can mimic several biological systems. One important parameter that influences the properties of these systems is the composition and structure of the amphiphilic block copolymer. Another parameter is the composition and cross-link density of the shell that determines the extent of swelling, controls the interactions with the environment, and influences the shell's permeability. The core provides a unique nanoenvironment for guests that are able to pass the shell barrier. Typical examples of such systems comprise assemblies of PS-poly(4-vinylpyridine) block copolymers in which the shell was cross-linked by applying quaternization reactions of the pyridine segments [231] or PS-poly(acrylic acid) cross-linked via amidation reactions in the shell [232]. Other reports used micelles of PS-poly(2-cinnamoylethyl methacrylate) or polyisoprene-poly(2-cinnamoylethyl methacrylate) diblock copolymers with photo-cross-linked shells [233], poly(solketal methacrylate)-block-poly(2-(dimethylamino)ethyl methacrylate) with 1, 2-bis(2-iodoethoxy)ethane cross-linked shells [234], 1, 2-bis(2-iodoethoxy)ethane cross-linked partially quaternized 2-(dimethylamino)ethyl methacrylate-*N*-(morpholino)ethyl methacrylate diblock copolymer micelles [235], or zwitterionic diblock copolymers [236].

5. POLYMER–INORGANIC CORE-SHELL NANOPARTICLES

Because of the simple availability of polymer latexes in combination with a wide range of sizes and functionalities, they are ideal building blocks for complex functional materials. For the deposition of precursors for inorganic shells the latex particles often require a charge. This charge can be introduced by applying ionic initiators in the free radical polymerizations. With this technique stable colloidal core-shell particles consisting of a PS core and a titania coating were prepared in one step by the hydrolysis of a titanium alkoxide in the presence of a cationic PS latex. The coatings obtained were very smooth and uniform and varied in thickness from just a few nanometers up to 50 nm [237].

The surface modification with magnetic compounds attracted much interest because of their possible applications for therapeutic or analytical purposes. In the first case, magnetic particle carriers permit either the guiding and release of a drug in a specific site of the body or the extraction of tumor cells from the organism and their curing *in vitro* [238, 239]. For this purpose different latex particles were covered with magnetic substances. For example, PS-poly(*N*-isopropylacrylamide) core-shell nanoparticles were

prepared, and iron oxide was adsorbed on the outer shell via electrostatic interactions [240].

Gold shells on PS latex were prepared by adsorbing polyethyleneimine polyelectrolyte to the polymer core via electrostatic and hydrogen-bonding attraction, followed by the adsorption of negatively charged Au particles with sizes of 3 nm or 15 nm [241]. The coverage of gold was increased by a seeding procedure, resulting in a Au shell thickness of 10 ± 5 nm.

The coating of anionic or cationic latexes with metals or metal salts is a general approach to core-shell nanoparticles. Examples of such systems are PS latexes with shells of Y basic carbonate [242], Zr compounds [243], TiO_2 [244], iron compounds [245], or copper and copper compounds [246]. These particles were synthesized via absorption and reaction of metal salts on the surface of the latexes. In several cases these particles were calcined and hollow spheres were obtained.

A different method for producing multilayer particles, for example, of a latex core with a corona of inorganic nanoparticles capping its surface, is the layer-by-layer method. Magnetite, titanium dioxide, silica, and laponite nanoparticles were used as the inorganic building blocks for multilayer formation on PS sphere templates [247, 248]. Composite organic–inorganic particles were formed by the controlled assembly of the preformed nanoparticles in alternation with oppositely charged polyelectrolytes onto PS microspheres. Inorganic nanoparticles with different diameters were shown to work effectively in this coating process. In addition, hollow capsules can be obtained from the precursor polymer–inorganic core-shell particles by direct removal of the core material by chemical or physical methods.

6. INORGANIC BIOMOLECULE CORE-SHELL SYSTEMS

In recent years nature motivated intense efforts to develop assembly methods that mimic or exploit the recognition capabilities and interactions found in biological systems. Many studies concentrated on fundamental principles by applying surface-modified nanoparticles with complementary receptor-substrate sites on their surface for the detection of biological molecules and/or for the recognition-driven self-assembly of ordered aggregates. The basic idea for the latter approach was transferred from biological systems in which organic molecules show a remarkable level of control over the nucleation and mineral phase of inorganic materials such as calcium carbonate and silica, and over the assembly of crystallites and other nanoscale building blocks into complex structures required for biological functions. Of particular value are methods that could be applied to materials with interesting electronic or optical properties. Similar to the interactions in enzymes, organic ligands can interact with the surface of metal or semiconductor nanoparticles. With this approach peptides with limited selectivity for binding to metal and semiconductor surfaces can, for example, be used for the particle modification [249].

A general approach is to prepare nanoparticles by wet chemistry in the presence of stabilizing agents that coordinate to the surface, such as citrates, phosphines, or thiols, of the resulting nanoparticles. These molecules prevent an uncontrolled growth and aggregation and are substituted in a further step with ligands that have a stronger interaction with the metal atoms at the surface. For example, gold nanoparticles were reacted with thiol-modified DNA sequences that allow recognition by specific particles of each other through the hydrogen bonds typical for these biomolecules. This technique in particular was used as a method for assembling colloidal nanoparticles rationally and reversibly into macroscopic aggregates [250, 251]. The method involves attachment of two batches of non-complementary DNA oligonucleotides capped with thiol groups as linkers to the surface of nanometer gold particles. When oligonucleotide duplexes with complementary ends are added to the two grafted sequences, the nanoparticles self-assemble into aggregates (Fig. 10). The assembly process can be reversed by thermal denaturation. This material synthesis approach has been extended to a wide range of biomolecules, including peptides and proteins [252–254], and a collection of nanoparticles, including gold and semiconductor quantum dots [255, 256]. However, gold proved to be ideal for this kind of materials since, for example, it was more difficult to modify CdSe and CdS quantum dots because of a surfactant layer that is very strongly bound to their surfaces and, consequently, difficult to displace [257]. Hence, if nanoparticle compositions different from Au were required, a typical route is to cover their surface with a gold layer and immobilize the oligonucleotides on this layer afterward [258]. Another possibility for activating the surface of quantum dots for the coupling of biomolecules is their coverage with silane coupling agents, which was used in the capping of core(CdSe)-shell(CdS) nanoparticles [107]. Other biorelated interaction techniques, for example, antibody-antigen recognition, were also applied for the directed self-assembly of Au and Ag nanoparticles [259]. The absorption of the biomolecules in these cases was carried out at a pH above the isoelectric point of the stabilizing citrate groups. The proteins then show a strong interaction with colloids by the positively charged amino acid side chains.

In addition to the possibility of enhancing the self-assembly of larger arrays, the use of recognition chemistry has found wide application in the development of highly sensitive and selective diagnostic methods [107, 260–264].

Major problems in the synthesis of biomolecule-capped nanoparticles are the avoidance of harsh reaction conditions, which often lead to the inactivation of the biofunctionalization and the strong fixation of the molecules to the surface of the particles.

Only a few examples from the field of nanoparticle-biomolecule interactions were given in this chapter. The interested reader is referred to a comprehensive review that shows the possibilities of combining inorganic materials with biomolecules [265].

As a summary of the different materials described within this chapter, we have collected in Table 2 most of the combinations, as well as their properties of interest and corresponding references.

Table 2. Summary of material combinations and properties.

Core	Shell	Synthesis method	Relevant property	Ref.

7. CONCLUSIONS

In this chapter we have reviewed the synthesis and properties of core-shell nanoparticles of various composition. A classification based on the nature of the core and the shell lead us to distinguish mainly between organic and inorganic materials, but also to find clear subdivisions taking into account the metallic, semiconductor, or dielectric nature of the inorganic materials, or the relative configuration of organic and inorganic material within the composite particles. We have shown that there is a plethora of possible combinations leading to nanomaterials with various functionalities, which has a great potential for applications in technology and life sciences.

GLOSSARY

Colloid A substance consisting of very tiny particles that are usually between 1 nm and 1000 nm in diameter and that are suspended in a continuous medium, such as a liquid, a solid, or a gaseous substance.

Core-shell nanoparticles Particles with size below 1 μm, composed of an inner, typically spherical core homogeneously surrounded by a shell of a different material.

Emulsion Drop-shaped distribution of one liquid in another while both of them are not miscible.

Latex A homogeneous colloidal dispersion of polymeric particles in water.

Nanoshells Spherical colloid particles with a hollow interior, usually filled with solvent.

Plasmon resonance Collective oscillation of conduction electrons in metal nanoparticles, induced by an electromagnetic wave.

Quantum dot Particle of matter so small that quantum size effects can be observed.

Silica coating Deposition of an amorphous silicon dioxide shell on a preformed colloid particle.

Surfactant Abbreviation for surface-active agent; soluble compound that reduces the surface tension of liquids, or reduces interfacial tension between two liquids or a liquid and a solid.

1. INTRODUCTION

Metallic nano/mesoparticles supported on conducting substrates such as carbons are of interest due to their unique physical chemistry properties, making them of importance in different fields of applied science [1–10] and for the eventual development of new techniques. The technology used to produce preformed mass selected atomic clusters on carbons involves nanometer-sized systems in which, as a result of the reduced average atomic coordination, the quantum size effect, and the modified screening response, clusters display novel electronic and magnetic properties [11–12]. The physicochemical properties of nano/mesoparticles depend strongly on the perturbations that arise from the large area/volume atom ratio in relation to bulk metals. Therefore, the manageability of pattern morphology of nano/mesoislands is of importance in dealing with catalysts, electrocatalysis, and nano/microfabrication and in developing materials with interesting properties such as giant magneto resistances, high saturation-moments, and high anisotropic binary clusters. A great research effort has been made to develop a predictive understanding of the relationship between particle size and structure, and physicochemical properties such as electronic and magnetic properties.

The understanding of the reactivity of supported nanometer-sized particles in heterogeneous catalysis can be approached by either a molecular standpoint in which small soft-landed metal clusters of 5–50 atoms are considered, or by taking into account the reactivity of extended single-crystal surfaces. Both approaches have advantages and limitations, particularly to explain the behavior of supported clusters a few nm in diameter, due to their intrinsic heterogeneities [11–12]. Significant progress in this direction has been made in the understanding of size-dependent catalytic behavior, showing that the high activity requires the minimum size compatible with metallic properties. In contrast, the fabrication of the nano/mesoparticles remains at present a rather empirical task due to the fact that the physical processes that determine shape and size at the nanometer scale are not systematically identified.

Metal nano/mesoparticles can be prepared by different techniques, such as vapor deposition, ultrahigh vapor deposition, chemical vapor deposition, chemical impregnation, homogeneous reactions in solution, electroless deposition, and electrodeposition. The success in obtaining particles with defined physicochemical properties relies on the possibility of obtaining a narrow particle size distribution. Precisely, major efforts in nano/microparticle preparation by electrochemical methods have focused on improving particle size distribution. At present, very homogeneous size particles can be prepared by nucleation and growth from solution [1–10], although this goal is still a pending issue for obtaining metallic particles supported on solid substrates [13–14]. For the latter, most of the present methods result in the formation of particles with a broad particle size distribution function, the broadening being dependent on growth conditions.

In principle, metal electrodeposition appears as an excellent route for nano/mesoparticle preparation on conducting substrates due to the easy control of the experimental variables [13–18]. In this method the reaction rate can be easily adjusted either for a surface reaction or for a reaction under a mass-transport kinetic regime. Therefore, metal electrodeposition can be taken as a model system to investigate possible relationships between particle size and shape, and growth kinetics. Recently, the preparation of narrowly dispersed particles with average diameter at the nano/micro scale and relative standard deviation RSD $\leq$ 30% by electrodeposition has been accomplished [13–14]. In this case, mesoparticles have been modeled as simple hemispherical objects produced either by using double pulse electrodeposition to nucleate first a large number of particles that later are allowed to grow slowly on the substrate, or metal and hydrogen codeposition under forced convection due to bubbles at the microscale [13–14].

For further advances in the above mentioned matters, one should understand the entire kinetics and mechanisms of the process at different length and time scales. This fundamental knowledge would provide a rational approach to prepare mesoparticles with different structures and shapes, to discover how physical and chemical processes determine particle structure and shape, and to determine the dependence of the physicochemical properties of mesoparticles on their structure and shape. Manipulation of mesoparticles is a "nanostructuring" problem, deserving theoretical and experimental consideration. Therefore, a combination of theoretical models that have been developed to understand the relationship between growth kinetics, shape, and structure based on both Euclidean and fractal concepts, and powerful experimental techniques able to image these objects at the nanometer scale, such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM), is required.

In this contribution, the state-of-the-art concerning our ability to handle physical variables of remarkable influence in determining the structure/shape of metal nano/mesoparticles produced by electrodeposition on highly oriented pyrolytic graphite (HOPG), that is, the basal plane of graphite (C(0001)), and to evaluate their catalytic activity for some test reactions is reviewed. Among the different carbon substrates HOPG exhibits unique properties for studies at the nanometer level by scanning probe microscopies (STM and AFM) because it is atomically smooth and chemically inert. Metal electrodeposition on HOPG was taken as a model system to disperse metallic particles, because it is a smooth substrate in which no metal underpotential deposition takes place, as in no complete metallic adlayer is produced [19]. In fact, due to the large difference between the metal and the carbon surface tension, metal particle deposition on HOPG follows the Volmer–Weber mechanism [20] rather than the Stranski–Krastanov [21] and the van der Merwe mechanisms [22] (Fig. 1). Furthermore, metallic particles dispersed on carbon are important in dealing with a number of electrocatalytic and heterogeneous catalytic systems [23]. Metal electrodeposition on HOPG has also been taken as a model system for the development of a new technology for nanostructure fabrication1 at wafer scale [24] and for the preparation of
Figure 1. Different growth modes of metal deposition on foreign substrate. (a) Volmer–Weber mechanism, 3-D metallic islands. (b) Frank–van der Merwe mechanism, layer by layer growth. (c) Stranski–Krastanov mechanism, 3-D islands on top of 2-D layer.

metallic wires [25, 26] as promising interconnectors in future nanoscale electronics. Metal-patterned HOPG has also been considered for directly embossing different polymeric materials [27].

The presentation of the material is organized as follows. First, some fundamental aspects of electrochemistry related to metal electrodeposition are described. Then, the preparation methods of metal nano/mesoparticles are considered. Special attention to the electrodeposition of crystals of platinum, palladium, and gold on HOPG is paid. These are typical examples of metal electrodeposition from which kinetic conclusions applicable to the growth of other metallic phases can be drawn. The correlation between kinetics and particle structure from the early stages of growth onward is described. Later, the electrodeposition parameters and the size and shape of HOPG-supported crystals are related to the physicochemical processes that determine the shape and structure at different temporal and length scales. In the third section, we compare nanoparticle growth by electrochemical techniques with vapor deposition methods. The influence of the applied electric potential on crystal shape is discussed. Finally, typical applications of metallic deposits supported on HOPG in nanowires, embossing, and electrocatalysis are given.

2. BASIC ELECTROCHEMICAL ASPECTS

2.1. Substrate Characterization

HOPG is commonly used in STM and AFM studies [28] because it exhibits micrometer-sized atomically smooth terraces separated by steps 0.35 nm in height (Fig. 2a) that
Figure 2. STM images of freshly exfoliated HOPG surface. (a) $2 \times 2 \ \mu m^2$, large and smooth terraces separated by steps are clearly seen. (b) Atomic resolution, $6 \times 6 \ nm^2$. Bright spots correspond to carbon atoms.

correspond to the interlayer spacing. Also, HOPG is chemically inert and can be handled in the atmosphere with negligible contamination. It is used for (x, y) piezoelectric calibration at the atomic level in STM. The STM imaging of a HOPG surface originates reproducible atomically resolved hexagonal lattices with $d = 0.246$ nm, where three of the six carbon atoms of the honeycomb structure of graphite are imaged (Fig. 2b). The smoothness of the HOPG surface in relation to other carbon substrates such as mechanically polished vitrous carbon, fractured vitrous carbon, and amorphous carbon turns it into the best substrate to study the morphology of nano/mesometallic particles.

2.2. Electrochemical Deposition of Metals

Metal particles dispersed on a HOPG surface can most frequently be obtained by electrodeposition from aqueous electrolyte solutions containing a relatively small concentration of depositing ions as either cations or anions. The electrochemical cell (Fig. 3) usually consists of a working cathode, such as a freshly exfoliated HOPG surface, a large area noble metal counter electrode, and a reference electrode.
Figure 3. Conventional three-electrode water-jacket electrochemical cell. (a) Reference electrode. (b) Counter electrode. (c) Working electrode. (d) Inert gas bubbler.

In general, the plating solution is deareated and kept under an inert atmosphere (argon or nitrogen) to suppress any interference of the oxygen electroreduction reaction at the cathode. The electrochemical cell is operated by a potentiostat that permits one to select either a constant potential or a constant current regime under nonstationary conditions when the electrolysis time (t_d) is properly adjusted to avoid both the coalescence of growing particles and the formation of a continuous metal layer.

Electrodeposition under potential control can be made by applying either a constant potential (E_d) or a linear potential sweep ($E_d = E_o - vt_d$, where E_o is the starting potential and v is the potential sweep rate). In the former case, the current transient (I_c versus t_d, where I_c is the electrodeposition current) is recorded. The integration of this transient yielding the electrodeposition charge (Q_c) passes between $t = 0$ and $t = t_d$. For the latter, the electrodeposition voltammogram is obtained, that is, the E versus I_c plot at the rate v, and the value of Q_c can also be determined from the voltammogram.

For electrodeposition under a constant current (galvanostatic), the potential transient (E_c versus t_d) is recorded. This procedure is interesting for electrodeposition under a constant flow of discharging ions on the cathode. The values of I_c and Q_c are usually referred to as the unit surface area (A) of the substrate as current density (j_c) and charge density (q_c) because a reliable definition of A for dispersed particles on a solid surface is not always feasible. Further details on electrochemical deposition techniques are given in reference [29].

3. ELECTROCHEMICAL PREPARATION

3.1. Previous Work

Metal particles of silver, gold, palladium, molybdenum, copper, and platinum can be easily electrodeposited on HOPG [13–18, 25, 26, 30–33]. Platinum mesoparticles (ca. 0.1 μm in diameter) on glassy carbon have been electrodeposited from H_2PtCl_6 in the potential of the first electroreduction wave (0.2 to 0.5 V versus SCE). At loading levels 10–20 μg cm^{-2}, these electrodes exhibit high particle stability and an exchange current density value for hydrogen evolution comparable to that for bulk platinum [34, 35]. Platinum particles of 2–2.5 nm diameter can also be formed by spontaneous reduction of H_2PtCl_6 at the plane edges and basal plane of HOPG caused by the incompletely oxidized surface functional carbon group [36]. Potentiostatic deposition on pyrolytic graphite of roughly circular platinum particles 0.3–1 μm in diameter, spatially distributed in a random fashion, has also been reported [37].

The electrodeposition of platinum on HOPG has been followed by AFM tapping mode. In the absence of a supporting electrolyte, two-dimensional (2-D) nanoparticles aggregate after reaching a critical mobile particle size. Subsequent growth is dominated by surface diffusion of mobile platinum particles. In aqueous perchloric acid, three-dimensional (3-D) growth is the dominant mechanism competing with 2-D/3-D growth. This leads to various morphologies. The process is also influenced by the presence of specifically adsorbed anions [38].

Platinum nanoparticles have been electrocrystallized on HOPG by a first reactant electrostatic adsorption, followed by electrochemical reduction on a 4-aminophenyl monolayer-grafted carbon substrate. The STM imaging shows a good size monodispersivity and particles well separated from one another [39].

Metal nano- and microparticles of silver, gold, platinum, molybdenum, and nickel narrowly dispersed by electrodeposition on HOPG have been formed by a two-step method—a 5 msec potential step to nucleate particles at an overvoltage $\eta_c = -0.5$ V, and a growth pulse set in the range $-0.02 \leq \eta_c \leq 0.250$ V to reach the desired particle diameter. The slow growth process leads to a particle dispersion ranging from 50 nm to 2 μm in diameter with a RSD as low 7% [13–14].

Carbon electrodes with an effective fiber radius of 1 nm can be prepared by different procedures: electrochemical etching of a carbon fiber, deposition of electrophoretic paint, and an inverted deposition technique for insulating the tip. Thus, the complete insulation of the whole body of the carbon fiber, except tip pinhole formation, is avoided [40].

3.2. Potentiodynamic Electrodeposition

A typical potentiodynamic polarization curve (j_c versus E_d) for metal electrodeposition on HOPG is shown in Figure 4 [41]. The values of E_d are referred to the standard calomel electrode scale. This example corresponds to palladium electrodeposition at $v = 5 \times 10^{-3}$ V/s from a palladium chloride-containing aqueous solution at 298 K [41]. The electrochemical deposition of a metal (Me) can be produced either from the discharge metal of ions (Me^{z+}) of charge z,

$$\text{Me}^{z+}(\text{aq}) + z\text{e}^- = \text{Me}(0) \qquad (1a)$$

or from the discharge of a metal-containing complex anion (MeX$_n^{z-}$) containing n ligands and charge z,

$$\text{MeX}_n^{z-}(\text{aq}) + z'\text{e}^- = \text{Me}(0) + n\text{X}^{(z+z')-} \qquad (1b)$$
Figure 4. Potentiodynamic polarization curve of HOPG in aqueous 7.5×10^{-4} M palladium chloride $+ 5 \times 10^{-2}$ M sodium perchlorate $+ 5 \times 10^{-3}$ M perchloric acid run from 0.85 V to -0.35 V at $v = 5 \times 10^{-3}$ V/s; 298 K. The cathodic current density (j_c) is referred to the working electrode geometric area. (1) Beginning of metal electrodeposition. (2) Main cathodic current peak. (3) Cathodic limiting current. (4) Hydrogen evolution reaction. The reversible potential (E_r) for Pd electrodeposition is indicated.

The reversible potential E_r of Equations (1a) and (1b) are given by the following Nernst equations, respectively,

$$E_r(1a) = E^o(1a) + (\mathbf{R}T/z\mathbf{F})\ln a[\text{Me}^{z+}]/a[\text{Me}(0)] \qquad (2a)$$

and

$$E_r(1b) = E^o(1b) + (\mathbf{R}T/z'\mathbf{F})\ln a[\text{MeX}_n^{z-}]$$
$$/a[\text{Me}(0)]a[\text{X}^{(z+z')-}]^n \qquad (2b)$$

$E^o[N]$, $N = $ (1a), (1b), and $a[i]$ being the standard potential and the activity of species i, and z, $\mathbf{F}$ and T the number of electrons per reacting species involved in the reaction, the Faraday constant (96,500 C/equivalent) and the absolute temperature, respectively. The activity of the metal is taken as 1. For values of E_d more negative than E_r, the cathodic potentiodynamic polarization curve first exhibits a low current portion (Fig. 4, region 1) extending from E_r to a value of E_d where a rapid increase in j_c leading to a current maximum (Fig. 4, region 2) is observed. As E_d is further increased negatively, the cathodic current density attains a limiting value j_L (Fig. 4, region 3) that extends to the potential range where the hydrogen electrode reactions on electrodeposited palladium commence (Fig. 4, region 4). Often, the first low current region approaches a E_d versus $\ln j_c$ linear relation indicating that the kinetics of metal electrodeposition is under charge-transfer control. However, as E_d is shifted more negatively, the kinetics of the electrodeposition reaction turns into a mass transport regime from the solution side to the cathode surface.

3.3. Potentiostatic Electrodeposition

Detailed information of the nucleation and growth of metallic particles on foreign substrates can be obtained from potentiostatic current transients. In this case, for diluted solutions, these transients exhibit a rapid increase in current that is frequently observed for the nucleation and growth of metal particles under mass transport control. Thus, following the potential step at E_d, the diffusion zones built up around growing nuclei begin to overlap, and after a time (t_M) the growth kinetics become a linear diffusion-controlled process. Finally, for a t_c that depends on E_d, the contribution of free convection increases, and j_c approaches the j_L value (Fig. 4, region 3).

Potentiostatic current transients run at different E_d can be analyzed with growth models that are applicable to the electrochemical formation of a new solid phase on a conducting substrate. Further details related to this subject are extensively described in the literature (see, e.g., [19]).

Current transients for palladium electrodeposition on HOPG were obtained by stepping the potential from $E \geq E_r$ to values of E_d lying within the different potential windows of the palladium electrodeposition regions (Fig. 4) [41]. For the potential regions 2–4 (Fig. 4), the current transients (Fig. 5a) exhibit an initial fast current decay due to the contribution of the double-layer charging that is significant for $t_d < 1$ sec. Subsequently, a fast increase in current up to a maximum value j_M at time t_M is observed. Subsequently, a slow decay characterized by a j_c versus $t_d^{-1/2}$ dependence is observed (Fig. 5b), as expected for a diffusion kinetic regime
Figure 5. Potentiostatic current transients (j_c versus t_d) for palladium electrodeposition on HOPG using the same solution as in Figure 4. (a) $E_d = 0.355$ V (o), $E_d = 0.385$ V (•). The current maximum j_M at t_M is indicated. (b) j_c versus $t_d^{-1/2}$ plot from current transient run at $E_d = -0.100$ V. The straight line corresponds to Cottrell–Sand equation for linear diffusion. The arrows indicate the j_L and t_c values. Reprinted with permission from [41], Y. Gimeno et al., *J. Phys. Chem. from the solution. As E_d is negatively increased j_M increases and t_M decreases. In all cases, after an E_d-dependent time t_c that is usually less than 30 sec, free convection sets in and all transients tend to approach the quasisteady convective-diffusion regime (Figs. 4 and 5b). Therefore, depending on t_d, the kinetics of palladium electrodeposition changes from a linear diffusion to convective diffusion control.

4. CRYSTAL GROWTH KINETICS

4.1. Initial Stages of Growth

Current transients similar to those described above for palladium electrodeposition have also been obtained for the electrodeposition of silver, palladium, gold, platinum, cadmium, and copper on HOPG from diluted aqueous solutions for $t_d \ll t_c$ [13, 33, 41]. These transients often fit equations predicted by either instantaneous or progressive nucleation and 3-D growth models under diffusion control [42–45]. The j_c versus t_d relationship can be expressed by the equations proposed by Scharifker and Hills [44], either for instantaneous nucleation,

$$j_c = (z\mathbf{F}c_i D_i^{1/2}/\pi^{1/2}t_d^{1/2})[1 - \exp(-\pi K_e D_i N_o t_d)] \quad (3a)$$

or for progressive nucleation,

$$j_c = (z\mathbf{F}c_i D_i^{1/2}/\pi^{1/2}t_c^{1/2})$$
$$\times [1 - \exp(-\pi K_e' D_i N_o A_c t_d^2/2)] \quad (3b)$$

In Equations (3a) and (3b), D_i, and c_i are the diffusion coefficient and the concentration of the electroactive species (i) in the bulk of the solution, respectively; N_o is the number of sites available for nucleation on the HOPG substrate; $K_e = (8\pi c_i M/\rho)^{1/2}$ and $K_e' = 4/3(8\pi c_i M/\rho)^{1/2}$; M and ρ are the molar mass and the density of the deposited metal, respectively; and A_c is the site-to-nucleous conversion frequency. Equations (3a) and (3b) reproduce the current transients for different metal electrodepositions. Figure 6 shows current transients for gold electrodeposition on HOPG and the comparison of these data to predictions from the models. More refined models including "clear field" effects around growing nuclei have been proposed [46, 47].

The nucleation rate ($A_c N_o$) for progressive nucleation can be determined from the current density transient maxima resulting from relatively low cathodic overvoltages, $\eta_c = E_d - E_r$. However, as very often current density maxima at high values of η_c are not observable at the time scale of conventional transient measurements, values of $A_c N_o$ can be estimated from the N_c versus t_d plots derived from STM and AFM imaging, and SEM micrograph data, using equation [44, 45, 48]

$$N_c = N_o[1 - \exp(-A_c t_d)] \quad (4)$$

N_c being the number of nuclei at t_d. Data from palladium electrodeposition were plotted according to Equation (4) (Fig. 7). In this case, for -0.10 V $< E_d < 0.365$ V, values of $A_c N_o$ fulfill equation [19, 47] (Fig. 8)

$$A_c N_o = K_1 \exp(-K_2/\eta_c^2) \quad (5)$$

In Equation (5), K_1 depends on both the nucleous dimension (2-D, 3-D) and nucleation mechanism, as in, whether the metal lattice grows under diffusion or charge transfer
Figure 6. Comparison of normalized current transient data (j_c/j_M versus t_d/t_M) for gold electrodeposition on HOPG at $E_d = 0.500$ V from aqueous 5×10^{-4} M gold chloride + 0.5 M sodium perchlorate + 1×10^{-2} M perchloric acid. Predictions from equations [3a and 3b] for the instantaneous (—) and progressive (...) nucleation and growth model under diffusion control are indicated.
Figure 7. N_c versus t_d plot for palladium electrodeposition on HOPG from the same solution as in Figure 4 and $E_d = -0.100$ V. The solid line corresponds to Eq. (4). Reprinted with permission from [41], Y. Gimeno et al., *J. Phys. Chem. B* 106, 4232 (2002). © 2002, American Chemical Society.

control. The constant K_2 is related to A_c by the following relationship [48]

$$K_2/\eta_c^2 = A_c/\mathbf{k}T \qquad (6)$$

$\mathbf{k}$ being Boltzmann constant. Equation (6) implies a linear $A_c N_o$ versus η_c^{-2} relationship (Fig. 8), and the value of K_2 can be determined from the slope of this linear plot. Likewise, the number of atoms (n^*) involved in the formation of the critical nucleus can be calculated from the expression

$$n^* = 2A_c/z\mathbf{e}_o(E_d - E_r) \qquad (7)$$

with $\mathbf{e}_o = 1.60 \times 10^{-19}$ Coulomb. Then, by combining Equations (6) and (7), it is possible to estimate values of n^* at different E_d. For palladium electrodeposition it results in $n^* = 2$ for $E_d = 0.38$ V, and $n^* = 0$ for $E_d = -0.1$ V. Comparable values of n^* have been reported for the electrocrystallization of several metals on foreign substrates [19]. In all these cases, the decrease in n^* with E_d has been related to a decrease in the activation energy for nucleation with η_c. Thus, combined electrochemical and microscopy data can be used to obtain reliable information about the very early stages of growth of metal nucleus on HOPG.

The preceding analysis points out that model predictions exclusively derived from electrochemical data should be checked against direct data from either STM or AFM imaging or SEM micrographs. In fact, for a number of metal electrodeposits, large discrepancies between values of N_o from imaging data and the number density of nuclei resulting from electrochemical data have been observed [32]. Likewise, for a particular system, the value of N_o depends on the carbon substrate. For silver electrodeposition on HOPG, the value of N_o increases from 5.7×10^6 to 3×10^7 cm^{-2} as E_d is shifted negatively, whereas values of N_o one order of magnitude smaller have been determined on mechanically polished vitrous carbon.

For an isolated nucleus, Equations (3a) and (3b) imply a radial growth equation of the form $\langle r \rangle \approx t_d^{1/2}$, where $\langle r \rangle$ is the average radius of the growing nucleous. This equation is obeyed by data from the initial stages of platinum electrodeposition on HOPG [38]. Furthermore, for $t_d > t_M$ the current decay obeys a $j_c \approx t_d^{-1/2}$ relationship (Fig. 6) as expected for pure diffusion. This behavior for j_c, which is observed in the range $t_M \leq t_d \leq t_c$, has also been found for the electrodeposition of different metals from diluted solutions [32, 33, 41, 42]. Deviations from the $j_c \approx t_d^{1/2}$ behavior are observed for $t_d \geq t_c$, as in when j_c tends asymptotically to j_L.

4.2. Electrodeposition Parameters: Shape and Size of Metal Crystals

The initial stages of metal electrodeposition on HOPG have been extensively studied by *in-situ* and *ex situ* STM and AFM combined with electrochemical techniques [19, 30, 31]. When electrodeposition proceeds close to equilibrium conditions, such as when E_d is slightly more negative than E_r, and a small charge density is involved, in the initial stages already metallic agglomerates (clusters) 1–2 nm in average diameter preferentially nucleated at step edges are produced. Under these conditions, there is agreement that the electrodeposition process takes place by the Volmer–Weber [20] growth mechanism (Fig. 1). For silver electrodeposition from acid plating solutions, the appearance of small ordered metallic domains has also been observed near step edges, probably acting as precursors to clustering [30]. For copper electrodeposition on HOPG, the formation of periodic arrays of clusters 2 nm in diameter following step edges has been observed [24]. Similar results have been obtained for platinum electrodeposition from acid plating baths on the same substrate [31], yielding clusters of average diameter $\langle d \rangle$ that roughly increases with t_d as $\langle d \rangle \approx t_d^{1/2}$ [49]. The aspect ratio (f) defined as the average height-to-average radius ratio is always small, $f = \langle h \rangle / \langle r \rangle \approx 0.1$.

The increase in either t_d or q_d as E_d is made slightly more negative than E_r, as in still maintaining a slow growth rate, results in the development of larger crystals that tend to develop regular patterns. Thus, at this stage, silver electrodeposition on HOPG yields triangular islands with closely packed (111) faces [31], whereas palladium electrodeposition on the same substrate produces quasi-hexagonal crystals [41]. Under comparably applied potential conditions [50], tetragonal tin crystals on both vitreous carbon and on

HOPG were grown from aqueous tin sulphate-sulphuric acid solution.

The increase in metal electrodeposition rate dramatically affects the shape and density of growing crystals. As a typical example, let us consider palladium electrodeposits on HOPG obtained for $q_d = 5$ mC/cm^2 as the electrodeposition rate is increased by shifting E_d negatively (Fig. 9). Thus, for $E_d = 0.380$ V ($E_d < E_r$), faceted hexagonal crystals with $\langle r \rangle = 200$–500 nm are grown (Fig. 9a) [41]. The corresponding crystal density evaluated from SEM micrographs is $N_c = 0.4 \times 10^8$ cm^{-2}. For $E_d = 0.125$ V, N_c increases to 3.6×10^8 cm^{-2} and $\langle r \rangle$ decreases markedly (Fig. 9b). The size distribution of these crystals is rather homogeneous with $\langle r \rangle \cong 80$ nm. The average height of these crystals measured from STM images is $\langle h \rangle = 35$ nm. Accordingly, the value f is still low enough to describe crystals as compact rounded disks rather than hemispherical crystals. On the other hand, for $E_d = -0.1$ V ($E_d \ll E_r$), such as when E_d is set in the potential range just preceding the hydrogen evolution reaction threshold potential, a large number, $N_c = 4 \times 10^9$ cm^{-2}, of small branched palladium crystals with $\langle r \rangle = 70$ nm is formed (Fig. 9c). The detailed structure of these small islands can only be resolved by STM imaging (Fig. 9d). A similar dependence of the crystal shape and size on E_d has also been observed for gold electrodeposits on HOPG [33].

The growth of the branched gold and palladium crystals for $E_d = -0.1$ V and different values of q_d was followed by sequential STM imaging. It should be noted that $q_d \propto t_d$. Thus, for $q_d = 1$ mC/cm^2 (Fig. 10a), irregular crystals with protrusions either randomly distributed over HOPG terraces or aligned and coming into contact with neighboring crystals, decorating HOPG steps are observed. The palladium crystals grown along step edges form metallic mesowires that have been recently used as hydrogen sensors [25]. Higher

resolution STM images (Fig. 10b) show that each metallic island consists of an agglomeration of small quasispherical particles with $5 \leq \langle d \rangle \leq 15$ nm forming a 3-D core. For $q_d = 1.5$ mC/cm^2 instabilities at crystal edges can be seen (Fig. 10c), and for $q_d = 3$ mC/cm^2, a net distinction between the central 3-D core and the 2-D branched pattern originated by instabilities around the core is observed (Fig. 10d). The quasi-2-D branched pattern is revealed by the fact that the maximum height of crystals remains almost the same as that of the 3-D core initially formed. Consistent with a (111) metallic lattice, the 2-D pattern around the core shows a net tendency to develop triangular crystals with most of the 2-D branches merging at 120° (Fig. 10e). Similar gold and palladium islands with preferential orientation (111) were grown on HOPG by vapor phase deposition at room temperature [51].

As recently reported [52, 53], STM images of palladium triangular crystals on HOPG produced from the vapor phase deposition demonstrate that for every stage before and after heating, irrespective of the degree of surface coverage, the deposit grows epitaxially in the fcc(111) direction. For palladium, secondary branches are separated by thin "fjords" 10 nm in width emerging from each main branch that have a tendency to produce a dense growth pattern. These patterns closely resemble those dense radial morphologies that have been observed for several metallic electrodeposits with a non-fractal mass and a self-affine fractal perimeter [54, 55]. Considering the crystal as a 2-D object, the fractal dimension (D_F) of branched crystal edge is $D_F = 1.3$. On the other hand, gold crystals tend to produce dendritic patterns with $D_F = 1.76$ [55]. Procedures for calculation of the fractal dimension of metallic crystals are given in [54–58].

For both gold and palladium electrodeposits, the cross section of crystals taken from the core border down to the tip of a main branch (Fig. 10f) approaches a 2-D profile with terraces almost atomically smooth (Fig. 10f, cross section). The height of each main branch decreases only about 5 nm in going from the core border to the branch tip with an average slope close to 3–4°. These tapering effects of the main branches mostly involve steps one atom high. Typical branch tip radii are close to 10 nm, whereas the tip height fluctuates between 2 and 4 nm. Finally, for $q_d = 4$ mC/cm^2 (Fig. 10g), the increase in both N_c and $\langle r \rangle$ leads to the partial overlap of neighbor branch centers.

The full width at one-half maximum height value (FWHM) from the crystal size distribution function of these palladium crystals increases with q_d (Fig. 11a–c) [13–14]. Thus, the relative standard deviation (RSD) in crystal diameter increases from 8.7% to 15.4% as $\langle d \rangle$ increases from 70 nm ($q_d = 1$ mC/cm^2) to 140 nm ($q_d = 3$ mC/cm^2).

4.3. Quantitative Kinetic Data from Different Stages of Growth

Quantitative kinetic data for the different stages of metal crystal growth can be obtained from the time dependence $\langle r \rangle$ and $\langle h \rangle$ derived by sequential STM and AFM images, as well as SEM micrographs. For the latter, in the case of 2-D-type deposits, only values of $\langle r \rangle$ can be derived. In general, both $\langle r \rangle$ and $\langle h \rangle$ fulfill power law dependences with
Figure 11. Particle size histograms for palladium electrodeposits. Data taken from Figure 10. (a) $q_d = 1$ mC/cm^2. (b) $q_d = 2$ mC/cm^2. (c) $q_d = 3$ mC/cm^2.

time, namely, $\langle r \rangle \propto t_d^n$ and $\langle h \rangle \propto t_d^m$, respectively. The values of the coarsening exponent, n and m, depend on E_d and q_d as the relative contribution of different rate processes to crystal growth changes with E_d and t_d. Correspondingly, for m $\neq$ n the value of f turns into a function of t_d, that is, $f(t_d) = \langle h \rangle(t_d)/\langle r \rangle(t_d)$. Values of n and m for gold and palladium are assembled in Table 1.

Table 1. Values of m, n, and f resulting from the electrochemical growth of palladium, gold, silver and platinum particles on HOPG at 298 K.

	Palladium	Gold	Platinum	Silver
m	$E_d < E_{pzc}$: 0.15	$E_d > E_{pzc}$: 0.40 $E_d < E_{pzc}$: 0.25	–	–
n	$E_d < E_{pzc}$: 0.40 $E_d > E_{pzc}$: 0.40	$E_d > E_{pzc}$: 0.40 $E_d < E_{pzc}$: 0.25	1/2	1/3
f	$f(t)$	0.3	0.1	–
Reference	[41]	[33]	[49]	[13–14]

For the early stages of a hemispherical or spherical cluster grown under diffusion from the solution side and $t_d \leq t_c$, a $\langle r \rangle \propto t^n$, dependence on n = 1/2 should be expected [44]. In this case $f = 1$, irrespective of t_d. On the other hand, for a 2-D-shaped cluster the same radial growth kinetic equation is obeyed, although in this case $f(t_d)$ approaches zero as t_d increases.

At later stages, for $t_d \geq t_c$, as in when crystal growth is under a convective-diffusion regime, growth models predict a $\langle r \rangle \propto t^n$ relationship with n = 1/3 [2]. Conversely, when particle growth proceeds under surface reaction kinetics, a $\langle r \rangle \propto t$ relationship is fulfilled [56–58].

Values of n for electrodeposition of various metals have been reported (Table 1). These figures for $E_d \approx E_r$ are consistent with diffusion and convective-diffusion regimes [13, 14, 49], whereas for $E_d < E_r$ values of n and m ranging from 1/4 to 2/5 are found [33, 41]. Otherwise, for gold crystal growth $f \approx 0.3$, a figure that is independent of t_d as n = m. The reverse situation occurs for the growth of palladium crystals as n > m, and f decreases rapidly with t_d. Values of f smaller than 1 indicate that a relatively fast surface metal atom relaxation takes place during crystal growth. It is well established that metal atom relaxation becomes a significant kinetic contribution for $T \ll 0.5T_m$, T_m being the melting temperature of bulk metal. Therefore, it is reasonable to consider that under this situation surface diffusion of metal adatoms contributes to crystal growth [59]. This conclusion is supported by the value n = 2/5 [60, 61] that was determined for disk-shaped gold and palladium crystals grown at E_d more positive than E_{pzc}, the potential of zero charge of the electrodepositing metal. For the growth of branched gold crystals at $E_d < E_{pzc}$, the value n = 1/4 [62] also sustains a surface diffusion contribution to the process, although in this case there is a significant influence of activation energy barriers for surface diffusion via step edges on the global process [63], as discussed later.

4.4. Models for Crystal Growth

In principle, as a first approach it seems reasonable to analyze the physical processes that determine the structure, shape, and size of crystals within the framework of the surface diffusion, deposition and aggregation (DDA) model [56–58]. This model is widely used for interpreting cluster growth data resulting from vapor phase deposition (Fig. 12a) [11, 64]. According to the DDA model, metal atoms impinging on the solid substrate diffuse as adatoms toward growing crystals to be captured at edges. Otherwise, adatoms impinging at the top of crystals diffuse downward to be captured at crystal edges. These processes occur without restrictions, as no activation energy barriers for adatom surface diffusion at step edges exist [63]. When a bump at a crystal edge is formed, it has a greater chance of capturing arriving atoms from the substrate rather than a reentrant, thus favoring tip growth and crystal branching (Fig. 12b) [56]. In the DDA model, tip splitting rather than tip stabilization becomes dominant, although tip stabilization resulting in dendritic patterns could also be produced by including the noise reduction technique in the model [65].

In principle, the DDA model could describe the growth of metal crystals on HOPG. For $E_d \rightarrow E_r$, the low flux of arriving particles implies a small nucleation rate (Equation (6))
Figure 12. Scheme of particle displacement in the DDA growth model. (a) Initial stages. (b) Advanced stages showing branching development.

and internuclei distances relatively large, so that the direct discharge of reactants on the susbtrate becomes possible. However, experimental compact disk-shaped island patterns with unstable edges that are formed for $E_d \rightarrow E_r$ do not evolve according to the predictions of a DDA-like model including dendrite formation. On the other hand, when the surface diffusion of adatoms at crystal edges is enhanced by increasing the substrate temperature, it results in a transition from DDA-like to rounded compact, kinked islands [56–58]. These results, therefore, support the idea that for $E_d \rightarrow E_r$, metal adatom surface diffusion at crystal edges plays a key role in eliminating either the DDA or dendrite-like structure.

Another drawback in describing experimental results in terms of the DDA model lies in the fact that it predicts perfect 2-D patterns, as there is no restriction for moving adatoms on growing crystals to reach crystal edges. For gold electrodeposition, the value $f = 0.3$, irrespective of E_r, indicates that gold adatoms produced by discharging $AuCl_4^-$ ions on crystal tops must surmount an activation energy barrier at gold crystal steps [63]. A scheme showing the location and the relative magnitude of activation energy barriers for intra- and interterrace diffusion at metal surfaces is shown in Figure 13. The activation energy barrier at step edges is due to the decrease in the coordination number of adatoms along their interterrace trajectories across step edges. For barrierless surface diffusion, the development of a completely flat interface similar to that predicted by the Edwards–Wilkinson model [66] should be expected (n = 1/2). For gold adatom interterrace diffusion, the corresponding energy barrier is larger than that for intraterrace diffusion [67, 68]. Therefore, in this case, interterrace adatom diffusion becomes rate determining. Accordingly, a clear deviation in the crystal shape from a perfect 2-D pattern should be expected. It should be noted that for isotropic
Figure 13. Qualitative scheme of Schwoebel–Erlich barrier for interterrace and intraterrace adatom surface diffusion. ΔE_k corresponds to the energy contribution to kink formation.

Figure 14. (a) Scheme of isotropic growth model. (b) Ball scheme of adatom surface diffusion across steps A and B on a (111) substrate. (c) Ball scheme of adatom surface diffusion at corner (1) and edges (2).

surface diffusion that implies the existence of a single activation energy barrier, the crystal evolves maintaining its original rounded or hexagonal shape.

The height of the activation energy barrier at step edges is closely related to the value of n. Values n ≈ 2/5 have been related to low activation energy barriers at step edges [60, 61]. The influence of the latter in determining the departure of the crystal shape from a perfect 2-D pattern can also be derived from the analysis of $f(t)$ values. Thus, as $f(t)$ decreases with t_d, crystals tend to approach 2-D patterns as in the case of palladium (111) (Table 1). In this case, mean-field calculations have shown that the height of step-edge activation energy barriers is considerably lower than that for gold (111), so that for palladium (111) intraterrace diffusion becomes rate controlling [68].

From the above discussion, for $E_d \rightarrow E_r$, it can be concluded that any DDA-like model applicable to the growth of metal electrodeposits on HOPG should include the presence of activation energy barriers at step edges to account for shape evolution. Therefore, to explain the nearly compact disks found in this potential region, either enhanced edge surface diffusion and/or an isotropic activation energy barrier at steps should be included. A scheme of this type of crystal growth under isotropic adatom surface diffusion is depicted in Figure 14a.

For E_d, which is more positive than the potential of zero charge of the depositing metal (E_{pzc}), the role played by metal adatom surface diffusion is sustained by the fact that the presence of a small amount of additive such as citric acid ($c = 0.1$ mM) in the plating solution eliminates branching and promotes the formation of rounded 3-D islands. As seen by *in-situ* STM imaging [69], this effect is caused by the adsorption of additive molecules at step edges, which hinders surface diffusion of gold atoms.

On the other hand, for fcc(111) surfaces, two different step edges, A- and B-type, should be distinguished [70]. The height of the activation energy barrier for interterrace adatom surface diffusion across A-type step edges is greater than across B-type step edges. This anisotropy in interterrace adatom surface diffusion results in the growth of triangular crystals. A scheme for anisotropic surface diffusion is shown in Figure 14b. Experimental data from gold and palladium electrodeposition show that anisotropic surface diffusion is approached for $E_d < E_{pzc}$. In this case, for $E_d \ll$
E_r, as a large number of nuclei is initially formed (Equations (4)–(6)), most of the ions coming from the solution are discharged on crystal tops, and the descending flux of adatoms across B-type steps is favored. Therefore, triangular crystals are by far preferentially formed. Hence, the existence of activation energy barriers of different height at A- and B-step edges leading to anisotropic surface diffusion of metal adatoms can explain the island shape obtained for $E_d < E_{pzc}$.

For $E_d \ll E_r$, dendritic patterns that are observed for both palladium and gold crystals also indicate the presence of anisotropic activation energy barriers at step edges [70]. From an atomistic standpoint, it is possible to distinguish two surface diffusion processes at island edges, depending on whether an adatom starts from a site that is laterally twofold (edge diffusion) (Fig. 14c) or onefold coordinated to the crystal edge (corner diffusion) [70]. Hexagonal lattice dendritic patterns with trigonal symmetry have been generated introducing anisotropic corner surface diffusion, whereas edge surface diffusion leads mainly to a thickening of island branching. For these surface diffusion processes, the symmetry of the substrate also plays a key role in the development of dendritic patterns [70]. This fact can explain, for instance, why under comparable experimental conditions, no dendritic crystals for gold electrodeposition onto amorphous carbon can be observed [71].

The preceding analysis provides a reasonable explanation to results obtained for $E_d < E_{pzc}$, but the question of why anisotropic surface diffusion is no longer observed for $E_d > E_{pzc}$ still remains open. In this case, an answer can be given after paying attention to the influence of the applied electric potential on surface diffusion processes.

4.5. The Electric Potential Influence

For metal electrodeposition processes, the height of activation energy barriers for adatom surface diffusion across step edges depends on the applied electric potential. Accordingly, it is possible to control the nanostructure and shape of metal

islands by properly adjusting the electrodeposition conditions, particularly the applied electric potential in potentiostatic experiments. For a potential-dependent metal island shape on HOPG, the adsorption of anions plays an important role. It is well known that anions in solution interact with the metal surface either electrostatically or specifically adsorbed. Both interactions depend on the electric potential applied to the electrochemical interface [72]. In principle, for $E_d < E_{pzc}$, the degree of metal surface coverage by adsorbed anions is negligible, as in this case the metal surface is negatively charged with respect to the solution. The reverse situation occurs for $E_d > E_{pzc}$. Then, as E_d is shifted positively, the electron density at the metal surface decreases and the degree of surface coverage by anions increases, eventually leading to the formation of a well-defined ordered anion adlattice [73]. For example, for either chloride or metal-chloride complex-containing plating solution, at $E_d > E_{pzc}$, anions accumulate at the metal/solution interface in the course of metal electrodeposition, and either chloride or metal-chloride complex ions become specifically adsorbed at growing metal islands. The global metal electrodeposition reaction from chloride containing metal anions is represented by Equation (1b) for Me = palladium, X = chlorine, and $1 \leq x \leq 6$.

When $E_d < E_{pzc}$, as the metal surface is negatively charged with respect to the solution, chloride ions produced by Equation (1b), as well as anions in general, diffuse outward from the metal/solution interface, and therefore, the influence of anion adsorption on metal electrodeposition becomes negligible. Then, the metal deposit approaches a dendritic growth pattern, as expected when an anisotropic corner diffusion regime operates. It is interesting to note that the same growth pattern has been observed for vapor phase deposition of silver islands on platinum (111) [70]. Conversely, at $E_d > E_{pzc}$, the metal being positively charged, chloride anions produced by Equation (1b) become specifically adsorbed on the growing crystal surface. Under these particular conditions, it is well-established that specific adsorption phenomena are enhanced at step edges. The increase in chloride ion adsorption with E_d correlates with an increase in the surface diffusion coefficient of metal adatoms, leading to an enhancement of both adatom surface mobility [72] and step displacement [73]. In fact, when E_d is increased from 0.30 V ($E_{pzc} \approx 0.25$ V versus SCE) to 0.80 V, the surface diffusion coefficient of gold adatoms on gold immersed in acid solution increases from $D_s = 1 \times 10^{-12}$ cm^2/s to $D_s = 8 \times 10^{-12}$ cm^2/s [74]. Hence, the specific adsorption of anions at step edges produces a decrease in the height of energy barriers for adatom surface diffusion, that is, isotropic surface diffusion conditions are then approached that favor the growth of kinked rounded crystals. For gold island electrodeposition, this explanation is consistent with the change of n from 1/4 to 2/5 [75]. On the other hand, values of D_s for palladium adatom surface diffusion on palladium, either in the presence or in the absence of chloride ions are not available yet, but they can be estimated from the Gjostein–Rhead equation [76–78]

$$D_s = 749 \times 10^{-4} \exp(-30 T_m / \mathbf{R} T)$$
$$+ 0.014 \times 10^{-4} \exp(-13 T_m / \mathbf{R} T) \qquad (8)$$

In Equation (8), T_m is the melting point of the surface species, and $\mathbf{R} = 1.987$ cal/mol K.

Let us consider Equation (8) to determine whether the most likely surface-diffusing species is closely related to palladium adatoms or to palladium-chloride-complex adsorbates. Based on electrochemical kinetic data [41], let us assume that for $E_d > E_{pzc}$, a PdCl$_2$ adsorbate on palladium is formed [77, 78]. Then, from the application of Equation (8) for palladium ($T_m = 1827$ K) and PdCl$_2$ ($T_m \approx 773$ K), it results in $D_s = 1.3 \times 10^{-14}$ cm^2/s for PdCl$_2$, and $D_s = 5.7 \times 10^{-24}$ cm^2/s for palladium at 298 K. Therefore, we can conclude that a palladium-chloride complex species [79] is responsible for the surface relaxation process occurring during the palladium crystal electrochemical growth. The increase in the value of D_s for palladium-chloride-complex-ion-containing solution follows the same tendency that has already been reported for the surface mobility of gold adatoms on gold under comparable conditions [74]. For such a high value of D_s, the average traveling rate of [PdCl$_2$] species on the palladium surface is about 1 nm/s. This figure is consistent with the surface relaxation rate that contributes to the formation of rounded islands for $E_d > E_{pzc}$. It should be noted that the high value of D_s referred to above is of the same order of magnitude as that of D_s that has recently been found for the surface diffusion of disk-shaped aggregates of cadmium sulfide nanocrystals on HOPG at 50–100 °C [80].

The role of chloride ions in the surface diffusion rate was confirmed by increasing their concentration in the plating solution. In fact, the addition of chloride salt promotes 2-D growth, that is, it decreases the value of f, and tends to hinder dendritic growth [69] as found from AFM imaging for the growth of flat cobalt crystals on HOPG by electrodeposition from chloride-containing solutions [50].

5. APPLICATIONS

5.1. Nanowires

Among the different methods for fabricating long metallic nano- and mesowires, the most successful ones are template synthesis [81–83] and step-edge decoration [84–87].

The electrochemical method for preparation of metallic meso- and nanowires is based on the selective electrodepositon of the metal directly at step edges utilizing HOPG substrate. This step-edge decoration method has been proposed by Liu et al. [13], Penner [14], Penner et al. [25], and Zach et al. [26] from either metal or metal oxide electrodeposition on HOPG.

For the preparation of palladium meso- and nanowires, the solid solution interface is perturbed by a routine consisting of three successive potential steps. The first step is adjusted to oxidize step edges on HOPG just prior to deposition; the second step, which involves a large cathodic overvoltage for metal deposition of about 0.3 V for 5–10 ms, favors metal nucleation; the third step involves a low cathodic overvoltage for metal growth of less than 0.1 V. The radius of the nanowires is controlled by the electrodeposition time [88, 89].

Metallic palladium meso- and nanowires can also be produced by a two-stage electrochemical process involving first the potentiostatic electrodeposition of palladium followed

by a controlled anodic stripping stage. A typical palladium nano/mesowire array prepared by this method is shown in Figure 15.

The preparation of metallic nanowires also proceeds via the electrodeposition of a metal oxide. This is the case of the electrodeposition of molybdenum dioxide on HOPG from dilute molybdate solution at pH 6.5. This process is followed by hydrogen reduction at 500 °C yielding HOPG-supported metallic molybdenum meso- and nanowires [88, 89].

Nanoparticles and nanowires are potentially very efficient chemical sensors. The chemical sensing mechanism is envisioned as the adsorption and eventually diffusion of the analyte species at the surface inducing there a change in a measurable property. An example of a chemical sensor operating on the above principle, which has been described recently [88, 89], is that of gold nanowires showing changes in the electrical conductivity upon exposure to thiols of amines.

Arrays of mesoscopic palladium wires have been applied as hydrogen sensors and hydrogen-actuated switches [25]. These devices have been constructed by transferring the palladium nanowire arrays from HOPG onto a cyanoacrylate or polyurethane film. In contrast to hydrogen sensors based on macroscopic palladium resistors, which become more resistive in the presence of hydrogen, the resistance of the palladium mesowire array decreases under hydrogen. From AFM and SEM observations, the likely mechanism that has been proposed for the operation of the palladium mesowire array to account for its response as a hydrogen-actuated switch involves the closing of nanoscopic break junctions along the step edges caused by the dilation of wire grains undergoing the reversible conversion of palladium to palladium hydride. Accordingly, in the absence of hydrogen, each break junction reverts to open circuit [25].

5.2. Pattern Transfer to Polymeric Materials

HOPG patterned with electrodeposited nanometer-sized metallic crystals has been used as a template to fabricate nanocavities on polymeric materials [27]. The procedure for
Figure 15. SEM micrograph of palladium islands on HOPG electrodeposited at $E_d = -0.100$ V, from the solution indicated in Figure 4, for $q_d = 5$ mC/cm^2, after anodic stripping in 0.1 M aqueous perchloric acid to reach $q_d = 1.3$ mC/cm^2.

pattern transfer is simple. It consists of pouring a prepolymer solution onto the patterned HOPG surface. After evaporation, a polymer film that can be easily released from the HOPG surface is formed. The inner face of the polymer film, which has been in contact with the HOPG surface, exhibits nanocavities—the pattern transfer from the HOPG surface to the polymeric material takes place. It should be noted that this simple method to produce nanocavities onto polymeric surfaces has also been performed using either patterned silicon or patterned metallic substrates. However, in these cases, the template surface has to be modified by a self-assembled monolayer of alkanethiols (metals) or silanes (silicon) in order to release the polymer film from the template without damage. The advantage of using patterned HOPG arises from the fact that, due to its extremely low chemical reactivity, no surface chemistry modification is needed to avoid damage. Note that depending on the metal-polymer interactions, the electrodeposited metal particles can either be transferred to the polymeric film (as described in Section 5.1) or remain on the HOPG surface forming cavities on the polymer (nanocavity fabrication).

5.3. Heterogeneous Catalysis

The reactivity of the nanometer-sized compact disks and branched palladium particles for hydrogen atom electroadsorption/electrodesorption reactions in aqueous 0.1 M perchloric acid was investigated by cyclic voltammetry at $v = 0.1$ V/s [90]. For the sake of comparison, blanks were run that utilized massive either palladium or platinum electrodes. For massive palladium, the voltammogram recorded from 0 V to -0.3 V (Fig. 16a) shows a cathodic current, essentially related to hydrogen absorption by palladium, and to some extent the initial formation of molecular hydrogen at higher cathodic overvoltage [91]. The reverse potential scan shows the electro-oxidation of absorbed hydrogen as the main anodic process with a broad anodic current peak at -0.075 V. This voltammogram shows no trace of adsorbed hydrogen as might be expected at -0.30 V and -0.15 V (Fig. 16a, inset). Therefore, in contrast to the voltammogram of polycrystalline platinum that exhibits conjugated pairs of current peaks related to weakly and strongly bound hydrogen adatoms at approximately -0.05 V and -0.20 V, respectively, no hydrogen atom electroadsorption/electrodesorption can be concluded from the voltammogram of smooth massive palladium.

Comparable voltammograms were recorded for nanometer-sized palladium crystals of different morphologies on HOPG, namely, compact disk-shaped crystals prepared at $E_d = 0.125$ V ($q_d = 5$ mC/cm^2) (Fig. 16b), and branched particles produced at $E_d = -0.100$ V ($q_d = 5$ mC/cm^2) (Fig. 16c). In contrast to massive palladium, both types of palladium islands exhibit voltammetric features resembling those for hydrogen atom electroadsorption/electrodesorption on platinum [92]. For palladium crystals supported on HOPG electrodes, these processes are characterized by peaks I and II at approximately -0.25 V and -0.15 V, respectively (Fig. 16c), and the anodic-to-cathodic voltammetric charge ratio approaches 1 as expected for relatively fast surface electrochemical processes [93, 94]. It can also be observed that for branched palladium islands
Figure 16. Current density versus potential curves recorded at 0.1 V/s from 0.30 to −0.30 V to reach the region where hydrogen atom electrosorption/electrodesorption reactions are observed. Aqueous 0.1 M perchloric acid. (a) Polycrystalline palladium electrode (0.125 cm² geometric area). The voltammogram (inset) corresponds to the cathodic potential limit −0.15 V. (b) Quasi-hemispherical palladium islands on HOPG, $E_d = 0.125$ V, $q_d = 5$ mC/cm². (c) The continuous trace corresponds to branched palladium islands on HOPG, $E_d = -0.10$ V, $q_d = 5$ mC/cm². 298 K. Electrodeposits have been obtained as indicated in Figure 9. Reprinted with permission from [90], Y. Gimeno et al., *Chem. Mater.* 13, 1857 (2001). © 2001, American Chemical Society.

supported on HOPG, the peak I/peak II charge ratio is increased, as compared to that resulting from compact disk-shaped crystals. Therefore, the contribution of the hydrogen adatom electrodeposition reaction

$$\mathrm{Pd(H)_{ad} = Pd + H^+ + e^-} \qquad (9)$$
as compared to hydrogen absorption is considerably enhanced on nanometer-sized palladium crystals supported on

HOPG, particularly on branched crystals. It should be noted that the voltammogram resulting from a palladium-plated HOPG electrode at $E_d = -0.100$ V ($q_d = 20$ mC/cm²) shows a contribution of hydrogen electroadsorption/electrodesorption much smaller than that observed for branched palladium crystals [95].

To confirm the high electrochemical reactivity of nanometer-sized branched palladium crystals, the electrochemical oxidation of hydrazine on massive palladium, nanometer-sized compact disk-shaped particles and nanometer-sized branched palladium crystals ($q_d = 5$ mC/cm²) supported on HOPG were also investigated [90]. For this purpose, aqueous 6×10^{-3} M hydrazine + 0.1 M potassium sulphate at 298 K was employed. For massive palladium (Fig. 17a), the voltammogram shows a broad anodic current peak at 0.31 ± 0.01 V related to the electro-oxidation of hydrazinium ions [90]. This peak is followed by another broad peak at approximately 0.6 V, which corresponds to the formation of the oxygen-containing layer on palladium [96, 97]. The latter is electroreduced as the potential scan is reversed, as seen by the broad current peak at approximately 0.5 V. For nanometer-sized compact disk crystals produced at $E_d = 0.125$ V (Fig. 17b), the anodic current peak potential related to hydrazinium ion electro-oxidation is 0.33 ± 0.01 V, whereas for branched palladium crystals (Fig. 17b) it is 0.26 ± 0.01 V. In this case, the conjugated cathodic reaction can also be observed at the same potential during the reverse potential scan. Furthermore, the initial portion of the voltammogram fits a linear E_d versus $\ln j_c$
Figure 17. Current density versus potential curves for hydrazine electro-oxidation recorded at 0.2 V/s. Aqueous 6×10^{-3} M hydrazinium sulphate + 0.1 M potassium sulphate. (a) Polycrystalline palladium electrode. (b) Quasi-hemispherical, $E_d = 0.125$ V (full trace), and branched, $E_d = -0.10$ V (open circles) palladium islands on HOPG ($q_d = 5$ mC/cm²). 298 K. The current density in (b) is also referred to the weight of electrodeposited palladium calculated from q_d. Reprinted with permission from [90], Y. Gimeno et al., *Chem. Mater.* 13, 1857 (2001). © 2001, American Chemical Society.

plot, with the slope $\Delta E_d/\Delta \ln j_c$ decreasing from 0.15 ± 0.01 to 0.09 ± 0.01 V/ln unit in going from smooth to branched crystals. These results are consistent with electrochemical kinetics under intermediate control [98].

Under the above-mentioned conditions, the voltammetric electrochemical oxidation of hydrazine is a 4-electron reaction

$$N_2H_5^+ = N_2 + 5H^+ + 4e^- \tag{10}$$
with a pair of conjugated peaks at the range 0.26–0.33 V. This complex electrochemical reaction depends on the crystallography, state, and history of the electrode surface, as has been concluded for platinum electrodes in the same solution [99]. The decrease in the value of the slope $\Delta E_d/\Delta \ln j_c$, the increase in height of conjugated peaks, and the displacement of their peak potentials by 0.07 V negatively indicate an increased catalytic effect of nanometer-sized branched-palladium crystals on HOPG-supported electrodes. Therefore, electrodes behave as the electrochemically most active material for both test reactions.

6. CONCLUSIONS

The electrodeposition of metallic crystals on carbon HOPG has been reviewed, in particular, in relation to crystal structure and shape. At the mesoscale, narrow particle size distributions of metal crystals can be obtained by conventional potentiostatic electrodeposition of metal ions from aqueous solutions. The shape and structure of mesocrystals depend on the applied electric potential. Over a wide potential range, the aspect ratio of crystals differs considerably from that of hemispherical particles. This departure can be explained by growth models, including surface adatom diffusion and step-dependent activation energy barriers at step edges. Anions adsorption from the solution plays a key role in determining the height of activation energy barriers for surface diffusion. The electrocatalytic activity of branched mesocrystals for different processes is considerably greater than that of compact disk-shaped mesocrystals of comparable size. Metallic electrodeposition on carbons can also be used for nano/mesowire fabrication with potential applications as chemical sensors, and promising interconnectors for nanoelectronic devices and polymer embossing. The discussion of these issues is important for facing problems related to the crystal engineering of metalic nanoparticles.

GLOSSARY

Exchange current density Value of the current density at the equilibrium potential of the electrochemical interface.

Mesoparticles Particles with size comprised between 100 to 1000 nm.

Nanoparticles Particles with size up to 100 nm.

Overvoltage The potential difference between the applied electric potential and the reversible potential of the electrochemical interface.

Potentiodynamic polarization curve A current versus potential record obtained under a single linear potential scan.

Voltammogram Current versus potential record obtained under a triangular potential scan between an upper and a lower switching potential.

CONTENTS

1. INTRODUCTION

Nanotechnology is a leading interdisciplinary science that is emerging as a distinctive field of research. Its advances and applications will result in technical capabilities that will allow the development of novel nanomaterials with applications that will revolutionize the industry in many areas [1, 2]. It is now well established that dimensionality plays a critical role in determining the properties of materials and its study has produced important results in chemistry and physics [3].

Nanoparticles are one of the cornerstones of nanotechnology. Indeed, even though the research in this field has been underway for a long time, many present and future applications are based on nanoparticles. For instance, the electron tunneling through quantum dots has led to the possibility of fabricating single-electron transistors [4–9]. One concept particularly appealing is a new three-dimensional periodic table based on the possibility of generating artificial atoms from clusters of all of the elements [10]. This idea is based on the fact that several properties of nanoparticles show large fluctuations, which can be interpreted as electronic or shell-closing properties with the appearance of magic numbers. Therefore, it is conceivable to tailor artificial superatoms with given properties by controlling the number of shells on a nanoparticle.

The development of nanotechnology can be approached from several directions; mesoscopic physics, microelectronics, materials nanotechnology, and cluster science. The different fields are now coming together, and a completely new area is emerging [11, 12]. Figure 1 illustrates how the different approaches are converging; it exhibits the domains of clusters and nanoparticles with different structures that result from an increase in the number of atoms. The different possible structures include nanorods, nanoparticles, fullerenes, nanotubes, and layered materials.

One of the most remarkable advances in this field has been the synthesis of ligand-capped metallic clusters. In a seminal contribution, Brust et al. [13] used the classical two-phase Faraday colloid separation combined with contemporary phase-transfer chemistry to produce small gold nanoclusters coated with alkanethiolate monolayers. Several groups have pursued this technique [14–21], and have introduced improvements and modifications to the original technique. Whetten and his group [15, 16] made important contributions to this technique.

A significant property of ligand-capped clusters is that they can be repeatedly isolated from and redissolved in common organic solvents without irreversible aggregation or decomposition. The properties of the monolayer-protected nanoparticles (MPNs and MPANs) allow handling in ways that are familiar to the molecular chemist since they are stable in air conditions. The MPNs of some metals such as Pt [22], Ag [23], Rh, and Pd [24] have been synthesized.

2. GEOMETRIC CONSIDERATIONS

2.1. Clusters and Nanoparticles

Since the pioneering work of Ino and Ogawa [25, 26], it was clear that, in most cases, the structure of nanoparticles cannot be described by the bulk crystallography of the used material. The concept of multiple twins was used to explain many of the structures, Such as the icosahedron and the decahedron. This concept was directly imported from the macroscopic metallurgical studies, and was certainly very useful for a first understanding of the structure of nanoparticles. Another related research field was the study of clusters formed by few atoms. From that field, we learned that structures are formed by shells, and the concept of a magic number was introduced [27]. Nanoparticles referred
to sizes of ∼5–10 nm, and clusters referred to sizes of ∼1 nm. In recent times, the computational tools for study clusters allow the analysis of a large number of atoms, and the methods to study nanoparticles allow interrogating smaller nanoparticles. The two fields are merging into one. In this chapter we will use the term particle and cluster indistinctly.

2.2. Clusters with Cubic Symmetry

When considering atom clusters of nanometric dimensions, it can be supposed that they correspond to some symmetry group. In previous works, small clusters (up to tents of atoms) of diverse forms (tetrahedron, hexahedron, octahedron, decahedron, dodecaheltahedron, trigonal, trigonal prism, and hexagonal antiprism, with and without a central site) have already been studied [28]. Partially and totally capped clusters were also considered (clusters to which a site has been added to each face of the polyhedron, equidistant to every site of the face), in order to vary the number of sites for all of the polyhedrons, and thus allowing the comparison as a function of the number of sites.

Geometric characteristics of the clusters formed by concentric layers can be considered, as formed by equivalent sites: sites located at the same distance from the origin, which occupy the same geometric place and have the same environment, that is, the same number and type of neighbors. These layers can be arranged in such a way that they group in shells forming clusters of different sizes, retaining the original geometric structure. The number of shells in the cluster is called the order of the cluster, and is represented by letter ν. The studied structures were: the icosahedron, the face-centered cubic structure fcc (the cubooctahedron), the body-centered cubic bcc, and the simple cubic sc [29].

In order to determine the stability of the structures from an energetic point of view, a study of the cubo-octahedral and icosahedral structure was performed using the embedded atom method (EAM) for the transition metals Cu, Pd, Ag, and Ni [30]. It was determined that for sizes smaller than 2000 atoms, the icosahedron is the most stable structure, and for larger sizes, the cubooctahedron. For this study, the advantage of having equivalent sites in the clusters was used to reduce computation time. In a latter study, based upon the same metals, small clusters of less than 100 atoms with regular polyhedron geometries were used, and to change the cluster size, partially and totally capped clusters were considered. Tetrahedral clusters showed the highest stability for sizes of less than 18 atoms, and icosahedra for larger sizes [31].

In this work, the structural stability competition among different regular structures of the concentric shell type is searched. Here, the studied geometries are reproduced, considering some other arrays of the layers in shells, which give rise to other geometries. The fcc structure considers many structures, which are divided into two groups: (1) with a central site, and (2) without a central site. Among the centered ones, the cubooctahedron, octahedron, and truncated octahedron are considered. For the ones not centered, the

Figure 1. Domains of nanoparticles and clusters with different structures.

octahedron and the truncated octahedron are considered. The bcc structure has the dodecahedron. The sc structure does not allow a study like the one presented here because, when a truncation is tried, second neighbor distances are obtained. Once the geometric properties of the structures are determined, the EAM is applied to them, and their stability is discussed.

2.3. Geometric Characterization

The following procedure was used to determine the geometric characteristics of the structures: (1) First, identify the structures, that is, their geometric shape; (2) the nature of the site coordinates which conform the structures; and (3) their neighbors with surrounding layers, in order to identify the equivalent sites and generate the concentric shell-type structures. Once this previous stage is completed, the geometric properties to be determined are defined, the structures are presented, and the geometric properties of each structure are numbered. Afterwards, based on the geometric characteristics of each structure, the analytic expressions are deduced as a function only of the cluster order for the defined properties.

An example of the concentric shell-type structures is shown in Figure 2, which presents the cubooctahedron in three different sizes. In this figure, a central site surrounded by 12 sites forming a cubooctahedron with one first shell can be seen; Figure 2(a). Then it is covered with another shell of sites distributed in three layers of equivalent sites, as will be seen later, but retaining the original geometric shape; Figure 2(b). And finally, Figure 2(c) presents a three-shell cubooctahedron.

The structures considered are the face-centered cubic fcc, [Fig. 3(a)], and the body-centered cubic bcc [Figs. 3(d) and (e)]. Although both are cubic, in Figure 3(a) the fcc does not seem to be cubic, but the face-centered cubic structure with a central site fccc [Fig. 3(b)], and the face-centered cubic structure without a central site fccs [Fig. 3(c)], show that they do have a cubic shape: 8 vertexes, 6 square faces, and 12 edges. The bcc structure has a central site, while the fcc structure can be considered with and without a central site. Truncating each one of them in a certain direction, noncubic structures are obtained, they have, besides vertexes (V), edges (E), and square faces (S), faces of different shapes: a triangular face (T), a hexagonal face (H), and a rombohedral face (R). The resulting structures are: the

Figure 3. Structures (a) face-centered cubic fcc, (b) face-centered cubic with central site fccc, (c) face-centered cubic without central site fccs, and (d), (e) body-centered cubic bcc.

cubooctahedron [Fig. 4(a)], the octahedron [Fig. 4(b)], the truncated octahedron [Fig. 4(c)], and the dodecahedron [Fig. 4(d)]. For the fccc, the obtained structures are the cubooctahedron CO, the octahedron OCTAC, and the truncated octahedron OCTTC; for the fccs, the structures obtained are the octahedron OCTAS, and the truncated octahedron OCTTS; and for the bcc, only the decahedron is obtained, DODE.

Table 1 presents the number of characteristic sites of each structure, in such a way that each structure is read as: the structure is formed by V vertexes attached by E edges forming X faces of different types, where $X = S$, T, H, R, as it corresponds. The icosahedron is included [Fig. 4(e)], because it can be obtained by an adequate distortion of the CO, and it is useful as a reference for a comparison of results. ICO, the fccc and its derivates, as well as the bcc and the DODE, present a central site. The OCTTC is centered over an octahedron with a central site of 19 sites, and the OCTTS over a regular octahedron of 6 sites.

2.3.1. Standard Coordinates

Each of the structures studied here, except the ICO, corresponds to a well-defined crystalline structure, fcc or bcc, so that the coordinates of the geometric sites which compose them are characteristic of each one of them. In each structure, the standard coordinates are described by triads (a, b, c), a, b and c are integers, where the total number of sites is obtained by doing permutations and commutations

Figure 2. Cubooctahedrons formed by a central site and (a) one layer, (b) two layers, and (c) three layers.
Figure 4. Polyhedrons resulting from truncation of fcc and bcc structures. (a) cubooctahedron, (b) octahedron, (c) truncated octahedron, and (d) dodecahedron. (e) as a result of an adequate distortion of the cubooctahedron, the icosahedron is obtained.

Table 1. Number of geometric sites corresponding to the structures of the first column. Last column presents the number of central sites of the structure.

	V	E	S	T	H	R	Central site

of the positive and negative values of a, b and c. Table 2 presents the characteristics of standard coordinates for each structure as a function of the cluster order ν. Sites ES [EH] in OCTTC are the sites on edges between hexagonal and squared [hexagonal] faces.

2.3.2. First Neighbors

There will be different types of equivalent sites, depending on the geometric structure, and each type will occupy a geometric position which will be of type vertex (V), edge (E), square face (S), triangular face (T), hexagonal face (H), and rombohedral faces (R), and it will have a total number of neighbors, coordination z, which will correspond to the structure, but the number of neighbors with layers of its same shell, with interior and exterior shells, will be characteristic of each site. Table 3 presents the different types of sites in the studied structures, as well as the number of first neighbors with layers of interior shells ($\downarrow$), in the same shell ($\leftrightarrow$), and with exterior shells ($\uparrow$). Also, total coordination z

			—	—	—	2	1	0	1		

Figure 5. fcc polyhedrons of (a) 13 sites (central site plus a sublayer of 12 sites), (b) 63 sites (a complete layer of 62 sites), (c) 171 sites (a sublayer of 108 sites over the order 1 fccc), and (d) 365 sites (two complete layers).

1×12 E sites, 5×6 S and 8 V, but looking carefully it will be noticed that the S sites are not equivalent because the one in the center of the squared face has a coordination of 4 with the surface sites, while the other has a coordination of 6, but both have a coordination of 4 toward external layers. It is also observed that in Figure 5(c) the four sites of type S at the center of the face have a coordination of 4 with the surface sites, and the other eight sites of type S have a coordination of 5 with surface layers, but all of them have 4 toward external layers, while in Figure 5(d) it is observed that the S sites near the vertexes have a coordination of 6 with sites over the same surface shell, and the ones close to sites E have a coordination of 5, this is why in Table 3 the coordination for S sites can be of three types, but all of them with a coordination of 4 toward external layers. That is why in fccc and fccs there are shells composed of two subshells, one that will contain the surface sites, and the other that will remain internal. Surface sites will interact with the internal sites, and these internal ones with those of the cluster and the surface ones.

From Fig. 4d it is worth noticed that the vertex sites for the dodecahedron are of two types: one on which four edges converge and another on which three edges converge. This is why in Table 3 the coordination for the V sites for the DODE structure are of two types.

2.3.3. Definition of Geometric Properties

Table 4 presents definitions and their mathematical expressions for the general geometric characteristics, which can be expressed analytically as a function of only the order of the cluster ν, for each structure or geometric array. The upper section of Table 4 refers to the geometric characteristics of the cluster, the middle section to the bonds, and it relates Table 3, and the superior part of Table 4, and the lower section of Table 4 to the average coordination based on the rest of Table 4.

The cluster can be defined as a nucleus and a surface over the nucleus. The number of I sites, the number of types of I sites and what refers to dispersions is over the surface, and the average number of bonds and coordination is over the involved sites of the cluster. In the expressions for $\mathcal{N}_{CC}$ and $\mathcal{N}_{SS}$, $(\uparrow)_I$ means the number of I site bonds in the internal layer (the nucleus surface) with sites in the external layer (the cluster surface), $(\downarrow)_I$ means the number of I-site bonds in the external layer (the cluster surface) with sites in the internal layer (the nucleus surface), and $(\leftrightarrow)_I$ means the number of I-site bonds in the surface of the cluster with

in the structure is presented. The truncated octahedron with a central site presents two types of edges, the edges between squared and hexagonal faces, ES, with coordination $(2, 5, 5)$, and the edges between hexagonal faces, EH, with coordination $(1, 6, 5)$, while all of the other structures have only one. It should be noticed that, in order to obtain structures of the concentric shell type in the fccc and fccs structures, two shells will be needed, as shown on Figure 5 for fccc (similarly for fccs); Figure 5(a) presents the fccc "cube" of 13 sites; Figure 5(b) shows the fccc of 63 sites, which will be a complete shell of 62 sites $(12 + 50)$ over the central site; Figures 5(c) and (d) present the fccc of 171 sites and the fccc of 365 sites, the latter is the one with two shells, one with 108 sites and the other with 194 sites. The surface sites in the fccc of 13 sites become internal when adding 50 to complete the fccc of 63 sites, the same happens for that one of the 171 sites when covering it to complete the one with 365. From Figure 5(b), it is observed that there will exist

Table 4. General definitions of geometric parameters for different structures.

Symbol	Definition	Mathematical expression
N	Total number of atoms in a cluster of order ν	
N_σ	Number of atoms in a crust or on the surface	
$\mathscr{D}$	Dispersion;	N_σ/N
N_I	Number of surface atoms on site I, $I = S, T, H, R, E, V$	
R_I^a	Number of shells in which are contained the I-sites (a = even, odd)	
N_{shell}^ν	Number of shells at the surface	
N_{shell}^T	Total number of shells in the cluster	
$\mathscr{D}_I$	Dispersion due to surface I sites;	N_I/N_σ
$\mathscr{N}_{CO}$	Number of internal bonds in a cluster of order ν;	$\frac{1}{2} \times z \times N(\nu - 1)$
$\mathscr{N}_{CC}$	Number of bonds between two adjacent crusts ($\nu - 1$) and ν;	$\sum_I (\uparrow)_I \times N_I(\nu - 1) = \sum_I (\downarrow)_I \times N_I(\nu)$
$\mathscr{N}_{SS}$	Number of bonds on the surface of a cluster of order ν;	$\frac{1}{2} \sum_I (\leftrightarrow)_I \times N_I(\nu)$
$\mathscr{N}_C$	Number of bonds in a cluster of order ν;	$\mathscr{N}_{CO} + \mathscr{N}_{CS} + \mathscr{N}_{SS}$
$\overline{Z}$	cluster average coordination;	$2\mathscr{N}_C(\nu)/N(\nu)$
$\overline{Z}_{CO}$	Core average coordination;	$2\mathscr{N}_{CO}(\nu)/N(\nu - 1)$
$\overline{Z}_{CS}$	Core–surface average coordination;	$\mathscr{N}_{CC}(\nu)/N_\sigma(\nu - 1)$
$\overline{Z}_{SC}$	Surface–core average coordination;	$\mathscr{N}_{CC}(\nu)/N_\sigma(\nu)$
$\overline{Z}_{SS}$	Surface average coordination;	$2\mathscr{N}_{SS}(\nu)/N_\sigma(\nu)$

sites in the same surface. It must be clear that, due to the fact that there are many ways to coordinate S sites in the surface for fccc and fccs structures, the formula for $\mathscr{N}_{CC}$ must only be used as $\sum_I (\uparrow)_I \times N_I(\nu - 1)$, and only for these two structures, the proposed equity does not apply.

2.4. fcc Structure

An fcc structure is that in which the unit cell is a cube with sites in the vertexes and in the center of squared faces, this means that there are 14 sites on a cube, 8 vertexes, and 6 squared faces [Fig. 3(a)], also, it can be seen as a completely capped octahedron. When attaching many of these arrays with common or shared sites in faces and vertexes, clusters are obtained with sites in vertexes, edges, and squared faces. The origin of coordinates can be chosen to be at the center of the cube or on a vertex, obtaining structures with and without a central site, respectively.

2.4.1. fcc Structure with a Central Site

In the fcc structure with a central site, the cubic cluster of order 1 is a cube with 63 sites, distributed in 5 layers around a central site [Fig. 5(b)]; it can be seen that it is an array of 6 unit cells with common sites. The order 2 cluster is obtained when covering the one of order 1 with 302 sites distributed in 13 layers to obtain a total of 365 sites [Fig. 5(d)], and so on. Layers of equivalent sites can be identified (Table 1): squared face (S), edges (E) and vertexes (V). Table 2 presents the standard coordinates and its characteristics, it can be seen that the sum of the standard coordinates a, b and c is an even number, and in Table 3 the coordination of each site. From Figures 5(a)–(d) it can be seen that a shell is composed of two subshells. Table 5 lists the geometric characteristics of the fccc structure, separating each shell into subshells to allow the calculus of surface dispersions and the number of bonds as defined in Table 4, and for each shell. General expressions for the geometric characteristics of Table 4 are presented in Table 6. These are shown when they are being considered as shells or subshells,

in both columns corresponding to subshells, the first one is for the internal, and the second one is for the external or surface. N_σ represents the number of sites added to the cluster of order $\nu - 1$, N_{sup} is the number of sites forming the surface, and it is the same for either of the considered cases because the internal shell does not form part of the surface. Besides this, the distinction is made among the different types of sites S forming the surface, N_S^j, where j is the coordination of the S sites with sites in the same layer, $j = 4, 5, 6$. In the calculus of the number of bonds between the two sublayers, the coordination from inside to outside was considered, because all of the types of S sites have a coordination of 4 with the exterior shell.

When grouping the layers of equivalent sites in shells in a different manner than the one given in fccc, geometries that present, besides squared faces, triangular and hexagonal faces will rise. Here, the cubooctahedron, octahedron, and truncated octahedron are considered.

2.4.2. Cubo-octahedra

The cubo-octahedron can be obtained by truncating an fcc structure in direction (111), this is shown in Figure 6(b), where a cubo-octahedron of 55 sites is presented, and is the result of removing the 8 corners of a cube of 63 sites. It is

formed by 8 triangular faces and 6 squared ones, attached by 24 edges and 12 vertexes; see Table 1. Consequently, the surface sites are localized in squared faces (S), triangular faces (T), edges (E), and vertexes). The CO of order 1 has a central site and a first shell with one single layer of 12 vertexes, Figure 6(a). The CO of order 2 is formed by adding one shell formed by 42 sites in order to complete 55 [Fig. 6(b)], distributed in three layers: one layer of 6 S sites, another of 24 E sites and a third one of 12 V sites. When adding a third shell of 92 sites, the third order CO of 147 sites is completed [Fig. 6(c)], sites are distributed in four layers: one of 24 S sites, another of 8 T sites, one more of 48 E sites, and a fourth one of 12 V sites. Successively, complete shells are added this way, forming clusters of order ν.

The standard coordinates for the cubo-octahedron are listed in Table 2, the number of neighbors for each site can be found in Table 3, and the geometric characteristics of the CO are listed in Table 7; from this table, it is possible to obtain the general expressions for the geometric characteristics of the cubooctahedron defined in Table 4. These expressions are presented in Table 11, for the cubo-octahedron and all the other fccc structures to be studied.

Figure 6(e) presents an icosahedron of 923 sites of order 6. When comparing with the CO, which has the same number of sites, from Figure 6(d), the distortion made to obtain the ICO can be observed. Table 3 shows the number of neighbors for each site, and Table 8 reproduces the geometric characteristics corresponding to the icosahedron, which have been reported previously [29]. A great similarity can be noticed between Tables 7 and 8, in the columns referring to the types of sites or layers by shell (columns for T, E, V), and in the sites at the surface, in the total (the two last columns of tables N_σ and N), and in the expressions for both in Table 11. Based on these latter, it is possible to obtain the dispersions due to the surface sites of both structures obtaining the graphic in Figure 7. Surface and vertex dispersion is exactly the same for both structures, they start close to 1 and in 1, respectively, and then they decrease. Dispersion in triangular faces, for both structures, shows a very similar behavior, they start in the same value, and increase with the size of the cluster, but D_T in the ICO increases

faster. Similarly for the edges, they increase rapidly from zero to a maximum value, and decrease slowly almost parallel. The predominance of D_T and D_C for large sizes has to be noticed for ICO and CO, respectively.

2.4.3. Octahedron with a Central Site

The octahedron with a central site has 6 vertexes (V), 12 edges (E), and 8 triangular faces (T), Figure 8. In this figure, the sides of the triangular faces have a length of $2\nu d_{NN}$, an even number times the distance to first neighbors; this means that the triangular faces do not present a central site, and the number of sites for each edge is odd. The number of neighbors for each site with sites in other layers can be found in Table 3, the standard coordinates in Table 2, and the geometric characteristics for the octahedron with a central site are listed in Table 9. From this latter, the general expressions of the geometric characteristics for the octahedron with a central site (OCTAC) can be deduced and are presented in Table 11. Figure 8(c) shows an octahedron of 891 sites with a central site.

With the same method applied for the CO and the ICO, the dispersions due to surface sites can be calculated from Table 5, and the results are presented in the graphic of Figure 9. It can be observed that the surface dispersion
Figure 8. Octahedron of 19 atoms with central site. Smaller atoms are presented in (a) to allow observation of first neighbor bonds and central site in (b). (c) Octahedron of 891 atoms, order 5, and with a central site.

and dispersions due to edges and vertexes decrease, while the one due to the triangular faces starts from zero and increases rapidly, being predominant for larger sizes.

2.4.4. Truncated Octahedron with a Central Site

A truncated octahedron is a structure centered over an octahedron of 18 sites (2 layers) with a central site (layer 0), and has 24 vertexes (V) 36 edges (E), 6 squared faces (S), and 8 hexagonal faces (H); Figure 10. Edges are of two types: 24 between squared and hexagonal faces (ES), and 12 between hexagonal faces (EH); the number of EH sites N_{EH} is always equal to 12, one site in each edge (EH), while the one in ES sites N_{ES} depends on the order of the cluster, this means that the length of the edges ES is variable, and the one of EH edges is $2d_{NN}$. And so, the hexagonal faces are irregular, except when the number of ES sites is 24 and the number of EH sites is 12, which occurs in the cluster of order 2. The number of first neighbors for each site can be found in Table 3, standard coordinates are in Table 2, and Table 10 presents the geometric characteristics of each structure. Figure 10(c) shows the truncated octahedron of 711 sites with a central site.

From Table 10 it can be observed that the number of EH sites is 12 and of V sites is 24 for all ν, besides this, it is possible to obtain the general expressions of the geometric characteristics for the truncated octahedron with a central site, as presented in Table 11.

ν	N_T	N_E	N_V	R_T	R_E	R_V	$N_{\text{shell}}^{\sigma}$	N_{shell}^{T}	N_{σ}	N
1	0	12	6	0	1	1	2	2	18	19
2	24	36	6	1	2	1	4	6	66	85
3	80	60	6	3	3	1	7	13	146	231
4	168	84	6	5	4	1	10	23	258	489
5	288	108	6	8	5	1	14	37	402	891
6	440	132	6	12	6	1	19	56	578	1469
7	624	156	6	16	7	1	24	80	786	2255
8	840	180	6	21	8	1	30	110	1026	3281
9	1088	204	6	27	9	1	37	147	1298	4579
10	1368	228	6	33	10	1	44	191	1602	6181
Figure 9. Dispersions due to surface sites of the octahedron with a central site.

Figure 11 presents the dispersions for the truncated octahedron and with a central site, derived from the data of Table 10. The predominance of the dispersion due to the sites in hexagonal and squared faces for large sizes can be observed. Dispersions due to other sites and the surface one decrease with the size of the cluster.

With support from Tables 4 and 6–10, it is possible to obtain the characteristics defined in the middle and lower parts of Table 4 for each and every studied structure. Characteristics in the middle part of Table 4 are presented in Table 11, and Figures 12–15 present the obtained graphics of the dependence of the number of bonds at the surface $\mathcal{N}_{SS}$, the number of bonds between the surface and the internal cluster $\mathcal{N}_{SC}$, the number of bonds in the internal cluster $\mathcal{N}_{CO}$, and of the total number of bonds in the cluster $\mathcal{N}_C$, respectively, for all of the structures studied here, the curves for the ICO and CO practically coincide, so that just the curve of CO will be presented, except for $\mathcal{N}_{CO}$. It is observed that for the structures with a central site, and taking as reference the CO and the ICO, the OCTAC has a larger number of surface bonds and the OCTTC has fewer. But for $\mathcal{N}_{SC}$, the CO and ICO surpass the OCTAC and the OCTTC. For $\mathcal{N}_{CO}$, the OCTAC and the OCTTC surpass the CO. For $\mathcal{N}_C$, there are some crossings for smaller sizes, while for larger sizes the OCTAC and OCTTC surpass the CO.
Figure 10. Truncated octahedron with central site of (a) order 1 and 79 atoms, (b) order 2 and 201 atoms, and (c) order 4 and 711 atoms.

2.4.5. EAM Applied to fcc Structures

The embedded atom method is applied, in the Foiles version [32] and with the parameters of copper, to clusters with central site fcc structures in order to calculate the cohesion energy per atom, determining in this way the stability of the clusters. The results are compared with the ones from the icosahedra and cubooctahedra previously reported [30]. Figure 16 presents the cohesive energy graphic as a function of $N^{1/3}$ for the octahedron and truncated octahedron clusters of fcc with central site type, for sizes from 300 to 3400 atoms. From Figure 16 it can be seen that the truncated octahedra ($\triangle$) have a higher stability than the icosahedra ($\bullet$) and cubooctahedra ($\blacksquare$), while the octahedra ($\diamond$) have it until sizes larger than 900 atoms.

In a previous work, it was found that the CO presented a higher stability than the ICO for larger sizes; when analyzing the number of bonds in the clusters, it is found that this condition is present when the number of bonds of CO surpasses the ICO ones. The competition among fcc structures with a central site and the icosahedron observed in the graphic of Figure 16 must have the same origin.

2.5. fcc Structure without a Central Site

In the fcc structure without a central site, the cubic cluster of order 1 has the same unit cell as the fcc structure of Figure 5(a), a cube with 14 sites, 8 in vertexes and 6 in the center of the squared faces. The second order cluster has 172 sites [Fig. 3(c)], which results from covering the first-order cluster with one shell of 158 sites, distributed in 8 layers; the second-order cluster is an array of 9 cubes attached by faces and common sites. The next cubic cluster is formed by the second-order one and a shell of 494 sites in 18 layers covering it, and so on. Equivalent sites layers can be identified: Table 1: squared face (S), edges (E) and vertexes (V). As in the fccc structure, each shell is composed of two subshells. Table 12 lists the geometric characteristics of the fccs structures, and the separation of subshells for each shell is done in order to allow the calculus of the number of bonds as defined in Table 2, and for each shell also. General expressions for the geometric characteristics of Table 12 are presented in Table 13. Table 2 presents the standard coordinates and their characteristics, it can be seen that the sum of the standard coordinates a, b and c is an odd number, and in Table 3 the coordination of each site is presented.

When grouping the layers of equivalent sites in shells, in a different way than given for fccs, the geometries presented are given: besides the squared faces, triangular and hexagonal faces are included. Here, the cubooctahedron, octahedron, and truncated octahedron will be considered.

2.5.1. Octahedron without a Central Site

The octahedron is formed by 6 vertexes, 12 edges, and 8 triangular faces. Figure 17 shows the octahedrons of 44 and 146 sites, without a central site. In these figures, it can be seen that there are sites in vertexes (V), edges (E), and in triangular faces (T). In this structure, the sides of the triangular faces have a length of $(2\nu - 1)d_{NN}$, an odd number times the distance to first neighbors d_{NN}, this means that the triangular faces can present a central site, and the number

of sites in each edge is even. The number of first neighbors is presented in Table 3, the standard coordinates in Table 2 and the geometric characteristics for the octahedron without a central site are listed in Table 14. Figure 17(c) shows the octahedron of 1156 sites without a central site.

The number of V sites N_V is equal to 6 for all ν, and they are of just one type. From Table 14, it is possible to determine, for the octahedron without a central site, the dependence of the geometric characteristics on the order of the cluster ν, and it is reported in Table 14. This same

Figure 13. Number of bonds between the surface and the internal cluster as a function of the number of sites.

procedure is applied for the truncated octahedron, and without a central site and with the ones from the dodecahedron, which will be studied afterwards. The surface dispersion and the one due to each surface site also can be obtained from Table 14, and are presented in the graphic of Figure 18. The strong predominance of the sites of triangular faces and the fast decrease of the dispersions due to the vertexes and edges can be observed.

2.5.2. Truncated Octahedron without a Central Site

The truncated octahedron without a central site, Figure 19, is formed by a central octahedron surrounded by 6 squared faces and 8 irregular hexagonal faces (3 sides of length 1 and 3 of length equal to the order of the cluster ν, in units of d_{NN}, alternated) attached by 24 vertexes and 36 edges, so the edges are of two types: 24 between squared and hexagonal faces and 12 between hexagonal faces; the first ones are

Figure 14. Number of internal bonds as a function of the number of sites.

Figure 15. Total numbers of bonds as a function of the number of sites.
Figure 16. Cohesive energy per atom as a function of the cubic root of the number of atoms in the cluster for the octahedrons and truncated octahedrons type fcc with a central site.

length dependent on the cluster order, and the second ones on length $1d_{NN}$, this means that there is not a single site in them, so the first 24 are simply called E. The number of first neighbors of each site is presented in Table 3, the standard coordinates in Table 2, and the geometric characteristics for the truncated octahedron without a central site are listed in Table 15. Figure 19(b) shows the truncated octahedron of 1288 without a central site.

The number of V sites N_V is equal to 24 for all ν, and they are of just one type. From Table 15 the expressions for the geometric characteristics for the truncated octahedron without a central site can be determined, and are presented in Table 16. Also, the surface dispersions can be determined, and are presented in the graphic of Figure 20. A not so strong predominance of the sites in squared and hexagonal faces can be observed, while the other dispersions decrease as the cluster size increases.

With support from Tables 4 and 15 it is possible to obtain expressions for the number of bonds for the different types of bonds in the truncated octahedron without a central site, which are presented in Table 16 and whose graphics are shown in Figures 12–15.

Table 12. Geometric characteristics for the face-centered cubic without a central site structure, fccs.

2.5.3. EAM Applied to fcc Structures without a Central Site

The embedded atom method is applied, in the Foiles version [32] and with the parameters of copper, to clusters with fcc structures without a central site to calculate the cohesion energy per atom, determining in this way the stability of the clusters. The results are compared with the ones from the icosahedra and cubooctahedra previously reported [30]. Figure 21 presents the cohesive energy graphic as a function of $N^{1/3}$ for the octahedron and truncated octahedron clusters of fcc without central site type, for sizes from 300 to 3400 atoms. From Figure 21, it can be seen that the truncated octahedra ($\triangle$) as well as the octahedra ($\diamond$) compete in stability with the icosahedra ($\bullet$) and cubooctahedra ($\square$). And most of all, the truncated octahedra show a higher stability than the octahedra.

2.6. bcc Structure

The body-centered cubic structure is a cube with sites in the vertexes and in the center of the cube, that is, there are 9 sites over a cube, 8 in vertexes, and 1 in the center of it; this is a cluster of order 1 with cubic arrays [Fig. 22(a)]. When attaching many of these arrays, clusters with sites in vertexes, edges, and squared faces are obtained. The cubic cluster of second order consists of an array of 8 cubes, which results from covering the first cube with a shell of sites distributed in three layers: 6 in squared face (S), 12 in edge (E), and 8 in vertexes (V) [Fig. 22(b)]. The next cluster has 56 sites distributed in 3 layers, and so on. From here, it is deduced that it is possible to identify layers of equivalent sites; these layers can be grouped into shells yielding noncubic geometries which present sites in vertexes, edges, and in rombohedral faces, such as in the dodecahedron.

2.6.1. Dodecahedra

The dodecahedron is formed by a central site, 14 vertexes of two types ($V1$ and $V2$), 24 edges (E) and 12 rombohedral faces (R), Figure 23. The two types of vertexes are: (1) 6 vertexes (V_1) of coordination 4 with sites of their own shell and of4 with sites of exterior shells; an (2) 8 vertexes (V_2) of coordination 1 towards sites of interior shells, 3 with sites of its own shell, and 4 with sites of exterior shells.

The number of first neighbors is found in Table 3, standard coordinates in Table 2, and the geometric characteristics of the decahedron are listed in Table 17, from which the dependence of geometric characteristics for the decahedron can be determined and are presented in Table 16. Surface dispersions originating from the different types of sites in the surface of the decahedron can also be shown graphically; Figure 24.

Based on Tables 3 and 17, it is possible to construct the expressions for the number of bonds for the different types of bonds in the dodecahedron, and are presented in Table 16 and their graphics in Figures 12–15.

2.6.2. EAM Applied to bcc Structures

The embedded atom method is applied, in the Foiles version [32] and with the parameters of copper, to clusters with bcc structures to calculate the cohesion energy per atom,

Table 13. Particular expressions of the geometric characteristics for the face-centered cubic without a central site structure, fccs.

	Layer	Sublayers	
N		$32\nu^3 - 24\nu^2 + 6\nu$	
N_σ	$96\nu^2 - 144\nu + 62$	$48(\nu - 1)^2$	$48\nu^2 - 48\nu + 14$

N_V	8	0	8
R_V	1	0	1
$\mathscr{N}_{CO}$		$12(16\nu^3 - 36\nu^2 + 27\nu - 7)$	
$\mathscr{N}_{CC}$		$24(8\nu^2 - 13\nu + 5)$	
$\mathscr{N}_{SS}$		$24(8\nu^2 - 6\nu + 1)$	
$\mathscr{N}_C$		$12(16\nu^3 - 4\nu^2 - 11\nu + 5)$	

determining in this way the stability of the clusters. The results are compared with the ones from the icosahedra and cubooctahedra previously reported [30]. Figure 25 presents the cohesion energy graphic as a function of $N^{1/3}$ for dodecahedral clusters, for sizes from 300 to 3400 atoms. From Figure 25 it can be seen that the dodecahedra ($\diamond$) compete in stability with the icosahedra ($\bullet$) and cubooctahedra ($\square$).

3. CLUSTERS AND NANOPARTICLES WITH PENTAGONAL SYMMETRY

3.1. Introduction

A cluster is defined as an aggregate of atoms; this can lead to clusters from two atoms (diatomic molecules), a lineal array of atoms, bidimensional, or three-dimensional arrays. This work presents the study of clusters with pentagonal symmetry, with sizes up to thousands of atoms in arrays of spherical or concentric layer types.

Arrays of linked atoms forming three-dimensional clusters are considered here as sites in geometric positions attached by the edges in such a way that faces of diverse forms are generated (triangular, squared, rombohedral, etc.). The distance between the sites is considered as the distance to first neighbors d_{NN}, which is normalized to one. There could be sites in the vertexes, edges, and faces, either in the surface or internals; also, there could be different types of sites, depending on their position and the number and type of neighbors in the geometric array. There also could be equivalent sites, which present the same geometric characteristics: to the same distance from the center of the geometric array, in the same type of site and with the same number and type of neighbors.

From the bicaped hexahedron or decahedron, Figure 26(a), pentagonal symmetry structures can be obtained. Among the clusters with structures of pentagonal symmetry, the following structures are considered: decahedra with and without a central site, icosahedra, pentadecahedra,

Figure 17. Octahedron without central site of (a) order 2 with 44 sites, (b) order 3 with 146 sites, and (c) order 6 with 1156 atoms.

Table 14. Geometric characteristics for the octahedra without a central site.

truncated decahedra (Marks decahedra), star-type decahedra, modified and developed decahedra, truncated icosahedra, and the *decmon*.

3.2. Decahedra

Decahedra are obtained from the bicapped hexahedra, and also from attaching two pentagonal-based pyramids from their bases and sharing their sites (which form the equator of the cluster), yielding geometrical bodies of 7 vertexes (2 at poles and 5 at equator), 15 edges (all from the same length, 5 at the equator), and 10 triangular equilateral faces: 5 of them converge on each pole, and by pairs, they form the edges of the equator. Decahedra can be without a central site, Figures 26(a) and (c), and with a central site, Figure 26(b), without losing the decahedral form. So, decahedra have the vertexes at the poles *VP*, vertexes at the equator *VE*, at the edges over the equator *EE*, edges at poles *EP*, and in triangular faces *T*. It has to be noticed that coordination, that is, distribution to first neighbors (NN), is what makes the difference in each type of sites, although the total coordination is the same for all of the sites of the corresponding cluster. Table 18 presents the coordination of each site, for example, the poles (*VP*) have 4 first neighbors (NN)
Figure 19. Truncated octahedron without a central site of (a) order 3 with 260 sites and (b) order 6 with 1288 sites.

Table 15. Geometric characteristics for the truncated octahedra without a central site.

ν	N_S	N_H	N_E	N_V	R_S	R_H	R_E	R_V	N_{shell}^σ	N_{shell}^T	N_σ	N
1	0	8	0	24	0	1	0	1	2	3	32	38
2	6	24	24	24	1	1	1	1	4	7	78	116
3	24	48	48	24	1	2	1	1	5	12	144	260
4	54	80	72	24	3	3	2	1	9	21	230	490
5	96	120	96	24	3	4	2	1	10	31	336	826
6	150	168	120	24	6	5	3	1	15	46	462	1288
7	216	224	144	24	6	7	3	1	17	63	608	1896
8	294	288	168	24	10	8	4	1	23	86	774	2670

10	486	440	216	24	15	12	5	1	33	144	1166	4796

with sites at their same shell, 1 NN toward the inner shell, and 4 toward the exterior shell. The decahedron of order 1, without a central site, Figure 26(a), has only 7 vertexes in two layers; the one from order 2, Figure 26(c), is obtained from covering the one of order 1 with a shell of 47 sites distributed as follows: 7 *V* sites of two types, 30 *E* sites in three layers (10 sites of one type ant the equator), and 10 at triangular faces (sites *T*, one for each triangular face) in one single layer, for a total of 54 sites in the cluster. Decahedra of superior order are formed by coverage of this cluster of order 2 with successive shells of many layers in each one.

The decahedron with central site of order 1, Figure 26(b), has 15 sites *E*, one per edge, of two types, 5 sites of one type at the equator, and 7 sites *V*, a total of 22 sites and the central one in five layers. The second-order cluster results from the order 1 cluster covered by a shell of 82 sites distributed in 8 layers: 45 *E* sites in 5 layers, 30 *T* sites in one single layer, and 7 *V* sites in two layers, for a total of 105 sites in the cluster, and so on for cluster of superior order.

Table 19 presents the geometric characteristics of decahedra with and without a central site. The first column, common for all decahedra, lists the cluster order ν. This is followed by two groups of 9 columns each, which correspond to the decahedron with and without central site. The first three columns of each group list the number of sites on each type of site in the cluster: triangular face (*T*) N_T, edge (*E*) N_E, and vertex (*V*) N_V. The two following columns show the number of sites per shell N_{SE}, and the total of sites in the plane just above the equator N_{tSE}, (the *SE* sites). The following two columns list the number of sites at the equator (sites *EC*) per shell N_{EC}, and in the whole cluster, N_{tEC}; the joint between *SE* and *EC* sites form the *SEC* layer, which will be needed afterwards, and they both form a pentagonal flat layer. Finally, the two last columns of each group, the number of sites in the shell N_σ, and the total of sites in the cluster *N*. Decahedra with (without) a central site have an odd (even) number of sites per edge, which is important for the star and truncated-type decahedra, detailed later.

From Table 19 it is observed that, for both decahedron types, the number of vertexes per shell is 7, 2 type *VP* and 5 type *VE*; We can also obtain, for each type of decahedra, the dependence with the cluster order of the number of *T* sites, *E* sites, the number of sites in the layer at the equator, as well as the total sites in the shell (or of the surface), and from the total of sites over the equator, at the equator and in the decahedron. Such dependency is expressed in the

following relations for the decahedra with a central site; it is to be noticed that, for $\nu = 1$, there are 11 sites at the equator because the central site is included:

$$N_E(\nu) = 15(2\nu - 1) \begin{cases} N_{EP}(\nu) = 10(2\nu - 1) \\ N_{EE}(\nu) = 5(2\nu - 1) \end{cases}$$

$$N_T(\nu) = 10(2\nu^2 - 1)(\nu - 1)$$

Figure 20. Dispersions due to surface sites of the truncated octahedron without a central site as a function of the cubic root of the cluster size.

$$N_{SE}(\nu) = 10(\nu - 1) + 5$$

$$N_{t_{SE}}(\nu) = 5\nu^2$$

$$N_{EC}(\nu) = 10\nu$$

$$N_{t_{EC}}(\nu) = 5\nu(\nu + 1) + 1$$

$$N_\sigma(\nu) = 20\nu^2 + 2$$

$$N(\nu) = \frac{20}{3}\nu^3 + 10\nu^2 + \frac{16}{3}\nu + 1$$

and for decahedra without a central site,

$$N_E(\nu) = 30(\nu - 1) \begin{cases} N_{EP}(\nu) = 20(\nu - 1) \\ N_{EE}(\nu) = 10(\nu - 1) \end{cases}$$

$$N_T(\nu) = 20\nu^2 - 50\nu + 30$$

$$N_{SE}(\nu) = 10(\nu - 1)$$

$$N_{t_{SE}}(\nu) = 5\nu(\nu - 1) + 1$$

$$N_{EC}(\nu) = 5(2\nu - 1)$$

$$N_{t_{EC}}(\nu) = 5\nu^2$$

$$N_\sigma(\nu) = 20\nu^2 - 20\nu + 7$$

$$N(\nu) = \frac{20}{3}\nu^3 + \frac{\nu}{3}.$$
Figure 21. Cohesion energy per atom as a function of the square root of the number of atoms in the cluster, for the octahedron and truncated octahedron with central site, type fcc.

Note that from the expression for N_A, and from Figures 26(c) and (d), the number of EP and EE per edge is $2\nu - 1$ $[2\nu - 2]$ for decahedra with [without] a central site.

If, instead of attaching the base of the two pentagonal base pyramids to form the decahedron, they are separated, two types of geometrical figures can be obtained, depending on the way the sites of the bases are connected: the pentadecahedron and the icosahedron.

3.3. Pentadecahedra

If the pentagonal pyramids which generate the decahedron when they are joined, are separated, they are in a position in which the vertexes of the base of both can be attached by 5 edges (EC) perpendicular to the base, yielding 5 rectangular faces, which form the pentadecahedra, Figure 27, that is, a decahedron with a wide waist or a developed decahedron. Separation can be done by adding intermediate layers of type SEC (formed by a layer of sites SE and another of sites EC as mentioned previously). The number of SEC intermediate layers, and the length of the edges perpendicular to the bases, depend on the desired separation. For example, the pentadecahedron from Figure 27 has 5 layers in the waist; to obtain it, 4 layers of type SEC are added to the order 6 decahedron of 1442 sites without a central site, which results
Figure 22. bcc structure of (a) 9 sites, and (b) 35 sites.
Figure 23. bcc dodecahedron of (a) order 1 with 15 sites, and (b) order 2 with 175 sites.

in edges $4d_{NN}$ long. It has to be noticed that, upon widening of the waist of a decahedron, from one equatorial layer to two equatorial layers, an SEC-type layer is added, when widening three equatorial layers, two SEC-type layers are added, that is, for each equatorial layer wanted to widen the decahedra waist, one type of SEC layer is added.

The pentadecahedra are polyhedra of 12 vertexes (2 poles and 10 in vertexes at the waist), 25 edges (20 of one type and 5 of the other, which join the vertexes of the two pyramids, and whose length depends on the number of intermediate layers added), 10 equilateral triangular faces and, 5 rectangular lateral faces (or squared, depending on the number of intermediate layers added) (Fig. 27). The number of sites in these pentadecahedra depends on the size of the original decahedron and how many intermediate layers are added; also, whether they are with and without a central site is considered, depending on the original decahedron from which they were generated. So, at the surface of the pentadecahedra, there are the same type and number of sites as in the decahedra, plus the N_{EC} sites added (because the N_{SE} are not at the surface), which are divided in sites type VE, sites EE, sites at vertical edges at the width of the waist EV and in rectangular faces RF. Table 20 presents the coordination of each type of site in the pentadecahedron. Notice that, upon comparison of Table 18, as expected, only the sites corresponding to the pentadecahedron are added, and those of the decahedron are not. Sites N_{SE} added, originally 5 EP sites, and the rest T sites (except for the pentadecahedron of order 11, without a central site) are converted in internal sites of coordination 12.

Table 17. Geometric characteristics for the dodecahedra.

ν	N_R	N_E	N_V	R_R	R_E	R_V	$N_{\text{shell}}^{\sigma}$	N_{shell}^{T}	N_{σ}	N
1	0	0	14	0	0	2	2	2	14	15

9	768	192	14	20	8	2	30	124	974	3439
10	972	216	14	25	9	2	36	160	1202	4641
Figure 24. Dispersion due to surface sites of the dodecahedron as a function of the cubic root of the cluster size.

For pentadecahedron order, we can use $\nu\mu$, ν for the decahedron order from which comes and μ for the number of layers at the waist, so regular decahedra would be pentadecahedra with $\mu = 1$. The number of layers of type *SEC* which are added to the decahedron referred to generate the pentadecahedron is $\mu - 1$, so that the number of sites added is equal to the sum of the total of sites *SE* and the total of *EC* sites of the corresponding decahedron, columns 6 and 8, and 15 and 17 of Table 19. So, in order to have a pentadecahedron of order 55 with a central site, one has to start with a decahedron of order 5, 111 sites, and an aditional 4 layers of type *SEC* of $125 + 151 = 276$ sites each, for a total of 1104 added sites and 2215 sites in the cluster.

The number of sites *T*, *EP*, and *VP* is the same as in the decahedron which originated from the pentadecahedron. The number of sites *EE* and *VE* is duplicated with respect to the original decahedron. The number of *EV* and *RF* sites
Figure 25. Cohesive energy per atom as a function of the cubic root of the number of atoms in the cluster for decahedron bcc type.
Figure 26. Decahedral polyhedrons. (a) bilayered hexahedron or decahedron of 7 atoms of order 1, without central site. (b) Decahedron of 23 atoms of order 1 with central site. (c) Decahedron of 835 sites of order 5, without central site. (d) Decahedron of 1111 atoms of order 5 with central site.

for the pentadecahedra with and without a central site is the same, and is presented in Table 21, which shows the geometric characteristics of the pentadecahedra with and without a central site respectively; only some of μ values are presented. There are three groups of three, four, and five columns, respectively. In the columns of the first group are listed the quantities common to the two types of pentadecahedra: cluster order ν and μ, and the number of sites *EV*, N_{EV}; for both polyhedra, in each following group, the geometric characteristics for each polyhedron are presented, those of the pentadecahedron both with and without a central site. A list of the number of *RF* sites N_{RF}, the number of sites added N_{ag}, of sites at the surface $N\sigma$, and the total of sites N in the cluster of order $\nu\mu$ is given. Note that, for $\mu = 1$, the values from Table 19 are obtained.

From Table 21, the analytic expressions for the number of sites *EV* can be obtained as a function of ν and v:

$$N_{EV}(\mu) = 5(\mu - 2)$$

as well as the number of *RF* sites, sites which are added, sites in the surface, and the total of sites for pentadecahedra

Table 18. Coordination or number of first neighbors (NN) of the different types of sites in the decahedron with sites in external, the same, and internal shell.

with a central site

$$N_{RF}(\nu, \mu) = 5(2\nu - 1)(\mu - 2)$$

$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)(10\nu^2 + 5\nu + 1)$$

$$N_\sigma(\nu, \mu) = 20\nu^2 + 2 + 10\nu(\mu - 1)$$

$$N(\nu, \mu) = \frac{20}{3}\nu^3 + 10\nu^2 + \frac{16}{3}\nu + 1 + N_{\text{ag}}(\nu, \mu)$$

and for pentadecahedra without a central site

$$N_{RF}(\nu, \mu) = 10(\nu - 1)(\mu - 2)$$

$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)(10\nu^2 - 5\nu + 1)$$

$$N_\sigma(\nu, \mu) = 20\nu^2 - 20\nu + 7 + 5(2\nu - 1)(\mu - 1)$$

$$N(\nu, \mu) = \frac{20}{3}\nu^3 + \frac{\nu}{3} + N_{\text{ag}}(\nu, \mu).$$

3.4. Modified Decahedra

In a certain decahedron, with or without a central site, the number of sites per edge increases in 2 sites per shell increased. For example, in the decahedron of 287 sites of order 3 with a central site, Figure 28(a), in the surface shell there are 5 sites in each edge, and in the one of order 4, there are 609 sites, Figure 28(b), there are 7 sites per edge. The decahedron modification can be done in two ways: (1) as channels at the surface, and (2) as surface reconstruction. Besides, modified and developed decahedra can be obtained, adding SEC-type layers in order to widen the waist of the modified decahedra.
3.4.1. Decahedra with Additional Faceting (*Channels at Twin Boundaries*)

When suppressing surface sites from the edges converging in the poles (*EP* sites) and from all of the vertexes in a decahedron, a one-channel decahedron is obtained, for example, from the decahedron of 609 sites of order 4 with a central site [Fig. 28(b)], a decahedron of 532 sites is obtained with one channel convergent to the pole, Figure 29(a), eliminating 77 sites. These result in a polyhedron formed by a decahedron of order 3 with triangular faces covered with sites corresponding to the decahedron of order 4, in a way that some surface sites that were T type are now type E. If, now, the following edges (which were type T sites) are eliminated from the surface, a triple-channel decahedron of 412 sites is obtained, 120 sites were eliminated [Fig. 29(b)]. It can be continued in this way until the desired number of channels is reached. The construction of the first channel, eliminating vertexes and *EP* edges from the surface, in other words, remains with a coordination lower than 12, which implies that there are free bonds. Type *VP* sites from the internal decahedron have two free bonds, sites *VE* have three and sites *EP* have four. So, surface sites are not only the difference between surface sites and the ones that

Figure 27. Pentadecahedron of 2766 atoms of order 65, obtained from a decahedron without a central site of order 6 with 5 layers in the waist, which means adding 4 *SEC*-type layers to the original decahedron.

Note: μ is the number of equatorial layers in the cluster. Number of sites AV, N_{AV}, R sites N_R, of sites added N_{ag}, surface site N_σ, and of total sites N in the cluster of order $\nu\mu$. Notice that, for $\mu = 1$, values of Table 1 are obtained. Even when μ can have any value higher than zero, here only some values are presented.

were eliminated, but the interior decahedron sites are added which have a coordination lower than 12.

Table 22, lists the geometric characteristics for the decahedra, with and without a central site, modified with surface channels. ν is the original cluster order. The only characteristics presented are for an $n = 1$, a single channel and 2, a triple channel. Eliminating the sites for the channel in the decahedron affects the number of sites *SE* and *EC* of the original decahedron. Table 22 lists the number of sites that are eliminated N_{el}, the number of sites *SE* and *EC*, per shell and in total, and the number of sites at the surface and in total in the final cluster. The number of sites *SE* and *EC* is needed in order to generate the decahedra with channels and developed, as was done for the pentadecahedron.

From Table 22 are deduced the analytic expressions for the number of sites eliminated in a decahedron in order to obtain the decahedron with channels, the number of *SE* and *EC* sites, and the number of sites in the surface and the number of total sites in the cluster, which are presented next

(a)   (b)
Figure 28. (a) Decahedron of 287 sites, of order 3, with a central site,(b) Decahedron of 609 sites, of order 4, with a central site.

(a)   (b)
Figure 29. Decahedron of 609 sites of order 4 and (a) a single channel, and (b) a triple channel per edge converging to the pole, of 532 sites and 412 sites, respectively.

for the decahedron with a central site and a simple channel:

$$N_{el}(\nu) = 20\nu - 3, \qquad N_{SE}(\nu) = 10(\nu - 1)$$
$$N_{t_{SE}}(\nu) = 5\nu^2 - 5, \qquad N_{EC}(\nu) = 10\nu - 5$$
$$N_{t_{EC}}(\nu) = 5\nu(\nu + 1) - 4, \qquad N_\sigma(\nu) = 20\nu^2 - 18$$
$$N(\nu) = \frac{20}{3}\nu^3 + 10\nu^2 - \frac{44}{3}\nu + 4$$

for the decahedron with a central site and a triple channel:

$$N_{el}(\nu) = 60\nu - 43, \qquad N_{SE}(\nu) = 10\nu - 20$$
$$N_{t_{SE}}(\nu) = 5\nu^2 - 15, \qquad N_{EC}(\nu) = 10\nu - 15$$
$$N_{t_{EC}}(\nu) = 5\nu(\nu + 1) - 14, \qquad N_\sigma(\nu) = 20\nu^2 - 58$$
$$N(\nu) = \frac{20}{3}\nu^3 + 10\nu^2 - \frac{164}{3}\nu + 44$$

and for the decahedron without a central site and a simple channel:

$$N_{el}(\nu) = 20\nu - 13, \qquad N_{SE}(\nu) = 10\nu - 15$$
$$N_{t_{SE}}(\nu) = 5\nu(\nu - 1) - 4, \qquad N_{EC}(\nu) = 10(\nu - 1)$$
$$Nt_{EC}(\nu) = 5\nu^2 - 5, \qquad N_\sigma(\nu) = 20\nu^2 - 20\nu - 13$$
$$N(\nu) = \frac{20}{3}\nu^3 - \frac{59}{3}\nu + 13$$

for the decahedron without a central site and a triple channel,

$$N_{el}(\nu) = 60\nu - 73, \qquad N_{SE}(\nu) = 10\nu - 25$$
$$N_{t_{SE}}(\nu) = 5\nu(\nu - 1) - 14, \qquad N_{EC}(\nu) = 10\nu - 20$$
$$N_{t_{EC}}(\nu) = 5\nu^2 - 15, \qquad N_\sigma(\nu) = 20\nu^2 - 20\nu - 53$$
$$N(\nu) = \frac{20}{3}\nu^3 - \frac{179}{3}\nu + 73.$$

In the same way used to generate the pentadecahedra, by modifying the decahedra, the new type of decahedra can be obtained, (Fig. 30). In order to do this, a layer of type *SEC* is added for each layer desired to increase the waist of the decahedron with channels. Table 22 lists the number of sites *SE* and *EC*, which are used to construct Table 23 for the decahedra with channels and developed.

Table 22. Geometric characteristics of decahedra with and without a central site, modified with surface channels.

		With a central site							Without a central site						
ν	n	N_{el}	N_{SE}	$N_{t_{SE}}$	N_{EC}	$N_{t_{EC}}$	N_σ	N	N_{el}	N_{SE}	$N_{t_{SE}}$	N_{EC}	$N_{t_{EC}}$	N_σ	N
2	1	37	10	15	15	26	62	68	27	5	6	10	15	27	27
3	1	57	20	40	25	56	162	230	47	15	26	20	40	107	134
	2	137	10	30	15	46	122	150	107	5	16	10	30	67	74
4	1	77	30	75	35	96	302	532	67	25	56	30	75	227	361
	2	197	20	65	25	86	262	412	167	15	46	20	65	187	261
5	1	97	40	120	45	146	482	1014	87	35	96	40	120	387	748
	2	257	30	110	35	136	442	854	227	25	86	30	110	347	608

Note: ν is the cluster order. Here are presented only the characteristics for a single channel, $n = 1$, and a triple channel, $n = 2$. The number of eliminated sites N_{el}, the number of sites *SE* and *EC* per shell, and the number of sites in the surface and in total in the final cluster are listed.

When adding layers to widen the waist, the number of sites *EE* and *VE* is duplicated with respect to the original polyhedron, and different type *EV* and *RF* sites are generated, as happened with pentadecahedra, and the number of sites is given by

$$N_{EV}(\nu, \mu) = 10(\mu - 2)$$

while the number of sites *RF*, the number of sites added N_{ag}, of which $N_{\sigma_{\text{ag}}}$ are added to the surface for μ equatorial layers for the polyhedron with central site and a single channel is:

$$N_{RF}(\nu, \mu) = 5(2\nu - 3)(\mu - 2)$$
$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)(10\nu^2 + 5\nu - 9)$$
$$N_{\sigma_{\text{ag}}}(\nu, \mu) = (\mu - 1)(10\nu - 5)$$

with a central site and a triple channel

$$N_{RF}(\nu, \mu) = 5(2\nu - 5)(\mu - 2)$$
$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)(10\nu^2 + 5\nu - 39)$$
$$N_{\sigma_{\text{ag}}}(\nu, \mu) = (\mu - 1)(10\nu - 15)$$

without central site and a single channel

$$N_{RF}(\nu, \mu) = 10(\nu - 2)(\mu - 2)$$

(a)   (b)
Figure 30. Decahedron of order 4 of 609 sites with a central site, with (a) one single channel, and (b) with a triple channel per edge converging to the pole, with three layers in the waist, of 874 sites and 714 sites, respectively.

$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)(10\nu^2 - 5\nu - 9)$$
$$N_{\sigma_{\text{ag}}}(\nu, \mu) = (\mu - 1)[10(\nu - 1)]$$

with central site and a triple channel

$$N_{RF}(\nu, \mu) = 5(2\nu - 3)(\mu - 2)$$
$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)(10\nu^2 - 5\nu - 39)$$
$$N_{\sigma_{\text{ag}}}(\nu, \mu) = (\mu - 1)(10\nu - 20).$$

3.4.2. Modified Decahedra with Surface Reconstruction

Surface reconstruction of a decahedron is obtained if each triangular face of the decahedron proceeds as follows: a triangular face is obtained exactly as the one from the original decahedron; it is transported outwards to the same distance as the one between parallel triangular faces, $0.7953d_{NN}$, which is the height of a tetrahedron with a base of $1.05d_{NN}$ from one side and the other sides of $1.0d_{NN}$, then in a parallel way is shifted to the waist to a distance of $0.606d_{NN}$, which is 2/3 of the height of the equilateral triangle of $1.05d_{NN}$ from one side, until the generated sites coincide with the triangle centers of the original triangular face, and finally, the complete edge of the waist is eliminated. Hereafter these polyhedra are called *mrdec* (Montejano's reconstructed decahedron) [33]. Figure 31 shows an example of a decahedron of 287 sites of order 3, to which 21 sites are added per face, this is 210 sites in total, for a *mrdec* of 497 sites. It should be noted that it seems that a decahedron with a surface channel is obtained, although the sites which seem to form the channel are at a distance of $1.13d_{NN}$, while in a decahedron with a simple channel they are at $1.63d_{NN}$. This is why, in this modification, a long bond is considered, and the *EP* sites of the interior decahedron do not form part of the surface. In fact, the surface of the resulting polyhedron is formed by the added sites and the sites *VE*, *VP*, and *EE* of the internal decahedron, which are those which also can be considered as surface because they remain with free bonds.

It should be noted that the planes above the equator and the sites in the plane of the equator of the original decahedron are not modified. The characteristics of these polyhedra are presented in Table 24. ν is the original cluster order,

Table 23. Geometric characteristics for the decahedra with and without a central site, modified with surface channels and with added layers in the waist.

	5	30	105	1064	662	2078	75	944	582	1798	120	864	547	1612	105	744	467	1352

Note: ν is the cluster order, μ is the number of equatorial layers added. Only the characteristics for a single channel, $n = 1$, and a triple channel, $n = 2$ are presented. Notice that for $\mu = 1$ Table 22 values are obtained. Although μ can take any value higher than zero, here are only presented some values.

N_{ag} is the number of sites added, N_σ is the number of sites in the surface, and N is the total number of sites in the cluster.

From Table 24, it is possible to obtain the analytic expressions as a function of the order of the original cluster for the different characteristics listed here, and they are presented next for the polyhedron with a central site:

$$N_{\text{ag}}(\nu) = 20\nu^2 + 10\nu$$

$$N_\sigma(\nu) = 20\nu^2 + 20\nu + 2$$

$$N(\nu) = \frac{20}{3}\nu^3 + 30\nu^2 + \frac{46}{3}\nu + 1,$$

and without a central site

$$N_{\text{ag}}(\nu) = 20\nu^2 - 10\nu$$

$$N_\sigma(\nu) = 20\nu^2 - 3$$

$$N(\nu) = \frac{20}{3}\nu^3 + 20\nu^2 - \frac{29}{3}\nu.$$
Figure 31. Decahedron of order 4 with 609 sites and with a central site, with 360 sites aggregated for a *mrdec* of 969 sites.

Alternatively, it is possible to generate the decahedra with surface reconstruction and developed. For this, simply add one *SEC*-type layer for each layer wanted to increase the waist of the decahedron with surface reconstruction, Figure 32. Table 19 presents the sites of type *SE* and *EC* of the original decahedron, used to construct Table 25 for the decahedra with surface reconstruction and developed.

When adding the layers to widen the waist of the sites *EE* and *VE* of the original decahedron, they duplicate and generate the sites of type *EV* and *RF*, as occurred with the pentadecahedra, and the number of sites is the same. The number of added sites N_{ag} from which $N_{\sigma_{\text{ag}}}$ are added to the surface for μ equatorial layers for the polyhedron with a central site is

$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)[10\nu^2 + 5\nu + 1]$$

$$N_{\sigma_{\text{ag}}}(\nu, \mu) = (\mu - 1)(10\nu),$$

and without central site

$$N_{\text{ag}}(\nu, \mu) = (\mu - 1)[10\nu^2 - 5\nu + 1],$$

$$N_{\sigma_{\text{ag}}}(\nu, \mu) = (\mu - 1)[5(2\nu - 1)].$$

Table 24. Geometric characteristics for the *mrdec*, decahedra with and without a central site, modified with surface reconstruction.

| | With a central site | | | Without a central site | | |
ν	N_{ag}	N_σ	N	N_{ag}	N_σ	N
2	100	122	205	60	77	114
3	210	242	497	150	177	331
4	360	402	969	280	317	708
5	550	602	1661	450	497	1285

Note: ν is the cluster order. The number of added sites N_{ag}, of surface sites N_σ, and the total number of sites N in the cluster are listed.
Figure 32. *mrdec* decahedron with a central site of order 4 (609 sites), with surface reconstruction (969 sites) and three equatorial layers (two layers *SEC* of 181 sites each one) for a total of 1331 sites in the polyhedron.
3.5. Truncated Decahedra (Marks Decahedra)

These result from the adequate elimination of some sites of a certain decahedron. The resulting geometry is a figure of 22 vertexes (of three types), 40 edges (of 4 types, 15 from the original decahedron, but shorter, and 25 which are generated by elimination of the adequate sites), 10 pentagonal faces (triangular faces from the original decahedron are converted to irregular pentagons), and 10 equilateral triangular faces (at the equator and joint by pairs) (Fig. 33).

The adequate elimination of sites is equivalent to eliminating the end sites of the edges which converge in the vertexes of the equator of the corresponding decahedron. Notice that in, each elimination, the equatorial edges lose two sites, while the edges which converge also toward the poles only lose one; this causes edges converging to the poles to be larger than the equatorial ones, but shorter then the ones from the original decahedron.

Table 25. Geometric characteristics for the *mrdec*, decahedra with and without a central site, modified with surface reconstruction and added layers in the waist.

	5	15	135	1104	802	2765	120	904	677	2189

Note: ν is the cluster order, μ is the number of equatorial layers in the polyhedron. Notice that, for $\mu = 1$, Table 24 values are obtained. Although μ can take any value higher than zero, here are presented only some values.

Figure 33. Truncated decahedron of 1372 sites of order 63, without a central site.

In the first step, $n = 1$, the equator vertexes from the equator of the exterior shell are eliminated, the last shell, 5 sites. In the second step, $n = 2$, two sites per equatorial edge are eliminated, and one of the rest of the edges, 20 sites of the previous stage are converted into 25. In the third step, $n = 3$, the step of the edges of the last shell is repeated, 20 sites, plus two sites of each triangular face, 20 sites, besides, in one shell before the last, the interior decahedron, the equator vertexes are eliminated, 5 more sites are needed in order to obtain 40 sites to be eliminated in this step, and there is a complete total of 70 eliminated sites in three steps. And so on, for $n < \nu$ because $N_{EE} = 5(2\nu - 1)[= 5(2\nu - 2)]$ for decahedra with [without] a central site, for $\nu = n - 1$, there are only 3 [2] sites *EE*, see Table 26.

Table 26 lists the truncated decahedra, resulting from decahedra with and without a central site, respectively. The order of the truncated decahedron consists of two numbers corresponding to the first and second columns of Table 26, the first column is the order of the decahedron generated ν, and the second column is the number of steps n needed to eliminate the adequate sites, or is half of the sites eliminated from each edge at the equator: $n = 1$ means that only the vertexes at the equator are eliminated, the first step in the elimination process. The third column lists the total number of sites eliminated from the original decahedron to obtain the truncated decahedron of order νn, $N_{(-)}$, in the fourth [eighth], the number of sites per equatorial site *EE* remaining in the originals are presented (taking into account that in these sites are included the two new vertexes *VE*) per edge, for the polyhedron with a central site [without a central site] (for $n = 1$ is the number of sites in edges in the original decahedron); finally, the fifth, sixth, and seventh columns [ninth, tenth, and eleventh] present the number of sites *SE* and *EC* and the total in the resulting truncated decahedron with a central site [without a central site]. For example, the truncated decahedron without a central site of order 63, Figure 33, is generated from the decahedron with a central site of order 6 (1442 sites, 10 sites per edge, 151 sites *SE* and 180 sites *EC*), and eliminating the 5 sites *VE*, 4 sites *EE* of each one of the equatorial edges of the surface, 2 sites *EP* from each edge toward the poles and the 5 *VE* sites from the immediate interior shell, so the truncated decahedron of order 63 has 6 sites per equatorial edge, 70

Table 26. Geometric characteristics for the truncated decahedra, constructed from a certain decahedra of order ν, with and without a central site.

	5	275	3	130	136	1558	2	101	105	1167

Note: n is the half of sites eliminated from each equator edge.

sites are eliminated, and it has a total of 136 sites SE, 150 sites EC and, 1372 in total.

The number of eliminated sites, the third column of Table 26, is the same for the two polyhedra, with and without a central site, and depends only on the number of steps n given and is obtained by

$$N_{(-)}(n) = \frac{5}{6}n(n+1)(2n+1).$$

Expressions for the number of sites SE, sites EC, and in total for the truncated decahedra with a central site

$$N_{t_{SE}}(\nu, n) = 5\nu^2 - \frac{5}{2}n(n-1)$$

$$N_{t_{EC}}(\nu, n) = 5\nu(\nu+1) + 1 - \frac{5}{2}n(n+1)$$

$$N(\nu, n) = \frac{20}{3}\nu^3 + 10\nu^2 + \frac{16}{3}\nu + 1 - N_{(-)}(n)$$

and for the truncated decahedra without a central site

$$N_{t_{SE}}(\nu, n) = 5\nu(\nu-1) + 1 - \frac{5}{2}n(n-1)$$

$$N_{t_{EC}}(\nu, n) = 5\nu^2 - \frac{5}{2}n(n+1)$$

$$N(\nu, n) = \frac{20}{3}\nu^3 + \frac{\nu}{3} - N_{(-)}(n).$$

The truncated decahedron is a polyhedron formed by 22 vertexes, joined by 22 vertexes, attached by 40 edges, forming 10 pentagonal faces and 10 triangular. Vertexes are of three types: VP, VE, and V'; VP (2 vertexes), and are the same as in the original decahedron, VE and V' (10 vertexes each) result by pairs from elimination of the original VE and from elimination of sites from EE and EP; sites V' are

found to be the end of the edges that converge toward the poles, that is, the edges EP join sites VP and V'. Edges are of 4 types: the original EP edges (10 edges) and EE (5 edges), but the shorter ET (20 edges) and EV' (5 edges) which make up the triangular faces TF (10 faces) formed upon elimination of the equatorial sites, the edges EV' join the vertexes V' by pairs, and the edges ET join sites VE and V'. So, any truncated decahedron will have vertex sites of type VP, VE, V', edges type EP, EE, ET, EV', and faces type TF and pentagonal face PF. The number of VP sites is 2, of V' is 10, and of VE is also 10. The number of remaining sites is variable, and is listed in Table 27 for the truncated decahedra with and without a central site. The number of surface sites is also listed as well as the total sites of the polyhedron. Columns 1 and 2 correspond to the order of the cluster ν and n respectively. Columns 3–8 [11–16] correspond to sites EP, N_{EP}, EE, N_{EE}, ET, N_{ET}, EV', $N_{EV'}$, PF, N_{PF}, and TF, N_{TF}, respectively, and the two last columns to the surface sites N_σ and the total of sites N for truncated decahedra with [without] a central site.

From Table 27 it is possible to deduct the analytic expressions for the number of sites of the different types of sites as a function of the order of the truncated decahedron, the resulting expressions, common for the polyhedra with and without a central site, but depending on the number of steps made for the elimination of the sites, are N_{ET}, $N_{EV'}$, and N_{TF}

$$N_{ET}(n) = 20(n-1)$$

$$N_{EV'}(n) = 5(n-1)$$

$$N_{TF}(n) = 5(n-2)(n-1).$$

The expressions for the other types of sites are as follows for the one with a central site:

$$N_{EP}(\nu, n) = 10(2\nu - 1) - 10n$$

$$N_{EE}(\nu, n) = 5(2\nu - 1) - 10n$$

$$N_{PF}(\nu, n) = 10(2\nu - 1)(\nu - 1) - 10n(n-1)$$

$$N_\sigma(\nu, n) = 20\nu^2 - 5n^2 + 2$$

and without a central site:

$$N_{EP} = 20(\nu - 1) - 10n$$

$$N_{EE} = 10(\nu - 1) - 10n$$

$$N_{PF} = 10(2\nu - 3)(\nu - 1) - 10n(n-1)$$

$$N_\sigma = 20\nu^2 - 20\nu - 5n^2 + 7.$$

3.5.1. Developed Truncated Decahedra

The same method used to generate pentadecahedra is used here. Intermediate layers can be added to the truncated decahedra in order to obtain polyhedra with 15 lateral faces, 5 rectangular, and 10 trapezoidal (before triangular) (Fig. 34). This means that a layer of SEC type is added per each layer wanted to widen the polyhedron, so the polyhedron of Figure 34 has 4 equatorial layers; this means that 3 SEC

Table 27. Geometric characteristics for the truncated decahedra with and without a central site. The number of surface sites for each type of site, the number of total surface sites, and in the polyhedron are listed.

ν	n	N_{ET}	$N_{EV'}$	N_{TF}	With a central site					Without a central site				
					N_{EP}	N_{EE}	N_{PF}	$N\sigma$	N	N_{EP}	N_{EE}	N_{PF}	N_{σ}	N
2	1	0	0	0	20	5	30	77	100	10	0	10	42	49
3	1	0	0	0	40	15	100	177	282	30	10	60	122	176
	2	20	5	0	30	5	80	162	262	20	0	40	107	156
4	1	0	0	0	60	25	210	317	604	50	20	150	242	423
	2	20	5	0	50	15	190	302	584	40	10	130	227	403
	3	40	10	10	40	5	150	277	539	30	0	90	202	358
5	1	0	0	0	80	35	360	497	1106	70	30	280	402	830
	2	20	5	0	70	25	340	482	1086	60	20	260	387	810
	3	40	10	10	60	15	300	457	1041	50	10	220	362	765
	4	60	15	30	50	5	240	422	961	40	0	160	327	685

layers were added. So, in a developed truncated decahedron, there will be the same sites as in one without development, except for the *TF* sites, triangular face, which convert into sites *TR* trapezoidal face, and the sites generated when adding the *SEC* layers, sites in the rectangular faces *RF* and in the vertical edges *EV*, joining the *VE* sites which are duplicated. The number of sites that will be added depends on the number of equatorial layers that the polyhedron will have, $N_{t_{SE}} + N_{t_{EC}}$ sites from the original truncated decahedron are added per each layer to widen them. It is to be noticed that, in this case, the *SE* sites corresponding to *EV'* and *ET* sites will be added to the surface also, that is, they will not remain internal, along with the *EC* sites. Table 28 lists the number of sites of the different types of sites in the truncated decahedron with and without a central site and developed.

When adding *SEC* layers to grow the truncated decahedron, the number of sites *VP*, *EP*, *ET*, *V'*, and *PF* are not modified, while the number of sites *VE*, and *EE* are duplicated, sites *EV'* increase and sites *TF* are converted to *TR* and they increase with respect to the original truncated decahedron. Sites *RF* and *EV* appear. From Table 28 it is possible to obtain the analytic expressions for the different number of sites in the developed truncated decahedron. The number of sites *EV'*, *EV*, and *TR* is common for the two

polyhedra with and without a central site, that is, they only depend on n and μ, and their analytic expression is the following:

$$N_{EV'}(\mu, n) = 5(n + \mu - 2)$$
$$N_{EV}(\mu) = 10(\mu - 2)$$
$$N_{TR}(\mu, n) = 5(n-1)(n + 2\mu - 4),$$

and the expressions for the other types of sites, for the one with a central site,

$$N_{RF}(\nu, \mu, n) = 5(2\nu - 2n - 1)(\mu - 2)$$
$$N_{ag}(\nu, \mu, n) = (\mu - 1)[5\nu(2\nu + 1) + 1 - 5n^2]$$
$$N_{\sigma}(\nu, \mu, n) = 10\nu(2\nu + \mu - 1) - 5n^2 + 2$$

and without a central site

$$N_{RF}(\nu, \mu, n) = 10(\nu - n - 1)(\mu - 2)$$
$$N_{ag}(\nu, \mu, n) = (\mu - 1)[5\nu(2\nu - 1) + 1 - 5n^2]$$
$$N_{\sigma}(\nu, \mu, n) = 10\nu(2\nu + \mu - 3) - 5n^2 - 5\mu + 12.$$

the total number of sites is equal to the total number of sites in the original decahedron plus the N_{ag} sites.

3.6. Star-Type Decahedra

If the method to obtain a truncated decahedron is applied to a decahedron without a central site, which has an odd number of edges, it could be possible to eliminate all of the sites from the equatorial edges, except one, obtaining the star-type decahedron, named after the shape it represents (Fig. 35). For this decahedron, the equator edges from the original decahedron are practically eliminated, with one site remaining which converts to a vertex. The edges toward the poles are reduced to a half. The resulting figure has 17 vertexes, 30 edges, 10 rhombohedral-shaped faces, and 10 lateral triangular faces (over the equator and joint in pairs). The types of sites present are the same as in the truncated decahedron, although the *PF* sites, pentagonal faces, change to *R* sites, rhombohedral faces. The number of *VP* sites is 2, of *V'* is 10, and of *VE* is 5; the number of sites *EP*, *ET*,

Note: νn is the cluster order, μ is the number of equatorial layers in the polyhedra. Notice that, for $\mu = 1$, Table 27 values are obtained. Although μ can take any value higher than zero, here are only presented some values.

and EV' per edge is the same, not the number of edges of each type.

Table 29 describes the geometric characteristics of the star-type decahedra, notice that they correspond to the truncated decahedron with a central site with $\mu = \nu$ (only one site remanins in the equatorial edges).

From Table 29 it is possible to obtain the analytic expressions for the star-type decahedra, and they are presented next:

$$N_{EP}(\nu) = 10(\nu - 1), \qquad N_R(\nu) = 10(\nu - 1)^2$$

$$N_{ET}(\nu) = 20(\nu - 1), \qquad N_{TF}(\nu) = 5(\nu - 2)(\nu - 1),$$

$$N_{EV'}(\nu) = 5(\nu - 1), \qquad N_{(-)}(\nu) = \frac{5}{6}\nu(\nu + 1)(2\nu + 1)$$

$$N_{t_{SE}}(\nu) = \frac{5}{2}\nu(\nu + 1), \qquad N_{t_{EC}}(\nu) = \frac{5}{2}\nu(\nu + 1) + 1$$

$$N_\sigma(\nu) = 15\nu^2 + 2, \qquad N(\nu) = 5\nu^3 + \frac{15}{2}\nu^2 + \frac{9}{2}\nu + 1.$$

To these decahedra, it is possible to add intermediate layers. The resulting figure has 10 trapezoidal lateral faces (which were triangular), and besides the 10 rhombohedral, 5 edges more, (Fig. 36). When adding layers of type *SEC*, the number of sites *VP*, *EP*, *ET*, *V'*, and *RF*, are not modified, while the number of sites *EE* and *VE* are duplicated; the number of sites EV' increases and the *TF* sites, triangular face, change to *TR*, trapezoidal face. Besides, sites *EV* appear. Table 30 lists the geometric characteristics of these polyhedra. Analytical expressions for the number of sites for the modified sites are presented next:

$$N_{EV'}(\nu, \mu) = 5(\nu + \mu - 2)$$

$$N_{TR}(\nu, \mu) = 5(\nu - 1)(\nu + 2\mu - 4)$$

$$N_{EV}(\mu) = 5(\mu - 2)$$

$$N_{ag}(\nu, \mu) = (\mu - 1)[5\nu(\nu + 1) + 1]$$

3.7. Additional Truncations in Decahedra

Just as in the decahedra, it is possible to add or eliminate sites to obtain modified structures of all of the types of decahedra previously described to obtain new structures. This is achieved by eliminating the sites on the edges which converge to a pole in a truncated decahedron, for example, the one of order 74 without a central site with 2139 sites, a truncated decahedron with one channel per edge converging to a pole is obtained, Figure 37(a), of 2032 sites, having an elimination of 107 sites, sites EP, VP, EV, and V'. If only the sites EP, VP, and V' are eliminated, Figure 38(a), a polyhedron of 2047 sites is obtained. If, now, the following edges are eliminated, the result is a truncated decahedron with a triple channel of 1822 sites, 210 sites were eliminated [Fig. 37(b)], and also, it is possible to eliminate only the sites at edges without eliminating the EV sites [Fig. 38(b)]. This process can continue until obtaining the desired number of channels.

Elimination of only the EP, VP, and V' sites does not affect the number of SE and EC sites from the original polyhedron, listed in Table 26, while upon elimination of the sites EV they do modify. Table 31 lists the geometric characteristics of some truncated decahedra with and without a central site and the resulting ones with single and triple channels when sites EP, VP, EV, and V' are eliminated. For the case when sites EP, VP, and V' are eliminated the geometric characteristics are listed in Table 32.
Figure 37. Truncated decahedron without a central site of order 74 with (a) one single channel and 2032 sites, and (b) a triple channel and 1822 sites, eliminating AP, VP, AV, and V' sites. [(a') and (b') are lateral views of superior (a) and (b) views, respectively].
Figure 38. Truncated decahedron without central site of order 74 with (a) one single channel and 2047 sites, and (b) a triple channel and 1857 sites, eliminating *AP*, *VP*, and *V'* sites. [(a') and (b') are lateral views of superior (a) and (b) views, respectively).

In both Tables the number of eliminated sites and the total number of sites in the cluster are enumerated. Besides that in Table 31 the total number of sites *SE* and *EC* are also enumerated.

From Tables 31 and 32, in both cases it is possible to obtain the analytical expressions for the total number of sites eliminated from these clusters. When sites *EP*, VP, EV and V' are eliminated from a truncated decahedron with a central site and a simple channel

$$N_{\rm el}(\nu, n) = 20\nu - 5n - 3,$$

for a triple channel,

$$N_{\rm el}(\nu) = 10(4\nu - 5),$$

for a truncated decahedron without a central site and a simple channel,

$$N_{\rm el}(\nu, n) = 20\nu - 5n - 13,$$

and for a triple channel,

$$N_{\rm el}(\nu) = 10(4\nu - 7).$$

And when only sites *EP*, *VP*, and *V'* are eliminated from a truncated decahedron with a central site and a simple channel,

$$N_{\rm el}(\nu, n) = 20\nu - 10n + 2,$$

for a triple channel,

$$N_{\rm el}(\nu, n) = 10(4\nu - n - 3),$$

for a truncated decahedron without a central site and a simple channel,

$$N_{\rm el}(\nu, n) = 20\nu - 10n - 8,$$

and for a triple channel,

$$N_{\rm el}(\nu, n) = 10(4\nu - n - 5),$$

Also from Table 31 it is possible to obtain the analytical expressions for the total number of *EC* and *SE* sites when sites *EP*, *VP*, *EV*, and *V'* are eliminated from a truncated decahedron. It can be notice that the behavior of these quantities do not depend if the polyhedron has or not a central site. For the case of a simple channel,

$$(N_{t_{SE}})_{\rm sc} = (N_{t_{SE}})_{\rm Marks} - \begin{cases} 5, & n \text{ odd} \\ 0, & n \text{ even} \end{cases}$$

$$(N_{t_{EC}})_{\rm sc} = (N_{t_{EC}})_{\rm Marks} - \begin{cases} 0, & n \text{ odd} \\ 5, & n \text{ even} \end{cases}$$

and for a triple channel,

$$(N_{t_{SE}})_{tc} = (N_{t_{SE}})_{cs} - \begin{cases} 0, & n \text{ odd} \\ 10, & n \text{ even} \end{cases}$$

$$(N_{t_{EC}})_{tc} = (N_{t_{EC}})_{cs} - \begin{cases} 10, & n \text{ odd} \\ 0, & n \text{ even} \end{cases}$$

The total number of sites in the cluster is the total number of sites in the truncated decahedron minus the eliminated sites.

With this, it is possible to add the layers type *SEC* to obtain truncated decahedra with channels and developed [Figs. 39(a) and (b)].

Another modification of a truncated decahedron with surface reconstruction, as explained for the decahedron, can be achieved by shifting the pentagonal face outwards and to the waist, eliminating then the sites *EE*, *VE*, *ET*, and *V′*, which reflects in adding N_{ag} sites (Fig. 40). Table 33 lists the geometric characteristics of the truncated decahedra modified by surface reconstruction. From this Table can be deduced that for the truncated decahedron with a central site the number of sites added, the number of surface sites and the total number of sites in the cluster are

$$N_{ag}(\nu, n) = 10[2\nu^2 + \nu - 2 - (n-1)(n+2)]$$
$$N_{\sigma}(\nu, n) = 20\nu(\nu+1) - 5n(n+2) + 2$$
Figure 39. Truncated decahedron without a central site of order 74 with (a) one single channel, and (b) a triple channel and three layers in the waist.
Figure 40. Truncated decahedron with surface reconstruction.

$$N(\nu, n) = \frac{20}{3}\nu^3 + 30\nu^2 + \frac{46}{3}\nu - \frac{5}{3}n^3 - \frac{25}{2}n^2 - \frac{65}{6}n + 1,$$

and for the truncated decahedron without a central site

$$N_{ag}(\nu, n) = 10[(2\nu - 3)(\nu + 1) - (\mu - 1)(\mu + 2) + 1]$$
$$N_{\sigma}(\nu, n) = 20\nu^2 - 5n^2 - 10n - 3$$
$$N(\nu, n) = \frac{20}{3}\nu^3 + 20\nu^2 - \frac{29}{3}\nu - \frac{5}{3}n^3 - \frac{25}{2}n^2 - \frac{65}{6}n.$$

When adding the sites for the surface reconstruction, the number of sites *SE* and *EC* is not affected. So, layers of type *SEC* can be added to obtain truncated decahedra with surface reconstruction and developed (Fig. 41). Table 34 lists the geometric characteristics for the truncated decahedron with and without a central site modified with surface reconstruction and with *SEC* layers added. From this table it is

$$N(\nu,\mu,n) = \frac{20}{3}\nu^3 + 10\nu^2 + \frac{16}{3}\nu + 1 - \frac{5}{6}n(n+1)(2n+1) + N_{ag},$$

and for polyhedra without a central site

$$N_{ag}(\nu,\mu,n) = (10\nu^2 - 5\nu - 10n + 5)(\mu - 1)$$

$$N_\sigma(\nu,\mu,n) = 20\nu^2 + 5n^2 - 10\mu^2 - 10\nu - 35\mu + 10\nu\mu + 22$$

$$N(\nu,\mu,n) = \frac{20}{3}\nu^3 + + \frac{1}{3}\nu - \frac{5}{6}n(n+1)(2n+1) + N_{ag}(\nu,\mu,n).$$

3.8. Icosahedra

The icosahedron (ICO) is a geometric figure with a central site, 12 vertexes, connected with 30 edges, and formed by 20 triangular faces; Figure 42 shows a 561 icosahedron. From this figure, it can be seen that the icosahedron can also be considered as two pentagonal pyramids with a rotation of 36° of one with respect to the other, and with intermediate layers, to adequately join the vertexes of both pyramids. Each icosahedral cluster presents a certain number of sites, but distributed in different layers, which are formed by equivalent sites: sites at the same distance from the origin, which have the same environment, and the same type of neighbors. Sites in the ICO are localized in triangular faces (*T*), edges (*E*), and vertexes (*V*). The order-1 ICO is formed by one central site and one first shell with only one layer of 12 vertexes. The second-order ICO is formed by the addition of one shell formed by 42 sites, to complete 55 sites, distributed in two layers: one layer of 30 sites *E* and a second layer of 12 sites *V*. When adding a third shell of 92 sites, the ICO of third order of 147 sites is completed, the added sites are distributed in three layers: one of 20 sites *T*, one more of 60 sites *E* and the third of 12 sites *V*. And successively, complete shells are added, forming clusters of order ν.

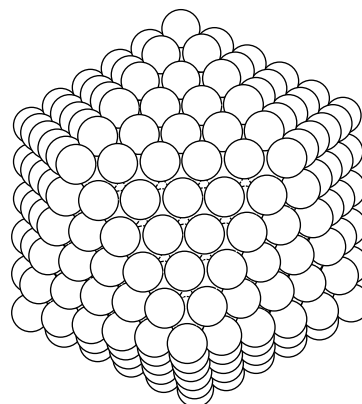
The geometric characteristics of the ICO are listed in Table 35, to clusters of order 10. The first column lists the order of the cluster ν. The following columns list the number of sites in each type of sites in the cluster. Next, is the number of sites of each site or the layers of each type of site. Finally, the number of sites in the shell and in the total


Figure 42. Icosahedron of order 5 with 561 atoms.

Table 35. Geometric characteristics for icosahedra.

ν	N_T	N_E	N_V	R_T	R_E	R_V	N_{shell}^{ν}	N_{shell}^{T}	N_{σ}	N

10	720	270	12	8	5	1	14	66	1002	3871

of sites in the cluster is given. From this table, it is possible to obtain the dependence on the cluster order ν from the total number of sites N, on the number of surface sites N_{σ}, the number of sites T N_T and of sites E N_E, as well as the number of layers of sites T R_T, and sites E R_E, which are expressed as

$$N(\nu) = \frac{10}{3}\nu^3 + 5\nu^2 + \frac{11}{3}\nu + 1, \qquad N_{\sigma}(\nu) = 10\nu^2 + 2$$

$$N_T(\nu) = 10(\nu - 1)(\nu - 2), \qquad N_E(\nu) = 30(\nu - 1)$$

$$R_T^m(\nu) = \begin{cases} \displaystyle\sum_{\alpha=1}^{m/2}(3\alpha + a) + \sum_{\alpha=1}^{(m/2)-1} 3\alpha; & m \text{ even} \\[6pt] & \begin{cases} \nu = 3m + a; \\ a = -1, 0, 1; \end{cases} \\[6pt] \displaystyle\frac{1+a}{1+|a|} + \sum_{\alpha=1}^{(m-1)/2}(6\alpha + a); & m \text{ odd,} \end{cases}$$

$$R_E(\nu) = \begin{cases} \nu/2; & \nu \text{ even,} \\ \nu - 1/2; & \nu \text{ odd.} \end{cases}$$

3.9. Decmon-Type Polyhedra

In contrast with previous polyhedra, decmon polyhedra are based on a decmon-type pyramid, which is constituted by 16 vertexes joined by 30 edges which form 15 faces: 5 rectangular type (100) and 10 triangular of type (111), 5 of which are equilateral and 5 isosceles; Figure 43. The 5 equilateral triangular faces (*TE*) have m edge sites per side, and each
Figure 43. Decmon type pyramid.

side of length $1.05(m+1)d_{NN}$, where d_{NN} is the distance to the first neighbors; the 10 isosceles triangle faces (*TI*) have n edge sites per side, two sides of length $(n+1)d_{NN}$ and one of length $1.05(n+1)d_{NN}$; the 10 rectangular faces (*RF*), with $m \times n$ sites, have sides $1.0(n+1)d_{NN}$ and $1.05(m+1)d_{NN}$. Equal sides of faces *TI* coincide with the sides of faces *RF*, and the different side forms part of the equator along with one of the sides of *RF* faces. Faces *TE* coincide with the pole, and have a common side; also, each face has a common face with one *RF* face. The angle between the planes of *RF* and *TE* faces is 190.66°, and between *RF* and *TI* faces is 161.94°. The 16 vertexes (*V*) are of three types: 1 pole, where the 5 TE faces converge, 5 where the three types of faces (*V*3) converge, and 10 at the equator, and where an *R* and a *TI* face converge (*V*4). These vertexes are joined by 30 edges (*E*) of 5 types: 5 of length $1.05(m-1)$, between *TE* faces and which converge at the poles and join the *VP* and *V*3 vertexes (*EE*); 5 of length $1.05(m-1)$, between *TE* and *RF* faces and join vertexes *V*3 (*E*3); 10 of length $1.0(n-1)$ between *TI* and *RF* faces and join vertexes *V*3 and *V*4 (*E*34); and 10 at the equator, 5 of them of length $1.05(m-1)$ of one *RF* (*ER*) face and 5 of length $1.05(n-1)$ of one *TI* (*EI*) face, which joins *V*4 vertexes.

Based on the decmon pyramid, many polyhedra can be obtained: the truncated icosahedron, the decmon, and the decmon with intermediate aggregated layers.

3.9.1. Decmon Icosahedra

The truncated icosahedron or icosahedron of decmon type is a polyhedron obtained upon adequate truncation and in a symmetric way of an icosahedron (however, they can be truncated asymmetrically also). An asymmetric truncation of an icosahedron is done in the following manner: surface sites forming a cover with a pentagonal pyramid shape over a vertex, yielding a decmon-type pyramid, with rectangular faces and a side with a length of d_{NN}. In order to perform a symmetrical truncation, first a cover like that previously presented has to be eliminated, but from the vertex diagonally opposite. The following truncations have to be done by elimination of sites which form a pyramid-shaped cover of decmon type. Figure 44 shows two icosahedra with their corresponding truncations. Figure 44(a) [Fig. 44(d)] shows a 561 (309) site icosahedron that, upon truncation, yields the 409 (207) sites TI_h (observe in this one the decmon-type pyramid); Figure 44b [Fig. 44(e)], which, when truncated, again yields the 257 (105) sites TI_h, Figure 44(c) [Fig. 44(f)]. From this figure, it can be observed that it is possible to obtain the TI_h of two different kinds: (1) the TI_{ha} [Fig. 44(f) and (b)], and (2) the TI_{hb} [Figs. 44(b), (c), and (e)].

3.9.2. Truncated Icosahedra TI_{ha}

As shown in Figure 44(f), it is formed by 22 vertexes, joined by 50 edges, forming faces of three types: rectangular, *RF* type (110), and two triangular of type (111), one equilateral (*TE*) and the other isosceles (*TI*). Also, from this figure it can be noticed that the TI_{ha} can be formed by attaching two decmon-type pyramids, with *TI* faces coinciding with *TI* faces at the equator or waist.
Figure 44. (a) Icosahedron I_h of 561 atoms. (b) Truncated icosahedron, TI_h of 409 atoms. (c) TI_h of 257 atoms. (d) I_h of 309 atoms. (e) TI_h of 207 atoms. (f) TI_h of 105 atoms.

3.9.3. Truncated Icosahedra TI_{hb}

As shown in Figures 44(b), (c), and (e), it is formed by 32 vertexes, joinrd by 80 edges of I order to form 50 faces. 10 vertexes, 30 edges, and 20 faces more than TI_{ha}. The 10 vertexes form one plane, and are of equator type from TI_{ha} and the 20 edges connect the vertexes from the two planes forming the 20 extra faces of trapezoidal type TR, now having the waist of the TI_{hb}.

TI_h are characterized by three numbers (m, n, r) where m (n) $[r]$ is the number of sites in one edge between faces TE, $(RF$ and $TI)$ $[TR]$, including vertexes, for example, in Figure 44(f), there is TI_{ha} $(3, 3, 1)$, and in Figures 44(b), (e), and (f), there are the TI_{hb} $(5, 2, 4)$, $(4, 3, 2)$, and $(4, 2, 3)$. It is clear that, based on this notation, to the icosahedron corresponds an $m = r$ and an $n = 1$, for example, $(6, 1, 6)$ and $(5, 1, 5)$ from Figures 44(a) and (d), respectively. From Figure 44, it can be seen also that TI_{ha} results from complete truncation (when there is only one or two edge sites from the original icosahedron) of an icosahedron with an odd number of sites in the edges.

By truncation of an icosahedron, only some TI_h are obtained, and upon truncation of another icosahedron, others are obtained; in each truncation, a certain number of sites are eliminated, but the same number in each truncation. Table 36 presents some of the geometric characteristics of TI_h. The first column shows the order of the icosahedron from where the ν comes, the second column shows the number of truncations done n_t, the third column shows the three characteristic numbers, in the fourth column is the number of sites eliminated from the original icosahedron n_-, in the fifth column the number of sites remaining in the surface N_σ is shown, and in the sixth column, the total number of sites in TI_h, N is shown. So, for example, the TI_h $(5, 3, 3)$, comes from the icosahedron of order 6, to which 424 sites were eliminated in two truncations, yielding a TI_h of 499 sites, of which 242 are at the surface.

Table 36. Geometric characteristics for truncated icosahedra TI_h.

5	0	6,1,6	0	252	561
	1	5,2,4	152	202	409
	2	4,3,2	304	152	257
6	0	7,1,7	0	362	923
	1	6,2,5	212	302	711
	2	5,3,3	424	242	499
	3	4,4,1	636	182	287

Note: n_t is the number of truncations made.

From Table 36 it can be seen that the maximum number of truncations is $\nu/2$ $[(\nu - 1)/2]$, for ν even [odd]; besides the values for m, n, r, and $m + n + r$ show the next characteristics

$$\left.\begin{array}{l}(\nu + 2)/2, \ \nu \ \text{even} \\ (\nu + 3)/2, \ \nu \ \text{odd}\end{array}\right\} \leq m \leq \nu + 1$$

$$1 \leq n \leq \begin{cases}(\nu + 2)/2, \ \nu \ \text{even} \\ (\nu + 1)/2, \ \nu \ \text{odd}\end{cases}$$

$$\left.\begin{array}{l}1, \ \nu \ \text{even} \\ 2, \ \nu \ \text{odd}\end{array}\right\} \leq r \leq \nu$$

$$\left.\begin{array}{l}\nu + 3, \ \nu \ \text{even} \\ \nu + 4, \ \nu \ \text{odd}\end{array}\right\} \leq m + n + r \leq 2(\nu + 1) + 1.$$

It is worth also notice that the parity of r is equal to the one for ν, and the maximum values of m and r coincide with the minimum value of n; m and n take values of one to one, while r takes values of 2 to 2. The analytical expressions for n_-, N_σ and N are

$$n_-(\nu) = 2n_t\left[1 + \frac{5\nu(\nu + 1)}{2}\right]$$

$$N_\sigma(\nu) = (N_\sigma)_{\text{ico}} - 10\nu n_t = 10\nu^2 - 10\nu n_t + 2$$

$$N(\nu) = (N)_{\text{ico}} - n_-$$

$$= \frac{10}{3}\nu^3 + 5\nu^2 + \frac{11}{3}\nu + 1 - 2n_t\left[1 + \frac{5\nu(\nu + 1)}{2}\right].$$

For the truncated icosahedra TI_{ha}, $r = 1$ and $m = n = (\nu + 2)/2$, ν even, based in the structure itself there are sites on vertexes VP, $V3$, and $V4$, on edges EE, $E3$, $E34$, ER, and EI, on triangular faces TE and TI, and on squared faces RF. The number of sites on vertexes are 2, 10 and 10, respectively. The number of sites for the other type of sites,

which is given in function of m, and the number of surface atoms can be obtained from the following expressions

$$N_{EE} = N_{E3} = 10(m-2), \quad N_{ER} = N_{EI} = 5(m-2)$$

$$N_{E34} = 20(m-2), \quad\quad N_{TE} = N_{TI} = 5(m-2)(m-3)$$

$$N_R = 10(m-2)^2, \quad\quad N_\sigma = 20(m-1)^2 + 2.$$

For the truncated icosahedra TI_{hb}, the number of sites $V4$, ER, and EI are duplicated with respect to the original polihedron, the number of surface sites is modified and the sites EL and TR, sites on lateral edges and on trapezoidal faces, are aggregated, and they are given by

$$N_{EL} = 10(r-2)$$

$$N_{TR} = \begin{cases} 0 & r = 2 \\ 10[n(r-1) - n - 1], & r \geq 3, \end{cases}$$

$$N_\sigma = \begin{cases} 5(m+n-2)(m+n-1) + 2, & r = 2 \\ 5(m+n-2)(m+n-1) \\ \quad + 10(r+nr-2n) - 28, & r \geq 3. \end{cases}$$

3.9.4. Decmon Polyhedra

A decmon polyhedra, Figure 45, is very similar to TI_{ha}, it has the same number of vertexes, edges, and faces, and the same type of sites. Also, it can be constructed by two decmon-type pyramids. The difference is that, at the equator or at the waist, faces TI have TI faces, and RF have RF faces.

The lengths of decmon edges, even when they are of three sizes, are related to the values m and n of the decmon pyramid, characterizing each particular decmon. mn can be considered as the order of the decmon (decmon mn), and the values taken by m and n are not limited. m and n are the (number-1) of edge sites EE and $E34$, respectively. Indeed, every decmon is formed by centered shells in one decmon of an order in which: (1) $m = 1$ and $n = 1$, (2) $m > 1$ and $n = 1$, or (3) $m = 1$ and $n > 1$, which are the smallest. For example, decmon of Figure 45 is of order 78, decm78, which in turn is a decm67 + one shell, decm67 is a decm56 + one shell, decm56 is a decm45 + one shell, decm45 is a decm34 + one shell, and decm34 is decm23 + one shell, decm23 is a decm12 + one shell, decm12 being the smallest of this family.

Decmon of order 11 (decm11) is the smallest of all decmons, and the edges at the equator are all the same;

Figure 46. Decmon-type decahedron of order 11. In (b) the sizes of the atoms of (a) were reduced to more clearly observe the squared and triangular faces by bondings to first neighbors, and to show that this is a polyhedron with a central site. (c) Decmon-type decahedron of order 44, decm44, of 609 sites.

Figure 46. It only has sites in vertexes, and is centered in one site, having a cluster of 23 sites. There is a decmon family mm, based on decm11, and the possible decmons to be created are decm22, decm33, decm44, decm55, and so on.

The geometric characteristics of a decahedra-type decmon of order mm are listed in Table 37. The first column lists the m value, the four following columns list the number of sites in each type of sites, rectangular face sites RF, in triangular faces T, in edges E, and in vertexes V. It should be clear that T sites include TE and TI sites, which in number are equal. Besides, the 5 types of edges are included in E, corresponding $1/5$ to each one of EE and $E3$, $1/10$ to ER, and another to EI and $2/5$ to $E34$. Vertexes are always 22, and from the three kinds already mentioned, 2 poles, 10 $V3$, and 10 $V4$. The following three groups of two columns list the number of sites in the plane above the equator, at the equator, and for the number of sites in clusters, for each shell and in total. Figure 46(c) shows the decmon for $m = 4$ and of 609 atoms.

From Table 37, it can be seen that, for a decmon of order m, the dependency with m values of the number of sites in a rectangular face N_{RF}, triangular face N_T, edges N_E, surface N_σ, and total N is given by the following expressions:

$$N_{RF} = 10(m-1)^2, \quad\quad N_T = 10(m-1)(m-2)$$

$$N_E = 50(m-1), \quad\quad N_\sigma = 20m^2 + 2$$

$$N = \frac{20}{3}m^3 + 10m^2 + \frac{16}{3}m + 1$$

Figure 45. Decmon-type polyhedron.

Table 37. Geometric characteristics for decmons of family of order mm based on decmons of order 11, decm11.

m	N_{RF}	N_T	N_E	N_V	N_{SE}	$N_{t_{SE}}$	N_{EC}	$N_{t_{EC}}$	N_σ	N
1	0	0	0	22	5	5	10	11	22	23
2	10	0	50	22	10	15	20	31	82	105
3	40	20	100	22	20	35	30	61	182	287
4	90	60	150	22	30	65	40	101	322	609
5	160	120	200	22	40	105	50	151	502	1111
6	250	200	250	22	50	155	60	211	722	1833
7	360	300	300	22	60	215	70	281	982	2815
8	490	420	350	22	70	285	80	361	1282	4097
9	640	560	400	22	80	365	90	451	1622	5719
10	810	720	450	22	90	455	100	551	2002	7721

also, expressions for the number of sites *SE* and *EC* can be calculated for each m, N_{SE}, N_{EC}, and total $N_{t_{SE}}$ and $N_{t_{EC}}$:

$$N_{SE} = 10(m-1), \qquad N_{t_{SE}} = 5(m^2 - m + 1)$$

$$N_{EC} = 10m, \qquad N_{t_{EC}} = 5m(m+1) + 1.$$

The next family decmon size, following the decmon family *mm*, is the decmon family *mn*, with $n = m - 1$ or $n = m + 1$, and based on the decm12 and decm21, respectively. Decm12 and decm21 have the same number of sites, a total of 54, although decm21 is more elongated toward the poles; Figure 47. Decm12 has 20 sites in edges *E34* and 5 in *EI*, while decm21 has 10 sites in edges *EE*, 10 in *E3*, and 5 in *ER*, and both are centered in a decahedron of 7 sites, regular for decm12 and more elongated toward the poles for decm21. From decm12, other decm can be generated: decm23, decm34, decm45, decm56, and so on. From decm21, the decm generated are decm32, decm43 decm54, decm65, and so on.

The geometric characteristics of decmon-type decahedra, of order *mn*, with $m = n - 1$ and $m = n + 1$, are listed in Table 38. The first two columns list the *m* and *n* values, and in the following 10 columns, the number of sites of each type of site, which considers only the sites in rectangular faces *RF*, equilateral triangular faces *TE*, isosceles triangular faces *TI*, of two types of edges: short edges *Em*, and large edges *En*, and in vertex *V*. It should be clear that sites in *Em* [*En*] include sites *EE*, *ER*, and *E3* [*EI* and *E34*], corresponding (2/5) to *EE*, (2/5) to *E3*, and (1/5) to *ER* [(4/5) to *EI* and (1/5) to *E34*]. The vertexes are always 22, and come from the three types already mentioned. The number of sites *RF* and *V* is common for the two decmon *mn* families, with $m = n - 1$ and $m = n + 1$, while the number of sites *TE* and *TI*, *Em*, and *En* are interchanged. Columns 8–11 correspond to the interchange of values of *m* and *n*; this is what happens with decmon families of order *mn* with $m = n + 1$. The following three groups of two columns list the number of sites in the plane above the equator (SE sites), at the equator (EC sites), and the numbers of sites in the cluster, per shell and in total, these values are common to the *m* and *n* values and are interchanged. Figures 47(c) and (d) show decmons of order 45 and 54, of 835 atoms.

After the *mn* decmon families, with $m = n - 1$ and $m = n + 1$, follow in size the ones of decmon of order *mn*, with $m = n - 2$ and $m = n + 2$, and are based on decm13 and decm31, respectively. The decm13 and decm31 decmon have the same number of sites, 105 in total, although decm31 is more elongated toward the poles, Figure 48. Decm13 has 40 sites in edges *E34*, 10 in *EI*, and 10 in faces *TI*, while decm31 presents 20 sites in edges *EE*, 20 in *E3*, 10 in *ER*,

and 10 in faces *TE*, and both are centered at a decahedron of 23 sites with central site, regular for the decm13 and more elongated toward the poles for the decm31. From the decm13, it is possible to generate the decm24, decm35, decm46, decm57, and so on. From decm 31, it is possible to obtain the decm42, decm53, decm64, decm75, and so on. The geometric characteristics of the decahedra type decmon of order *mn*, with $m = n - 2$ and $m = n + 2$, are listed in Table 39, with the same indications for the columns as in Table 38. Figures 48(c) and (d) show the 1111 atoms decmon of order 46 and 64.

From Tables 37–39, it is deduced that, for a decmon order *mn*, the dependency on the *m* and *n* values of the number of sites in rectangular face N_{RF}, sites in the equilateral triangular face N_{TE}, of sites in an isosceles triangular face N_{TI}, of sites in the edge type *Em* (*EE*, *E3*, and *ER*), N_{Em}, of sites in the edge type *En* (*EI* and *E34*) N_{En}, and of sites in the surface N_σ is given by the following expressions:

$$N_{RF} = 10(m-1)(n-1), \qquad N_{TE} = 5(m-1)(m-2)$$

$$N_{TI} = 5(n-1)(n-2), \qquad N_{Em} = 25(m-1)$$

$$N_{En} = 25(n-1), \qquad N_\sigma = 5(m+n)^2 + 2.$$

Also, it is possible to obtain the number of sites in the immediate superior plane over the equator for each *m* and *n*, N_{SE} and in total $N_{t_{SE}}$, and in the equator N_{EC} and $N_{t_{EC}}$ for the number of sites in the surface and the number of sites for each *m* and *n* and in total for the decmon for each combination of *m* and *n* used here. For $m = n \pm 1$

$$N_{SE} = 10m, \qquad N_{t_{SE}} = 5m(m+1) + 1$$

$$N_{EC} = 10m + 5, \qquad N_{t_{EC}} = 5(m+1)^2$$

$$N_\sigma = 20m^2 \pm 20m + 7, \qquad N = \begin{cases} \dfrac{20}{3}m^3 + 20m^2 + \dfrac{61}{3}m + 7; \\ \qquad\qquad\qquad \text{for } (+) \\ \dfrac{20}{3}m^3 + \dfrac{1}{3}m; \quad \text{for } (-) \end{cases}$$

and for $m = n \pm 2$

$$N_{SE} = 10m + 5, \qquad N_{t_{SE}} = 5m(m+2) + 5$$

$$N_{EC} = 10(m+1), \qquad N_{t_{EC}} = 5m^2 + 15m + 11$$

$$N_\sigma = 20m^2 \pm 40m + 22, \qquad N = \begin{cases} \dfrac{20}{3}m^3 + 30m^2 + \dfrac{136}{3}m + 23; \\ \qquad\qquad\qquad \text{for } (+) \\ \dfrac{20}{3}m^3 - 10m^2 + \dfrac{16}{3}m - 24; \\ \qquad\qquad\qquad \text{for } (-) \end{cases}$$

3.9.5. Modified Decmon

To obtain decmon type decahedra, widened with extra layers, the same procedure is followed as with the decahedra, separating the decmon as two pyramids with parallel bases, making the vertexes coincide, and adding layers of type *SEC*, Figure 49. The obtained figure has 10 regular lateral faces besides the ones previously mentioned, and 10 more edges.

Figure 47. Decmon-type decahedrons of (a) order 12, and (b) order 21 with 54 sites. Decmon-type decahedron of 835 sites of (c) order 45, decm45, and (d) order 54, decm54.

Table 38. Geometric characteristics for decmons of family of order mn with $m = n - 1$ and $m = n + 1$ based on decmons of order 12, decm12, and of order 21, decm21.

			mn				nm										
m	n	N_{RF}	N_{TE}	N_{TI}	N_{Em}	N_{En}	N_{TE}	N_{TI}	N_{Em}	N_{En}	N_V	N_{SE}	$N_{t_{SE}}$	N_{EC}	$N_{t_{EC}}$	N_σ	N
1	2	0	0	0	0	25	0	0	25	0	22	10	11	15	20	47	54

Besides to the type of sites for decmon-type polyhedra, the modified decmon presents the lateral and vertical edges sites EV, sites on rectangular faces that join triangular faces RI, and sites on rectangular faces that join rectangular faces RR. The number of sites $V4$, ER, and EI are duplicated with respect to the original polyhedron, and the number of surface sites is modified. The analytical expressions for them are the following

$$N_{V4} = 20, \qquad N_{Em} = 30(m-1)$$
$$N_{En} = 30(n-1), \qquad N_{EV} = 10(\mu - 2)$$
$$N_{RI} = 5(n-1)(\mu-2), \qquad N_{RR} = 5(m-1)(\mu-2)$$
$$N_\sigma = 5(m+n)(m+n+1) + 2 + 5(\mu-2)(m+n).$$

The number of sites that are aggregated to the surface and to the total number of sites in the cluster for $n = m \pm 1$ are given for

$$N_{ag} = (10m^2 + 15m + 6)(\mu - 1)$$
$$N_{\sigma_{ag}} = (10m + 5)(\mu - 2)$$

and for $n = m \pm 2$

$$N_{ag} = (10m^2 + 25m + 16)(\mu - 1)$$
$$N_{\sigma_{ag}} = 10(m + 1).$$

4. SYNTHESIS OF NANOPARTICLES

Metal clusters have been formed in a supersonic beam, this method to prepare colloidal metals in nonaqueous media was first reported by the group of Andres at Purdue
Figure 48. Decmon-type decahedra of (a) order 13 and (b) order 31. Decmon-type decahedron of 1111 sites of (c) order 46, decm46, and (d) order 64, decm64.

University [34–36]. A supersonic beam source was used; this instrument produces metal clusters with a controlled mean diameter in the range of 1–20 nm in size. Once the clusters have nucleated, the cluster aerosol is directed through a spray chamber to be placed in contact with a fine spray of organic solvent and surfactant.

However, conceptually, the simplest method of preparing colloidal metals is the condensation of atomic metal vapor into a dispersing medium [37]. Given the high oxidation potential of most atomic metals (for example, the oxidation potential for atomic gold is −1.5 V), the use of water as the diluent's phase can be ruled out, so exclusively inert organic liquids are going to be used in this procedure. Since the activation energy for the agglomeration of metal atoms is very low, the possibility for competing molecular complex formation processes which have higher activation energies can be mitigated by operating at low temperatures.

The use of metal vapors cocondensed with organic vapors to prepare colloidal metals in nonaqueous media was first reported by Roginski and Schalnikoff in 1927 [38], some 50 years before the recent wave of activity in metal vapor chemistry. The organosols were prepared at reduced pressure by the evaporation of relatively volatile metals such as cadmium, lead, and thallium, and a subsequent cocondensation of these with the vapors of organic diluents such as benzene and toluene on a liquid air cooled cold finger. After cocondensation was complete, a colloidal suspension of the metal was obtained by warming up the frozen matrix and collecting the liquid (Fig. 50).

A new metal vapor synthesis system for the preparative scale cocondensation of metal vapors with aerosols of organic liquids was recently achieved by Bradley's group [39]. The use of aerosol overcomes one limitation of the other methods, in which the organic diluent must be either volatile or has a liquid range which extends to a temperature low enough to reduce its vapor pressure to a useful value. The aerosol droplets, *ca.* 1μm in diameter, are generated by feeding the organic liquid (neat liquid, polymer solutions, solutions of nonvolatile ligands) into an ultrasonic atomizing nozzle from which they fall onto a rotating plate cooled to 77 K in a vacuum chamber, as shown in Figure 50. Vapors of one or more metals, obtained by simultaneous sputtering from metal or alloy targets, are then cocondensed with the aerosol. This results in the formation of a frozen organometallic matrix, which is then warmed up to allow the

Table 39. Geometric characteristics for decmons of family of order mn with $m = n - 2$ and $m = n + 2$ based on decmons of order 13, decm13, and of order 31, decm31.

aggregation of the metal atoms. The resulting colloid solution is removed from the reactor under helium atmosphere for characterization and further studies.

In the 1980's, several research groups in Japan prepared metal particles of Al, Mg, Mn, Be, Te, Fe, Pb, Co, Ni, Cd, Ag, In, Pd, and Au by this method [40–49]. The work most recently performed was by Uyeda in 1991 [50]. This study demonstrated the feasibility of producing films of almost any metal or semiconductor by metal vapor deposition in a noble gas high-pressure atmosphere.

Another method to produce nanoparticles is the bioreduction method. Several researchers established that live and nonlive biologic systems such as algae have the ability to absorb metal ions from solutions through their cell walls and various cellular constituents [51, 52]. Studies have shown that algae are able to bind gold ions from aqueous solutions and form colloidal particles on their surfaces, yet the mechanisms have not been fully understood [53–57]. Several plants have been studied for their unique biochemical ability to accumulate metal compounds over extended periods. In fact, plant species such as *Douglas-fir* and *rye grass* are utilized as biological indicators of geologic gold deposits [58, 59]. Some other plants such as Indian mustard have been utilized for phytomining; the accumulation of valuable metals comes from low concentrations in soils by plants [60, 61]. Furthermore, Lujan and co-woekers reported that a purple color, similar to "Purple of Cassius", resulted when aqueous

Au(III) was reacted with the biomaterials in their study, indicating the formation of gold colloids [62–64]. Plants may possess a unique natural chemical stabilization mechanism that allows the formation of nanoparticles. In addition, the plant biomaterials may be isolated for a more thorough study of the colloidal information mechanisms. Therefore, by taking advantage of the naturally occurring compounds found within the plant systems, a novel method may be found to generate similarly sized stable metal colloids. While consistency in nanoparticle size and shape is important to many materials, differences in nanoparticle synthesis may also lead to changes in particle conformation and spatial arrangement, which may provide better nanoscopic building blocks to form new raw materials with distinctly different properties than their macroscaled counterparts.

Recently, it was shown that live plants can uptake metal solutions and produce nanoparticles [65]. This approach is very promising for further developments in nanotechnology.

All of the particles reposited in the present work were produced by the methods described above.

A third way to prepare metal nanoparticles is the colloidal methods discussed in the introduction. In the original Brust reaction [13], the addition of dodecanethiol to the organic-phase $AuCl_4^-$ (1:1 molecule), followed by reduction
Figure 49. Decmon-type decahedron of order 78 with 6 intermediate layers added.

with BH_4^-, led to dodecanethiolate protected Au clusters having a 1–3 nm range of core diameters

$$AuCl_4^- (\text{toluene}) + RSH \rightarrow (-AuSR^-)_n (\text{polymer})$$

$$(-AuSR^-)_4 + BH_4 \rightarrow Au_x(SR)y$$
Subsequent reports have shown that a wide range of alkanethiolate chain lengths ($C3$–$C24$) [66], ω-functionalized alkanethiolates, and dialkyl disulfides [67] can be employed in this same protocol. An example of a passivated nanoparticles formula is $Au_{145}(S(CH_2)_5CH_3)_{50}$.

Pt, Rh and Pd salts can be used following the same method. One of the possible reactions is

$$AuCl_4^- (\text{toluene}) + PtCl^- + R - SH$$

$$\rightarrow (-Au_xPt_ySR^-)_n (\text{polymer})$$

$$(Au_xPt_ySR^-)_4 + BH_4 \rightarrow Au_xPt_y(SR)_z$$
The details of these reactions have not been completely understood; however, the behavior of the reaction is consistent with a nucleation-growth-passivation process: (1) larger thiol: gold mole ratios give smaller average nanoparticle metal core sizes [68, 69], and (2) fast reductant addition and cooled solutions produce smaller, more monodisperse nanoparticles [70, 71], and (3) quenching the reaction immediately following reduction produces higher abundances of very small core sizes (≤ 2 nm).

The Schiffrin reaction tolerates considerable modification with regard to the protecting ligand structures. While alkanethiolate passivated nanoparticles (a) are nonpolar, highly polar ligands (b–d) can yield water-soluble passivated nanoparticles in modified synthesis. Nanoparticles passivated with arenethiolate [72–75] (e–g) and (γ–mercaptopropyl) trimethyloxysilane ligands (h) have also been prepared. Sterically bulky ligands tend to produce smaller Au core sizes (relative to alkanethiolate-passivated nanoparticles prepared using equal thiol/$AuCl_4^-$ ratios), suggesting a steric connection (as yet unproven) with the dynamics of core passivation [76].

The core metal of passivated nanoparticles can also be modified. Alloy nanoparticles with Au/Ag, Au/Cu, Au/Ag/Cu, Au/Pt, Au/Pd, and Au/Ag/Cu/Pd cores [77] have been reported.

It is well known for the case of bare particles that noncrystallographic structures are formed in many cases, these being predominantly icosahedral and decahedral. In other cases fcc, bcc, or single twinned particles are also produced. Extensive literature is found on shape observations and the kinetic growth conditions in which the different types of particles are produced [78–90].

5. TRANSMISSION ELECTRON MICROSCOPY (TEM) AND SIMULATIONS OF IMAGES OF NANOPARTICLES

5.1. Introduction

Since its inception in the 20th century, electron microscopy has developed into a powerful tool for scientific research. Indeed, the use of electron microscopy has facilitated many

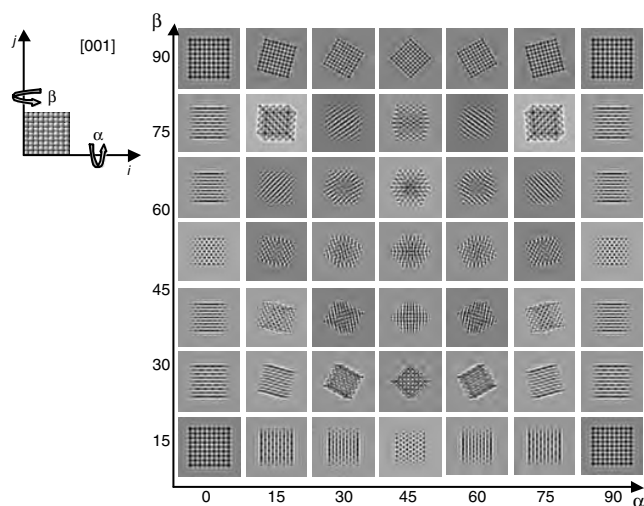
fundamental discoveries. This technique has itself been subject to constant evolution thanks to unceasing design efforts in the scientific and manufacturing transmission electron microscopy (TEM) community. The advances in this field have been characterized by a series of quantum leaps in technology. For instance, the double condenser lens and tilting stages revolutionized the study of defects in metals in the late 1950s and early 1960s. The high lattice resolution achieved in the 1970s, along with improvements in vacuum methods and lens control, produced a less complicated instrument capable of achieving rapid results with minimal training. Consequently, the TEM (Transmission Electron Microscopy) gained enormous popularity in the materials community. In the second half of the 1980s, a new quantum leap was realized by the achievement of atomic resolution on a routine basis. Microscopes with a point resolution of 0.17 nm coupled with spectacular advances in diffraction theory led to many fine examples of materials characterization. In the 1990s another quantum leap occurred with the introduction of highly coherent field emission electron sources and electron loss analyzers. Combined with X-ray analysis, this established the TEM as a powerful analytical machine. For the first time, images, diffraction, and spectroscopy could be obtained from a single instrument. The TEM has become a standard instrument for many scientific fields. During the second half of the 1990s, the substantial increase in the number of papers published in *Physical Review Letters* containing electron microscopy studies attests to this fact. Other important developments include the introduction of electron holography and dark field images produced using incoherently scattered electrons (*Z*Contrast).

The next quantum leap in electron microscopy will be produced by the introduction of aberration correctors for the objective lens and STEM lens-forming system, and by the development of monochromators for the incident beam. These techniques will undoubtedly usher in a new era for TEM. Improved point resolution of 0.007 nm, an increased information limit, enhanced energy resolution, and improved stages using MEMS technology will allow 3D reconstruction of amorphous materials such as glasses. Refined X-ray techniques will facilitate chemical analysis essentially at the single atom level. Still more exciting, $\mathscr{C}_s$-corrected microscopes will allow more space in the objective lens gap, thus making it possible to construct stages for the *in-situ* examination of materials at atomic resolution and analysis with atomic accuracy [91]. The most recent developments in TEM coincide with the emergence of nanotechnology [92], and because the TEM probe size is ideal for nanoscale studies, it is clear that advanced TEM will be a major instrument in subsequent nanotechnological developments. The TEM will also be fundamental in areas of rapid development such as advanced materials research, biotechnology, and microelectronics. The automation of modern TEM has led to applications in semiconductor fabrication processes, and energy filtering will permit the study of polymers and biological materials with unprecedented accuracy.

Transmission electron microscopy is one of the most important techniques to study nanoparticles. The resolution of the TEM is well below the size of most of the

particles and in the order of magnitude of the metal–metal bonds. There are several papers which have explained in a very detailed way the electron microscopy methods to study nanoparticles. We will not discuss in this chapter dynamical diffraction methods, but we rather refer the reader to those publications [93–96].

Images were obtained using a JEOL 2010-FEG microscope, with a resolution of 0.19 nm and a tilting possibility of ±30°, and a JEOL 4000EX with a resolution of 0.17 nm. HREM (High Resolution electron microscopy) images of nanoparticles were obtained at the first optimum defocus (Scherzer focus) or at the second optimum defocus condition, resulting in images of atomic columns as black (first maximum) or white (second maximum) dots. Molecular Dynamics software was used to build theoretical models of the particles. Simulated images were obtained using the Simula TEM software of the Institute of Physics at UNAM, which is especially adequate for studying nanoparticles with noncrystallographic symmetries. A comparison of experimental and simulated data will allow us to interpret the experimental images.

In general, in order to recognize a nanoparticle in a nonambiguous fashion, it is necessary to obtain a tilting sequence of HREM. Figure 51 illustrates the changes in contrast when the orientation of the particle is changed with respect to the electron beam. This case corresponds to a cubooctahedral particle. This image illustrates a remarkable difference between nanoparticles and large crystals. In the latter case, the image will be very sensitive to tilting, and will disappear with small tilts. The nanoparticle, on the other hand, always shows images despite the large angle of tilting. In many cases, the images correspond to pseudolattice images. Considerable caution should be taken when analyzing fringe images of nanoparticles. The images out of a low-index direction do not necessarily reflect a structural feature. In diffraction terms, the finite size of the nanoparticles in real space results in real rods in reciprocal space. The Ewald sphere will always cut the reciprocal space points despite the angle.


5.2. fcc Particles

The fcc particles are straightforward to identify. Figure 52 illustrates the contrast produced by an fcc by a pyramid formed by two tetrahedrons and their diffraction pattern (which in most instances is identical to the FFT, Fast Fourier Transform, of the image). Experimental examples of a pyramidal and of a tetrahedral particle are shown in Figure 53.

5.3. Decahedral Particles

Very important cases to consider are the images produced by pentagonal particles such as the one shown in Figure 54.

Typical TEM images of pentagonal particles are shown in Figure 55. The fivefold symmetry of the FFT can be observed. However, these patterns are a combination of the diffraction patterns of different portions of the particle, as shown in Figure 56. This indicates that the overall structure of the particle has a fivefold symmetry but this is not the result of fivefold symmetry in each portion of the particle. Because of that, it is more correct to consider that the particle has a pseudofivefold symmetry. This is in sharp contrast with the case of quasicrystals [97].

It should be remembered that another important effect in the images observed in a TEM is due to the defocus condition which can change the image significantly. Figure 57 illustrates this effect for the case of a regular decahedron. In this case the calculations were made for a JEOL 4000 microscope. As is known from image theories [98], there are two defocus conditions in which the image represents the true atomic columns which correspond on the figure to −40.5 nm (black atoms) and −70.2 nm (white atoms). If another defocus is used, the image does not necessarily reflect the atomic positions, but useful information still can be obtained. For instance, a defocus of −35.5 increases the grain boundary contrast, and the nature of the interfaces can be examined. At an even lower defocus of −20.5 nm, the pentagonal particle structure is reflected on the image.

An experimental example of a pentagonal particle showing well-defined atomic resolution is shown in Figure 58. In this case, some of the twin boundaries are incoherent. An example of the structure formed at a defocus condition below the optimum value is shown in Figure 59.

Figure 51. Simulation of HREM images of a cubooctahedral particle in different orientations with respect to the electron beam.
Figure 52. Models of a fcc pyramid formed by two tetrahedra. Observe their contrast in the second row and their diffraction pattern in the third row.
Figure 53. Bright field images of: (a) pyramidal particle, (b) Tetragonal particle, (c) FFT of (b), (d) diffraction pattern of (b).

A commonly observed type of pentagonal particle corresponding to a rounded shape and the respective model of the particle are shown in Figures 60(a) and (b), respectively. A complete set of images at different tilting angles is shown in Figure 61. Obtaining different images at different tilting angles and referring to this sequence should be enough data to fully identify the structure of that particle.

In the previous sections, we described a new type of pentagonal structure that was described originally by Montejano [99] and was termed a decmon type of particle. This type of structure belongs to a more general family of decahedral nanoparticles, which includes the truncated decahedron
Figure 54. Bright field image of a pentagonal gold particle.

(Marks) [100], the pancake structure of Koga and Sugarawa [101], and the truncated icosahedron of Ascencio et al. [102].

A tilting sequence for three different decmon structures is shown in Figures 62–64. We also include the calculation a 64-order pentadecahedron in Figure 65. An experimental example of this type of particle is shown in Figure 66. This image corresponds to a dark field taken in a weak beam condition. In this case, a continuous set of thickness fringes is expected. However, because of the decmon shape, a pentagonal profile is formed at the center of the particle.

Another experimental example is shown in Figure 67(a). The particle marked by an arrow can be identified using a model with surface reconstruction, as shown in Figure 67(b). We have found that surface reconstruction particles are formed very frequently when the sample approaches the equilibrium condition. For instance, the particle in Figure 67(a) was obtained after heating the sample with an electron beam and allowing recrystallization. In this process, the total surface energy of the nanoparticle will tend to be a minimum. There are several ways to achieve this surface energy minimization. Marks described truncations on the decahedron structure [100] that result in a more stable structure.
Figure 59. (a) High-resolution image of a pentagonal particle with a defocus below the optimal value. (b) Corresponding FFT indicating the fivefold symmetry.

Figure 61. Images of a pentagonal particle obtained as a function of the tilting angles α and β. The origin of the coordinate system indicates a 0, 0 position, and the range of the angles is 90°. The model and typical bright field and HREM image (including FFT) are shown in the left portion of the figure.
Figure 62. HREM images calculated for a decmon 10 structure shown in the left portion of the figure. The rotation angles α and β go from 0 to 90°.
Figure 63. HREM images calculated for a decmon 12 structure shown in the left portion of the figure. The rotation angles α and β go from 0 to 90°.

However, the energy landscape has many structures with similar energy. Another possibility is to introduce faceting along the twin boundaries of the decahedra, resulting in the structure shown in Figure 68(a). If images are formed at the Scherzer condition, the channels can be visualized [Fig. 68(b)], in contrast to the case of the regular decahedron. We have described these particles previously in this chapter.

A full map of images for these channeled structures as a function of the tilting angle for the optimum defocus is shown in Figures 69(a) and (b). This type of decahedron is often observed in larger particles, as shown in Figure 70.

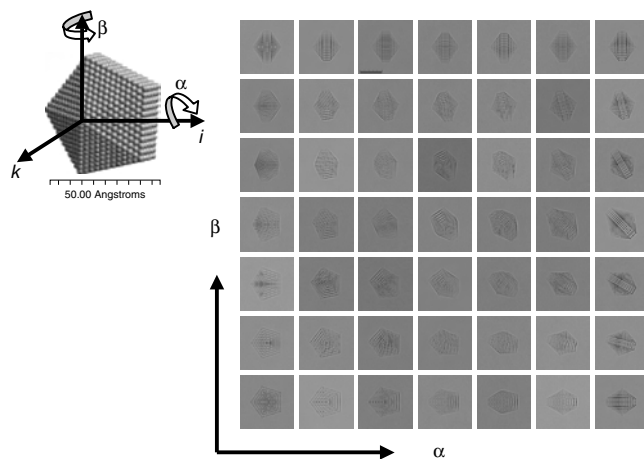
Another very interesting possibility has been suggested by molecular dynamic simulations of Chushak and Bartell [103] and other group [104]. This work indicates that, in the twin boundaries, a stacking fault is formed. In other words, the
Figure 64. HREM images calculated for a decmon structure with less degree of truncation, as the model shown in the left portion of the figure. The rotation angles α and β go from 0 to 90°.


Figure 65. HREM images calculated for a pentadecahedral structure as the model shown in the left portion of the figure. The rotation angles α and β go from 0 to 90°.

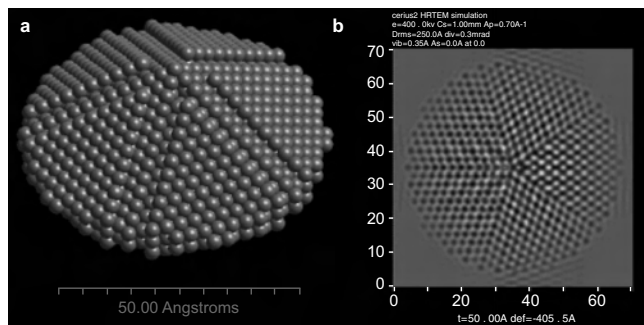

Figure 68. (a) Model of decahedron showing faceting along the twin boundaries. (b) Simulated TEM image of a decahedron in Scherzer condition, where the channels can be observed.

ABC stacking will be converted to *ABAB* stacking in the boundary region.

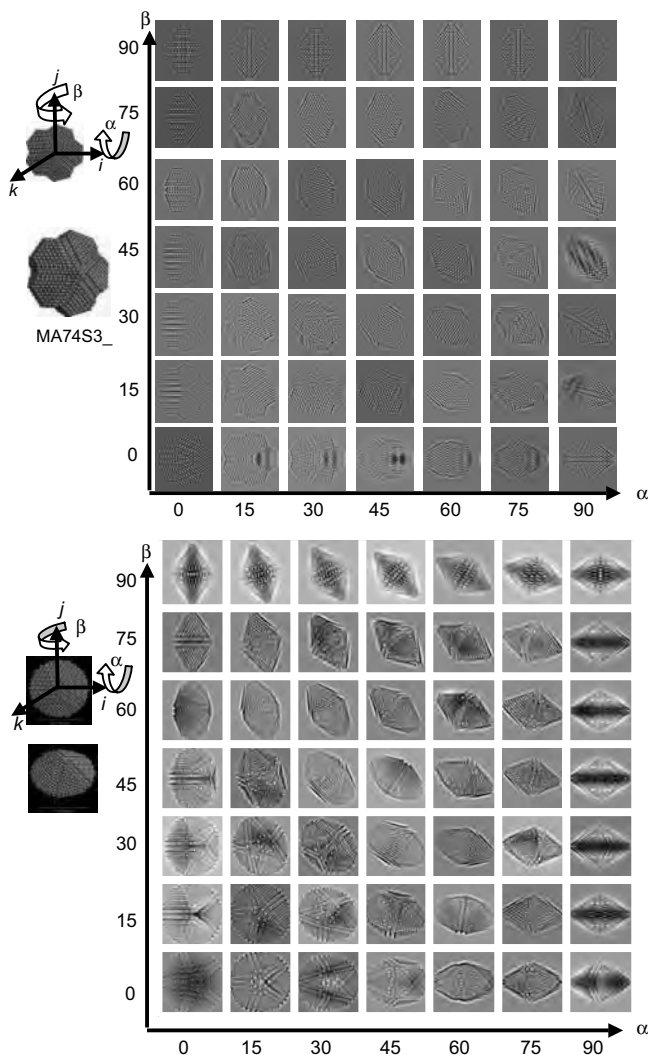
A different situation corresponds to the structure reported in Figure 68. In this case, the stacking is altered only in the last layer of the packing. This is illustrated in


Figure 69. (a) Map of images for the truncated decahedron as function of the tilting angle for the optimum defocus.
Figure 70. (a) Bright field image of a large particle produced by biore-duction showing a typical contrast of channels in the twin boundaries in the interface. (b) and (c) show the high-resolution image of deca-hedral shape in which the contrast at the boundaries does not change with defocus and can be explained by the model of interface channels discussed in the theoretical section.

Figure 71 in which a regular stacking in a unit of the dec-ahedra is altered in the surface. In other words, the *ABCA* sequence becomes *ABCB*. In Figure 71, each layer is illus-trated in a different color. The yellow atoms correspond to the surface sites. We have found experimentally that this type of decahedron is very stable, especially at small sizes.

The contrast of this particle is very peculiar, and is shown in Figure 72 for a different defocus. In this case, the bound-aries show a very strong contrast at all defocus conditions. This provides a practical way to distinguish this particle from other types of decahedra which, under some focus condi-tions, can produce boundary contrast, as shown before. The contrast of the boundaries will be very strong, as shown in Figure 72. This type of particle is often observed experi-mentally in nanoparticles with sizes ~1.5 nm, as shown in Figure 73(a), or when two metals are present. Figures 73(b)
Figure 71. (a) Packing of atoms in a decahedron showing a stacking fault in the last atomic layer. Different colors correspond to differ-ent layers of the packing sequence, and the *ABCA* sequence becomes *ABCB*. (b) Another view of the same packing, in which the surface atoms are drawn in a smaller size. (c) Side view of the resulting stricture in which a missing atom in the center can be observed.
Figure 72. Sequence of simulated images of a decahedron particle with a missing atom in the center (fivefold site) as the result of surface recontruction. The image is calculated at a different defocus.

and (c) show the HREM image of a particle of Au-Pd at 50%–50% in which, in many places, it is possible to observe the surface atom vacancy. In general, it can be said that the central atom vacancy is a unique feature of this type of particle.

Finally in some cases irregular or asymmetric decahedral shape is produced. This was described by Uppenbrink and Wales [105] and most likely is the result of the kinetics of growth; a typical example is shown in Figure 74. When the particles grow larger some special shapes are seen as indicated in Figure 75.

5.4. Icosahedral Particles

One of the most frequently observed particles at small sizes corresponds to the icosahedral structure. A typical TEM image of these particles is shown in Figure 76. The profile is typically hexagonal in the threefold orientation.

The most common images are in the two- and three-fold orientation. The calculations of these images are shown in Figure 77 and are consistent with previous calculations [106]. Experimental images of a gold icosahedral particle in a threefold orientation and a twofold orientation are presented in Figures 78(a), (b) and (c), (d) including the FFT, which indicates the symmetry. A less commonly observed orientation is the fivefold. This is probably due to the fact
Figure 73. Decahedral particles, in which a defect was formed in the last layer of atoms. Notice that the particle in (a) does not have a central atom in the fivefold site. The particles in (b) and (c) correspond to an Au-Pd system, and atom vacancies in several sites are observed.
Figure 74. Distorted decahedral particle.

that, under flat surfaces, particles will be tilted until one triangular face (111) becomes in contact with the substrate. This results in most cases in a twofold orientation.

However when the particles are around 1–2 nm, it is possible to observe the fivefold orientation more frequently. This is probably due to truncations on the surface in contact with the substrate. An example of this contrast and an experimental example are shown in Figure 79.

When a bimetallic particle is synthesized, the frequency of the icosahedral particle increases, particularly at the smallest sizes [107].

5.5. Single Twinned and Complex Particles

Twinning is a very general phenomenon which might happen in the very early stages of growth and does not necessarily result in a decahedral or icosahedral particle. In many cases,
Figure 75. Large irregular decahedral particle grown from a distorted decahedral particle.
Figure 76. Bright field of an icosahedral gold particle showing a typical hexagonal profile.

we can observe a pyramidal particle with a single twin. This particle is shown in Figure 80.

We have observed particles down to 1.5 nm in size which present single twins. Therefore, it is safe to assume that, in some cases, twinning proceeds in the very early stages of growth. However, when the particles grow to larger sizes, coalescence can occur, leading to a more complex type of particles. We have found by molecular dynamics that a double icosahedral structure can be produced very often. In this structure, we have two interpenetrating icosahedra to form a double icosahedron, as shown in Figure 81. This structure
Figure 78. Experimental images of icosahedral particles and their corresponding FFT. (a), (b) threefold orientation. (c), (d) twofold orientation.
Figure 79. Model and image simulations of an icosahedral particle in fivefold symmetry (upper portion) and experimental images for a gold particle in the lower part. In both cases, we include the FFT.

Figure 80. HREM image of a single twin particle and its corresponding FFT.
Figure 81. (a) Model for a double icosahedron obtained by molecular dynamics. (b) simulated image. As can be seen, one part of the structure is a fivefold orientation and the other one is at fivefold orientation.
Figure 82. HREM image of a gold particle showing surface faceting.

corresponds to a minimum in the total energy, and has been observed experimentally by Hofmeister's group [108].

5.6. Surface Faceting in Nanoparticles

In many cases, the particles can present a surface faceting, especially when they are annealed or heated *in-situ*. This faceting is relevant since it can be related to the catalytic activity of the particles; an example is shown in Figure 82. The presence of steps will increase the particle curvature, yielding an almost spherical particle. We have observed that faceting results in (110) and (112) faces.

6. CONCLUSIONS

We have made a systematic description of the most significant geometries which are formed in nanoparticles. We have calculated the number of different atomic sites and growth characteristics of the nanoparticles. It has been shown that the models correspond closely with the experimental HREM and diffraction data. New types of particles have been described in this work, which correspond to a new family of decahedral structures. We expect that, as the field advances and new synthesis routes for particles ~1 nm are developed, all the if predicted clusters will be observed. This work also illustrates the richness of the crystallography of nanoparticles and clusters. Unlike the bulk materials, fivefold symmetry in nanoparticles produces a very rich landscape of structures.

LIST OF SYMBOLS

ν	Order of the cluster of Number of crusts in the cluster
z	Total coordination
N_σ	Number of surface sites
N	Total number of sites in the cluster
N_{shell}^ν	Number of layers in the shell ν
N_{shell}^T	Total number of shells in the cluster of order ν
S	Squared face
T	Triangular face
H	Hexagonal face
RF	Rectangular face
R	Rhombohedral face
TR	Trapezoidal face
PF	Pentagonal face
TF	Equatorial triangular face
TI	Isosceles triangular face
TE	Equilateral triangular face
E	Edge
EE	Edge on the equator
EV	Vertical edges on the equator
ET	Edges between PF and TF
EI	Edge between TI faces
ER	Edge between R faces
EP	Edge toward pole sites
ES	Edges between square and hexagonal faces in truncated octahedrons
EH	Edges between hexagonal faces in truncated octahedrons
EV'	Edges joining V'
$E34$	Edges joining V3 and V4
V	Vertex
V'	Vertex at the end of truncated *EP*
VE	Vertex on the equator
VP	Vertex on pole sites
$V3$	Vertex where converge TI, TE and RF
$V4$	Vertex where converge TI and RF
SE	Sites in a plane just over the equator
EC	Sites on the equator
SEC	Layer of the total of SE sites plus the total of EC sites
N_I	Number of I sites, I= S, T, H, R, RH,
$N_{t_{SE}}$	Total number of SE sites in the cluster
$N_{t_{EC}}$	Total number of EC sites in the cluster
fcc	Face-centered cubic
fccc	Face-centered cubic with a central site
OCTAC	Octahedron with a central site type fccs
OCTTC	Truncated octahedron with a central site type fccs
fccs	Face-centered cubic without a central site
OCTAS	Octahedron without a central site type fccs
OCTTS	Truncated octahedron without a central site type fccs
bcc	Face-centered cubic
DODE	Dodecahedron
CO	cubooctahedron
ICO	Icosahedron
TI_h	Truncated icosahedron
decmon	Decahedron of Montejano, described originally by J. M. Montejano-Carrizales

mrdec Montejano's reconstructed decahedron, described originally by J. M. Montejano-Carrizales and J. L. Rodríguez-López

TEM Transmission electron microscope/microscopy

STEM Scanning transmission electron microscope/microscopy

HREM High resolution electron microscope/microscopy

MEMS Micro-electro-mechanical system

FFT Fast Fourier transform

GLOSSARY

Equivalent sites Sites located at the same distance from the origin, which occupy the same geometric place and have the same environment, that is, the same number and type of neighbors.

EC layer The layer formed by the total of sites in the plane of the equator of decahedral structures.

Geometric characteristics The set of the number of the different type of sites, the number of sites for each type of site, the number of sites by shell, of surface sites and the total of sites for each structure.

SE layer The layer formed by the total of sites in the plane just above the equator of decahedral structures.

SEC layer The layer formed by the joint between the SE layer and the EC layer.

Site coordination The number of first nearest neighbors of the site with layers of its same shell, with interior and exterior shells, and it will be characteristic of each site.

Standard coordinates Site coordinates described by triads (a, b, c), a, b and c are integers, where the total number of sites is obtained by doing permutations and commutations of the positive and negative values of a, b and c.

Cyclodextrins and Molecular Encapsulation

J. Szejtli

Cyclolab Ltd., Budapest, Hungary

CONTENTS

1. INTRODUCTION

The interaction of two or more molecules which results in significant changes in their properties without establishing covalent chemical bond(s) between them is the subject of the supramolecular chemistry. Because one molecule is the possible smallest unit of any compound, the smallest nanostructure is a few nanometer sized molecular structure. A larger cylinder-shaped molecule, which is able to include another smaller molecule (of adequate size and polarity) into its axial cavity itself is a capsule of molecular size.

The temporary or static inclusion of other molecules into the cavity of a so-called "host" molecule without establishing covalent bond results in broadly and practically very well utilizable effects, which belong to the ultimate limits of the nanotechnology.

The cyclodextrins are toroidal (conical cylinder) shaped hollow molecular structures; their outer diameter is 13.7 to 16.9 nanometers, height uniformly 7.8 nanometers, and their axial cavity about 0.57 to 0.95 nanometers wide. They are produced by a relatively simple enzymic conversion technology from starch.

A cyclodextrin (CD) molecule is the possible smallest (nano)capsule: in most cases another, smaller molecule can be inserted into its axial cavity. This "molecular encapsulation" results in smaller or larger changes in the physical and chemical properties of the encapsulated molecules.

While in the 1970s this possibility was not more than a scientific curiosity, by the beginning of the 21st century it became a widely used industrial technology; cyclodextrins are produced and utilized in thousand ton amounts. The number of cyclodextrin containing products and cyclodextrin utilizing technologies increases steadily—the cyclodextrin market increases yearly by about 15 to 20%.

By end the of 2002, the number of CD-related publications is more than 26.000, representing more than 170,000 printed pages [1–26].

While 30 years ago about four to five CD papers were published monthly, in 2002 that many are published daily.

About 16% of all CD-relevant publications are dedicated to the fundamentals of cyclodextrin chemistry and technology (i.e., the physical and chemical properties of cyclodextrins, their enzymology, toxicology, production, and derivatives). This section also includes the numerous review articles on CDs.

Nearly 22% of the publications are dedicated to studies of the CD-inclusion phenomena. These works are generally not directly practice-oriented, dealing with energetics and kinetics of inclusion, X-ray, Fourier transform infrared, liquid and solid phase nuclear magnetic resonance (NMR), electron paramagnetic resonance, circular dichroism, Raman spectroscopy, enhancement of luminescence and phosphorescence, thermal analysis, interaction of CDS with specific guest types, enzyme modelling with CDs and CD derivatives, preparation, analysis of cyclodextrin complexes, etc. These methods, as well as the correlation between the complexation and various structural and external parameters, form the basis for all practical applications of CDs.

The largest group of CD papers, nearly 25%, is dedicated to the pharmaceutical application of CDs. The large number (nearly 5000) of drug/CD related papers and patents is a little misleading, because many authors publish the same result in different journals under different titles, but with virtually identical content. Rediscoveries are published frequently, simply because the authors did not read the earlier literature; in essence they have discovered something that was published earlier. Because of the many repetitions, and the

nonfeasible ideas, only about 30% of the published papers disclose really new and significant results.

Actually only 7% of the CD-related papers are dedicated directly to the food, cosmetic, and toiletry applications of CDs, but at the same time about 70% of all cyclodextrins produced are used in this field. The approval process for CD-containing products in this field is much simpler and faster than in the case of the drug/CD formulations. The amount of CD used in a single cosmetic or toiletry product might be larger, by orders of magnitude, than the total amount used in drugs.

Presently, about 11% of the CD literature is dedicated to the application of CDs in the chemical and biotechnological industries.

About 25% of the CD literature involves the application of cyclodextrins in analytical chemistry and diagnostic preparations. The analytical applications of CDs refer mainly to the application of cyclodextrins in gas chromatography, in high performance liquid chromatography, and in capillary zone electrophoresis, but some dozen papers are dedicated to thin-layer chromatography, to enhancement of ultraviolet-visible (UV-VIS) absorption, luminescence/phosphorescence by CDs, and to increasing the sensitivity of the related analytical methods. Apparently, it is difficult to find a separation problem on an analytical scale which could not be solved by using the appropriate CD.

2. CYCLODEXTRINS

2.1. Chemistry

Cyclodextrins comprise a family of three well known industrially produced major and several rare, minor cyclic oligosaccharides [1, 4, 9, 19]. The three major cyclodextrins are crystalline, homogeneous, nonhygroscopic substances, which are toruslike macrorings built up from glucopyranose units (Fig. 1). The α-cyclodextrin (Schardinger's α-dextrin, cyclomaltohexaose, cyclohexaglucan, cyclohexaamylose, αCD, ACD, C6A) comprises six glucopyranose units, βCD (Schardinger's β-dextrin, cyclomaltoheptaose, cycloheptaglucan, cycloheptaamylose, βCD, BCD, C7A) comprises seven such units, and γCD (Schardinger's γ-dextrin, cyclomaltooctaose, cyclooctaglucan, cyclooctaamylose, γCD, GCD, C8A) comprises eight such units (Fig. 1). The most important characteristics of the CDs are summarized in Table 1.

As a consequence of the $^4C_1$ conformation of the glucopyranose units, all secondary hydroxyl groups are situated on one of the two edges of the ring, whereas all the primary ones are placed on the other edge. The ring, in reality, is a cylinder or, better said, a conical cylinder, which is frequently characterized as a doughnut or wreath-shaped truncated cone. The cavity is lined by the hydrogen atoms and the glycosidic oxygen bridges, respectively. The nonbonding electron pairs of the glycosidic oxygen bridges are directed toward the inside of the cavity producing a high electron density there and lending to it some Lewis-base characteristics.

The C-2-OH group of one glucopyranoside unit can form a hydrogen bond with the C-3-OH group of the adjacent
Figure 1. Chemical structure of α-, β-, and γCDs.

glucopyranose unit. In the βCD molecule, a complete secondary belt is formed by these H-bonds; therefore the βCD is a rather rigid structure. This intramolecular hydrogen bond formation is probably the explanation for the observation that βCD has the lowest water solubility of all CDs.

The hydrogen-bond belt is incomplete in the αCD molecule, because one glucopyranose unit is in a distorted position. Consequently, instead of the six possible H-bonds, only four can be established simultaneously. The γCD is a noncoplanar, more flexible structure; therefore it is the more soluble of the three CDs.

Figure 2 shows a sketch of the characteristic structural features of CDs. On the side where the secondary hydroxyl groups are situated, the cavity is wider than on the other side where free rotation of the primary hydroxyls reduces the effective diameter of the cavity.

The cyclodextrins are produced from starch by enzymic conversion [9, 17].

The starch might be of any origin: maize, potato, tapioca, etc. All starch consists of two essential components: the amylose (2 to 70%), which is a linear glucose polymer (several hundreds or thousands of D-glucopyranose units are linked by α-1,4 glucosidic linkages), and the amylopectin, which is a ramified structure. The main linkage type between the D-glucopyranoside units is also of α-1-4 type, but every 20th to 30th glucose is connected to another polyglucan chain by an α-1,6-glucosidic linkage.

Splitting the glucosidic linkage (catalyzed by acid, or enzyme) the formed free carbenium cation will react immediately with another hydroxyl-containing molecular entity. If

Table 1. Characteristics of α-, β-, and γCD.

Parameter	α	β	γ
No. of glucose	6	7	8
Mol. wt.	972	1135	1297
Solubility in water (g/100 ml^{-1}) at room temp.	14.5	1.85	23.2
$[\alpha]_D$ 25°	150 ± 0.5	162.5 ± 0.5	177.4 ± 0.5
Cavity diameter (Å)	4.7–5.3	6.0–6.5	7.5–8.3
Height of torus (Å)	7.9 ± 0.1	7.9 ± 0.1	7.9 ± 0.1
Diameter of outer periphery (Å)	14.6 ± 0.4	15.4 ± 0.4	17.5 ± 0.4
Approx. volume of cavity (Å)^3	174	262	427
Approx. cavity volume in 1 mol CD (ml)	104	157	256
In 1 g CD (ml)	0.10	0.14	0.20
Crystal forms (from water)	hexagonal plates	monoclinic parallelograms	quadratic prisms
Crystal water wt%	10.2	13.2–14.5	8.13–17.7
Diffusion constants at 40 °C	3.443	3.224	3.000
Hydrolysis by A. oryzae α-amylase	negligible	slow	rapid
pK (by potentiometry) at 25 °C	12.332	12.202	12.081
Partial molar volumes in solution (ml mol^{-1})	611.4	703.8	801.2
Adiabatic compressibility in aqueous solutions (ml mol^{-1} bar^{-1} 10^4)	7.2	0.4	−5.0

the reaction partner is water, the reaction is called hydrolysis; the final product is glucose. If the reaction partner is, for example, methanol, the reaction product is methyl-glucopyranoside. If the reaction partner is the sixth, seventh, or eighth glucopyranose unit of the same amylose

Figure 2. Dimensions and hydrophilic/hydrophobic regions of the CD molecules.

molecule or amylopectin molecule side chain, the product is a cyclodextrin. Because the minimum energy conformation for both the amylose as well as the segments of the amylopectin molecule is the helical (wormlike) structure, one turn is composed of six, seven, or eight glucose units. Consequently the sixth, seventh, or eighth glucopyranose unit will be in the immediate vicinity of the newly formed carbenium cation. This "splitting and the ring closing" process is catalyzed by the so called cyclodextrin-glucosyl-transferase enzyme.

2.2. Production

The cyclodextrin glucosyl transferase enzyme (CGT-ase) is produced by a large number of microorganisms, like Bacillus macerans, Klebsiella oxytoca, Bacillus circulans, Alkalophylic bacillus No. 38-2, etc. Genetic engineering has provided more active enzymes, and probably, in the future, mostly these enzymes will be used for industrial CD production [17].

The first step in CD production is the liquefaction of the starch at elevated temperature. To reduce the viscosity of the rather concentrated (around 30% dry weight) starch solution, it has to be hydrolyzed to an optimum degree. The prehydrolyzed starch must not contain glucose or low molecular oligosaccharides, because they strongly reduce the yield of the formed CDs. After cooling to the optimum temperature, CGT-ase enzyme is added to the starch solution. In the so-called nonsolvent technology, the formed α-, β-, and γCDs have to be separated from the complicated partially hydrolyzed mixture. In the case of the solvent technology, an appropriate complex-forming agent is added to the conversion mixture. If toluene is added to this system, the formed toluene/βCD complex is separated immediately, and the conversion is shifted toward the formation of βCD (Fig. 3). If n-decanol is added to the conversion mixture, mainly αCD will be produced, while in case of cyclohexadecenol the main product is γCD. Various other complex-forming agents can be used. The selection depends on price,
Figure 3. Production of βCD: in the presence of toluene the formed βCD is converted immediately to a water-insoluble toluene/βCD complex. Therefore the main product will be βCD. In the presence of decanol αCD, hexadecenol γCD is the isolated final product.

toxicity, and explosivity, but mainly on the efficiency of the removal of the solvents from the crystalline end-product. The insoluble complexes are separated from the conversion mixture by filtration. The removal of the solvents from the filtered and washed complex is generally made after suspending it in water by distillation or extraction. The aqueous solution obtained after removal of the complexing solvent is treated with activated carbon and filtered. The cyclodextrins are then separated from this solution by crystallization and filtration. The homegeneity of the industrially produced cyclodextrins is generally better than 99%.

2.3. Biological Effects

2.3.1. Absorption and Metabolism

For application of cyclodextrins in the pharmaceutical and food industry, the fate of cyclodextrins in the mammal organisms is a crucial question. Cyclodextrins are consumed by humans or animals (as orally administered pharmaceuticals, or as food additives) either as free cyclodextrins or their inclusion complexes, containing some drug, flavor, or other guest substance. The inclusion complexes undergo very rapid dissociation under physiological conditions in the gastrointestinal tract; therefore only the absorption of the free cyclodextrin deserves attention [8, 16, 17].

Summarizing the available data and experimental observations the following conclusions can be drawn. The CD molecule is a relatively large molecule. Its outer surface is strongly hydrophilic. It is a true carrier. It brings the hydrophobic guests into solution, keeps them in dissolved state, and transports them to the lipophilic cell membrane, but after delivering the guest to the cell (because it has higher affinity to the guest than the cyclodextrin), the cyclodextrin remains in the aqueous phase.

Only an insignificant amount of orally administered CD is absorbed from the intestinal tract in intact form. The source of eventual CD-elicited toxic phenomena might be that CDs can solubilize and facilitate the otherwise insoluble, nonabsorbable toxic compounds, like polyaromatic hydrocarbons, pesticides, etc. The preponderant part of orally administered cyclodextrin is metabolized in the colon, by

the colon microflora. The primary metabolites (acyclic maltodextrins, maltose, and glucose) are then further metabolized, absorbed like the starch, and finally excreted as CO_2 and H_2O.

While the metabolism of starch takes place in the small intestines, the cyclodextrin is metabolized in the colon. Correspondingly the maximum intensities of metabolism are observed for starch around 1 to 2 hours and for CDs 6 to 8 hours after consumption, respectively.

The metabolism of αCD is slower and that of γCD is much faster than that of βCD. The chemically modified CDs are, however, very resistant to enzymic degradation. Methylated and hydroxypropylated CDs (and probably all other more or less substituted CD derivatives) can be absorbed from the intestinal tract to a quite considerable extent and can get into the circulation.

2.3.2. Toxicology

Upon parenteral administration all CDs can interact with the components of cell membranes, but the extent of this interaction is very different. This cell-damaging effect can be characterized by CD concentration, which results in an 50% haemolysis of the erythrocytes or which reduces to 50% the luminescence of an Escherichia coli suspension. In these experiments, the more hydrophobic (but very well soluble) derivatives like dimethyl βCD showed the largest effects. Because the cell-damaging effect is a consequence of CD complexation of cell-wall components like cholesterol and phospholipids, βCD and particularly its more hydrophobic derivatives, like the dimethyl βCD, show the strongest cell-membrane damaging effect among all CDs. The γCD and its derivatives are less toxic, because their affinity (through the wider CD cavity) to cholesterol and phospholipids is lower. Administering the CDs at a rate that their actual concentration does not reach the haemolytic threshold concentration (slow infusion, or absorption from the intestinal tract, or through the skin), this immediate toxic consequence can be avoided, but not the kidney-toxic effect. Parenteral administration of βCD is not possible, because it forms the most stable cholesterol/CD complex, which will be accumulated in the kidneys, destroying cells. Apparently γCD is free from this noxious property: it is well soluble and does not form stable, easily crystallizable complexes with any vital component of the circulation. The cavity of γCD is too large and that of the αCD is too small for cholesterol.

HPβCD (hydroxypropyl βCD) does not form insoluble kidney-damaging cholesterol complex crystals; therefore it can be injected even in rather large doses without any irreversible consequences, but chronic treatment again showed unwanted side-effects: it forms soluble cholesterol/HPβCD complex in the circulation. In the kidneys this less stable complex dissociates. The HPβCD will be excreted, but the cholesterol remains in the kidneys. Long-term parenteral administration of HPβCD will heavily load the kidneys with cholesterol—not considering other toxic effects of HPβCD.

Parenterally only such CDs can be administered that have a low affinity to cholesterol. The best CD would be the one that is stable in aqueous solution, has a high drug solubilizing and stabilizing capacity, but after injecting into the circulation rapidly decomposes. Regrettably we have not yet such a derivative.

3. CYCLODEXTRIN DERIVATIVES

3.1. Aim of Derivatization

For a series of reasons (price, availability, approval status, cavity dimensions, etc.) the βCD is the most widely used and represents at least 95% of all presently produced and consumed CDs. It is used for many purposes; however, its anomalous low aqueous solubility (and the low solubility of most of its complexes) is a serious barrier in its wider utilization. Fortunately by chemical or enzymatic modifications the solubility of all CDs can be strongly improved, and instead of the 18 g/L aqueous βCD solutions 500 g (or more)/L aqueous βCD derivative solutions can easily be prepared.

In the cyclodextrins every glucopyranose unit has 3 free hydroxyl groups which differ in both their functions and reactivity. The relative reactivities of C(2) and C(3) secondary and C(6) primary hydroxyls depend on the reaction conditions (pH, temperature, reagents). In βCD 21 hydroxyl groups can be modified substituting the hydrogen atom or the hydroxyl group with a large variety of substituting groups like alkyl-, hydroxyalkyl-, carboxyalkyl-, amino-, thio-, tosyl-, glucosyl-, maltosyl-, etc. groups, thousands of ethers, esters, anhydro-deoxy-, acidic, basic, etc. derivatives can be prepared by chemical or enzymatic reactions. The aim of such derivatizations may be:

- to improve the solubility of the CD derivative (and its complexes)
- to improve the fitting and/or the association between the CD and its guest, with concomitant stabilization of the guest, reducing its reactivity and mobility
- to attach specific (catalytic) groups to the binding site (e.g., in enzyme modeling),
- to form insoluble, immobilized CD-containing structures, polymers, (e.g. for chromatographic purposes).

3.2. Derivate Types

From the thousands of CD derivatives described in hundreds of scientific papers and patents only a few can be taken into consideration for industrial scale synthesis and utilization. Complicated multistep reactions, using expensive, toxic, environment-polluting reagents and requiring purification of the products by chromatography, are feasible to prepare derivatives only on laboratory scale. To produce tons at an acceptable price only about a dozen of the known CD derivatives can be taken into consideration.

Among industrially produced, standardized, and available (even in ton amounts) βCD derivatives the most important ones are the heterogeneous, amorphous, highly water soluble methylated βCD and 2-hydroxypropylated βCDs (Fig. 4). Due to its heterogeneity the HPβCD cannot be crystallized, which is an important advantage (e.g., at producing liquid drug formulations).

The first hydroxypropyl-βCD and hydroxypropyl-γCD containing drug formulations are already approved and marketed in several countries.

A methylated βCD is more hydrophobic than the βCD itself; therefore it forms a more stable (but soluble) complex with cholesterol. Its affinity to cholesterol is so strong that it extracts cholesterol from the blood cell membranes, resulting in hemolysis already at around 1 mg/mL concentration.
Figure 4. Structure of the heptakis (2,6-O-dimethyl)-βCD and of a hydroxypropyl βCD of DS∼4.

A particular methylated βCD, the heptakis (2,6-di-O-methyl-βCD) is a crystalline product (Fig. 4). It is extremely soluble in cold water but insoluble in hot water. Therefore, its purification, and also the isolation, of its complexes is technically very simple. Up to now no better solubilizer has been found among the CDs. It is available in better than 95% isomeric purity for injectable drug formulation (for example radio-pharmaceuticals) but for widespread industrial application the cheaper noncrystalizable randomly methylated βCD (called RAMEB) is produced and marketed.

Enzymatically modified CDs are produced, for example, by reacting βCD with starch in the presence of pullulanase enzyme. One or two maltosyl or glucosyl groups will be attached to the primary side of the CD ring with α-1,6 glycosidic linkage. The product is the so-called "branched" CD (mono- or dimaltosyl or mono- or diglucosyl CD) which is very well soluble in water, being a heterogeneous, noncrystallizable substance. It is produced and used in the food industry, mainly in Japan, for example, for production of stable flavor powders.

There has been increasing interest toward the per-acyl-CDs. All acetylated CDs from per-acetyl to per-octanoyl esters have been studied partly as retarding drug carriers and partly as bioadhesive, film-forming substances to be used in transdermal drug delivery systems. The heptakis-(sulfobutyl)-βCD is very well soluble in water, is noncrystallizable, and even at extreme high doses seems to be free from any toxic side-effects. It can be used as a chiral separating agent in capillary zone electrophoresis, but the aim of the intensive research is to use it as a parenteral drug carrier, for preparation of aqueous injectable solutions of poorly soluble drugs. A few such drug complexes are already approved and marketed.

The CD sulfates possess many similar properties as the heparin without its anticoagulating effect. Apparently they can reduce the blood supply of tumor tissues through inhibiting the formation of new arteries (=antiangiogenesis).

The monochloro-triazinyl βCD is produced on industrial scale from CDs and cyanuric chloride. It is reactive with cellulose fibers in alkaline medium (see at the application of CDs in textiles).

To elongate the actual CD cavity substituents are attached to the primary or secondary side. This elongation may be hydrophylic in which case hydroxyalkyl groups are attached

to the ring, or it might be hydrophobic. For example substituting the primary hydroxyl groups with long fatty-acid chains, "medusa"-like molecules can be prepared. These molecules behave as detergents while retaining their complex forming ability. The coming years will decide how utilizable these derivatives are.

The chair conformation of the CD ring can be modified by inverting the position of some hydroxyl groups. For example eliminating the tosyl group in alkaline medium from a CD-tosyl derivative, 2,3-anhydro derivatives can be prepared. Opening the anhydro ring one hydroxyl group will take up an inverted position, and this way cycloaltrins are formed. Eliminating an appropriate leaving group from the primary side, 3,6-anhydro-CDs are formed. Because of the twisted conformation of the anhydro glucopyranose unit the properties of CDs—for example, their solubility—are strongly increased.

It is possible to close one side of the CD cavity, for example, by overbridging the primary or secondary side with an appropriate bifunctional substituent. It is expected that these overbridged CDs will form more stable complexes with certain guests.

A dozen various CD derivatives are used in gas chromatography, liquid chromatography, and capillary zone electrophoresis.

For other industrial purposes where toxicological demands do not play a decisive role, epichlorohydrin cross-linked, hydroxyethylated, or sometimes (apparently rather fancy, but by its use justified) mixed ethers–esters, like heptakis (2,6-di-O-methyl)-3-O-trifluoroacetyl-βCD and similar derivatives, are produced and utilized.

It seems to be very probable that for drug carrier purposes four or five different CD derivatives will be developed and produced in the future, because no one of them is able to fulfill alone all the very strict requirements, which are usual in the case of a parenteral drug carrier.

For other industrial purposes the production of hundreds of tons of alkylated, hydroxyalkylated, and acylated CDs is prognosticated by end of first decade of the 21st century.

4. INCLUSION COMPLEXES

4.1. Mechanism and Equilibria

In an aqueous solution, the slightly apolar cyclodextrin cavity is occupied by water molecules which are energetically unfavored (polar–apolar interaction) and therefore can be readily substituted by appropriate "guest molecules" which are less polar than water (Fig. 5). The dissolved cyclodextrin is the "host" molecule, and the "driving force" of the complex formation is the substitution of the high-enthalpy water molecules by an appropriate "guest" molecule. One, two, or three cyclodextrin molecules contain one or more entrapped "guest" molecules. Most frequently the host:guest ratio is 1:1. This is the essence of "molecular encapsulation" [17].

This is the simplest and most frequent case. However, 2:1, 1:2, 2:2, or even more complicated associations and higher order equilibria exist, almost always simultaneously.
Figure 5. Schematic representation of the association–dissociation of the host (CD) and guest (p-xylene). The formed guest/host inclusion complex can be isolated as a microcrystalline powder.

The formed inclusion complexes can be isolated as stable crystalline substances. Upon dissolving these complexes, an equilibrium is established between dissociated and associated species, and this is expressed by the complex stability constant K_a. The association of the CD and guest (D) molecules, and the dissociation of the formed CD/guest complex is governed by a thermodynamic equilibrium:
$$CD + D \rightleftharpoons CD \cdot D$$

$$K_{1:1} = \frac{[CD \cdot D]}{[CD][D]}$$

Generally, the study of the interaction between a CD and a potential guest begins with registration of the solubility isotherm (phase solubility diagram, Fig. 6). Adding the potential "guest" to an aqueous solution and agitating (stirring, shaking) until the equilibrium is attained
Figure 6. Registering the solubility of a poorly water soluble guest as a function of the CD concentration in aqueous solution, different solubility isotherms can be obtained, depending on the type of CD and properties of the guest. Solubility isotherm types: S_o = solubility of guest in the absence of CD; S_t = concentration of dissolved guest (free + complexed); and S_c = solubility limit of the poorly soluble complex. Isotherm types A_p, A_L, and A_N = very soluble complexes formed (solubility limit determined by solubility of the CD). Isotherm B_S = complex of limited solubility is formed. Isotherm B_I = insoluble complex is formed.

(from 3 h to 1), the following visual observations may be expected:

If the guest is *well soluble* in water then

- No visual change, but a shift in the UV spectrum, a change in the NMR chemical shift values, enhanced fluorescence, or induced circular dichroism, etc. may recorded.
- Precipitate is formed already at low concentrations of the guest which allows one to conclude to the complex formation. (The majority of water miscible solvents at high concentration precipitate the CDs, but it does not necessarily mean complex formation.)
- Solubility of the CD increases significantly (e.g., solubility of βCD increases from 18 to over 100 mg/ml) which points to a strong interaction with the CD, but not necessarily inclusion.

If the guest is *poorly soluble* in water, and it is able to form complex with the CD, then its solubility as a function of the CD concentration in most cases will change. This change may be an increase, either monotonously or only to a certain limit, or it may even decrease. The correlation between guest solubility and CD concentration is illustrated by Figure 6.

If only dissolved complex is formed the phase-solubility isotherm is of "A" type, whereas if the solubility of the formed complex is limited, then the isotherm is of the "B" type. In cases where the formed complex is insoluble (type B_I, Fig. 6) the solubility of the guest remains unaltered until all guest molecules are converted into insoluble complexes. Thereafter the concentration of dissolved guest begins to decrease.

When the complex is more soluble than the free guest, but its solubility limit can be reached within the studied CD concentration range, the (S_t) first increases from the aqueous solubility of the guest (S_O) until point "A," where the solubility limit of the complex is reached.

Any further increase in the CD concentration results in no further increase in solubility, but in precipitation of the microcrystalline complex (B_S-type isotherm). Reaching point "B" means that all solid guest has been converted to a less soluble inclusion complex, therefore adding even more CD to the system. The association–dissociation equilibrium will be shifted to association, and the solubility asymptotically approximates to the inherent solubility limit of the complex (S_c).

Theoretically the concentration increase from S_o to A should be identical with the one from zero to S_c (i.e., at point "A" the solution is just saturated for both the guest and its complex). This is, however, only a theoretical case, because in many instances the stoichiometry of a formed complex depends on the concentration ratios. While at the beginning only a 1:1 complex is formed, at higher CD concentration the stoichiometry is more complicated (1:2, 2:3, etc.).

The prevailing complex structure and stoichiometry are not necessarily identical in solution and in the solid state.

If within the studied CD-concentration range the solubility limit of the complex is not reached, the isotherm is of type "A," and "A_L" means a linear increase with unchanged stoichiometry. The "A_P"-type isotherm shows a positive deviation from linearity and this indicates a continuous increase in the stoichiometry of the complex, (i.e., the original 1:1 complex tends to associate with further guests, forming 2:3, etc. compositions). If the isotherm is of "A_N" type, the system is even more complicated because it can point either to an increase of the host ratio within the complex (1:1 to 2:1) or a change in the solute-solvent interaction (hydration, ionization of the guest) or both.

The determination of the complex stability constants and the problems associated with their interpretation are treated in Section 6. The theoretically incorrect, but for practical purposes utilizable, apparent complex stability constant K_C (association constant) for a 1:1 complex can be calculated from the slope and intercept of the initial straight line portion of the diagram as follows:

$$K_c \frac{(S_t - S_o)}{S_o\{[CD]_t - (S_t - S_o)\}} = \frac{\tan \alpha}{S_o(1 - \tan \alpha)}$$

The stoichiometry of the inclusion compound can be deduced by analyzing the length of the plateau region, AB, according to the following equation:

$$\frac{[\text{guest}]}{[\text{CD}]} = \frac{(\text{total guest added to system}) - (\text{guest in solution at point A})}{[\text{CD}]_t \text{ corresponding to plateau region}}$$

This equation means that the concentration of CD, corresponding to the plateau, is equal to that of the host which is consumed for the conversion to the solid inclusion compound, with no free solid guest remaining at point A. The stoichiometry thus estimated by this method should be confirmed by isolation and chemical analysis of the solid inclusion compound. In the case of the B_1-type diagram, the initial rise is not detectable because the inclusion compound is practically insoluble. In the same way, the K_c value is calculated from the A_L-type diagram according to the first equation. From the A_p-type diagram K_c is calculated by iteration. The value of K_c cannot be calculated from an A_N-type diagram.

4.2. Stoichiometry and Crystal Structure

Geometrical rather than chemical factors are decisive in determining the kind of guest molecules which can penetrate into the CD cavity [9, 17]. The α-, β-, and γCDs, with different internal diameters, are able to accommodate molecules of different size. Naphthalene is too bulky for αCD, and anthracene fits only into γCD. Propionic acid is compatible with αCD, but it has no satisfactory fitting in the large cavities. (Fig. 7). The included molecules are normally oriented in the host in such a position as to achieve the maximum contact between the hydrophobic part of the guest and the CD cavity. The hydrophilic part of the guest molecule remains, as far as possible, at the outer face of the complex. This ensures maximum contact with both the solvent and the hydroxyl groups of the host.

Complex formation with molecules significantly larger than the cavity may also be possible. This is done in such a way that only certain groups or side chains penetrate into
Figure 7. Examples of CD complexes: the same CD with different guests, and the same guest with different CDs. Toluene/βCD (A), diphenylamine/βCD (B), long-chain fatty acid/CD (C), short chain fatty acid + diethyl ether ternary βCD complex (D), prostaglandin E2/αCD (E), prostaglandin E2/βCD complex (F), prostaglandin E2/γCD (G) [9].

the carbohydrate cavity (e.g., aromatic amino acid moieties of a polypeptide or protein).

The fitting between host and guest can be visualized by computer graphics. Computer programs are available which, using crystallographically determined bond length and bond angle values and appropriate interaction energy functions, can rapidly ascertain the most probable conformations of a complex. However, if an inclusion can be established on the screen of a computer monitor, it does not necessarily mean that the complex can really be prepared, because the crystallographic data cannot take into account those factors that exist only in aqueous solutions: hydration, ionization, and concomitant torsion of the conformation.

A 2:1 complex of CD and a guest molecule may be formed when the guest is too large (long) to find complete accommodation in one cavity, and its other end is also amenable to complex formation. Such complexes are formed in the case of the vitamin D_3/βCD complex and the much "slimmer" aliphatic chains of n-alkanes and αCD.

In solution both the α- and βCD are highly associated with benzoic acid, but only the βCD complex can be readily crystallized. A crystalline 2:1 complex with αCD and benzoic acid will give a low yield. βCD will perfectly include a benzoic acid molecule; the carboxyl group forms a hydrogen bond with one secondary CD hydroxyl.

The role of substituents in complex formation is demonstrated by the methylnitrophenols. Relative to 4-nitrophenol, methyl groups in positions 2 and 6 have no significant influence on the stability of the αCD complex, but one methyl group in the 3-position will lower the stability of the complex by about two orders of magnitude. 3,5-Dimethyl-4-nitrophenol fails to give a complex at all.

Strongly hydrophilic molecules (very soluble in water) and strongly hydrated and ionized groups are not or are only very weakly complexable. Only molecules which are less polar than water can be complexed by CDs.

Excessively strong cohesive forces between the molecules of the guest impede their separation, which is a precondition for the inclusion. A measure of the cohesion between the molecules of a crystalline substance is the melting point. When the melting point is higher than 250 °C a stable CD complex cannot generally be prepared.

The structure of crystalline CD complexes is not necessarily identical to that of the complexes in solution. In the dissolved state the guest molecule or its corresponding group is located within the cavity of the CD and the whole complex is surrounded by a multilayer hydrate shell. In the crystalline state, however, guest molecules and also some CD molecules include only water molecules; consequently they are incorporated into the crystal lattice as water complexes. Therefore, the isolated amorphous or crystalline complexes are practically never of strictly stoichiometric composition; however, they are stable even if the ring cavities are only partially saturated by apolar guest molecules.

In solution the association–dissociation equilibrium determines the uncomplexed/complexed ratio for the guest and the host. However, depending on properties such as size and shape of the guest, not only 1:1, but also 1:2, 2:1, or 2:2 host:guest complexes may coexist in solution. This will also depend on the CD and/or guest concentration. Even two identical or different guest molecules may be included in one host (ternary complex). For example sodium 1-pyrenesulphonate with βCD forms a 1:1 low stability ($k = 1$ M^{-1}) complex, but with γCD a very stable ($k = 10^6$ M^{-1}) 2:1 complex is formed. At higher γCD concentrations, however, one further γCD will react, resulting in a 2:2 complex. Similarly, γCD forms a 1:1 complex with methyl orange in dilute solution; depending on the concentration 1:2 and 2:2 complexes can also occur. Generally, in aqueous solution with no extreme concentrations, the 1:1 complex is predominant.

CD inclusion complexes always contain water as crystal hydrate. For example, the p-iodoaniline/αCD complex contains four and the krypton and the methanol/αCD complexes contain five molcules of water of crystallization.

In crystalline αCD inclusion complexes, the packing depends largely on the type of guest molecule. The cage-type structure (see Fig. 8) is characteristic for small guests, which fit completely into the cavity. The channel type is observed when the guest is so large that it protrudes on both sides of the cavity.

The structure of the complex changes from the cage to channel type in the homologous series of carboxylic acids. Acetic, propionic, and butyric acids form cage-type structures, but valeric acid is too long to be accommodated in the cage, and from valeric acid onward, only channel-type structures are formed. The ionization of a small guest also results in the conversions of the cage to channel structure. Thus, acetic acid forms a cage-type structure, whereas the ionic potassium acetate prefers a channel-type arrangement.

The brickwork-type cage structure is characteristic of small, neutral, but not fully incorporated guests, which only weakly protrude on one side of the cavity (e.g., monocyclic aromatic compounds). This kind of brick-type cage arrangement has so far only been observed with α- and not with β- and γCD.
Figure 8. Channel (A), herringbone (B), brick-wall (C), head-to-tail (D), and head-to-head (E) alignment of CD rings in their complex crystal structures.

The βCD complexes crystallize with a fishbone, dimeric cage or channel structure.

The typical fishbone structure has been observed only with a few small guests: water, methanol, and ethanol. Larger guests, such as n-propanol, are accommodated in cavities which are formed by two βCD molecules arranged in a head-to-head fashion, although n-propanol is small enough to be enclosed in a monomeric cavity. It appears that the head-to-head dimer formation is favored by βCD.

These "double volume cages" (i.e. head-to-head arranged dimers or even tetramers) are arranged side-by-side in layers. Such adjacent layers are displaced so that the cavities of the dimers or tetramers are closed at both ends, or they are stacked on top of each other. This leads to cage-type structure formation, although the βCD molecules are arranged in a channel-type form. In fact, all the channels formed by βCD are more or less irregular because this molecule has seven glucose units in one ring.

If γCD is crystallized as an "empty" molecule from water, it arranges in a fishbone-type cage structure similar to that observed for α- and βCDs. If, however, a small guest, such as n-propanol, is added, a channel-type structure is formed in which the γCD molecules, with an eightfold symmetry, are stacked along a fourfold symmetry axis, and exactly linear channels are produced.

4.3. Effects of Inclusion

The most important primary consequences of the interaction between a poorly soluble guest and a CD in aqueous solution are as follows:

(a) The concentration of the guest in the dissolved phase increases significantly, while the concentration of the dissolved CD decreases. This latter point is not always true, however, because ionized guests, or hydrogen-bond establishing (e.g., phenolic) compounds may enhance the solubility of the CD.

(b) The spectral properties of the guest are modified. For example, the chemical shifts of the anisotropically shielded atoms are modified in the NMR spectra. Also, when achiral guests are inserted into the chiral CD cavity, they become optically active and show strong induced Cotton effects on the circular dichroism spectra. Sometimes the maximum of the UV spectra are shifted by several nm and fluorescence is very strongly improved, because the fluorescing molecule is transferred from the aqueous milieu into an apolar surrounding.

(c) The reactivity of the included molecule is modified. In most cases the reactivity decreases (i.e., the guest is stabilized), but in many cases the CD behaves as an artificial enzyme, accelerating various reactions and modifying the reaction pathway.

(d) The diffusion and volatility (in case of volatile substances) of the included guest decreases strongly.

(e) The formerly hydrophobic guest, upon complexation, becomes hydrophilic; therefore its chromatographic mobility is also modified.

And in the solid state:

(f) The complexed substance is molecularly dispersed in a carbohydrate matrix forming a microcrystalline or amorphous powder, even with gaseous guest molecules.

(g) The complexed substance is effectively protected against any type of reaction, except that with the CD hydroxyls, or reactions catalyzed by them.

(h) Sublimation and volatility are reduced to a very low level.

(i) The complex is hydrophilic, easily wettable, and rapidly soluble.

When, in an aqueous system, the formation of the CD-inclusion complex can be detected (e.g., by NMR or circular dichroism, or through a catalytic effect), this does not mean necessarily that a well-defined crystalline inclusion complex can be isolated. The two main components of the driving force of the inclusion process are the repulsive forces between the included water molecules and the apolar CD cavity, on the one hand, and between the bulk water and the apolar guest, on the other hand. This second factor does not exist in the crystalline (dry) state. Therefore it is not uncommon that the complex formation is convincingly proven in solution, but the isolated product is nothing other than a very fine dispersion of the CD and the guest.

The absolute majority of all practical applications of CDs are based on their inclusion complex forming capacity.

4.4. Preparation of CD Complexes

The preparation of cyclodextrin inclusion complexes is simple; however, the conditions have to be "tailor made" for any guest substances [2, 4, 17]. The complexation may be performed in homogeneous solution, or in a suspension, under pressure, or by simple mixing of the components, by melting together the potential guest with the CD. The principle is illustrated in Figure 9.

When preparing a CD complex in solution the presence of water is absolutely necessary. Either pure water or some
Figure 9. Schematic representation of the production of a CD complex.

aqueous system containing an organic solvent can be used. The use of organic solvent is necessary when the guest molecule is hydrophobic, or its melting point is over 100 °C. Therefore it cannot be dispersed finely in an aqueous CD solution. In such a case, organic solvents have to be used for solubilization of the guest.

Only a very limited number of organic solvents can be used, because the majority of them are excellent complex-forming partners. Using ethanol, at least a small amount of it will be retained very firmly in the formed complex (seldom more than 1–2% by weight of the product). Other solvents, like diethyl ether, do not form a stable complex with βCD; however, together with, for example, prostaglandin-$F_{2\alpha}$, a small amount of a ternary complex is formed, and then the diethyl ether cannot be removed, even at 105 °C in *vacuo*.

Complex for gases (xenon, chlorine, ethylene, krypton, carbon, dioxide, etc.) can be prepared by exposing a saturated αCD solution to the gas at 7–120 atm for 5–8 days at 20 °C.

In the so-called "slurry" method the CD and the guest are not dissolved but only finely suspended in water at ambient temperature with vigorous stirring. (The use of ultrasonification may even improve the procedure by accelerating the dispersion of solid phase.)

The reaction mixture is stirred intensively for 4–8 h (generally in the case of light oils, e.g., essential oils, terpenoids), or even for several days (24–72 h) in the case of heavy oils (e.g., natural waxes, higher terpenoids, balms) or when the guest substance is solid and no solvent is used. This method is the most feasible for industrial purposes.

A variation of this method uses even less water.

In the so-called "kneading" method the cyclodextrin is intensively kneaded with a small amount of water to which the calculated amount of the guest component is added directly without using any solvent. Because the initial cyclodextrin–water complex is energetically less favored than the CD–guest complex, the cavity water molecules will

be substituted by the guests. Besides this, the crystal lattice of the complex is also different from that of the water–CD complex. Therefore the reaction runs toward inclusion. Owing to their different crystal structure, the molecular layers of the inclusion complex formed on the surface of the parent cyclodextrin will dissociate from the crystal. Thus the entire cyclodextrin crystal quickly becomes disorganized and transformed into the guest–CD complex.

Industrially the solution or slurry is freeze-dried in the case of expensive and very sensitive guests, like prostaglandins, vaccines, and taxanes, or spray-died like omeprazole, or simply kneaded and dried in air or *in vacuo* like nitroglycerin, essential oils, etc.

5. INDUSTRIAL APPLICATIONS

5.1. Pharmaceutical Industry

The complexation of a drug molecule with a CD should be taken into consideration when the bioavailability and/or the chemical stability of the drug is not satisfactory, or the usual formulation methods do not result in an acceptable product. Indications for CD complexation include:

- The bioavailability of the drug (upon oral, dermal, pulmonar, mucosal, etc. application) is incomplete or irregular, because the drug is poorly soluble.
- The rate of dissolution is low; even in case of a complete absorption, the time to reach the effective blood level of the orally administered drug is too long.
- The drug is chemically unstable (on account of its autodecomposition, polymerization, or degradation by atmospheric oxygen, absorbed humidity, light, etc.). No marketable formulation with satisfactory shelf-life can be produced.
- The drug is physically unstable. Volatilization or sublimation result in losses. By migration the originally homogeneous product becomes heterogeneous. On account of its hygroscopicity it liquifies by atmospheric humidity.
- Because of the low solubility no aqueous eye-drop or injectable solution (or other liquid formulation) can be prepared.
- The drug is a liquid, but its preferred pharmaceutical form would be a stable tablet, powder, aqueous spray, etc.
- The drug is incompatible with other components of the formulation.
- The dose of the lipid(like) hardly homogenizable drug is extremely low. Therefore content uniformity of the product is problematic.
- The acceptability of the drug is bad, because of bad smell, bitter, astringent, or irritating taste.
- Relief of serious side-effects (throat, eye, skin, or stomach irritation) is required.
- Because of the extreme high biological activity (in case of drugs of extremely low doses) working with such powder is rather dangerous.

The advantageous results of CD complexation of (CD-complexable) drugs are as follows:

- improved bioavailability from solid or semisolid formulations (Fig. 10),
- enhanced stability, elongated shelf-life,
- reduced side-effects,
- uniform, easy to handle powders, even from liquids, and
- aqueous, injectable solution from poorly soluble drugs.

Speaking only of the numerous advantages of drug/CD complexation can be bitterly misleading, because there are just as many limiting factors which restrict the applicability of CDs to certain types of drugs, because not all drugs are suitable for CD complexation. Many compounds cannot be complexed, or complexation results in no essential advantages. Inorganic compounds generally are not suitable for CD complexation. Exceptions are nondissociated acids (HCl, HI, H_3PO_4, etc.) halogens, and gases (CO_2, C_2H_4, Kr, Xe, etc.). Inorganic salts as KCl, Fe salts, etc. can not be complexed.

General preconditions (not without exceptions!) to form a medicinally useful CD complex of a drug molecule are the following:

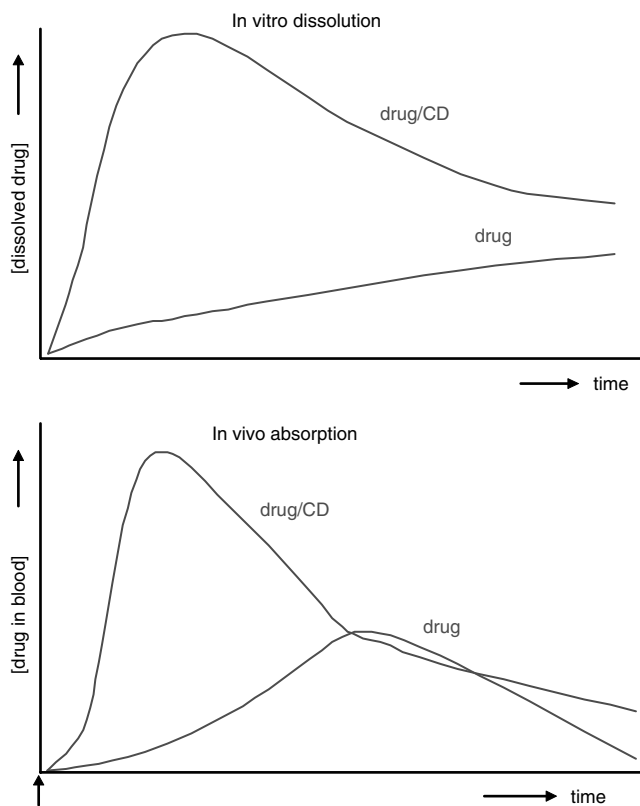
- More than five atoms (C, P, S, N) form the skeleton of the drug molecule.
- Its solubility in water is less than 10 mg/ml.


Figure 10. The bioavailability of a poorly soluble drug will be improved by CD complexation, because it will be dissolved faster, will attain a higher solubility, will be absorbed faster [the time between administration and onset of biological effect (e.g., pain reduction) will be shorter], and will result in a more complete absorption.

- Its melting point temperature is below 250 °C (otherwise the cohesive forces between the molecules are too strong).
- The molecule consists of less than five condensed rings.
- Its molecular weight should be between 100 and 400 (with smaller molecules the drug content of the complex is too low; large molecules do not fit the CD cavity).

Strongly hydrophilic, too small or too large molecules (e.g., peptides, proteins, enzymes, sugars, polysaccharides, etc.) generally cannot be complexed. Nevertheless, when large water soluble molecules contain appropriate complex forming side-chains (e.g., an aromatic aminoacid in a polypeptide) it will react with CDs in aqueous solutions, resulting in modified solubility and stability (e.g., the stability of an aqueous solution of insulin or many other peptides, proteins, hormones, and enzymes is significantly improved in presence of an appropriate CD).

An unavoidable limiting factor in selecting the drug for complexation is the dose of the complex that has to be administered. A fundamental requirement is that the mass of a tablet should not exceed 500 mg. Since the drugs to be complexed have molecular weights between 100 and 400, and the CDs have rather large molecular weights (972, 1132, and 1297 for α-, β-, and γCDs) a 100 mg complex contains only about 5–25 mg of active ingredient. If the single dose of a drug is not more than 25 mg then even a complex of 5% active substance content can carry the necessary dose in a single tablet of 500 mg weight. Otherwise the possibility of a powder sachet or sparkling-tablet formulation has to be taken into consideration. Thus, in the case of complex forming drugs, the relationship of the required dose and the molecular weight determines the feasibility of oral administration in CD complexed form.

Similarly, the volume of an injection should be less than 5 ml, or even better not more than 2–3 ml (i.e., to dissolve the necessary amount of the drug in 2–3 ml of 40% HPBCD solution 800–1200 mg HPBCD can be used). In liquid formulations the use of CD derivatives in large excess is possible. For example, in the case of prostavasin injection the molar ratio of prostaglandin E_1 to αCD is 1:11 (20 μg PGE_1 + 646 μg αCD/dose). In slow infusion the parenteral administration of several grams of a noncrystallisable CD derivative is possible. For example, in a liquid itraconazole formulation the weight ratio of the drug to hydroxypropyl βCD is 1:40! One single intravenous infusion dose of the commercial product Sporanox® contains 250 mg itraconazole and 10,000 mg HPβCD.

A 3000 I.U. D_3-vitamin tablet contains only 0.075 mg cholecalciferol. A prostarmon-E tablet contains only 0.5 mg PGE_2. The active ingredient content of a nitroglycerin tablet is 0.5–4 mg. These and similar drugs are ideal for CD complexation, but even the 20 mg piroxicam containing Brexin® tablet is a widely marketed, successful product.

If the K_a stability constant of a complex is low (less than 10^2 mol^{-1}) the existence of the complex can be evidenced in solution, but removing the water the obtained product is not seldom only a mixture (e.g., a coprecipitate) which contains the host and guest in an intimately fine dispersion. Removing the water is also an important component, as the driving force for complexation is

eliminated: the repulsive forces between water and the hydrophobic drug. Upon contacting with water the complex formation is an instantaneous process (i.e., in solution the guest is really included in the CD cavity, and the dissociation–association equilibrium is reached within seconds). In such cases the guest is not protected against external destructing factors, like oxygen or humidity, but if the guest is stable enough, only its low solubility means problems. Such intimate mixtures can be utilized for preparation (e.g., solid formulations of improved bioavailability). If, however, the guest is instable then only a full, also in anhydrous state prevailing complexation can help.

In the case of extremely high complex stability constants (over about 10^4 M^{-1}) the bioavailability can even be reduced. The complex is practically not absorbed, only the released, molecularly dispersed (=dissolved) drug molecules. In such cases the co-administration of an even better complex forming competitor molecule (e.g., phenylalanine) can help.

Hundreds of published examples illustrate the stabilizing, solubility, and bioavailability enhancing, side-effect reducing, and advantageous technological effects of CD complexation of the instable, poorly soluble, locally irritating drugs. Table 2 illustrates a selection of CD containing drugs, approved and marketed in various countries.

5.2. Food Industry

Flavor substances are generally volatile, easily deteriorating substances. Most of them (e.g., terpenoids, phenylpropan derivatives) form stable complexes with CDs and in dry complexed form remain stable for long time, without any further protection, at room temperature. Such powder flavors are approved, produced, and used in several countries like France, Japan, and Hungary. For example lemon-peel oil/βCD complex mixed with powdered sugar is used in pastries or spice-flavor mixtures complexed with CDs in preparation of canned meat and sausages. Peppermint oil/βCD complex is used in chewing gum, etc. In Germany garlic oil/βCD complex is marketed as odorless dragées (to substitute garlic and a number of various unstable garlic preparations, consumed to reduce blood cholesterol level).

βCD cannot be considered tasteless. Its taste threshold value is lower than that of sucrose (detection: 0.039% cf. 0.27%; recognition: 0.11% cf. 0.52%). An aqueous solution of a 0.5% βCD was as sweet as sucrose, and a 2.5% solution was as sweet as a 1.71% sucrose solution. When βCD is used in food processing, its sweetness cannot be ignored. Sucrose sweetness and βCD sweetness are additives.

Emulsion stability, water retention, and storability can be improved in many cases by addition of cyclodextrins to the food component or food. A solid composition containing sugars and amino acids for food or pharmaceutical purposes is known to undergo browning and caking. This can be prevented by incorporating in such a composition at least 40% of an oligo- or polysaccharide, such as dextrin, starch, or CD, with a water content of not more than 3%. For example the addition of 20% βCD to a powdered juice consisting of anhydrous glucose, sodium L-aspartate, DL-alanine, citric acid, and inorganic salts resulted in a product of excellent stability. After 30 days at 40 °C there was no apparent discoloration or caking. The control, without βCD, began to cake on the second day and to turn brown on the fourth.

CD can be utilized for the preparation of stable water-in-oil emulsions, such as mayonnaise and salad dressing. Natural food coloring components in tomato ketchup can be stabilized by adding 0.2% β-CD. The ketchup thus prepared

Table 2. Some approved and marketed CD-containing pharmaceutical products.

Drug	Trade name	Formulation	Indication	Company/country
PGE$_1$-αCD 20 μg/amp.	Prostavasin	intraaterial	chronic arterial occlusive disease, etc.	Ono, J. Schwarz, D.
PGE$_1$-αCD 500 μg/amp.	Prostadin 500	infusion	controlled hypotension during surgery	Ono, J.
PGE$_1$-βCD	Prostarmon E	sublingual tablet	induction of labor	Ono, J.
OP-1206-γCD	Opalmon	tablet	Buerger's disease	Ono, J.
Piroxicam-βCD	Brexin, Cicladol	tablet, sachet, and suppository	Analgesic, antiinflammatory	Chiesi, I, Masterpharma, I.D., B., NL., etc.
Garlic oil-βCD	Xund, Tegra, Allidex, Garlessence	dragées	antiatherosclerotic	Bipharm, Hermes, D., Pharmafontana, H., D., USA
Benexate-βCD	Ulgut, Lonmiel	capsules	anti-ulcerant	Teikoku, J., Shionogi, J.
Iodine-βCD	Mena-Gargle	garling	throat disinfectant	Kyushin, J.
Dexamethanose, Glyteer-βCD	Glymesason	ointment	analgesic, antiinfammatory	Fujinaga, J.
Niroglycerin-βCD	Nitropen	sublingual tablet	coronary dilator	Nippon Kayaku, J.
Cefotiam-hexatil-αCD	Pansporin T	tablet	antibiotic	Takeda, J.
New oral cephalosporin (ME 107)-βCD	Meiact	tablet	antibiotic	Meiji Seika, J.
Thiaprofenic acid-βCD	Surgamyl	tablet	analgesic	Roussel-Maestrelli, I.
Chlordiazepoxide-βCD	Transillium	tablet	tranquilizer	Gabor Ar.
Hydrocortisone-HPβCD	Dexacort	liquid	mouthwash against ahpta, gingivitis, etc.	Icelandic Pharm., Isl.
Itraconazol-HPβCD	Sporanox	liquid	AIDS, oesophagal candidiosis	Janssen, B
Diclofenac-Na	Voltaren Ophtha	eyedrop	anti-inflammatory	Novartis CH,D,F, etc.

did not discolor on heating at 100 °C for 2 hours, whereas the control did. Addition of CDs to emulsified foods or cheese can increase water retention and shelf life. In processed meat products CD improves water retention and texture.

The addition of 0.005 to 1% βCD to canned citrus products prevents precipitate formation, which is mainly due to the poorly soluble, bitter tasting hesperidin and naringin. When the concentration of these substances is too high in grapefruit juice resulting in a bitter taste, they can be selectively removed by passing the fruit juice through a cyclodextrin polymer filled chromatographic column.

In Belgium low-cholesterol butter is produced. The molten butter is mixed with βCD which does not react with triglicerides but forms complexes with cholesterol, and the βCD complex is easily removable from the butter. More than 90% of the cholesterol can be removed in one step. The butter does not retain any CD. Other low-cholesterol milk products, like cheese, cream, or even low-cholesterol eggs, are produced by this technology.

CDs, incorporated into food packaging plastic films very effectively, reduce the loss of aroma substances. Incorporating fungicide CD complexes into films—for example, packaging of hard cheeses—significantly elongates the shelf life of the product by inhibiting the rapid development of mold colonies on the surface of the packaged cheese.

5.3. Cosmetics and Toiletry Industry

Many active principles of interest in cosmetics have been complexed with cyclodextrins achieving very positive, interesting results. For instance, the inclusion of retinol in hydroxypropyl-β-cyclodextrin leads to a water-soluble product, sufficiently stable, of higher bioavailability and lower toxicity compared to free retinol. Similarly to retinol, it is possible to include in cyclodextrins almost all (fat-soluble) vitamins, with unquestionable advantages as concerns their stability and bioavailability. The main advantages of using CD complexes in functional dermocosmetics are similar to those in the pharmaceutical formulations:

- increase of the bioavailability of incorporated active components (vitamins, hormones, glycolic acid, depigmenting agents, etc.)
- protection from oxidation (vitamin A, retinol, hydroquinone, arbutin, DHA, etc.)
- reduction of toxicity and aggressivity (glycolic acid, hydroquinone, essential oils, fragrances, etc.)
- formation of hydrosoluble complexes even if the incorporated molecule is liposoluble
- increased stability of emulsion and gel products
- easy formulation (the complex is added to the final formulation, dispersing it in the aqueous phase at 35–40 °C)
- no added preservatives

Some special advantages were observed for the sunscreen agent/CD complexes:

- increased stability (photostability) of cream formulations
- decreased cytotoxicity

- increased/improved functional activity
- reduced smell
- reduced fabric staining

Thus the markedly increased photostability is associated with decreased phototoxicity and/or photosensitization risk coming from the production of free radicals primed by the sun photochemical attack on the filter molecule itself.

Cyclodextrins are suitable not only for real skin treatment products, but also for the formulation of make-up cosmetics which are to stay on the face and skin for a number of hours (about one whole day).

CD complexation can be used to stabilize emulsion, color, and perfume or aroma. For instance, most perfume concentrates, such as rose oil, citral, and citronellal, can form complexes and can be used in any solid preparation, such as powdered detergents. The collateral irritant effect caused by a scent in a shampoo can be reduced through the use of CD complexes. A solution of iodine-βCD can be used as a deodorant for the body, for baths, or as a refresher for the oral cavity. CD complexes with detergent molecules can act as antifoam agents, etc.

5.4. Textile Industry

The first cellulose-CD copolymer was described in 1980. Alkali-swollen cellulose fibers were reacted with CD and epichlorohydrin. The chemically bound CD retained its complex forming ability and could be "loaded" with biologically active guests, like drugs (to prepare medical bandages), insect repellents, antimicrobial agents, etc. The drug is adsorbed partly to cellulose and partly complexed with CD. Upon contact with skin the fabrics made from such fibers ensure immediate drug release from cellulose and a sustained drug release from CD.

α-, β-, and γCD has been grafted onto a nonwoven polypropylene support. The fabric was first activated by electron beam irradiation, followed by the graft polymerization of glycidyl methacrylate, a polymerizable monomer carrying epoxide groups. CDs were then fixed onto the fibers by reaction with the epoxide groups. The final CD content after this second step of the reaction increased to 150 mmol per gram of support (20% in weight). 2-Naphtol and p-nitrophenol were sorbed in batch and dynamic filtration systems by the CD grafted supports.

Polycarboxylic acids such as citric acid, 1,2,3,4-butanetetracaboxylic acid, or polyacrylic acid have been used as cross-linking agents of cyclodextrins depending on the reaction conditions, and according to the adapted experimental process, polyesters of CDs or textiles carrying CDs could be obtained. Permanent fixation of CDs onto textiles occurred either through reaction of the functional groups of the fibers (covalent bonding), or through the formation of a cross-linked polymer that is tangled up in the fibers (noncovalent bonding) (Fig. 11).

Presently the use of monochlorotriazinyl-βCD seems to be the most promising approach. βCD was condensed with cyanuric chloride in an aqueous medium at 0–5 °C in the presence of NaOH to give a 4-chloro-6-hydroxy-triazin-2-yl-βCD Na salt with degree of substitution of active Cl 0.4. This product is a reactive CD derivative that can be
Figure 11. Fiber-cyclodextrin binding types: (a) triazinyl chloride reacted with cyclodextrin and the product reacted with the fiber; (b) polycarboxylic acid reacted with the fiber, the formed ester converted to cyclic anhydride, and then it reacted with cyclodextrin; and (c) the cyclodextrin and epichlorohydrine reacted with strong alkaly treated cellulose.

covalently fixed to nucleophilic substrates by a condensation reaction carried out by the usual finishing procedure. This new type of surface modification means a permanent transfer of CD properties to the treated materials. The finish is applied by standard methods—analogous to those of reactive dyeing—on conventional equipment. The dissolved monochlorotriazinyl-βCD (MCT-βCD) is drawn up from a dipping bath, the textile is squeezed, and the CD is fixed on the fiber at elevated temperature. Unattached CD is simply removed by washing. Both alkaline and acidic methods for MCT-βCD finishes have been developed. While fixing temperatures and times are the main parameters for the fixing reaction, other variables such as dampness of the fabric and the MCT-βCD concentration are also important. An MCT-βCD finish is wash resistant. Cotton for T-shirts, sports socks, and so forth is particularly amenable to CD modification. However, the latest studies also reveal that very good fixing results may be obtained with blended fabrics, such as cotton/polyurethane and cotton/polyurethane/polyamide. This is especially important for top-of-the range lingerie. Given suitably adapted processes, moreover, wool can also be finished with MCT-βCD. Encapsulation of sweat or cigarette smoke greatly reduces the intensity of odors on articles of clothing or furniture textiles. In the washing machine, the encapsulated substances are washed out, and

the CD is free again to trap odors. CD textiles can be recharged selectively with the most diverse guest substances by dipping or spraying. Particularly interesting is the treatment with fragrances and antimicrobial or pharmaceutical preparations which can be released continuously over a long period on exposure to moisture. The higher the level of moisture, the more guest substance is liberated. CD-modified fabrics, therefore, "respond" to varied ambient conditions (Fig. 12).

In Germany 5 million people suffer from neurodermitis, 2 million from psoriasis, and a further 3 million from dermal diseases of occupational origin (like hairdressers' allergic reactions on the hands, athlete's foot, etc.). The corresponding article of clothing (underwear, gloves, socks) can be loaded with the necessary antifungal, antihistaminic, anti-inflammatory, etc. agents.

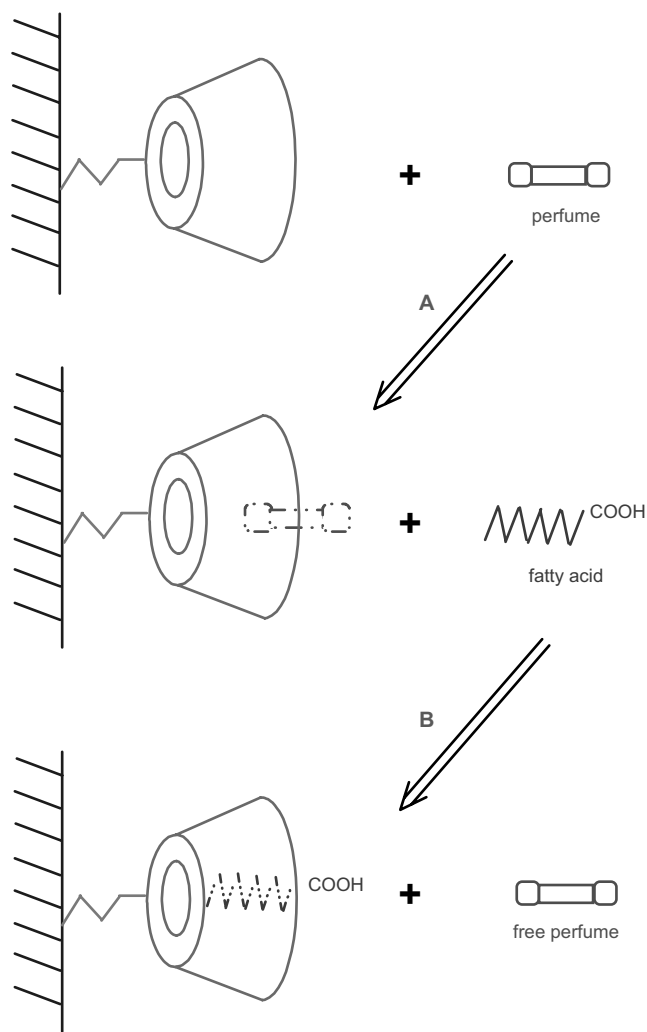
A further application is towels, which start smelling after drying one's hands. Also bed linen may release a pleasant odor after going to bed. Curtains with cyclodextrins


Figure 12. Guest exchange, for example, perfume release and sweat component entrapment. (A) Loading the fixed cyclodextrin with perfume. (B) During wearing, upon the effect of sweat, humidity, and excreted short chain fatty acids, the guest will be exchanged, the perfume gets released, and the fatty acids are entrapped.

can be used to improve the air in rooms or offices with smokers.

The identification of the organic compounds excreted from patients through their skin enables new methods in medical diagnostics. Up to now blood or urine tests have normally been used due to the problems of taking a sweat probe from a patient. This becomes easy by wearing for 24 hours a T-shirt which contains chemically bound βCD. After extraction of the T-shirt, the substances—characteristic, for example, of metabolic disorders—excreted through the skin are detectable by gas chromatography. The complexation of organic substances from sweat results in a preconcentration and their identification becomes easier.

Mixing CD or CD–polymer fragrance complexes to the melt mixtures of synthetic fiber polymers (e.g., polyester) and weaving the fabric from such fibers, washfast fragrant fabrics can be produced.

5.5. Biotechnology

The majority of biotechnology processes mean an enzyme-catalyzed transformation of a substrate in aqueous medium. The main difficulties which used to arise were the following:

- The substrate is hydrophobic, sparingly (or hardly) soluble in water.
- The enzyme or the enzyme-producing microbial cells are sensitive to the toxic effects of the substrate or to inhibitors which can even be the product of the transformation.
- The substrate or the product is unstable under the conditions of the enzymatic transformation.
- Isolation of the product from the very heterogeneous system is difficult.

Cyclodextrins and their derivatives enhance the solubility of complexed substrates in aqueous media and reduce their toxicity, but they do not damage the microbial cells or the enzymes. As a result, the enzymatic conversion of lipophilic substrates can be intensified (accelerated, or performed at higher substrate concentrations), both in industrial processes and in diagnostic reagents, the yield of product-inhibited fermentation can be improved, organic toxic compounds are tolerated and metabolized by microbial cells at higher concentrations, and compounds in small amounts can be isolated simply and economically from complicated mixtures.

Examples illustrate the rapidly growing and promising uses of cyclodextrins in various operations: the intensification of the conversion of hydrocortisone to prednisolone, the improvement in the yield of fermentation of lankacidine and podophyllotoxin, the stereoselective reduction of benzaldehyde to L-phenylacetyl carbinol, and the reduction in toxicity of vanillin to yeast, or organic toxic substances to detoxificating microorganisms. In the presence of an appropriate cyclodextrin derivative (e.g., 2,6-dimethyl-β-cyclodextrin), lipidlike inhibitor substances are complexed. The propagation of *Bordatella pertussis* and the production of pertussis toxin therefore increases up to a hundredfold. Cyclodextrin and their fatty acid complexes can substitute mammalian serum in tissue cultures.

In recent years Leprae bacillus (Mycobacterium leprae) was considered to be not cultivable under *in vitro* conditions. The most important energy source for bacillus is palmitic (or stearic) acid which, however, cannot penetrate through the thick strongly hydrophilic shell of the Mycobacterium. Solubilizing, however, the fatty acids (or fatty alcohols) with dimethyl-β-cyclodextrin, the Mycobacterium can be cultivated *in vitro*, on synthetic medium. This discovery will facilitate the screening of drugs against similar difficultly cultivable microorganisms.

The biological remediation of carcinogenic polyaromatic hydrocarbon polluted soils is a very slow process, because the dangerous polluting hydrocarbons are adhered very strongly to the soil particles. They are not available for the soil micro-organisms. Adding CDs (for example, the randomly methylated βCD) to such soils, the CD mobilizes the hydrocarbons and makes them available for the micro-organisms, resulting in an accelerated remediation of the soil.

5.6. Chemical Industry

Fragrant paper or paper containing protective substances can be prepared using CD complexes of perfumes, insecticides, rust inhibitors, mold- and mildew-proofing agents, fungicides, and bactericides. For example, fenitrothion βCD complex sprayed on a wet paper web, passed between drying rollers heated to 100 °C, resulting in an insecticide containing paper, was shown to be effective for more than 6 months.

Conservation of wood-made products which are prone to attack of micro-organisms, like frames of windows, doors, and buildings constructed from wood, usually has been made by impregnating the wood with fungicides, which are generally water insoluble. Therefore they had to be dissolved in organic solvents. After impregnation the solvents escaped into the atmosphere. A new process dissolves the fungicides in aqueous CD solutions; the impregnation and conservation of the woods can be made without using organic solvents.

Emulsion-type coatings (paints) contain emulsion polymer binders, to give—after drying—a resistant, continuous protecting film on the coated surface. To ensure the formation of a good film, the applied layer has to contain various compatible components, like solvent, pigment, thickener, and binder. The rheological properties of the paint are determined by the thickener, which is usually a hydrophobically modified polymer, like polyurethane, polyacrylamides, cellulose ethers, etc. To avoid a concomitant too high viscosity (which makes difficult the formation of a uniform coating of the surface to be covered) viscosity suppressors has to be added to the emulsion. Adding organic solvent to such emulsions, the viscosity can be reduced, but use of organic solvents has to be avoided because of safety, health-damaging, environmental polluting effects. Also surfactants can strongly reduce the viscosity of such emulsions, but their use results in the formation of a less resistant coating.

The viscosity enhancing effect of hydrophobically modified macromolecules in aqueous emulsions is based on the hydrophobic–hydrophobic interactions between these molecules. Adding CDs to this emulsion the CD molecules

will associate with the hydrophobic sites and, being strongly hydrated, inhibit the association of the macromolecules, resulting in a strong reduction of the viscosity. The RAMEB was shown to be the most effective viscosity suppressor.

The CD complexes are compatible with thermoplastic resins. Mixing a dry pulverized CD complex of a perfume, for example, a geraniol αCD complex, with a thermoplastic resin (polyethylene), and molding it yielded plastic products with a long lasting (at least 6 months) fragrance. Rapid loss of the perfume by volatility and thermal decomposition can be avoided in this way.

Mixing CD complexes of thymol, eugeneol, isobutylquinoline, etc., to molten PVC (=polyvinylchloride) a natural leather odor emitting (leatherlike) material was prepared (e.g., for automobile door internal coverings).

The epoxyresin adhesives are produced and stored as separated components mixed just before utilization. Complexing the curing agent (polymerization catalyst) with βCD a one-package composition can be prepared. Upon layering such a composition between metal plates and heating to 130 °C for 5 min, binding will take place.

Properties of cyanacrylate adhesives can be improved significantly by heptakis(2,6-di-O-butyl-3-O-acetyl)-βCD. The ethyl-2-cyanacrylate monomer is stabilized with 20 ppm phosphoric acid, 20 ppm SO_2, and 100 ppm hydrochinon. Various amounts of the dibutyl-acetyl-βCD were added to this mixture, and using an adhesive, for example, to bind hard cartoon papers by quick heating to 200 °C, the polymerization (binding) of cyanacrylate has been accelerated, and the tear-strength of the binding increased significantly.

Explosive substances, like nitroglycerin or isosorbidedinitrate, when complexed can be handled without any danger. The pernitro-γCD complex of the extremely explosive nitramine can be used as a controlled missile propellant.

Important properties such as relative sensitivity and the fog of silver halide containing photographic materials can be improved by adding CDs to the light sensitive photographic gelatin layers.

Additives, dyes, stabilizers, and fog inhibitors used in the photographic industry should be fixed to a certain layer of the film or photopaper. This can be achieved by using derivatives with "heavy" side chains. It seems to be more convenient to prepare the water soluble polymer complexes of these substances. In complexed form their mobility is markedly reduced, and they become fixed to the required layer. A diminished diffusion can be observed either on preparing, processing, or storing the film. Another advantage of the soluble polymer complex is that poorly soluble or even water insoluble stabilizers can be applied to the film in aqueous solutions. A CD-gelatin composition as photographic layer shows a lower water absorption and accelerated diffusion of the developing agents.

Silane resins are made using a 1,5-cyclooctadieneplatinum catalyst. Once the catalyst is added, the reaction proceeds. Complexing the catalyst with βCD, it became possible to produce a single component heat-curable silicone with a shelf life exceeding 7 months since complexation prevented immediate catalysis and reaction. No gelation occurred at ambient temperature, only when the mixture was heated up to 150 °C.

Active ingredients of pesticides (insecticides, fungicides, herbicides, etc.) can be complexed with the same technologies and same consequences as drug molecules.

The selectivity of an insecticide can be improved. For example, complexing an insecticide, which kills herbivorous insects, will not be toxic for the honey-bee. Stability against sunlight accelerated decomposition of pyrethroids can be improved ensuring a longer lasting insecticidal effect. Wettability or solubility of poorly soluble benzimidazole type antifungicides can be improved, allowing the reduction of the dose and the pollution of the environment. The possibilities of utilization of CDs in pesticide formulations have already been elucidated in numerous scientific papers. However, until recent years the price of βCD did not allow its utilization for such purposes because the pesticide industry is very cost sensitive. By the end of the 20th century the price of βCD dropped to such a low level that the price will no longer be a restricting factor in its utilization for pesticide formulations.

The preparative- and technical-scale chiral resolution of enantiomers is one of the biggest challenges in industrial utilization of CDs. The utilization of CDs in this area is still in its infancy but some results are encouraging. For example, a continuous method for separation of dichlorophenyldichloronapthalenone enantiomers has been published using different γCD derivatives in a multiple solvent extraction technology. A continuous, easy to scale up preparative chiral separation device, a slowly moving "chiral" belt coated with 3,5-dimethyl-phenyl-carbamoyl-βCD, enters into and passes through different solutions in separate troughs. The solutions contain different solvents: trough 1 contains the racemic analyte (R,S-oxprenolol), troughs 2 and 3 are filled with a hexane:i-propanol mixture for enantioselective desorption of analyte, while only hexane is in trough 4 for rinsing/regenerating the belt. The continuous process results in 2 hours in the enrichment of R-oxprenolol isomer in trough 1, while trough 3 becomes rich in the S-isomer (about 68%). Despite the encouraging results in the preparative scale resolution a reliable and economic technology for the routine enantiomer separations in 1 or 10 g pure enantiomer per batch still remains a challenging task of the future.

5.7. Analytical Chemistry

5.7.1. Chromatographic Separations

CDs and mainly specific derivatives are widely used in chromatographic separations. In 1990–2000 about 25 papers were published monthly on successful application of CD in gas or liquid chromatography. In gas chromatography the CDs are used only in the stationary phase, while in high pressure liquid chromatography (HPLC) the CD is used either as dissolved in the mobile phase or bound to the surface of the stationary phase. In capillary zone electrophoresis the most used chiral selectors are the CDs and their anionic, cationic, or alkylated derivatives.

5.7.2. Diagnostics

The actually used and marketed chiral separation products include HPLC, gas chromatographic columns, and capillary electrophoresis buffer additives.

In medicinal diagnostic kits frequent problems are the limited, uncertain solubility of some essential component, the stability, and the storability of the kit. Complexing with CDs as the typical components, such problems can be eliminated. Frequently intensity of color reactions or of fluorescence can be significantly enhanced by the presence of CDs, resulting in a higher sensitivity of the method.

In the following a few examples illustrate the application of CDs in clinical sample preparation, in enhancement of sensitivity of analytical methods, CDs used for solubilization and/or stabilization of reagents, and CD based sensors and indicators.

In clinical chemistry:

- βCD is used for the selective and highly effective extraction of serum Digoxine in one single run enabling the convenient determination of the drug in biological samples by the RIA method.
- βCD is also used for the determination of steroid hormones in human serum traditional solvent extraction of serum samples, followed by a re-extraction of the steroids into an aqueous cyclodextrin solution.
- A pre-column containing immobilized βCD-sulfate was successfully applied for the on-line enrichment and separation of heparin binding proteins.
- The treatment of lipemic serum with aqueous solutions of CDs will produce an immediate and quantitative precipitation of the lipoproteins. αCD was found to precipitate chylomicrons, very low, low, and high density lipoproteins.
- CDs can selectively remove disturbing components from complex biological samples. The presence of fatty acids in blood samples disturbs colorimetric analysis and causes an underestimation of the actual Ca^{2+} level. αCD was found to eliminate this interference, completely.
- An automated LDL-cholesterol assay has been recently marketed that employs αCD together with Mg ions to effectively mask interfering lipoproteins present in clinical samples.

Through complexation of analyte and/or the color-forming reagent by CDs in the spectrophotometric determination of a wide variety of compounds, the sensitivily of the method is significantly improved. For example:

- The spectrophotometric determination of copper in leaves and in human hair was improved by CDs, as the sensitivity of the color reaction of Cu(II) and mesotetrakis-(4-methoxy-3-sulfophenyl) porphyrin was enhanced by 50% in the presence of αCD.
- In the determination of microamounts of Zn based on the Zn-dithizone color reaction sensitized with βCD, the apparent molar absorptivity at 538 nm is 8.37 times larger than that in the absence of βCD.
- CDs often can result in significant enhancement of the fluorescence or phosphorescence of the complexed analyte. A substantial enhancement of the fluorescence emission of aflatoxins in the presence of aqueous solutions of α- and β-di-O-methyl-βCD and hydroxypropyl-βCD was observed, which enabled the determination of minute amounts of these toxins in food samples.

- Determination of selenium in biological matrices was improved using βCD by which the relative fluorescence of the reagent 4,5-benzopiaselenol is about 150-fold higher than that without CD.
- The application of βCD in beryllium analysis allowed the determination of 10–40 ng/mL beryllium, compared to 60–500 ng/mL in the absence of the CD.
- CD-assisted spectrofluorimetric assay enabled the detection of mescaline in the 0.8–1.4 ppm range.
- The application of CD enabled a limit of detection of 0.07 μg/ml zirconium.
- βCD stabilizes dichlorofluorescein against autoxidation and enhances its fluorescence, a dual benefit that can be used to improve the determination of serum uric acid and glucose.
- Improved sensitivity was reported on trace cadmium determination from hair, nails, water, etc., which was based on the enhancement of the chromogenic reaction due to βCD complexation. This method enabled the determination of about 0.4 ng/ml cadmium.

The solubilizing effect of cyclodextrin complexation for lipophilic reagents or analytes provides the possibility to replace organic solvents and detergents with aqueous CD solutions. For example:

- Complexation of the unstable, insoluble substrate L-γ-glutamyl-4-nitroanilide with CDs eliminated the errors occurring in the determination of γ-glutamyl-transferase activity caused by its poor solubility.
- Poorly soluble antigens can be solubilized by βCD in immunoassay used for determination of progesterone in human serum by the solid phase EIA (enzyme immunoassay) method.
- Fluorescent labeling of proteins done with dansyl-chloride organic water-soluble complex with βCD enables the labeling of proteins in aqueous solutions.
- SIN-1A/γCD complex is a stable analytical standard suitable for reliable determination of NO and calibration of NO detectors.
- By complexing highly unstable ortho-phenylene-diamine, an immunodiagnostic reagent with βCD, and simply tabletting the solid complex, a stable reagent with extended shelf life was prepared.

5.7.3. Sensors

CD-based supramolecular assemblies or covalent new chemical entities have been developed as selective sensors, detectors, and indicators. For example:

- A benzene-vapor detecting piezoelectric quartz crystal was constructed by coating the surface with 2,6-O-$tert$-butyl-dimethyl-silyl-αCD. This detector is highly selective for benzene even in large excess of methane, propane, butane, pentane, ammonia, nitrobenzene, and toluene.
- βCD fixed on a quartz oscillator surface was shown a very sensitive sensor for cholesterol suitable for determination of blood cholesterol level.
- Various compounds including steroids, bile acids, terpenes, etc. have been selectively detected with a specifically designed cromphore bearing CD derivatives.

- Voltammetric responsive sensors based on organized self-assembled βCD derivatives in monolayers on gold electrodes were studied for analysis of electroinactive organic analytes.
- A fiber-optic CD-based sensor was developed using laser excitation and fluorescence detection, with βCD as the reagent phase immobilized at the tip of an optical fiber. The sensitivity of the fiber-optic CD-based sensor was found to be 14 times greater than that of a bare optical fiber.
- Lipophilic cyclodextrins were used for construction of guanidinium ions and choline, acetylcholine selective sensors.

5.7.4. Standards

CD complexation offers the possibility for preparation of flavor standards.

There are cases when human taste and smell sensors cannot be substituted even by the most sophisticated analytical instruments. In organoleptic evaluation, comparison of identical food products of different origin—for example, beers—the dosing of extremely small but exactly known amounts of flavor components (for example ppm amounts of mercaptanes, butyric acid, hydrogen sulphide, etc.) is necessary. To store and dose these volatile, unstable substances becomes very simple when they are complexed with CDs, diluted with inert excipient to the appropriate grade, and filled in known amounts into hard gelatine capsules. Adding the content of one or more capsules of different flavors to the sample at sensoric "titration," the differences between the products can be expressed unambiguously and numerically.

6. CYCLODEXTRIN BASED NANOSTRUCTURES

Cyclodextrins belong to the most appropriate rotaxane forming molecules. A long slim guest molecule can be threaded through the CD cavity. Then both ends can be terminated by bulky groups or the terminal group can be ionized and therefore the threaded molecule cannot slip out of the cavity (Fig. 13). Upon various environmental effects (pH, irradiation, electric field, etc.) this threaded molecule may rotate
Figure 13. Principle of the CD-rotaxane formation.
Figure 14. A light driven shuttle.

around its axis; otherwise its mobility is restricted. Similarly the CD-ring mobility is also restricted; it can move only along the axis.

This way a molecular "shuttle" or "switch" can be constructed. Threading an azobenzene derivate through an αCD ring, the azo-bridge will be allocated in the CD cavity. Attaching 2,4-dinitrophenyl-bipyridinium "stoppers" to both ends of the threaded axis molecule, a shuttle rotaxane is formed. Irradiation of its aqueous solution with UV light (360 nm) causes isomerization of the azobenzene moiety from a *trans* to *cis* configuration: the isomerization can be reversed when the solution is irradiated with visible light (430 nm). This configuration change is reflected in a dramatic alteration of the geometry (Fig. 14). The αCD ring resides around the azo-bridge; when the azobenzene unit adopts the *trans* configuration the αCD ring migrates toward one of the bis-(methylene) spacers. The photoswitching process is reversible, and this is an excellent example of a light driven molecular shuttle.

Threading a long slim guest through a number of CD rings, a "molecular necklace" can be prepared (Fig. 15). Recently the nylon/CD complex, by reacting the βCD complex of hexamethylene diamine with CD-complexed diacylchloride, has been published. This way new materials with quite interesting properties can be produced.

"Molecular tubes" can be prepared for example by complexing polyethylene glycol-bis-amin with αCD; then the formed polyrotaxane is reacted with 2,4-dinitrofluoro benzene. This way both ends of the long chain guest are terminated by bulky groups. Reacting this polyrotaxane with epichlorohydrine the vicinal CD rings will be interconnected through glyceryl bridges between the primary and secondary sides of the CDs. Finally, upon the effect of strong alkali, the dinitrofluorobenzene groups will split off and the long polymer chain will slip out from the polymeric tube (Fig. 15).
Figure 15. Scheme for the sequential formation of αCD pseudopolyrotaxane, polyrotaxane (molecular necklace), and molecular tube.

If the threaded molecule itself is closed to form a closed ring, then the formed structure is called catenane or, if it includes more than one CD ring, polycatenane (Fig. 16).

Metal ions can be complexed with CDs in different ways:

- The metal ion reacts with the hydroxyl groups of the CD molecule.
- The metal ion forms a coordination complex with the usual organic ligands and this coordination complex will be included in the CD cavity.
- The metal atom is bound covalently in a metallorganic compound which will form a regular inclusion complex with a CD molecule.
- The metal ion is bound by an anhydro-CD.

In the first case, a hydroxo complex is not an inclusion complex; more likely it is an outer sphere complex (e.g., Cu^{2+} or Mn^{2+} ions in alkaline solutions form such CD-hydroxo-metal complexes).

The second case means the formation of ternary complexes: CD + organic ligand + metal ion. This is a real second sphere coordination metal complex. For example, a ferrocene is a coordination complex which consists of an iron ion, sandwiched between two cyclopentadiene molecules, forming a stable iron-coordination complex. This coordination complex can form a true inclusion complex with CDs and this inclusion strongly modifies the physical and chemical properties of the included coordination complex. The technecium-99 ethylcysteinate dimer for brain imaging or the technecium-99 nitrido-dithiocarbamate for myocardial scintigraphy can be used only after solubilizing them with an appropriate CD.
In the third case, the complexation of organometallic compounds—this is a binary complex—also results in the modification of important properties of the included compound (e.g. in pharmaceutical preparations).

The ferrocene complexes can be prepared easily, in crystalline form, with good yield. The excess of sublimable ferrocene can easily be removed by vacuum sublimation, while the CD-bound ferrocene is stable up to the temperature of the caramelization of CDs.

The orientation of an ionizable ferrocene within the CD cavity depends on the pH of the solution (Fig. 17). On the basis of circular-dichroism spectra the ferrocene carboxylic acid was assumed to orient itself inside the CD cavity parallel to its axis, while the ionized carboxylate ion was perpendicular to it (at pH 9 in water).

In aqueous solution the antitumor carboplatin forms an 1:1 complex only with αCD, but not with β- or γCD (Fig. 18). The cyclobutane ring penetrates the CD cavity, with additional stability arising from hydrogen bonds between the ammine ligands and hydroxyls. Also dimethyl-αCD forms a similar complex with carboplatin. In contrast, the platinum phosphine complex trans-Pt(PMe$_3$) Cl$_2$(NH$_3$) forms an 1:1 complex with βCD but not with αCD, and the hydrophobic trimethylphosphine ligand resides in the CD cavity.

The 3,6-peranhydro-2-O-methyl-αCD showed a surprisingly high affinity for lead (1.2×10^7 M^{-1}) and for strontium (1.8×10^4 M^{-1}). Eventually this and similar CD derivatives will be utilizable for decontamination or detoxication by sequestering selectively certain metal ions from the contaminated environment, or even from intoxicated organisms.

The essence of the photodynamic tumor therapy is that such compounds have to be delivered to the tumor tissues, which upon strong light irradiation become toxic through isomerization, splitting, etc. In this case upon strong light irradiation the photosensitive molecules will become toxic just for the tumor cells. For such targeting of the drug very stable (10^5–10^7 M^{-1}) complexes are needed. The duplex or triplex homo- or heterodimers of CDs (constructed only from one or two different CDs) form complexes which are

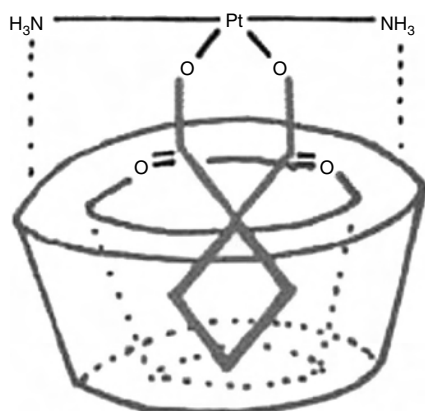
Figure 16. Various catenanes.
Figure 17. Orientation of an included ionizable ferrocene depends on the pH of the solution.


Figure 18. Structure of carboplatin.

more stable by orders of magnitude than the singular CDs (Fig. 19). Interconnecting two CDs with appropriate bridges such duplex CD derivatives have been prepared which can form stable complexes with photosensitive porfirinoid structures and to transport them to the target organs.

In "antennae" bearing CDs receptor specific oligosaccharide units are attached to the CDs, which will be bonded in the living organism only to certain specific receptors. The aim of this effort is to synthetize a receptor-targeting carrier; that is, the drug complexed with an antenna bearing duplex CD would transport the specific drug just to the target organ.

CDs are considered to be not very selective receptors for a very large number and variety of relatively small (CD-cavity compatible) molecules. A promising new challenge is the synthesis of such artificial receptors, which will show selectivity for nanometer scale large molecules. One promising approach is molecular imprinting. Polymerizing (with appropriate cross-linking agents) the cholesterol/βCD complex and then removing the guest (e.g., by excessive organic solvent extraction) the obtained "empty" polymer will show an interesting specific affinity for cholesterol. No other potential guest will fit so correctly into the cavity of the ordered assembly than cholesterol. A nonimprinted βCD polymer hardly bounds any cholesterol.

The assembly of CDs is ordered by the template (=guest) molecule, which facilitates the fixing of the position and orientation of the CD units by cross-linking just in the most advantageous position for maximum cooperation in
binding the guest. Using this principle a large variety of single molecule specific "accommodations" can be memorized by such ordered and fixed assemblies (Fig. 20).

The most complicated CD derivatives are synthetized for enzyme-modeling experiments. For all enzymes it is characteristic that they have a substrate binding site and an active, catalytic group. The CDs are similar; the axial cavity is the binding site, and the hydroxyl group can attack, for example, an ester linkage of an included ester-type guest. This enzymelike activity is, however, weak and restricted to only a few well studied examples. Very active and specific artificial enzymes can be constructed by using the CD molecule as a scaffold. The axial cavity can be elongated (e.g., by alkaline substitution on the primary face) and one or more CD hydroxyls can be substituted by active, prosthetic groups. This way artificial hydrolase, isomerase, lyase, transferase, oxydoreductase, etc. enzyme models have been synthesized. In some cases their activity approaches well the activity of natural enzymes. Combining the molecular imprinting technique with enzyme modeling, very probably artificial enzymes of high activity and specificity will be produced, both for industrial applications and for *in vivo* (e.g., detoxicating) purposes.

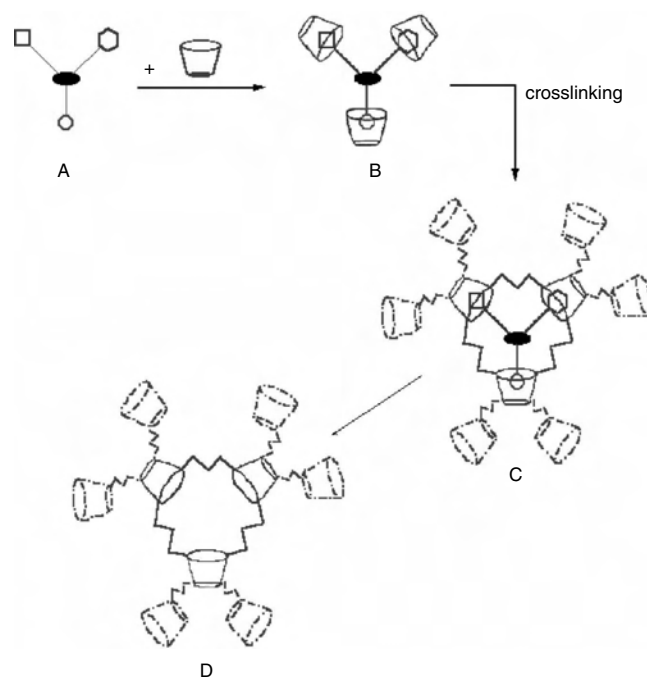
A βCD dimer (Fig. 21) with a linker containing a bipyridil group can form a coordination complex with metal ions. These are very effective at hydrolyzing ester substrates which have two hydrophobic arms that can be fixed by the CD cavities of the catalyst.


Figure 20. Principle of molecular imprinting: a guest (A) is complexed with a CD in solution (B). Then the CDs will be cross-linked with an appropriate agent (C) forming either a water-soluble oligomer ($M_w < \sim 10,000$) or a water-insoluble polymer ($M_w > \sim 10,000$). Finally the guest is removed (e.g., by an appropriate organic solvent) from the imprinted structure. The size, shape, and allocation of binding sites are memorized. This cavity hardly fits with other potential guests but shows high selectivity for the original "template" guest.

Figure 19. A triplex CD.
Figure 21. A cyclodextrin dimer which can bind both ends of a substrate and hold it onto a catalytic metal ion (La³⁺) is a very effective catalyst for ester hydrolysis.

Attaching four CD molecules to a porphyrin, or only 2 but in the A–C (or B–D) position, it will bind sufficiently long bifunctional "inclusion" guests (E of F) and keep them stretched with their aliphatic or olefinic section in close proximity to the center of the porphyrin structure. If the nitrogens of prophyrin are coordinated with an Mn(III) atom, then the aliphatic segment of the guest will be hydroxylated or the olefinic segment will be epoxidated (Fig. 22). When the two CDs are linked at the vicinal (A–B, B–C, C–D) positions no guest binding takes place.
Figure 22. Porphyrin carrying four attached CD rings binds strongly to an appropriate two-armed guest and, forcing its oxidizable center near to the Mn³⁺ ion atom, results in hydroxylation of a –CH₂– unit or epoxidation of an olefinic bond.

GLOSSARY

Administration routes Mode of incorporation of a drug into the organism: i.v. = intravenous, p.o. = per oral, i.m. = intramuscular, s.c. = subcutaneous, i.p. = intraperitoneal, etc.

AUC value (area under curve) The integrated area under the curve blood level versus time (counted from time of administration till end of the observation, e.g. 24 h).

Bioavailability The absorption (penetration) of drugs through the absorption sites (gastrointestinal system, skin, lung, mucous membranes, etc.) is frequently far from being complete, and biological utilizability (bioavailability) depends on numerous factors, but the prevailing one is the solubility, and dissolution rate of the administered drug.

CTG ase (cyclodextrin trans glucosylase enzyme) This enzyme splits the glucosidic linkages between the sixth, seventh, eight (etc.) glucopyranose units in the amylose or amylopectin molecules (components of starch of any origin) then establishes new glucosidic linkages between both ends of the formed break-down products resulting in formation of cyclic dextrins = cyclodextrins.

Cyclodextrin 6,7,8 (or more) glycopyranose units are bound through α-1,4-glycosidic linkages. The outer surface of these conical torus-shaped (doughnut shaped) molecules is hydrophilic, in aqueous solution strongly hydrated but the internal cavity of well defined diameter and length is apolar, ready to incorporate appropriate apolar guest molecules.

Cyclodextrin catalysis Cyclodextrins similarly to all enzymes have a substrate binding site (the CD cavity) and active catalytic moieties, the secondary and/or primary hydroxyl groups. Substituting one or more CD hydroxyls with appropriate substituents aritificial enzyme models can be synthetized.

Cyclodextrin derivatives The hydrogen from one or more hydroxyl group or the complete hydroxyl group are replaced by substituent(s), resulting in ester, ether, deoxy-, amino-, carboxy-, halogen-, etc. derivatives of CDs.

Degree of substitution Number of substituents, attached to the CD ring.

Guest molecule A molecule, which at least one part of it can penetrate into the CD-cavity, to form an "inclusion" complex.

Host molecule A molecule, which has an open cavity of appropriate size and polarity for incorporation of an appropriate "guest" molecule.

Inclusion complex A guest molecule (or a part of appropriate size and polarity of it) is included, and bound by non-covalent forces in the cavity of a host molecule.

Molecular necklace Rotaxane, which consists of long slim axis guest molecule and several CD-hosts around it.

Molecular encapsulation Inclusion complexation.

Molecular switch (or shuttle) In a rotaxane the host CD changes its position along the axis guest molecule, upon external effects (light, pH) or the orientation of the (partly) included guest is modified relative to the CD-cavity.

Outer-sphere complex The host (cyclodextrin) is linked through a non-covalent bond to a non-incorporated guest (e.g., by hydrogen bond, through the CD-hydroxyls).

Rotaxane   A long slim guest molecule threaded through one or more CD cavity, then both ends are terminated by "stopper" moieties, which cannot penetrate through the CD-cavity, impeding the "slip out" of the axis guest molecule.

Deformation Behavior of Nanocrystalline Materials

Alla V. Sergueeva, Amiya K. Mukherjee

University of California, Davis, California, USA

CONTENTS

1. INTRODUCTION

1.1. Nanocrystalline Materials

Nanostructure science and technology is a broad and inter-disciplinary area of research, and development in this field has been growing very significantly worldwide in the past few years. It has the potential for revolutionizing the ways in which materials and products are created and the range and nature of functionalities that can be accessed. It is already having a significant commercial impact, which will assuredly increase in the future. Nanotechnology implies direct control of materials and devices on molecular and atomic scales, including fabrication of functional nanostructures with engineered properties, that takes advantage of physical, chemical, and biological principles that originate in the nanometer scale. New observed properties are attributed to a reduction in length scales to the point where known models for physical phenomena and interactions become larger than the actual size of the structure. New behavior at the nanoscale is not necessarily predictable from that observed at large size scales. The most important changes in behavior are caused not by the order of magnitude size reduction, but by newly observed phenomena intrinsic to or becoming predominant at the nanoscale, such as size confinement, predominance of interfacial phenomena, and quantum mechanics effects. Once it is possible to control feature size, it is also possible to enhance material properties and device functions beyond those that we currently know or even consider as feasible.

Few reviews on the basic concepts, physics, structural features, properties, and applications of nanocrystalline materials (NCM) have been written in the past few years [1–8]. Many researchers in recent years have increasingly focused on the synthesis and processing of NCM, which have a great potential for functional applications (see next Section).

Mechanical testing of NCM is characterized by features that are different from those documented for coarse-grained materials. The amount of the NCM produced by advanced processing methods is often small, and it is therefore difficult to prepare large bulk samples with nanocrystalline structures in comparison with those for conventional materials. The gauge length of testing specimens, unlike those used in testing coarse-grained materials, is usually on the order of several tens of micrometers to a few millimeters. However, due to the fact that the grain size is in scale of nanometers, it is anticipated that the experimental data obtained from these miniature specimens would still represent the bulk behavior of materials.

1.2. Severe Plastic Deformation

There are many different methods developed for the production of NCM such as mechanical alloying [9], evaporation and condensation [6], precursor decomposition [10], powder consolidation [6], electrodeposition [11, 12], sputter deposition [13, 14], thermal or plasma spraying [15], crystallization from the amorphous state [16], and severe plastic deformation [17, 18]. Reviews on some of these methods were made by Morris [8] and by Froes et al. [19]. Nevertheless, as it was determined by recent investigations [20, 21], properties in NCM are very sensitive to their initial microstructures. Two grades of a nanocrystalline material (same composition and structure) that are prepared by different procedures and that have a similar grain size may exhibit different mechanical properties. On this basis, discrepancies may exist when comparing experimental data reported by investigators who used different processing techniques in producing the same nanocrystalline material.

Moreover, it is very difficult to produce large bulk NCM that is free from porosity and other flaws and that has a wide range of grain size. Because of this difficulty, the dependence of strain rate on stress, grain size, and temperature in NCM is at present unclear and can be controversial. From the methods mentioned above, the technique of severe deformation under pressure (SePD) can produce bulk NCM free of porosity and surface flaws. This technique includes such methods as equal channel angular pressing (ECAP) [17], high pressure torsion (HPT) [17], and multiple forging (MF) [18, 22], and has been intensively applied for producing of NCM. The current analysis on superplastic behavior is made for NCM produced mostly by HPT. The basic idea of torsion straining (Fig. 1) is to apply a very large pressure (5–7 GPa) to a sample and then twist to introduce large amount of torsion strain (up to true strain of 7) into the sample. The detailed description of this method can be found in [17].

1.3. Theoretical Predictions

NCM materials contain a very large density of interfaces, causing them to differ structurally from crystals and glasses with the same chemical composition. Based on the classical scaling laws developed for conventional coarse-grained materials (grain size, $d > 10 \ \mu$m), expected behavior would include very high yield strength, σ_y, at low temperature due to constraints on dislocation motion (e.g., the Hall–Petch model predicts $\sigma_y \propto d^{-1/2}$) and low strength/high ductility at higher temperatures due to short diffusion paths (e.g., the strain rate, $\dot{\varepsilon}$, in Coble creep scales as $\dot{\varepsilon} \propto d^{-3}$). In addition, one might expect deviations from the classical scaling laws as grain size decreases. For example, when grain size becomes so very small, usual predictions based on dislocation theory may not be valid, and Hall–Petch behavior is expected to break down when the crystallite size becomes smaller than the average dislocation spacing or stable loop size. Diffusional flow might also deviate as the volume fraction of triple junctions increases.

Past, experimental studies focused on (a) whether the Hall–Petch relation, which is well-established for coarse-grained materials, is valid for grain sizes in the nanocrystalline range [23]; (b) whether grain boundary diffusion creep [24], which is expected to be dominant at moderate temperatures (0.4–$0.6T_m$), where T_m is the melting point

of the material, and low stresses, becomes significant at low temperatures (for example, room temperature); and (c) whether structural superplasticity [25], which has been observed at high temperatures ($T > 0.5T_m$) and moderate strain rates (10^{-5}–10^{-2} s^{-1}), can be observed at low temperatures and high strain rates.

There have been several reports on the variation of hardness with grain size that deviates from the normal Hall–Petch relationship [20, 21]. Attempts have been made to calculate an approximate value for the grain size at which the Hall–Petch relationship breaks down (see for example [26]). Several derivations of the Hall–Petch equation are based on the concept of dislocation pile-ups at grain boundaries. (For a review of Hall–Petch theories, see for example [27].) However, transmission electron microscopy (TEM) evidence indicates that yielding involves the emission of dislocations from grain boundaries, rather than pile-ups against them [28, 29]. As it was shown by Gryaznov and Trusov [30], parametric dependencies for the Hall–Petch relationship in NCM will be different from that for typical polycrystals, because the basic defects responsible for nanocrystal deformation are interface dislocations having Burgers vectors smaller than lattice dislocations. The large volume fraction of intercrystalline regions must strongly affect mechanical behavior. The nature of the structure of grain boundaries in NCM has been a controversial area. Early studies [31] proposed that interfaces in NCM represent a new class of solid-state structure lacking both short- and long-range orders. More recent studies [28, 32, 33] have disputed this view, and it is now concluded that the boundaries in NCM do not differ fundamentally in nature from those in coarser-grained materials. However, specific interface structures with a large amount of atomic disorder have been observed by Ranganathan et al. [33] in nanocrystalline palladium and titanium thin films.

Theoretical discussion of nanomaterial at ambient temperature usually relates to the following: Starting with the concept of intragranular dislocation plasticity, as the grain size is progressively decreased, the formation of continuum dislocation pile-ups should become more difficult, and transition to discrete pile-up behavior will occur (end of Hall–Petch correlation). At smaller values of grain size, a pile-up approaches the limit of one dislocation. Then only an Orowan bowing type of mechanism is admissible. Finally, at some critical and yet lower length scale, no dislocations can be formed. Beyond this point, these authors believe [34] along with Masumura et al. [35] that plasticity, if it still exists, has to be interface driven. All of these transitions from traditional dislocation behavior can lead to a new grain size dependence of strength and plasticity, which may cause a fundamental change in deformation behavior of NCM.

Intensive investigation of the deformation processes in NCM focuses on the main question of whether lattice dislocations exist and play the same role in nanograin interiors as with conventional coarse grains. As pointed out in the literature [36–38], the existence of dislocations in either free nanoparticles or nanograins composing a nanocrystalline aggregate is energetically unfavorable if their characteristic size, nanoparticle diameter, or grain size is lower than some critical size. And the critical size depends on such material characteristics as the shear modulus and the resistance to
Figure 1. High pressure torsion (HPT).

dislocation motion. The dislocation instability in nano-volumes is related to the effect of the so-called image forces occurring due to the elastic interaction between dislocations and either free surface of nanoparticle or grain boundaries adjacent to a nanograin [36–38]. The lack of mobile dislocations in nanograins has been well documented in electron microscopy experiments [21, 39]. Moreover, it was suggested that mechanisms of plastic flow may be different in nanocrystals in comparison to usual polycrystals [40, 41].

However, if the available literature concerning deformation behavior of NCM at room temperature was intensively investigated, we would find that very little is known about creep behavior and the actual diffusional accommodation at elevated temperatures [41]. At very low stresses and small grain sizes, early theoretical considerations indicated that vacancies, rather than dislocations, may be responsible for the production of creep strain. Two models, Nabarro–Herring creep [42, 43] and Coble creep [24], have been formulated to account for such plastic flow. Nabarro–Herring creep [42, 43] involves the diffusion of vacancies through the grain volume; the creep rate is given by

$$\dot{\varepsilon}_{NH} = A_{NH} \frac{D_l G b}{KT} \left(\frac{b}{d} \right)^2 \frac{\sigma}{G} \qquad (1)$$

where A_{NH} is a dimensionless constant, D_l is the lattice diffusivity, G is the shear modulus, b is the Burger's vector, K is Boltzmann's constant, T is the absolute temperature, d is grain size, and σ is the applied stress. In Coble creep [24], vacancies diffuse along the grain boundaries; the creep rate is given by

$$\dot{\varepsilon}_{Co} = A_{Co} \frac{D_{gb} G b}{KT} \left(\frac{b}{d} \right)^3 \frac{\sigma}{G} \qquad (2)$$

where A_{Co} is a dimensionless constant and D_{gb} is the grain boundary diffusion coefficient.

The Nabarro–Herring and Coble processes represent two independent and parallel mechanisms, so the faster process controls the creep behavior. Coble creep should predominate over Nabarro-Herring creep when

$$\left(\frac{b}{d} \right) \frac{D_{gb}}{D_l} > \frac{A_{Co}}{A_{NH}} \qquad (3)$$

This condition prevails at low homologous temperatures and very small normalized grain sizes. On this basis, it is expected that due to the ultrafine grain size and the large fraction of intergrain areas in NCM, Coble creep (diffusional creep along grain boundaries) would become important in these materials when crept at low temperatures. Room temperature diffusional creep, however, predicted to be appreciable in nanocrystalline samples, was not confirmed in subsequent investigation [44]. At the smallest grain sizes the significant volume associated with triple points must also become important [45]. However, according to a model proposed by Suryanarayana et al. [46], when the grain size is about 30 nm, which is very close to the grain size in Ni-P and Fe-B-Si used by Wang et al. [47], Deng et al. [48], and Xiao and Kong [49], the volume fraction of triple junctions is less than 1%, while the fraction of grain boundaries is about 10% by assuming grain boundary thickness of

1 nm. Based on this information, the triple junction process is likely to be important when the grain size is less than 10 nm [45].

Another important prediction for NCMs is their high ability for superplastic deformation. The ability of some materials to exhibit extensive plastic deformation, often without the formation of a neck prior to fracture, is generally known as structural superplasticity. Superplastic behavior is indicated in tension tests by large elongations, usually greater than 200 percent and sometimes in excess of 2000 percent. The two basic requirements for the observation of structural superplasticity are (a) a temperature greater than about one-half of the melting temperature, T_m, and (b) a fine and equiaxed grain size (<10 μm) that does not undergo significant growth during high-temperature deformation. In addition to these two requirements, grain boundaries need to be mobile, high-angled, and able to resist tensile separation.

Superplasticity in microcrystalline materials is well established as a grain size dependent phenomenon that can be described by the constitutive equation for conventional superplasticity [25]

$$\dot{\varepsilon} = A \frac{DGb}{kT} \left(\frac{b}{d} \right)^p \left(\frac{\sigma}{E} \right)^2 \qquad (4)$$

where $\dot{\varepsilon}$ is the strain rate, D is the appropriate diffusivity (lattice or grain boundary), G is the shear modulus, b is the Burger's vector, K is the Boltzmann's constant, T is the test temperature, d is the grain size, p is the grain size exponent (usually 2 for lattice diffusion controlled flow and 3 for grain boundary diffusion controlled flow) and σ is the applied stress. Behavior described by this equation has been observed for metals, intermetallics, and ceramics materials. According to this relationship between grain size, superplastic strain rate, and superplastic temperature, a shifting of the optimum strain rate to higher values and/or the optimum temperatures to lower values with microstructural refinement has been predicted. Both aspects happen to have attractive technological significance and were extensively studied. For example, mechanically alloyed aluminum alloys having a typical grain size of 0.5 μm exhibit superplasticity at strain rates >1 s^{-1}, which is comparable to conventional hot forming rates. In comparison, the superplastic strain rates of a material with a typical grain size of 15 μm are 10^{-4}–10^{-3} s^{-1} [50]. The relationship between grain size and optimum strain rate of aluminum alloys is shown in Figure 2a (data taken from [50]) while Figure 2b shows the variation of superplastic temperature with grain size (data taken from [51, 52]). From these figures, it is clear that by manipulating the grain size it is possible to (a) increase the superplastic strain rate and (b) decrease the superplastic temperature.

The purpose of this chapter is to review the experimental data reported for deformation behavior of SePD processed NCM at elevated temperatures including our own results.

2. DEFORMATION BEHAVIOR

Because of specific microstructural features (very small grain sizes, high volume fraction of grain boundaries and triple points, lattice distortions, etc.), it is not surprising
Figure 2. The relationship between grain size and (a) optimum strain rate or (b) superplastic temperature demonstrates that by reducing the grain size it is possible to increase the strain rate or decrease the superplastic temperature (data taken from [50–52]). Both effects have technological significance.

that NCMs reveal specific variations of several fundamental physical parameters as compared to their large-grained counterparts, such as Curie and Debye temperatures, elastic modulus, diffusion coefficients [53], etc. Consequently, novel

physical and mechanical properties are obtained; for example, brittle ceramics may become ductile in nanocrystalline state [54]. However, it should be noted that data on mechanical properties of nanocrystals show contradictory trends. The possible reason for this is an expected difference in structure (porosity, density gradients, contaminations, internal stresses, defects including microcracks, etc.) of samples prepared in different laboratories even for the same grain size. Often this difference in structure is due to uncertain processing history and/or lack of proper control of process variables. Thus, most of the novel properties are found to be very sensitive to the procedure for sample preparation [20, 21]. Thus, NCM produced by the powder sintering procedure did not demonstrate any superplasticity [55]. Moreover, among the NCM produced by other methods, some of them have shown the ability for superplastic flow, while others did not. The summary of our data and some additional literature data on deformation behavior of SePD NCM are given in Table 1.

On the basis of the experimental results on SePD NCM, Mishra et al. [56] proposed an "exhaustion plasticity" mechanism. It is known that severe plastic deformation introduces a large population of dislocations into the specimen. In this "exhaustion plasticity" mechanism, the flow stress at the initial stage of deformation is not high enough to nucleate new dislocations for slip accommodation because of the very small value of grain size. The applied stress moves the pre-existing dislocations, and grain boundary sliding is accommodated by the movement of these dislocations. As the easy paths of grain boundary sliding and dislocation movement get exhausted, the flow stress increases, which is indicated by a strain hardening stage observed in the superplastic deformation of the NCM. According to Mishra et al. [56], the peak flow stress can be viewed as the critical stress required to generate new dislocations during grain boundary sliding. Hence, the experimental results on commercially pure Ti and NiTi alloy have confirmed that nanostructure as well as excess of dislocations are not sufficient conditions for SePD materials to show superplasticity.

Table 1. A summary of observation of superplasticity in nanocrystalline materials.

Material and reference	Gain size[a] (nm)	Strain rate (s^{-1})	Temp. (°C)	Stress at $\varepsilon = 0.1$ (MPa)	Max. stress (MPa)	Elong. (%)	Remarks
Al-Ni-Mm[b] (Higashi et al., 1993)	70	7×10^{-1}	600	18	—	500	
Ti-6 Al-3.2 Mo (Salishchev et al., 1993)	60	5×10^{-4}	600	150	—	600	Stress at $\delta = 40\%$
Zn-Al (Mishra et al., 1997)	80	5×10^{-4}	120	18	—	230	
Ni$_3$Al alloy (Mishra et al., 1998)	50	1×10^{-3}	650	400	1530	380	Extensive strain
			725	270	790	560	hardening
Al-Mg-Li-Zr alloy (Mishra et al., 1998)	100	1×10^{-1}	250	106	154	330	Extensive strain
			300	33	146	850	hardening
Ti-6 Al-4 V (Unpublished, 1998)	70	1×10^{-3}	575	165	—	215	

[a] Denotes the starting average grain size.
[b] This alloy showed significant coarsening during heating, so the microstructure during testing was not nanocrystalline.

According to literature [57], the deformation of microcrystalline commercially pure Ti is associated with dislocation climb controlled by lattice diffusion. The stress exponent obtained by different investigators is close to 5, and activation energy is found to be 210–250 kJ/mol. This mechanism of deformation, namely five-power-law creep seems to be also operative in Ti in the nanocrystalline range at temperatures higher than $0.4T_m$ and at "conventional" strain rates ($10^{-4} \cdots 10^{-2}$ s^{-1}) [12]. Apparent activation energy for both microcrystalline and nanocrystalline states seems to be higher than that for lattice diffusion reported for commercially pure Ti (153 kJ/mol [58]). In a NiTi alloy with nanostructure obtained by the same method (HPT), the deformation mechanism seems to be related to viscous glide of dislocations with a stress exponent of 3 [12]. Such a deformation mechanism is common for ordered structures. There is a lack of data on diffusion related processes in NiTi in the literature, but an approximate estimation of activation energy for self-diffusion gives a value of 220–230 kJ/mol [12]. So, the apparent activation energy of 210 kJ/mol calculated from the experimental data is in good agreement with such estimation, assuming that the activation energy for viscous glide, which is controlled by Darken interdiffusivity, is close to volume self-diffusivity in this case. Despite the fact that the grain size of this material is on the nanometer scale, and the volume fraction of grain boundaries is therefore significant, it seems that grain boundary sliding or operation of Coble creep are suppressed in NiTi.

The results on NCM that did undergo superplastic deformation have established a number of general trends of the mechanical behavior of NCM at elevated temperatures such as excessive strain hardening during tensile tests, high flow stresses (compared to microcrystalline materials at comparable temperature and strain rate), a correlation between microstructural instability (in terms of onset of grain growth), and superplasticity, which will be discussed below.

In microcrystalline superplasticity, the stress concentration that arises at grain boundary triple points (or ledges) due to grain boundary sliding is accommodated by diffusional processes or by (dislocation) slip processes. One of the fundamental issues in nanocrystalline superplasticity is: Which of the two accommodation processes is most important? In recent years, the possibility of superplasticity in NCM has been discussed in terms of diffusional flow. However, a grain boundary sliding mechanism with diffusional accommodation will not be able to explain all of the trends described above. These trends indicate that the mechanism of superplasticity in NCM is significantly different from the well-established mechanisms in microcrystalline materials.

2.1. Significant Differences

2.1.1. Excessive Strain Hardening

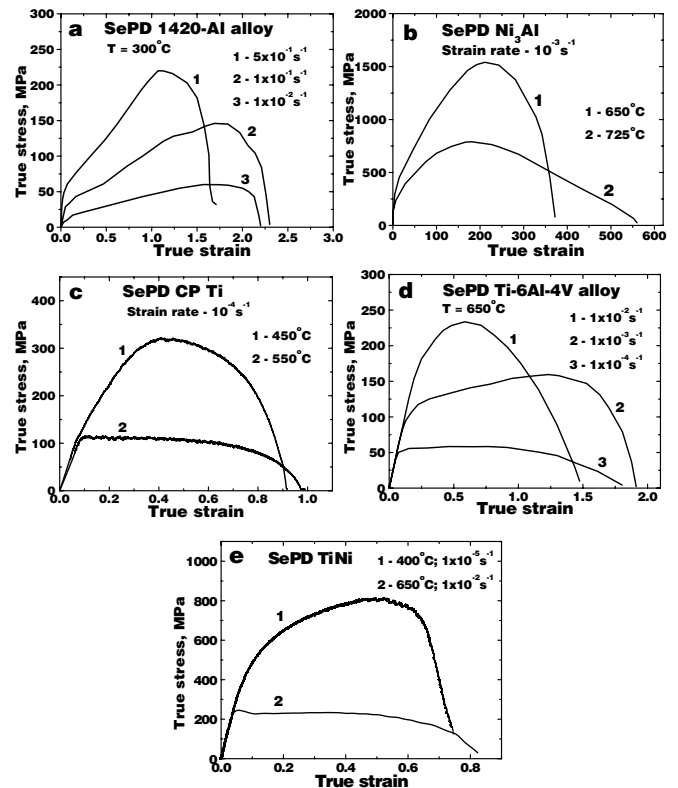
Figure 3 shows flow curves of SePD 1420-Al and Ni$_3$Al alloys, commercially pure Ti, Ti-6Al-4V, and NiTi alloys. Excessive strain hardening was observed for all these materials when their grain size does not exceed 100 nm. Intensive grain growth at high temperatures (Fig. 3c and e) or low testing strain rate (Fig. 3d) leads to dramatic change in the deformation flow, and no strain hardening was observed. It is important to note that the strain hardening in the 1420-Al


Figure 3. Flow curves for (a) 1420-Al alloy at different strain rates, (b) Ni$_3$Al alloy at different temperatures, (c) CP Ti at different temperatures, (d) Ti-6Al-4V alloy at different strain rates, and (e) NiTi intermetallic at different temperatures show excessive strain hardening. Note the increase in strain hardening with increasing strain rate in 1420-Al alloy and Ti-6Al-4V alloy.

alloy (Fig. 3a) and Ti-6Al-4V alloy (Fig. 3d) increases with increasing strain rate. We have observed a similar trend in other SePD processed materials as well, for example, Zn-Al and 2124-Al alloys [59, 60].

Similar elongations were reached in CP Ti (with initial grain size of about 120 nm) at 450 and 550 °C and at a strain rate of 1×10^{-4} s^{-1} (157% and 166% respectively, but the shape of the flow curve has changed dramatically with decrease of test temperature (Fig. 3c). The flow curve at 450 °C shows an extensive hardening period and stress dependence on strain (Fig. 3c, curve 1), whereas the curve at 550 °C, when grain size was already more than 200 nm, has a shape typical for nearly steady state flow with relatively low stress flow (Fig. 3c, curve 2).

These observations establish a trend. There is some grain growth in these NCMs during superplastic deformation. Because of the grain size dependence in the constitutive relationship for superplastic flow, strain hardening during superplasticity has been conventionally explained in terms of grain growth. However, such an explanation would not predict higher strain hardening at higher strain rate. A detailed microstructural investigation is required to explain this trend.
Figure 4. A comparison of flow curves for Ni_3Al alloy in microcrystalline and nanocrystalline state. Note the higher flow stress in the nanocrystalline state, although both specimens showed similar ductility.

2.1.2. High Flow Stresses

Figure 4 shows a comparison of the flow curves during superplasticity in a Ni_3Al alloy. This alloy was tested in both microcrystalline and nanocrystalline states. The high flow stresses during superplasticity of the nanocrystalline Ni_3Al alloy are apparent. Although the test temperature and grain size is different for the two microstructural conditions, the comparison is interesting because the overall ductility in both cases is similar. One of the features of conventional superplasticity in microcrystalline material is low flow stress. The observation of superplasticity with high flow stresses in NCM needs a new approach to explain the origin of such high flow stresses. First, the starting flow stress is around 170 MPa. Second, after significant strain hardening, the flow stress reaches the level of 780 MPa at 725 °C. At 650 °C, the flow stress values are even higher (Fig. 3b).

Figure 5 shows the variation of normalized stress with temperature and grain size compensated strain rate for Ti-6Al-3.2Mo alloy. The raw stress-strain rate data were taken from Salishchev et al. [18, 22]. Also, the data for a microcrystalline Ti-6Al-4V alloy [61] and the expected behavior from the grain boundary diffusion controlled mechanisms of deformation [62] are included. Titanium alloys
Figure 5. The variation of normalized flow stress with temperature and grain size compensated strain rate for Ti alloys (data taken from [18, 22, 61, 62]).

exhibit slip accommodated lattice-diffusion controlled grain-boundary sliding. Two things are apparent from Figure 5: (a) the data for microcrystalline alloy agree well with the expected trend for slip accommodated lattice-diffusion controlled grain-boundary sliding, and (b) the data for the submicrocrystalline alloy and nanocrystalline material show higher flow stress. Higher flow stresses have been also observed for NCM, produced by other methods [63]. This suggests a transition in micromechanisms or additional difficulty in grain boundary sliding, which is opposite to some of the earlier expectations of enhanced superplasticity in NCM.

One way to explain the origin of higher flow stresses for superplasticity in NCM is to consider the possible influence of grain size on slip accommodation during grain boundary sliding. Recently, Mishra and Mukherjee [64] have suggested that dislocation nucleation is difficult in NCM. A preliminary estimate of the stress required for nucleating such a dislocation can be obtained by using a relationship proposed by Hirth and Lothe [65] for dislocation generation by a Frank–Read source in the crystal lattice, which after simplification can be written as

$$\tau = \frac{\mu b}{4\pi L(1-\nu)}\left(\ln\frac{L}{b} - 1.67\right) \qquad (4)$$

where L is the distance between the pinning points, ν is the Poisson's ratio, and τ is the shear stress required to generate the dislocations. For superplastic deformation, the tensile stress needed to nucleate dislocation for slip accommodation can be calculated by approximating $L = d/3$, $\nu = 0.33$, and $\sigma = \sqrt{3}\,\tau$. The choice of $L = d/3$ is based on the fact that the edge of the tetrakaidecahedron grain is one-third of the distance between the faces of the grains [66]. Equation (4) does not have (a) strain rate dependence (which is an integral part of high temperature deformation), (b) temperature dependence other than the modulus, and (c) the details of dislocation generation from grain boundaries. These effects can be significant, as the flow stress at high temperatures is known to be strain rate and temperature dependent in the superplastic region.

2.1.3. Parametric Dependencies

In general, in order to understand the nature and origin of deformation mechanisms at high temperatures, information related to the dependence of strain rate on stress, temperature, and grain size is essential, and constitutive equations are very helpful in this case. For superplasticity, it is customary to evaluate the stress exponent, activation energy, and grain size exponent. Based on the values of these parametric dependencies, one can decide on the dominant micro mechanism of deformation. So far, there is very limited data on stress exponent and activation energy for superplastic flow in NCM. These data are listed in Table 2. We note that during some of the tests used to obtain the values mentioned below, significant grain growth occurred. The extent to which the results summarized below are influenced by concurrent grain growth is not clear. The stress exponent values for the alloys are close to the theoretically expected value of 2 for grain boundary sliding mechanisms. The activation energy in some cases is significantly higher than the activation energy for grain boundary diffusion. This is intriguing, because with

Table 2. Parametric dependencies for superplastic flow in nanocrystalline materials.

Material and reference	Superplastic parameters		Activation energy[a] (kJ/mol)	
	Stress exponent	Activation energy (kJ/mol)	For lattice diffusion	For grain boundary diffusion
Al-Ni-Mm alloy (Higashi et al., 1993)	~2	151	142	84

the abundance of grain boundaries in NCM, an activation energy for grain boundary related deformation mechanism is expected at elevated temperatures.

2.1.4. Effect of Short Annealing

A unique experimental observation is related to the effect of a short anneal on the flow behavior. An example of this is shown in Figure 6. The annealing of SePD processed nanocrystalline Ni$_3$Al does not change the grain size significantly, but it has a dramatic effect on the flow behavior. The initial flow stress increases and the shape of the flow curve changes. The overall ductility reduces from 350% in the as received condition to ~100% after the short anneal.

It should be noted, that a strong effect of the short annealing of SePD Ti was revealed at room temperature tensile tests. Thus, short annealing of SePD Ti at 300 °C results in a 30% increase in strength combined with adequate plasticity (Fig. 7, curve 2) as compared to as-deformed state

(Fig. 7, curve 1) [67]. Annealing for a longer time even at lower temperature decreases strength (Fig. 7, curve 3). A number of tensile tests of severe plastic deformed CP Ti after annealing at different temperatures for 10 min revealed a strong dependence of strength characteristics on annealing temperature with a peak in the range of 250 °C to 300 °C. Microstructural analysis revealed a formation of specific ordered structure in grain boundary regions (Fig. 8) [68], which was not observed in as-deformed SePD Ti. In the sample, which has demonstrated the highest strength, about 80% of grain boundaries have a such special structure.

2.1.5. Correlation Between Microstructural Instability and Superplasticity

The driving force for grain growth is quite high in NCM because of the high interfacial area per unit volume. We have observed a nice correlation between the temperature for microstructural instability and onset of superplasticity in
Figure 6. Effect of a short anneal on flow behavior of a nanocrystalline Ni$_3$Al alloy.

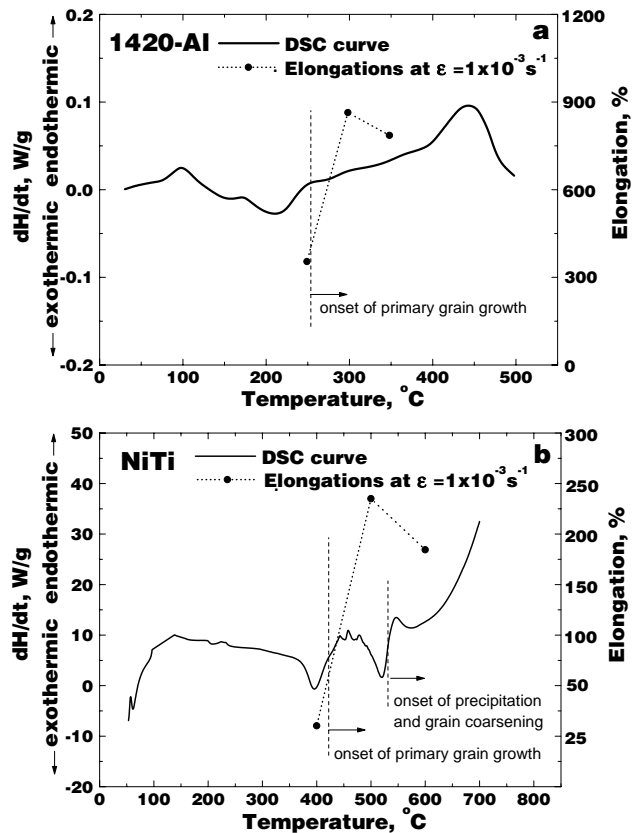
Figure 9. Combined plots showing variation of DSC signal and elongation with temperature for SePD (a) 1420-Al alloy and (b) NiTi.

NCM. In some ways this is to be expected because both grain boundary migration and grain boundary sliding involve diffusion. An important implication of this is that one needs to establish the narrow temperature range in which there is enough thermal activation for grain boundary sliding but the grain growth rate is relatively low. This is important for observing the grain boundary sliding regime without significant influence of grain growth, particularly from the viewpoint of obtaining parametric dependencies for constitutive modeling. We are investigating the microstructural instability by three different methods: differential scanning calorimetry (DSC), *in-situ* TEM heating, and TEM of heat treated specimens. The correlation between the DSC signal for thermal stability and increase in ductility is shown for SePD processed 1420-Al and NiTi alloys in Figure 9. The onset of grain growth was independently established by analyzing the video recording of *in-situ* TEM heating. The results show that the DSC can work as a very good tool to establish the optimum superplastic temperature for NCM.

2.1.6. Microstructural Observations

We have conducted two types of TEM investigations: (a) microstructural investigation of thin foils at room temperature and (b) video recording of microstructural changes during *in-situ* heating. We have established that the present results at some temperatures reflect superplasticity in the truly nanocrystalline state, as the microstructure remained nanocrystalline during the entire test. For example, Figure 10 shows the microstructure of the nanocrystalline Ni$_3$Al alloy after testing at 650 °C to 380% elongation. In general the dislocation activity appears to quite limited. A few lattice dislocations were visible, as marked in Figure 10. It is interesting to note that dislocation 2 has one end in the grain boundary. The appearance of these types of dislocations suggests the grain boundaries as sources of dislocations. This would be consistent with slip accommodation during grain boundary sliding. The 1420-Al alloy showed high strain rate superplasticity at a relatively low temperature where the nanostucture was relatively stable. It is necessary to note that in the earlier studies [69, 70]


intensive grain growth prior to testing or during testing to the submicrocrystalline range was detected.

Microstructural investigation was also conducted of nanocrystalline commercially pure Ti, which showed high elongation but with parametric dependencies different from that for classical superplasticity (Table 2). This material has demonstrated a five-power-law creep that associated with dislocation climb controlled by lattice diffusion. The enhanced plasticity observed in this pure metal and TEM
Figure 10. A bright field transmission electron micrograph of a Ni$_3$Al specimen superplastically deformed at 650 °C to an elongation of 380%. Some of the lattice dislocations are marked by arrows.

observations of the structure after deformation suggest that grain boundary sliding also took place during deformation at elevated temperatures. Figure 11 presents the microstructure of Ti produced by severe plastic deformation and deformed at 350 °C (Fig. 11a and b) and 600 °C (Fig. 11c, d, and e) to strain of 65% and 190%, respectively. It is seen that despite such high elongations the grains remain equaxied in both cases. Twinning was not observed during deformation at 350 °C (Fig. 11a and b), while at 600 °C twins were formed (Fig. 11c). Moreover, some twins emerging from grain boundaries were revealed (Fig. 11d). Such twinning can be formed as a result of grain boundary sliding in order to resolve stress concentration on grain boundary. So, during elevated temperature deformation there seems to be a competition between these two mechanisms and both of them play a role in the deformation process. As shown by analysis of stress-strain curves, the rate controlling deformation mechanism in investigated range of strain rates and temperatures is dislocation glide controlled by dislocation climb. High dislocation activity should be noted in the deformed structures (Fig. 11a and d). In the sample deformed at higher temperature, stacking faults have been also observed (Fig. 11e). Some of them look like regular extended dislocation (marked as "A"), whereas the others

have triangular shape and might be formed by dissociation of stair rod dislocations (marked as "B").

2.1.7. Absence of Cavitations

Microcrystalline superplastic materials have shown clear evidence for intergranular cavitation. This includes observation on Al-Cu-Li-Zr alloy [71] and Ni_3Al alloy [72]. However, current investigation on NCM fails to reveal any evidence of cavitation. A critical question may be: Can one maintain the stress concentration at grain boundary triple points, grain boundary ledges, or at particles on the grain boundary long enough so that cavity nucleation can take place? Or can it be that diffusional relaxation in NCM is so fast that one cannot maintain that condition? In an analysis of cavity nucleation in superplasticity [73], the authors have proposed a competition between the characteristic relaxation time for grain boundary sliding leading to the development of stress concentration at ledges. Cavities may nucleate at these sites, if the incubation period for cavity nucleation is less than the characteristic time for the relaxation of stress concentration by localized diffusion creep. The analysis yields a quantitative cavity nucleation map in terms of normalized stress versus normalized cavity height/spacing. The analysis also suggests that in such ultrafine grain materials, it is possible for cavities to nucleate under some rather limited experimental conditions.

3. MAIN ISSUES

3.1. Effect of Processing

On the basis of the experimental results on SePD NCM, Mishra et al. [56] proposed an "exhaustion plasticity" mechanism. It is known that severe plastic deformation introduces a large population of dislocations into the specimen. In this "exhaustion plasticity" mechanism, the flow stress at the initial stage of deformation is not high enough to nucleate new dislocations for slip accommodation because of the very small value of grain size. The applied stress moves the pre-existing dislocations, and grain boundary sliding is accommodated by the movement of these dislocations. As the easy paths of grain boundary sliding and dislocation movement get exhausted, the flow stress increases, which is indicated by a strain hardening stage observed in the superplastic deformation of the NCM. According to Mishra et al. [56], the peak flow stress can be viewed as the critical stress required to generate new dislocations during grain boundary sliding. Mishra et al. [56] further predicted that the NCM prepared by sintering of nanocrystalline powders would not exhibit large tensile plasticity due to the lack of the large population of pre-existing dislocations.

From the evaluation of the behavior of NCM, it is clear that a nanocrystalline grain size does not appear to be a sufficient condition for superplasticity. A number of pure metals and alloys processed by severe plastic deformation to grain sizes <100 nm did not exhibit classical superplasticity (Table 1). The effect of short annealing on deformation behavior (see above) has clearly demonstrated that microstructural features other than grain size can play a considerable role. Moreover, the ability of NCMs to deform

Figure 11. Microstructure of CP Ti produced by severe plastic deformation and deformed at 350 [(a) bright field; (b) dark field images] and at 600 °C [(c)–(e): (d) is enlarged image of the selected area on (c); (e) is enlarged image of the selected area on (d).]

by superplastic flow seems to be strongly dependent on the method of their synthesis [74].

What are the necessary conditions for obtaining superplasticity in nanocrystalline materials? The answer is not clear at present, but obviously some microstructural features other than just grain size also can be responsible for the material behavior.

3.2. Deformation Mechanisms

The specific characteristics of dependency of the hardness and yield stress on grain size in NCM are definitely caused by their structural details related to the nanoscale dimension and the extremely high volume fraction of the grain boundaries. In this context, adequate theoretical understanding of the grain size dependency of the yield stress in NCM will essentially contribute, on one hand, to the understanding of the fundamentals of structure-property relationships in nanoscale solids, and, on the other hand, will serve as a basis for development of newer technologies that exploit the outstanding mechanical properties of NCM.

Slip accommodation is an important feature in superplastic deformation of microcrystalline metallic materials. Most of the superplastic models incorporate this feature [62, 75] and transmission electron microscopy does indicate intragranular dislocation activity. However, as the grain size is decreased, slip accommodation should become more difficult. In that case, the grain size dependence of superplasticity may show a fundamental change for NCM. The most fundamental question for the accommodation for stress concentration due to grain boundary sliding is: Diffusional accommodation or Slip accommodation? In recent years the possibility of superplasticity in NCM has been discussed in terms of diffusional flow. However, a grain boundary sliding mechanism with diffusional accommodation will not be able explain all of the trends. The only way to explain strain hardening by diffusional mechanisms is grain growth. Our TEM investigation of a Ni_3Al alloy before and after deformation at 650 °C suggests that grain growth alone would not be able to explain this behavior.

One of the open questions on the micromechanism of superplasticity in NCM is the role of slip accommodation. As noted earlier, the micrograined materials do show significant intragranular dislocation activity, and these dislocation features are interpreted as evidence for slip accommodation. On the other hand deformed NCMs have shown very little dislocation activity, and theoretical calculations [36–38] appear to support this lack of dislocation activity.

3.3. Modeling

The preliminary experimental data (Table 1) indicate that the stress exponent and activation energy for superplastic flow is similar for microcrystalline and NCM, although the details are not clear at this stage. The initial results in the last two years have established a number of trends: excessive strain hardening, high flow stresses, a strong annealing effect on flow behavior, and a correlation between microstructural instability and superplasticity (Section 3). Based on the limited data, the kinetics of superplastic flow is suggested to undergo a transition at a critical grain size.

The key points that are interesting for the future theoretical studies of plastic deformation processes and associated phenomena in NCM are as follows:

- A theoretical description of the critical grain size at which the general equations for superplastic deformation will break down.
- A theoretical analysis of the specific features of plastic flow in NCM.
- A development of the generalized model that will describe the combined action of different deformation mechanisms (such as lattice dislocation motion in grain interiors, grain boundary sliding, grain rotation, and diffusion based plasticity mechanisms associated with grain boundary diffusion and triple junction diffusion) whose contribution to plastic flow in NCM is dependent on the material characteristics, grain size distribution, and conditions of loading.

One of the problems in modeling of the deformation behavior of NCMs is related to their high thermal instability and a lack of experimental data on elevated temperature properties. Another problem is the limited data on diffusion coefficients in the materials at significantly diminished length scale. Recent analysis of the existing models based on classical diffusion creep and grain boundary sliding controlled by dislocation climb from the head of a pileup [76] has shown to be ruled out as not being consistent with the experimental observations. In concept of the increasing role of grain boundaries with decreasing grain size, the model based on the grain boundary structure seems reasonable. For example, a model of secondary grain boundary dislocations [76], which is based on the basic theory of grain boundary structure, was shown to cover such processes as grain rotation and grain boundary migration. These mechanisms are predicted to play a sufficient role in deformation of materials with grains in the nanometer range.

An increasing role of grain boundaries in NCM, especially as source and sink of mobile dislocations, was also demonstrated by molecular dynamics simulation [77]. The authors observed grain boundary generation of dislocations in a 45 nm grain size high stacking fault energy metal (12% strain) at room temperature (Fig. 12). Such dislocation motion has already been captured by videocamera at room
Figure 12. Dislocation nucleation at grain boundary. Molecular dynamics simulation of room temperature deformation of fcc high stacking fault energy metal. Grain size = 45 nm.

temperature in Ni$_3$Al ordered matrix (Fig. 13). More detailed information can be found in [78].

4. CONCLUDING REMARKS

Although NCMs are a subject of intensive investigation nowadays, there are no systematic data on their mechanical behavior and superplasticity. The size limit of nanocrystalline materials is often a matter of debate. In some publications and reviews [3], only materials with a microstructure the characteristic length scale of which is on the order of a few (typically 1–10) nanometers are determined as nanocrystalline or nanostructured materials. According to others [79] the grain size for nanocrystalline and nanostructured materials should be smaller than 500 nm. A most common definition for NCM is materials having average grain sizes below 100 nm, and this review includes mostly data on mechanical behavior of this type of materials. Nevertheless, it seems reasonable to connect this definition with characteristic features or quality changes in the material properties. The critical grain size for such changes can be slightly different for different materials but for most of them it is in the range of 20–30 nm (deviation from Hall–Petch relationship, sharp changes in magnetic properties, etc.). This seems to be the lower grain size limit for most well-known constitutive models on mechanical behavior of the materials including superplasticity. Nanomaterials seem also to have a limit in a minimum grain size, which is determined by the grain size limit of the crystalline state, and, for example, for selenium was determined to be about 4 nm [80]. It was also suggested by D. Wolf et al. [81] that below a critical grain size NCM should be unstable with respect to the amorphous phase.

Theoretical models of plastic deformation processes in NCM are mostly restricted to room temperature behavior with emphasis on Hall–Petch relationship [82]. Thus, an elevated temperature behavior of NCM is an area of high potential interest that has not been studied yet. Decreasing grain size leads to changes in deformation mechanism of the materials by eliminating some of them (a classical dislocation glide, twinning) and activation of others (grain boundary sliding, grain rotation, triple junction diffusion).

The analysis of their effect on the material properties and a development of the generalized model, which will describe the combined action of different deformation mechanisms, are the major subjects of the oncoming theoretical and experimental investigations.

GLOSSARY

Creep Time-dependent plasticity under a fixed stress at an elevated temperature.

Equal channel angular pressing (ECAP) Deformation of massive billets via pure shear that introduces an intense plastic strain into materials without changing the cross section area of billets.

High-pressure torsion (HPT) Torsion straining of the materials under high pressure.

Nanocrystalline materials (NCM) Materials with grain size in nanometer range.

Severe plastic deformation (SePD) A plastic deformation of the materials under high pressure (up to 7 GPa) to high strain (up to 7).

Superplasticity The ability of a polycrystalline material to exhibit, in a generally isotropic manner, very high tensile elongations prior to failure.

Dendrimer–Metal Nanocomposites

Kunio Esumi

Tokyo University of Science, Tokyo, Japan

CONTENTS

1. INTRODUCTION

Dendrimers are macromolecules with a regular and highly branched three-dimensional architecture. The first example of an iterative synthetic procedure toward well-defined branched structures was reported by Vögtle et al. [1], who named this procedure a "cascade synthesis." In the early 1980s, Denkewalter et al. [2] patented the synthesis of L-lysine-based dendrimers. A paper concerning dendrimers, which have received widespread attention, was presented by Tomalia et al. in the first international polymer conference at Kyoto in 1984 and was published in *Polymer Journal* in 1985 [3]. At the same time, Newkome et al. [4] reported on "arborol" for branched polymers. In 1980s, many different dendrimers were synthesized. Tomalia's poly(amidoamine) (PAMAM) dendrimers and Newkome's arborol have been obtained by the divergent method, while Fréchet et al. [5] introduced the convergent approach for precise synthesis of dendrimers. In the 1990s, for intriguing properties of dendrimers as well as their synthesis and possible applications, many types of dendrimers systems were developed [6–11].

Since dendrimers consisting of a regularly branched structure are controlled by chemical structure, molecular weight, and its distribution as well as molecular size and molecular shape, dendrimers are classified as unique macromolecules with many functional properties. In addition, it is possible to make molecular design of dendrimers from the standpoint of core, branched chain, and surface functional groups, and the pore space of dendrimers can also be utilized. Dendrimers can provide a dimensional functionality which is different from conventional linear polymers; although conventional linear polymers can be modified by grafting branched chains, dendrimers have superior properties to build up three-dimensional molecular architectures.

Through intensive research developments, dendrimers have been recognized to be important and interesting materials from the standpoint of basic and applicable new material. For example, dendrimers have many applicable potentials such as nanocapsules, gene vectors, catalysis, magnetic resonance imaging agents, electron conduction, and photon transduction. Large scale production of dendrimers can also promote dendrimers as a new generation material. Furthermore, the science of dendrimers has grown through a deep connection with disciplines that include physical and materials chemistry, biotechnology, and applied physics. At the present, poly(amidoamine) dendrimers and poly(propyleneimine) dendrimers are available commercially which are made by the divergent method.

Since dendrimers can interact with many chemicals which can be applied to many fields, synthesis and characterization of dendrimer–metal nanocomposites are discussed in this chapter.

2. SYNTHESIS AND CHARACTERIZATION

Before discussing synthesis of dendrimer–metal nanocomposites it is better to show some information about the evolution of the size and shape of dendrimers. Figure 1 shows transmission electron microscope (TEM) images of PAMAM dendrimers stained positively for G10 to G5, respectively [12]. The dendrimer molecules appear as dark objects on a light background of the amorphous carbon substrate and they are spherical to a first approximation for G10 to G7, with some molecules showing "edges" or slightly polyhedral shapes. For G6 and G5, the shapes become more indistinct because the substrate is closer in size to the molecule and the edges become more difficult to delineate. The mean and median diameters of each generation are listed in Table 1, along with the standard deviation of the measurement. In general, the agreement between the mean and median diameters is good, indicating that the distribution is approximately Gaussian in shape. The mean diameters range from 14.7 nm for G10 to 4.3 nm for G5. The
Figure 1. PAMAM dendrimers positively stained with 2% aqueous sodium phosphotungstate imaged by conventional TEM: (a) G10, (b) G9, (c) G8, (d) G7, (e) G6, (f) G5. The scale bars indicate 50 nm. For G6 and G5, a small amount of G10 has been added as a focusing aid. Reprinted with permission from [12], C. J. Jackson et al., *Macromolecules* 31, 6259 (1998). © 1998, American Chemical Society.

diameters of PAMAM determined by size-exclusion chromatography are much smaller than those by TEM. Further, the diameters of PAMAM dendrimers are larger than the equivalent poly(propyleneimine) dendrimers [13].

Preparation of metal particles has been intensively investigated because metal nanoparticles have been applied in electrooptical devices, electronic devices, imaging materials, catalysis, and so on [14–20]. Fabrication of nanoparticles becomes one of the important topics in nanotechnology. For that purpose, it is required that reliable nanoscale devices control particle size, shape, and size distribution of metal nanoparticles.

Since dendrimers contain a large number of regularly spaced internal and external functional groups, it is expected that they operate as templates to grow inorganic crystal in

Table 1. Size measurements on PAMAM dendrimers from computer analysis of TEM images.

Generation	Mean diameter (nm)	Median diameter (nm)	No. of dendrimers	Standard deviation
10	14.7	14.8	413	1.1
9	12.4	12.5	1331	0.8
8	10.2	10.3	459	0.8
7	8.0	8.0	576	0.7
6	6.9	6.9	239	0.5
5	4.3	4.3	285	0.7

the internal or external region of the dendrimer which provides organic–inorganic hybrid nanostructures [21–44].

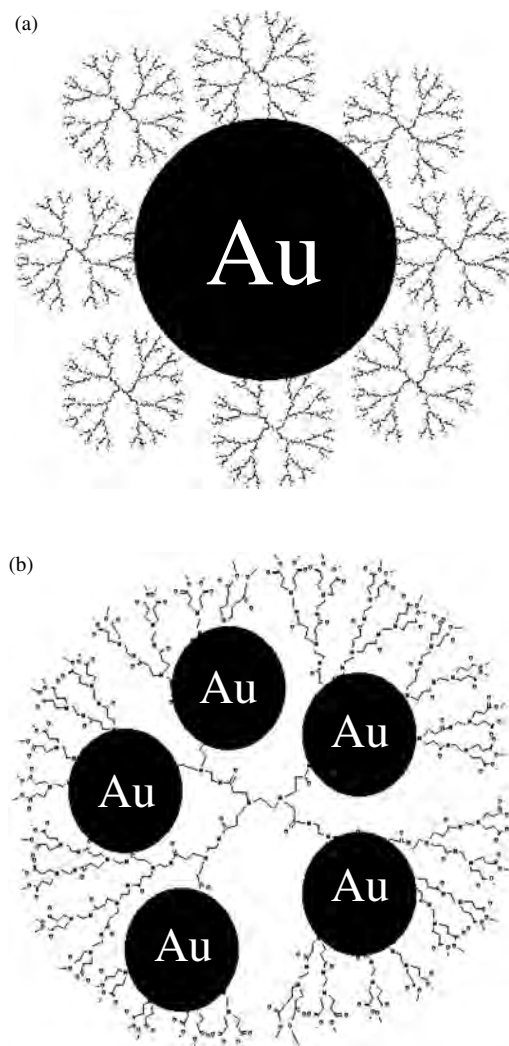
When metal ions are mixed with PAMAM dendrimers in solutions complex formation by ligand–metal ion interaction, acid–base interaction, and other interactions might occur at the surface or inside of the dendrimers. After the reduction the location of metal particles in nanocomposites strongly depends on the place of the complex formation. Accordingly dendrimer–metal nanocomposite structures are schematically illustrated in Figure 2. In Figure 2a, metal ions interact with surface functional groups of the dendrimers and the resulting nanoparticles are present on the surface of the dendrimers. Also, for lower generation dendrimers whose diameters are smaller than those of metal particles a nanocomposite structure as in Figure 2a might be suggested. On the other hand, when metal ions are diffused into the dendrimers complexed with the binding sites, metal particles after the reduction are encapsulated into the dendrimers as shown in Figure 2b. Such encapsulation might occur in higher generation dendrimers. In addition, there is


Figure 2. Schematic illustration of dendrimer–metal nanocomposite structures: (a) gold nanoparticle surrounded by dendrimers; (b) dendrimer-encapsulated gold nanoparticles.

a possibility of a mixed structures of Figure 2a and b. The results of dendrimer–metal nanocomposites synthesized so far are discussed below.

The dendrimer–copper nanocomposites were first synthesized using PAMAM dendrimers with various surface functional groups in aqueous solution [22, 23]. In the case of copper sulfate and dendrimer with surface hydroxyl group, chemical reduction of Cu^{2+}-loaded G4 dendrimer (G4-OH) with a fivefold molar excess of sodium borohydride results in intradendrimer Cu clusters. The solution color immediately changes from blue to golden brown: the absorbance bands originally present at 605 and 300 nm disappear and are replaced with a monotonically increasing spectrum of nearly exponential slope toward shorter wavelengths. This behavior results from the appearance of a new interband transition arising from the formation of intradendrimer Cu clusters. TEM results indicate the presence of intradendrimer Cu clusters after reduction. Micrographs of Cu clusters within G4-OH reveal particles having a diameter less than 1.8 nm, much smaller than the 4.5 nm diameter of G4-OH. Clusters formed in the presence of G4-OH are stable for at least 1 week in an oxygen-free solution. However, in air-saturated solutions the clusters revert to intradendrimer Cu^{2+} ions overnight. When G4 dendrimers with surface amino group are used as templates, they adsorb Cu^{2+} ions which bind primarily to the surface amino groups. Reduction of a solution shows a formation of Cu clusters having diameters more than 5 nm. This large size is a consequence of agglomeration of Cu particles adsorbed to the unprotected dendrimer exterior. Another study for the synthesis of dendrimer–copper nanocomposites using copper acetate and hydrazine as a reductant agent suggests that copper particles are present at both the interior and exterior of the dendrimer with surface amino groups. Dendrimer–copper nanocomposites are also synthesized using amine-terminated poly(propyleneimine) dendrimer with a diaminobutane core. The size of copper clusters decreases with increasing dendrimer generation. In the case of fourth generation of dendrimer it is possible to have some degree of encapsulation of the copper clusters. Thus, depending on the polarity of the dendrimer surface substitutes, the metallic particles may be directed near the dendrimer surface or deeper into the interior.

The dendrimer–gold nanocomposites have been synthesized by reduction of $AuCl_4^-$ with ultraviolet (UV) irradiation in aqueous solution [21]. The absorption band of colloidal gold appears at around 520 nm, and its intensity increases with an increase of the irradiation time. In the case of the low generation PAMAM dendrimers the plasmon band is shifted to longer wavelength with increasing UV irradiation time due to coagulation of gold particles. Typical TEM images of gold colloids obtained in the presence of G5 dendrimer with surface amino group (G5-NH2) and their particle size distributions are shown in Figure 3. At the ratio of [surface amino]/[HAuCl₄] = 1 : 1, the particle size of gold colloids is in the 2–18 nm range, having a broad size distribution. When the ratio is increased to 4 : 1, monodispersed gold particles with a diameter less than 1 nm are obtained. The average particle sizes of gold colloids obtained in the presence of G(0-5)-NH2 are shown in Figure 4. The average
Figure 3. TEM images and particle size distribution of gold nanoparticles, molar ratio of surface amino group of PAMAM G5 and HAuCl₄: (a) 1 : 1; (b) 4 : 1. Reprinted with permission from [21], K. Esumi et al., *Langmuir* 14, 3157 (1998). © 1998, American Chemical Society.

particle size decreases with increasing concentration of surface amino group for each dendrimer. In particular, it is interesting to note that ultrafine gold colloids with a diameter less than 1 nm are obtained in the presence of a higher
Figure 4. Variation of average particle size of gold nanoparticles with concentration of surface amino group of PAMAM dendrimers G(0-5). Reprinted with permission from [21], K. Esumi et al., *Langmuir* 14, 3157 (1998). © 1998, American Chemical Society.

concentration surface amino group of higher generation dendrimers. These results suggest that the dendrimers of lower generation G0 do not operate as effective protective colloids, but dendrimers of higher generations provide sites for complex formation with $AuCl_4^-$ as well as an effective protective action. Dendrimer–silver nanocomposites are also synthesized in the presence of amino- (G4) or carboxylate-terminated (G3.5) PAMAM dendrimers by UV irradiation [38]. The silver nanoparticles with average size of about 7 nm diameter are obtained using amino-terminated dendrimers, while a larger size (about 31 nm) is observed in the case of carboxylate-terminated dendrimer.

By addition of reductants such as sodium borohydride into noble metal ion–dendrimer aqueous solutions, dendrimer–noble metal particles nanocomposites (gold, silver, platinum, palladium) have also been synthesized [24–27, 30, 32, 37, 40–42, 44]. The average sizes of gold decrease with an increase of the concentration of surface amino groups for G(3–5) dendrimers, while the average sizes of platinum particles are independent of the generation of the dendrimers above a certain ratio of [amino group]/[Pt^{4+}] [30]. It should be mentioned that a much higher concentration of the dendrimers is required to stabilize platinum colloids compared to that for gold colloids. Since it is expected that Ag$^+$ ions strongly adsorb on the dendrimers having surface carboxyl groups through electrostatic attractive forces, the reduction of AgNO$_3$ by addition of sodium borohydride in the presence of G(3.5–5.5) dendrimers has been carried out. Figure 5 shows the change in optical spectra of silver colloids obtained in the presence of G5.5 dendrimer with various concentrations. Although a typical plasmon band of silver colloids is observed at 380 nm at the ratio of
[G5.5]/[Ag$^+$] = 1 : 1, another band at around 450 nm appears. Further, the absorbance at both bands considerably decreases. The color of silver colloids also changes with increasing concentration of G5.5 dendrimer; yellow at the ratio of [G5.5]/[Ag$^+$] = 1 : 1 turns to orange at the higher ratios. In the case of G3.5 and G4.5 dendrimers, a result similar to that of G5.5 dendrimer is observed. At above the ratio of [G5.5]/[Ag$^+$] = 5/1 we cannot observe any silver particles by TEM because the particle size is too small to detect in the condition used. From Fourier transform infrared (FTIR) spectra it may be suggested that metal colloids adsorb on the exterior of the dendrimers. On the other hand, by using fourth-generation PAMAM with surface hydroxyl group, it has been reported [24] that platinum or palladium nanoparticles can be encapsulated inside the dendrimer. This is probably due to different interactions of metal nanoparticles with various functional groups of dendrimers. In addition, it has also been suggested [33] that the structure of dendrimer–gold or –silver nanocomposites is a function of the dendrimer structure and surface functional groups as well as the formation mechanism and the chemistry involved.

To verify the structure of dendrimer–gold nanocomposites gold nanoparticles synthesized by reduction of HAuCl$_4$ with sodium borohydride in the presence of PAMAM with surface amino groups (G2–G10) have been characterized by TEM, SANS, and SAXS [32]. Figure 6 shows a TEM image of gold particles containing G9 PAMAM dendrimer. The image indicates that gold colloids are formed inside the dendrimer. Under slow reaction conditions, one gold particle per dendrimer is predominantly formed. The sizes estimated

Figure 5. Absorption spectra of AgNO$_3$ in the presence of PAMAM dendrimer, G5.5, after reduction with NaBH$_4$. Reprinted with permission from [30], K. Esumi et al., *Langmuir* 16, 2604 (2000). © 2000, American Chemical Society.
Figure 6. TEM images of gold containing G9 PAMAM dendrimer obtained for 1:1 loading. The dendrimers have been stained with phosphotungstic acid and appear gray; the gold colloids appear black. (a) Fast reduction (NaBH$_4$ in 0.1 M NaOH); (b) slow reduction (NaBH$_4$ in 0.3 M NaOH). Reprinted with permission from [32], F. Grohn et al., *Macromolecules* 33, 6042 (2000). © 2000, American Chemical Society.

for the dendrimer and gold are 13 and 4 nm, respectively. SANS measurements have been performed on solutions of dendrimer–gold hybrid particles in deuterium oxide. The radius of gyration obtained from Guinier extrapolation is 5.1 ± 0.1 nm. This is within the same experimental error as the unmodified dendrimer, indicating that the hybrid particles also do not form larger aggregates in solution. Furthermore, the higher order sphere form factor features, which are pronounced in the case of the unmodified dendrimer, nearly completely disappear for the hybrid samples. SAXS provides more detailed information about the colloid structures; an estimate of the dimensions of the inner-sphere and outer-sphere diameter by SAXS confirms the diameters of the gold (4 nm) and the dendrimer (13 nm) estimated by TEM. More importantly, this result proves that the gold is formed inside the dendrimer. Further, it has been suggested for the dendrimers with various generations that several dendrimers surround the surface of gold particle formed for G2–G4 dendrimers, while gold particles are completely formed inside individual dendrimers for G6–G10 dendrimers. For G10, multiple gold particles within one dendrimer molecule are formed due to the more crowded volume inside the dendrimer. Thus, such a transition has been shown from colloid stabilization by low molecular mass molecules to polymer nanotemplating with an increase of molecular mass but unchanged chemistry of the stabilizing species.

For metal ions that do not form either covalent bonds or strong complexes with the interior amine groups of PAMAM dendrimers a method for preparing dendrimer-encapsulated metal nanoparticles has been reported [26]. For example, when G6 dendrimer (with surface hydroxyl group)-encapsulated copper is exposed to a solution containing ions more noble than copper, the copper is displaced and the more noble ions are reduced. By using this method, silver, gold, palladium, and platinum dendrimer-encapsulated metal particles have been obtained.

Gold and silver nanoparticles can also be synthesized in the presence of sugar-persubstituted PAMAM dendrimers (sugar ball) without reductants [34]. Actually, the hydroxyl groups of glucose residue of sugar balls can operate as reductants. In the case of silver nanoparticles, the addition of NaOH is required to reduce Ag$^+$ ions. It is suggested that gold or silver nanoparticles having diameters between 2 and 6 nm are present on the surface of sugar balls. In addition, the kinetics of the formation of gold and silver nanoparticles is affected by the generation of sugar balls as well as the concentration of sugar balls. The observed rate constants increase with the concentration of sugar balls, where the rate constants for low-generation sugar balls are greater than those for higher generation. Such noble metal–sugar nanocomposites are of considerable interest in biochemical and medical applications.

Dendrimer–gold and –platinum nanocomposites have been synthesized [31, 36] in ethyl acetate by reduction of respective metal salts with dimethylamineborane, where PAMAM dendrimers with surface methyl ester groups have been used. When ethyl acetate solution of HAuCl$_4$ is added to dendrimers in ethyl acetate, the formation of dendrimer–Au^{3+}complex is observed. HAuCl$_4$ shows an intense absorption at 324 nm which can be assigned to the LMCT band of

AuCl$_4^-$. On the other hand, G5.5 dendrimer shows a small absorption maximum at 278 nm. On mixing Au^{3+} with the dendrimer, a new band develops at 280 nm at the expense of the 324 nm band and the latter completely disappears in 15 minutes of stirring. In addition, an isobestic point is found at 304 nm, indicating that a ligand substitution from AuCl$_4^-$ to another Au^{3+} complex occurs through a participation of the dendrimer. It is also found from FTIR measurements that the bands for surface methyl ester groups at 1044, 1200, 1438, and 1736 cm^{-1} do scarcely change by introducing Au^{3+}, while the amide I band at 1647 cm^{-1} for interior amide groups undergoes a high-frequency shift to 1649 cm^{-1} and a single peak for the amide II band splits into two peaks by addition of Au^{3+}. A similar result for the formation of complex of dendrimer–Au^{3+} is obtained for G3.5 dendrimer. Au^{3+} ions in the presence of the dendrimers in ethyl acetate are readily reduced by adding an excess amount of dimethylamineborane. Interestingly, it is found that at above the ratio of [G]/[Au^{3+}] $\geq$ 10 the maximum particle size of gold is less than the hydrodynamic diameter of the dendrimer (G3.5 and G5.5), while in the case of G1.5 dendrimer the maximum size of gold is larger than the hydrodynamic diameter of G1.5. These results may suggest that the encapsulation of gold nanoparticles by G3.5 or G5.5 dendrimer occurs, while gold nanoparticles are stabilized by adsorbing G1.5 dendrimers. These suggestions are supported by the results of interactions between Au^{3+} and several model compounds such as acrylamide, N-methylpropionamide, trimethylamine, and N,N-dimethylglycine methyl ester.

Gold nanoparticles have also been obtained by addition of sodium borohydride into formamide solution of HAuCl$_4$ in the presence of PAMAM dendrimer with surface methyl ester group [39]. The particle size decreases with an increase of the dendrimer concentration as well as the generation. Further, the particle size of gold is affected by the elapsed time for the solution before reduction because HAuCl$_4$ in formamide is reduced to some extent without reductant. In N,N-dimethylformamide in the presence of the dendrimers relatively monodispersed gold nanoparticles are obtained. It may be suggested that stable gold nanoparticles are prepared by adsorbing a low dendrimer on the nanoparticles, while dendrimer-encapsulated gold nanoparticles are obtained in the case of a higher generation dendrimer.

Platinum nanopaticles have also been synthesized in ethyl acetate in the presence of PAMAM dendrimers with surface methyl ester group [31]. The elapsed time after mixing of H$_2$PtCl$_6$ and PAMAM dendrimers in ethyl acetate is very important to control the particle size, which is different from the preparation of gold nanoparticles. Figure 7 shows TEM images of platinum nanoparticles obtained in the presence of PAMAM 5.5 at 5 min of elapsed time after mixing. One can see that even at different concentrations of dimethylamineborane large (about 18 nm in diameter) and small (about 3 nm in diameter) platinum particles are formed. In particular, when the concentration of dimethylamineborane is 90 times that of H$_2$PtCl$_6$, it is visualized that the large particles are coated by PAMAM G5.5, where the thickness of coating is about 4–5 nm and is smaller than the hydrodynamic diameter (7.6 nm) of PAMAM G5.5 determined by dynamic light scattering measurements in ethyl acetate. It is suggested that PAMAM G5.5 dendrimers
Figure 7. TEM images of (A) platinum nanoparticles obtained in the presence of PAMAM G5.5 after 5 min elapsed time. (B) Enlargement of the particle in (A). (C) Enlargement of the particle in (B). are flattened on the surface of the platinum particle. Actually, the structural distortion of the dendrimers on gold surfaces has been reported [45]: the height of PAMAM G8 on a naked gold surface ranges from 3.5 to 4.0 nm, which is less than the ideal-sphere diameter of 9.7 nm. On the other hand, it is seen that the small platinum particles are encapsulated by PAMAM G5.5 in which the diameter of a PAMAM G5.5-encapsulated platinum particle is about 10 nm. It seems that the PAMAM G5.5-encapsulated platinum particle is flattened on the grid surface [46]. When the concentration of dimethylamineborane is reduced to 10 times that of H_2PtCl_6, the image of visualized dendrimers is not observed, although similar large and small platinum particles are obtained. It is speculated that the visualization of PAMAM G5.5 dendrimer by TEM is caused by the interaction between dimethylamineborane and PAMAM G5.5 dendrimer. It should be mentioned that the visualization of PAMAM G5.5 dendrimer from mixtures of dimethylamineborane and PAMAM G5.5 dendrimer is not observed, suggesting that platinum particles play an important role for the visualization of PAMAM G5.5 dendrimer to some extent. Such a formation of large and small platinum particles at short elapsed time may occur due to nonuniform distribution of Pt^{4+} ions in the solution and in the PAMAM G5.5 dendrimer. When the elapsed time after mixing is increased, the average particle diameter decreases: the average diameters are about 1.7 nm (standard deviation 0.3 nm) at 1 day of elapsed time and 0.8 nm (standard deviation 0.1 nm) at 3 days of elapsed time. Since the particle size is considerably smaller than the diameter of PAMAM G5.5 dendrimer, it is conceivable that many clusters of platinum are entrapped in the interior of the PAMAM G5.5 dendrimer. When the ratio of [G5.5]/[H_2PtCl_6] is varied from 150/1 to 50/1, the average diameter of platinum is not appreciably changed.

Also, from the results of the reduction of $PtCl_6^-$ in the presence of PAMAM G3.5 or PAMAM G1.5 dendrimer in ethyl acetate it is suggested that PAMAM G3.5-encapsulated platinum particles are formed, while PAMAM G1.5 dendrimers adsorb on the surface of platinum particles because the particle size of platinum obtained is larger than the diameter of PAMAM G1.5 dendrimer.

In toluene, which is a less polar organic solvent than ethyl acetate, dendrimer–gold nanocomposites have been synthesized in which a hydrophobically modified PAMAM dendrimer has been used [35]. The hydrophobically modified PAMAM is synthesized by reaction of PAMAM with surface amino group with 1,2-epoxydodecane [47, 48]. Solution of the hydrophobically modified PAMAM dendrimer in toluene is carefully layered on top of $HAuCl_4$ aqueous solution. After the solution stood for several hours at room temperature, a bright yellow color emerges in toluene. The extraction experiment is continued for 1 day. Since $HAuCl_4$ is not soluble in toluene solution, it is reasonable to consider that $AuCl_4^-$ ions should be incorporated in the interior of the hydrophobically modified PAMAM in toluene. Then, by addition of dimethylamineborane–toluene solution, $AuCl_4^-$ ions are reduced. The average diameters of gold nanoparticles obtained range between 2.5 and 3.4 nm which is smaller than the diameter (4.5 nm) of PAMAM G4. This suggests that gold nanoparticles are encapsulated in the hydrophobic PAMAM dendrimer. A similar result has also been obtained using chloroform as an organic solvent.

Another approach for the preparation of dendrimer–metal nanocomposites in toluene is a process driven by acid–base chemistry and ion pairing [28]. At first, palladium nanoparticles are synthesized by reducing aqueous K_2PdCl_4 with sodium borohydride in the presence of PAMAM G4 dendrimer where the pH of dendrimer solution is adjusted to about 2. The low pH protonates the exterior amines to a greater extent than the less basic interior tertiary amines. Accordingly, Pd^{2+} binds preferentially to the interior tertiary amines and upon reduction palladium particles form within the dendrimer interior. After complete reduction, the pH of solutions is adjusted back to about 8.5. Then, these nanocomposites can be quantitatively transported from the aqueous phase into toluene containing 10–20% of dodecanoic acid. The transition is visualized by the color change: the brown aqueous solution of PAMAM dendrimer–palladium nanocomposites becomes clear after addition of the acid, while the toluene layer turns brown.

In addition, dendron-stabilized gold nanoparticles have been synthesized using Fréchet-type dendrons possessing a single thiol group at the focal point, and their diameters are 2.4–3.1 nm [49].

3. PROPERTIES

Since dendrimers act as template and stabilizer for synthesizing metal nanoparticles, we can control particle size and particle stability. In addition, for dendrimer–metal nanocomposites metal nanoparticles are present in the interior or exterior of the dendrimer. These two different structures allow different interactions with substrates. Accordingly, dendrimer–metal nanocomposites would exhibit an unique property in the field of catalysis.

Dendrimer-encapsulated metal nanoparticles such as platinum and palladium have been examined as catalysts for hydrogenation and Heck reactions [40, 50–54]. The catalytic hydrogenation of allylic alcohol to 1-propanol has been carried out by dendrimer-encapsulated palladium nanoparticles in water. The turnover frequency calculated from the rate of hydrogen uptake is 218 mol of H_2(mol of Pd)$^{-1}$ h^{-1} at 20 °C [55]. Similar data have been obtained for dendrimer-encapsulated platinum nanoparticles. In addition, the turnover frequency for the allyic alcohol reduction using toluene solutions of dendrimer-encapsulated palladium nanoparticles is 760 mol H_2 at 20 °C [28], which compares favorably with the value in water.

Dendrimer-encapsulated palladium nanoparticles has been applied to fluorous biphasic catalysis [56–58] in order to facilitate recovery and recycling of soluble catalysts. These catalysts are active in fluorous biphasic systems for the hydrogenation of alkenes and for the isomerization of terminal alkenes and are also recycled 12 times without appreciable loss of catalytic activity [28].

Perfluorinated catalysts also allow the use of supercritical CO_2 in which they are soluble. Using perfluorinated dendrimer-encapsulated palladium nanoparticles, Heck coupling between aryl halides and n-butylacrylate has been carried out and it is 100% selective for the production of n-butyl-$trans$-formylcinnamate with unoptimized isolated yields up to 70% [59].

The effect of dendrimer generation on the catalytic activity using dendrimer–platinum nanocomposites has been reported [60]. The time course of hydrogenation of cyclohexene using PAMAM–dendrimer–platinum nanocomposites synthesized in ethanol is shown in Figure 8. It is clearly demonstrated that PAMAM G1.5–platinum nanocomposites
Figure 8. Hydrogenation of cyclohexene by platinum nanoparticles prepared in the presence of PAMAM dendrimers in ethanol. Reprinted with permission from [60], K. Esumi et al., *J. Jpn. Soc. Colour Mater* 73, 434 (2000). © 2000, Japan Society of Colour Material.

have much higher catalytic activity than those of PAMAM G3.5 or G5.5–platinum nanocomposites. At a reaction time of 24 h, the conversion to cyclcohexane is about 86% for PAMAM G1.5 dendrimer and 48% for PAMAM G3.5 and G5.5, respectively. Thus, the catalytic reaction can be controlled using dendriemers of various generations. Such characteristics may be derived from a unique structure of dendrimer so that cyclohexene molecules are less able to penetrate into the interior platinum nanoparticles of dendrimers when the generation of dendrimer increases.

Optical properties of nanoscale metal domains in dendrimer–metal nanocomposites are interesting and strongly influenced by the surface plasmon resonance of metal nanoparticles [61, 62]. In particular, gold, silver, and copper nanoparticles exhibit characteristic plasmon bands. This is relevant for the case of optical limiting where the material's absorption is dependent upon the intensity of the input beam. It is demonstrated [63] that PAMAM dendrimer–silver nanocomposites can exhibit large optical limiting at 532 nm by factors up to 115. The mechanism governing the optical limiting observed is nonlinear scattering, most probably due to bubble formation at the small laser spot. This important finding indicates the feasibility of using novel dendrimer–metal nanocomposites for application in optical limiting devices and medicine. Further, time-resolved fluorescence from dendrimer–gold or –silver nanocomposites has been measured [64]. The dendrimer architecture allows for strongly enhanced measurable fluorescence intensity from the metal nanoclusters. It is suggested by fluorescence anisotropy measurements that the metal emission shows a relatively polarized character while the dendrimer host shows a relatively polarized emission. The proposed mechanism of the emission decay is due to electron–electron and electron–surface scattering processes, and there may also be a contribution from the interaction of emission dipoles of the dendrimer host and surface plasmon of the metal.

Dendrimer–gold nanocomposites can be used to remarkably change the laser-induced optical breakdown threshold of a material, owing to a large enhancement of the local electric field [65]. The observed statistical behavior of the breakdown process is attributed to a laser-driven aggregation of individual nanocomposite particles. The breakdown threshold value of the nanocomposites has been found to be up to two orders of magnitude lower than that of pure dendrimers.

4. APPLICATIONS

Since fabrication of ordered semiconductor and metallic nanoparticles on solid substrates has recently been a topic for substantial research due to their multifunctional electronic, optical, and catalytic properties, it is important to explore a method to assemble dendrimer–metal nanocomposites to form well-defined thin films. Formation of multilayer thin film using dendrimer–metal nanocomposites has been reported [66]. The dendrimer–gold nanocomposites have been deposited as a multilayer thin film using electrostatic layer-by-layer deposition techniques. The fabrication procedure of poly(sodium 4-styrenesulfonate) (PSS)/dendrimer–gold nanocomposite multilayers is schematically presented

in Figure 9. A negatively charged solid support is primed by adsorbing a poly(dimethyldiallylammonium chloride) (PDAC) layer onto its surface. The primed substrate is then immersed in PSS solution. The modified substrate is then rinsed with water and dried using nitrogen. It is subsequently immersed in a dendrimer–gold nanocomposite solution. This process is repeated. The multilayer formation has been confirmed by using ultra violet-visible (UV-vis), TEM, and atomic force microscopy.

Also, other methods for multiplayer construction using dendrimers should be noted. The procedure involves the deposition of PAMAM dendrimer with surface amino group onto a Pt^{2+}-bearing surface, followed by reactivation with K_2PtCl_4 [67]. In a typical preparation, a silicon wafer is first silylated with (3-aminopropyl)triethoxysilane, immersed in a solution of K_2PtCl_4, and rinsed with water and methanol. Repetition of this procedure yields corresponding multilayers. The formation of multilayers of dendrimers has been confirmed by ellipsometry and X-ray photoelectron spectroscopy studies. Multilayer films of dendrimers are also fabricated by self-assembly of dendritic macromolecules of two adjacent generations using electrostatic layer-by-layer deposition [46]. PAMAM with surface amino groups for generations 4, 6, and 10 and with surface carboxyl groups for generations 3.5, 5.5, and 9.5 has been used as building units. All even generations are observed to form homogeneous, stable monolayers on a silicon surface. The thickness of a single monolayer varies with generation from 1.8 (G4) to 2.8 (G6) and 5.6 nm (G10). The average thickness of a molecular layer in multilayer films is much smaller than the diameter of ideal spherical dendritic macromolecules. The model of molecular ordering of dendrimer films assumes compressed dendritic macromolecules of oblate shape with the axial ratio in the range from 1:3 to 1:6. A tendency to higher spreading of high generation dendrimers corresponds to the surface behavior predicted by molecular dynamic simulations.

In addition, it is also important to describe preparation and characterization of dendrimer monolayers adsorbed to gold [68]. Single-component monolayers of PAMAM are prepared by exposing an Au substrate to ethanolic solutions of amine- or hydroxy-terminated PAMAM dendrimers.
Figure 9. Schematic illustration of the procedure for fabrication of the PSS/gold–dendrimer nanocomposite film on the negatively charged substrate and the architecture of the resulting film. The resulting monolayers are highly stable and nearly close-packed for dendrimer generations ranging from G4 to G8. Electrochemical ac-impedance measurements indicate that the dendrimer surface is very porous toward the electroactive redox couple $Fe(CN)_6^{3-/4-}$. Exposure of higher generation dendrimer monolayers to ethanolic solutions of hexadecanethiol results in a dramatic compression of the dendrimers and causes them to reorient on the surface from an oblate to prolate configuration. The dendrimers originally present on the surface do not desorb as a consequence of this configurational change. It is also suggested that the structure and ion-transport function of the mixed dendrimer/alkanethiol monolayers is somewhat analogous to that of phospholipid/protein membranes. It is interesting to note for the stability of dendrimer surfaces as chemically sensitive interfaces that the response to volatile organic compounds decreases in the order acid > alcohols > hydrophobic dosants. This response order is more pronounced for the G4–G8-modified surfaces and is dictated by the PAMAM structure which possesses hydrogen-bonding exoreceptors and endoreceptors. The G4-modified surface is the most responsive material probably; although it is the smallest of the spheroidal dendrimers, its interior endoreceptors are most accessible. G0 and G2 dendrimer films are not as effective at discriminating between the three different classes of probes since these surfaces have few or no free amine terminal groups and no coherent endoreceptors ability. An atomic force microscopy investigation of PAMAM G4 and G8 dendrimers adsorbed on Au surfaces has been carried out [69]. Heights measured for isolated, adsorbed dendrimers indicate that they are substantially more oblate than expected from their spherical shapes in solution. By controlling dendrimer concentration and exposure time during adsorption, modified surfaces ranging from isolated molecules to near-monolayer coverage are obtained. Exposure of surfaces bearing adsorbed isolated dendrimers to hexadecanethiol solutions changes their conformation from oblate to prolate as more stable thiol–Au bonds replace some of the amine–Au bond. Surfaces of near-monolayer coverage gradually agglomerate, forming dendrimer "pillars" up to 30 nm high.

Vapor-sensitive thin-film resistors comprising gold nanoparticles and different types of dendrimers such as polyphenylene, poly(propyleneimine), and poly(amidoamine) have been prepared via layer-by-layer self-assembly and characterized by UV-vis spectroscopy, atomic force microscopy, and conductivity measurements [70]. Dosing the films with vapors of toluene, 1-propanol, and water significantly increases the film resistances. It is demonstrated that the chemical selectivity of this response is controlled by the solubility properties of the dendrimers.

Interactions between alkanethiols and dendrimer–gold nanocomposites in ethyl acetate have been investigated by adding alkanethiols such as 1-decanethiol and 1,10-decanedithiol into PAMAM dendrimers with surface methyl ester group–gold nanocomposites [71]. In the case of PAMAM G1.5 dendrimer–gold nanocomposites (diameter: 2.1 nm), the addition of 1-decanethiol leads to smaller gold particles, while that of 1,10-decanedithiols provides the formation of large, highly regular, spherical clusters with diameters of 40–60 nm. On the other hand, in the case

of PAMAM G5.5 dendrimer–gold nanocomposites (diameter: 2.4 nm), the addition of 1-decanethiol shows a distinct tendency into smaller and larger spheres, whereas that of 1,10-decanedithiols gives irregular spherical clusters with diameters of 30 nm. Such morphology changes by addition of alkanethiols occur due to stronger interaction between gold and alkanethiols than that between PAMAM dendrimer and gold.

Finally, bioapplications of dendrimer–metal nanocomposites are briefly described. Since PAMAM dendrimers are able to solubilize many organic materials or inorganic materials, bioactive materials may be combined in one nanoscopic delivery vehicle such as dendrimer. Studies using antibody/dendrimer conjugates *in vitro* and *in vivo* in experimental animals have demonstrated these conjugates to be nontoxic and able to target biologic agents to specific cells [72, 73]. Dendrimer–silver nanocomposites display antimicrobial activity comparable to or better than those of silver nitrate solutions [74]. Interestingly, increased antimicrobial activity is observed with dendrimer carboxylate salts. This effect may be caused by the very high local concentration of nanoscopic size silver composite particles that are accessible for microorganisms. PAMAM dendrimers have been used for imaging but only after appropriate surface modification. The potential of PAMAM–metal chelate–antibody constructs in radioimmunotherapy and imaging has been recognized [75]. Generally, fluorescent markers, such as fluorescein, or chelated metal ions, such as Gd^{3+} for magnetic resonance imaging, are used to generate a measurable signal [76, 77]. Radioactive dendrimer nanocomposites also have the potential to be delivered to the tumor.

GLOSSARY

Dendrimer Macromolecules with a regular and highly branched three-dimensional architecture.

Dendrimer–metal nanocomposite Organic–inorganic hybrid structure consisting of metal nanoparticles in the internal or external region of dendrimer.

Plasmon resonance band of gold An extinction maximum band due to the dipole resonance of small gold spheres.

Transmission electron microscopy Transmitted-light microscopy using an electron beam and magnetic lenses to produce a magnified image on a fluorescent screen.

CONTENTS

1. INTRODUCTION

The search for new materials with unusual properties is a vital area of research. Since the original reported syntheses by Newkome et al. [1] and Tomalia et al. [2], dendrimers have assumed a prominent role in this search for new materials. In the past four years, this role has grown rapidly as evidenced by the large numbers of papers appearing in literature since 1998. A cursory review of cited journals indicates the importance and level of interest in the scientific community concerning dendrimer research. The research on dendrimers is now a multidiscipline effort involving synthetic chemistry, inorganic chemistry, organometallic chemistry, analytical chemistry, and polymer science.

This level of scientific interest is driven by several properties of dendrimers. Among these are an unusual melt viscosity due to the hyperbranched structure (as described below), unusual properties when studied as thin films on surfaces, the ability to hold catalysts and influence the catalytic properties of catalysts within them, an emerging ability to foster cavities within them that can be used to bind small molecules, and the ability to mimic biomolecules and potential for drug and gene delivery. Several of these properties derive from the encapsulating abilities of dendrimers. The phenomenon of encapsulation can be observed in a multitude of different situations from atomic to macro scale. Medicines are regularly encapsulated within water-soluble capsules for delivery. Life exists because the components of cells are encapsulated by plasma membranes. Enzymes exhibit remarkable substrate binding specificity and perform remarkable organic chemistry in aqueous environments because active sites are encapsulated by the protein structure. Power cords are encapsulated by insulating material so that electric current can be channeled to power computers and lab equipment. In the broadest terms, encapsulation is the establishment of a barrier to control the access of some system to its surroundings.

Dendrimers represent a way to accomplish encapsulation on the molecular scale. Molecules with potentially useful physical and/or chemical properties can be encapsulated as the core of dendrimers. Ideally, dendritic encapsulation will result in new properties for the core molecules and ultimately new materials. This is the essence of materials research.

1.1. Synthesis of Dendrimers

Dendrimers are a class of macromolecules consisting of one or more polymeric, regularly branching arms, known as dendrons, which radiate from a central core (Fig. 1). They are synthesized in a stepwise iterative fashion which follows either divergent or convergent methodology [3]. In the divergent methodology, first used by Newkome et al. and Tomalia et al. [1, 2], the core molecule serves as a polyvalent initiation point and the dendrons are grown outward from the core in a repetitive activate/couple cycle. Each time a coupling cycle occurs, a new layer of branch points, referred to as a "generation," is added to the growing dendrimer. The divergent methodology is fast, efficient, and can yield large dendrimers. Its principal disadvantage is that the yield of complete coupling decreases as the generation and thus the number of reaction sites increases, creating some polydispersity in the molecular weight of the final product.

In the convergent methodology, first reported by Hawker and Fréchet [4], the dendrons are synthesized by starting at the tips, which will be the periphery of the dendrimer, and working backwards to a single reactive functional group. Again, each time a coupling cycle occurs, a new layer of branch points is added and the "generation" of the dendrimer increases. Once the dendrons are fully synthesized, they are linked to the core in a final activate/couple cycle. Monodisperse dendrimers can be obtained this way, but the purification after each step renders a practical limit to the size of the molecules that can be synthesized. Furthermore, steric congestion may limit the efficiency of coupling in this approach as well. The essential difference between the two methodologies is in the fashion in which the dendrimer is assembled. In the divergent methodology, as soon as the activate/couple cycle begins, an actual dendrimer is synthesized and subsequent repetitions of the activate/couple cycle

Focal linker   Branching repeat unit   Peripheral functional group
Figure 1. Conceptual Dendrimer—The relative spatial orientation of the various parts of the dendrimer are shown. The central core is attached to the dendrons, which define the nanoenvironment around the core. The peripheral functional groups define the solubility of the dendrimer and/or provide multiple reactive sites for chemistry. The dendrimer shown here has three layers of branch points in the interior and would thus be designated a third-generation dendrimer.

serve to increase the size of the dendrimer. With the convergent methodology, a dendrimer is not actually assembled until dendrons of a desired size have been synthesized and then coupled to a core. Numerous reviews and articles have thoroughly covered dendrimer synthesis and the many types of dendrimers that have been prepared using both methodologies [3, 5–12].

Dendrimers are particularly well suited for the function of encapsulation (Fig. 1). When a dendrimer becomes sufficiently large, normally measured by generation number, it adopts a globular shape. This globular shape is the natural result of an architecture in which large bulky dendrons are focally attached to a central core. DeGennes dense packing, sterics, and simple mass effect cause the dendrons to envelope the core molecule, thus leading to encapsulation. While encapsulation by dendrimers can lead to alteration of physical and chemical properties, there is some scientific and semantic difficulty in defining the critical size or generation or molecular weight required to effect this change [13]. The term "site isolation" is often used when encapsulation is determined to be complete; this term is subject to interpretation.

For dendrimers, it is possible to encapsulate many different types of core molecules in different types of "nanoenvironments" for the purpose of understanding structure–property relationships. A basic understanding of structure–property relationships is the key to the development of new materials with unusual properties and is one of the core tenets of scientific research. This ultimately is the basis for the broad-based, multidisciplinary interest in dendrimers.

1.2. Advantages of Dendrimers

As stated previously, encapsulation begins by surrounding a core molecule with a material. This effect could be achieved using conventional polymers. However, studies comparing dendrimer versus polymeric encapsulation have shown considerable differences between the two systems [14]. Structurally, dendrimers are composed of a core moiety surrounded by dendrons radiating from the core (Fig. 1). Such a structural arrangement predisposes dendrimers towards encapsulation when compared to linear polymers. There is substantial precedent for the synthesis of dendrimers as monodisperse or nearly monodisperse species. Linear polymers could be synthesized in the same, stepwise fashion, but protocols to isolate and to purify these types of molecules are less precedented. The mode of synthesis of dendrimers also facilitates the installation of different functionalities at the center and periphery. Dendrimers are modular in construction and composition, thus allowing the core, the interior dendrimer nanoenvironment, and the dendrimer peripheral functional groups to be changed independently of each other with relative ease [15]. The value of the "modular" nature of dendrimers and the potential applications for encapsulation lead to a number of possibilities for design of new functional molecules [16].

1.3. Dendrimer Cores

Dendrimer cores can be classified as "nonfunctional" or "functional." "Nonfunctional" cores are molecules that have no specifically interesting chemical or physical properties; and serve only as a polyvalent focal point of the dendrimer. Dendrimers assembled with "nonfunctional" cores either focus on materials applications other than encapsulation [17], such as supramolecular constructs [18] and self-assembly processes [19–23] or utilize the dendrimer as a polyvalent scaffold, as in DNA transfection [7, 24, 25], drug delivery [26–28], or even soluble solid-state synthesis [29]. In some of these applications, the dendrimer is used for encapsulation of small molecule guests. This type of non-covalent encapsulation is interesting and potentially useful, especially for extraction, solubility, and drug delivery. It is not, however, treated in any detail here.

A second class of encapsulating dendrimers is based on functional cores. "Functional" cores are moieties which, in addition to serving as the polyvalent focal point for the dendrimer, have some observable and potentially useful physical and/or chemical property. For dendrons containing a "functional" core, encapsulation is the predominant research focus. Observable physical/chemical properties fall into three broad categories [30]: photophysics (absorbance, luminescence, fluorescence, and phosphorescence), electrochemistry (kinetic electron transfer rate and thermodynamic redox potential) [9, 31, 32], and ligand binding (ligands, gas binding, and catalysis) [6, 8, 33, 34].

A wide variety of molecules have been employed as "functional" cores (Table 1). Most can be classified in one of four categories: porphyrins/phthalocyanines, inorganic clusters, ionic complexes/organometallics, and fluorescent dyes. Porphyrin and phthalocyanine moieties [30, 35, 36] are especially useful because they exhibit three classes

of observable properties: photophysics, electrochemistry, and ligand binding. Many dendrimers have been synthesized with porphyrin/phthalocyanine cores. Several different types of inorganic clusters have served as cores. One impetus behind the use of clusters as cores is ligand binding and when mimicking and studying enzyme active sites [37, 38]. Clusters that have been used include iron-sulfur, Fe_4S_4 [39], rhenium-selenide, Re_6Se_8 [40, 41], molybdenum-chloride, Mo_6Cl_8 [42], oxymolybdo-sulfur, $MoOS_4$ [37], and metal nanoparticles [34, 43]. Ionic complexes and organometallics [44, 45] have been popular because of the well-established synthetic conditions by which a dendrimer may be assembled around such a core. Examples of ions used to make ionic/organometallic cores complexes include ruthenium(II), osmium(II), iron(II), iridium(II), and various lanthanides. The influence of the dendrimer on the photophysical and electrochemical response of these cores has been studied. Lastly, fluorescent dyes have been employed as cores for their light emission properties. Tremendous interest in fluorescent dye core dendrimers has developed in the field of organic light-emitting diode (OLED) research.

Table 1. Classification of the functional cores used in dendrimer chemistry.

Molecule	Properties	Ref.
Porphyrins/Phthalocyanines		
Si- Phthalocyanine	U	[36]
Zn-Porphyrin	U, E, F, LB	[47, 64, 65, 74–76]
Pd-Porphyrin	P, LB	[80]
Fe-Porphyrin	U, E	[72]
Free-base Porphyrin	F	[50, 63]
Inorganic Clusters		
Mo^VOS_4	EPR, E	[37]
Fe_4S_4	E	[39, 66]
Mo_6Cl_8		[42]
Re_6Se_8	U, E	[40, 41]
Organometallic/Ionic Complexes		
$Ir(ppy)_3$	L, U	[15]
Lanthanide, (Ln^{3+})–$(RCOO^-)_3$	FT-IR, U, E	[59, 60]
Ferrocene	E	[67, 68]
Methyl Viologen	E	[69, 70]
Dyes		
4-(N-methylamino)-1-nitrobenzene	U	[46]
p-dimethoxybenzene	F	[48]
Tryptophan	F	[49]
Coumarin 343, Pentathiophene	L	[51]
Rhodamine B	F	[52]
4-(dicyanomethylene)-2-methyl-6- (4-dimethylaminostyrl)-4H-pyrane	F	[81]
3-[dimethylamino]phenoxy group	F	[57]
Coumarin 343	F	[62]
Dansyl chloride	FQ	[77]
(S)-1,1′-bi-2-naphthol	F, LB	[78]

Note: U = UV-vis absorbance, F = fluorescence, FQ = fluorescence quenching, P = phosphorescence, L = luminescence, E = electrochemistry, LB = ligand binding, EPR = electron paramagnetic resonance, FT-IR = FT-IR.

2. ENCAPSULATION

Encapsulation has been defined as altering an observable physical/chemical property of a molecule by surrounding it with material. The very simplest example of encapsulation is changing the solubility of a core molecule. Although influencing solubility can be accomplished via methods other than encapsulation, in the case of dendrimers, such control of solubility has turned out to be extremely useful, especially in OLED research. Most experiments that study the role of dendritic encapsulation focus on the influence of encapsulation on photophysical behavior, electrochemical behavior, and the kinetics and thermodynamics of ligand binding. Altering these properties is less straightforward than making something soluble and influencing them requires controlling the nanoenvironment around the core [30]. Generally, correlation of a change in one of these three properties, for any given core molecule, to an increase in the generation of a dendrimer indicates encapsulation.

2.1. Effects on Photophysical Properties

Observation of photophysical properties has been an extremely useful tool for the evaluation of dendritic encapsulation. The absorbance and/or emission of light by a core is easy to measure, is nondestructive, and is extremely sensitive to the effects of dendritic encapsulation. Fréchet and co-workers first reported dendrimer encapsulation when shifts in the UV-vis absorbance maxima were observed for a *p*-dimethylamino-nitrobenzene core aryl-ether based-dendrimer (Fig. 2) in a variety of solvents [46]. In all solvents used for UV absorbance, a noticeable increase in the absorbance maximum occurred between the third- and fourth-generation dendrimers. This increase was interpreted
Figure 2. First Demonstration of Encapsulation—Shifts in UV absorbance maxima were observed between generation 3 and generation 4 of this molecular architecture in various solvents. Adapted with permission from [46], C. J. Hawker et al., *J. Am. Chem. Soc.* 115, 4375 (1993). © 1993, American Chemical Society.

to mean a significant change in the nanoenvironment around the core indicative of encapsulation.

Initial evidence for actual "site isolation" was reported by Aida and co-workers for aryl-ether-based dendrimers with Zn-porphyrin cores [47]. In fluorescence studies, quenching was observed between first-generation free-base dendrimers and first-generation zinc porphyrin dendrimers. No quenching was observed in the same experiments with fourth-generation zinc porphyrin dendrimers substituted. Attenuation of quenching was not universal as it was observed that quenching by vitamin K_3, a much smaller molecule, was actually enhanced as the dendrimer grew larger. Moore and co-workers reported shifts in the fluorescence maximum for phenylacetylene dendrimers with a *p*-dimethoxybenzene core [48]. Expected bathochromic shifts were observed for lower-generation dendrimers while at higher generations, abnormal shifts were observed that were very solvent dependent. From Aida and Moore's work it was clear that encapsulation was not just a general effect and could possibly be controlled.

Smith and co-workers demonstrated a level of control of encapsulation using dendrimers with tryptophan cores. The dendrons were designed to present a hydrogen bonding environment (Fig. 3) [49]. Thus, in solvents that were not hydrogen donors or acceptors, a dendritic effect was observed as a shift in the maximum emission wavelength for tryptophan. The shift was due to hydrogen bonding between the dendron and the tryptophan core. In solvents that were hydrogen
Figure 3. Controlled Encapsulation—A second-generation dendrimer for which controlled encapsulation was demonstrated. By altering the solvent from a non-hydrogen bonding to a type that was hydrogen bond donating and/or accepting, the emission spectra of the core tryptophan could be shifted [49].

bonding donors or acceptors, the dendritic effect was not observed due to competitive binding between the solvent and the dendron. Vinogradov and Wilson also demonstrated control of encapsulation through pH manipulation of a zinc porphyrin core polyglutamate dendrimer [50]. A substantial decrease in the fluorescence emission for the porphyrin core was reported as the pH of the solution was decreased. The shift in the periphery from anionic to neutral eliminated electrostatic shielding on the surface of the dendrimer and allowed the porphyrin cores to behave more like free porphyrins. Substantial amounts of self-quenching of the porphyrin cores occurred at lower pH values.

Encapsulation and site isolation by dendrimers have been used with great effect in the field of organic light-emitting diode (OLED) research. After an initial illustration by Thompson and Fréchet and co-workers [51], several groups have capitalized on the use of dendrimers to isolate chromophores and prevent exciton quenching which reduces efficiency. Otomo and co-workers synthesized Fréchet-type dendrimers with rhodamine B cores [52]. Dendrimer thin films spun onto silica, 10% by weight of dendrimer, had no loss in fluorescence emission intensity and demonstrated mirrorless laser emission. Site isolation and laser emission were also observed in a dendrimer host/guest system with reported nonlinear increases in emission in response to excitation [53]. Following several previous illustrations [54–56], Markham et al. most recently illustrated green phosphorescence in LEDs made from *fac*-tris-2phenylpyridine iridium, Ir(ppy)$_3$, core dendrimers [15]. In addition to increased luminescence efficiency due to site isolation of the core, the dendrimers altered the solubility of the Ir(ppy)$_3$ core. This allowed the Ir(ppy)$_3$ normally evaporated to form an OLED, to be spin-cast in thin layers up to 20% by weight.

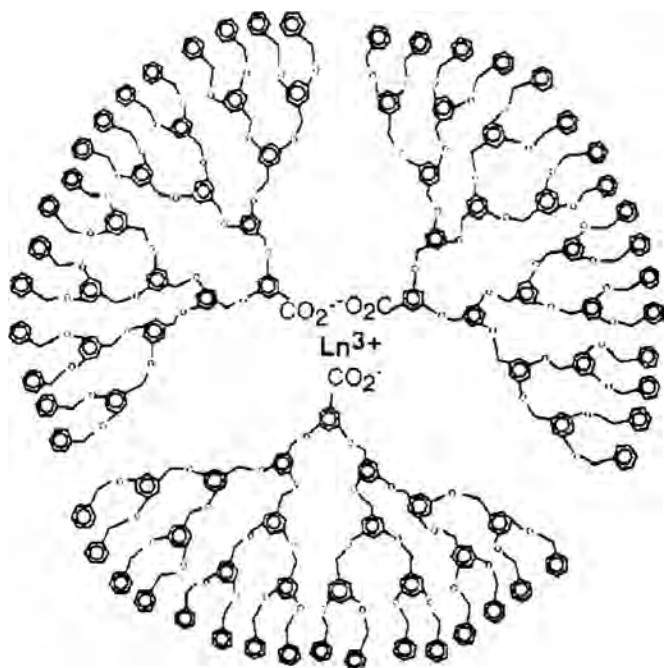
Dendrimer encapsulation also can have a pronounced energy-harvesting "antenna" effect on photoactive cores. Stewart and Fox [57] and Devadoss et al. [58] first illustrated that energy could be collected from chromophores in the periphery of the dendrimer and funneled the core of the molecule. Kawa and Fréchet demonstrated that this effect correlated to increasing generation in lanthanide ion/tricarboxylate core dendrimers (Fig. 4) [59, 60]. Enhanced luminescence could be observed by (a) changing the lanthanide ion used to form the dendrimer complexes, (b) site isolation of the core by the dendrimer blocking self quenching, and (c) increasing dendrimer generation leading to enhanced energy collection and transfer to the core. Fréchet and co-workers have also used the polyvalent nature of dendrimers to enhance the generation-dependent "antenna" effect by attaching light-harvesting chromophores to the periphery of the dendrimer. Energy transfer from the periphery chromophores to the core dye was highly efficient [61, 62]. The "antenna" effect appears to be influenced greatly by dendrimer conformation. Jiang and Aida reported fully substituted dendritic porphyrins had much greater quantum yields for energy transfer than the partially substituted analogues [63]. Fluorescence emission from the series of porphyrin dendrimers was nonlinear in response to the number of dendritic substituents.


Figure 4. Dual-Purpose Encapsulation—A fourth-generation dendrimer that achieves two effects. The aromatic rings serve as light-harvesting units and funnel the energy to the lanthanide core resulting in emission. This emission was enhanced due to the steric shielding provided by the dendrimer which prevents self-quenching by the lanthanide cores. Reprinted with permission from [60], M. Kawa and J. M. J. Fréchet, *Chem. Mat.* 10, 286 (1998). © 1998, American Chemical Society.

Figure 5. Site Isolation of a Zn-Porphyrin Core—A zinc–porphyrin core was encapsulated by an aryl-ether-based dendrimer. Electrochemical characterization of the core showed a considerable attenuation of the kinetic electron transfer rate upon going from the second-generation to the third-generation dendrimer. The rate of electron transfer was attenuated past that observable by cyclic voltammetry by the fourth generation. Reprinted with permission from [65], K. W. Pollak et al., *Chem. Mat.* 10, 30 (1998). © 1998, American Chemical Society.

2.2. Effects on Electrochemical Properties

Electrochemically active cores have also been instrumental for investigating dendritic encapsulation [9, 31]. Electrochemically active cores have proven useful because two properties, the rate of electron transfer and thermodynamic redox potential, can be altered by encapsulation. Attenuation of electron transfer rates is primarily influenced by steric hindrance and is distance dependent. However, the type of units within the dendrons also has an effect. Encapsulation effects on redox potential, in contrast to electron transfer attenuation, have been less well understood, though some progress has been made [13].

Multiple dendrimer systems with different types of cores and architectures have been reported in which electron transfer rates were attenuated. Diederich and co-workers reported the first attenuation of electron transfer rates for porphyrin core dendrimers [64]. This attenuation increased as the dendrimer generation increased. Fréchet, Abruña, and co-workers demonstrated electrochemical site isolation for Zn-porphyrin dendrimers (Fig. 5) [65]. Third-generation and larger dendrimers attenuated the rate of electron transfer such that it could not be observed using cyclic voltammetry.

Gorman and co-workers elucidated structure–property relationships for electron attenuation using Fe_4S_4 cores with two different dendrimer architectures (Fig. 6) [39]. These dendrimer architectures exhibited remarkable, and seemingly contradictory, behaviors in solution and in thin films. In N,N-dimethylformamide (DMF) solution, attenuation of the heterogeneous electron transfer rates was observed from the Fe_4S_4 cores to a Pt electrode for both "flexible" and "rigid" dendrimers as generation increased (Fig. 6). The "rigid" architecture was more effective at encapsulating the core than the "flexible" architecture. Correlating this behavior with the results of computational conformational searches, it was suggested that the distance of electron transfer in the "rigid" architecture was greater than that of a "flexible" architecture for a given molecular weight as the former held the core more towards the center of the molecule than the latter. When the electron transfer rates were correlated to an approximation of the average distance of electron transfer, the "flexible" architecture attenuated the rate more than the "rigid" architecture for that given, approximate distance.

In these experiments, in solution, very little shift was observed in the thermodynamic redox potential of the Fe_4S_4 core with increasing dendrimer generation. However, when the same series of "flexible" dendrimers were spin-cast onto a platinum electrode surface, the thermodynamic redox potential shifted dramatically with increasing dendrimer generation [66]. It was proposed that, in solution, solvent could penetrate the dendrimer and define the microenvironment around the iron-sulfur cluster. In the film,
Figure 6. Effects of Repeat Unit on Encapsulation—"Flexible" and "rigid" Fe_4S_4 core dendrimers were studied to determine the effect of repeat unit on conformation and subsequent electron transfer rate attenuation. Generation 3 dendrimers are shown (where the circled-D represent arms identical to the one drawn). Analogous generation one through four dendrimers were studied. Reprinted with permission from [39], C. B. Gorman et al., *J. Am. Chem. Soc.* 121, 9958 (1999). © 1999, American Chemical Society.

however, solvent was largely excluded, and the differing size of dendrimers provided a difference in microenvironment at different generations. As the generation of the dendrimer increased, the effective microenvironment around the iron-sulfur cluster became more hydrophobic, making the cluster thermodynamically more difficult to reduce.

Kaifer and co-workers have demonstrated controlled encapsulation using ferrocene core single-arm offset dendrimers (Fig. 7) [67]. By altering the pH of the solution in which electrochemistry was performed, it was proposed that the carboxylate periphery could be made to orient towards an amine-SAM covered electrode surface, effectively stopping free rotation of the molecule. This net effect was detected as attenuation of electron transfer of the ferrocene core which had been correspondingly oriented away from the electrode surface. In further experiments with similar ferrocene core single-arm offset dendrimers, attenuation of electron transfer in both organic and aqueous solvents was demonstrated [68].

While these experiments provide a good basis to rationalize the factors for altering electron transfer via encapsulation, some recent results do not fit the simple pattern that increasing size results in increasing encapsulation. Kaifer and co-workers and Balzani and co-workers independently synthesized identical methylviologen core dendrimers up to the third generation (Fig. 8) [69, 70]. Both groups found no correlation between the electron transfer kinetics and dendrimer generation. The simplest explanation for this behavior would be that the dendrimers were not sufficiently large to encapsulate the core. However, Alvarro et al. worked with the same molecules and reported that electron transfer quenching with anthracene was inhibited by the second-generation dendrimer [71]. The interpretation of this data with regards to encapsulation remains unresolved.

The other aspect of electrochemistry influenced by encapsulation is the thermodynamic redox potential. Fréchet, Abruña, and co-workers have observed shifts in redox potential in Zn-porphyrin core dendrimers [65]. Diederich and co-workers reported solvent-dependent effects for various Fe-porphyrin dendrimers [64, 72]. Stone and co-workers reported similar effects for ferrocene core dendrimers [73]. Gorman and co-workers, however, reported no effect on the redox potential of Fe_4S_4 cores for two different dendrimer architectures in solution [39]. The same dendrimers in thin films, however, exhibited tremendous changes in redox potential [66]. A model in which the difference in charge states between the oxidized and reduced forms of a core and the relative hydrophobicity of a dendrimer has been advanced to rationalize the results [13]. However, it is unclear how generally applicable this model will be.

2.3. Effects on Ligand Binding

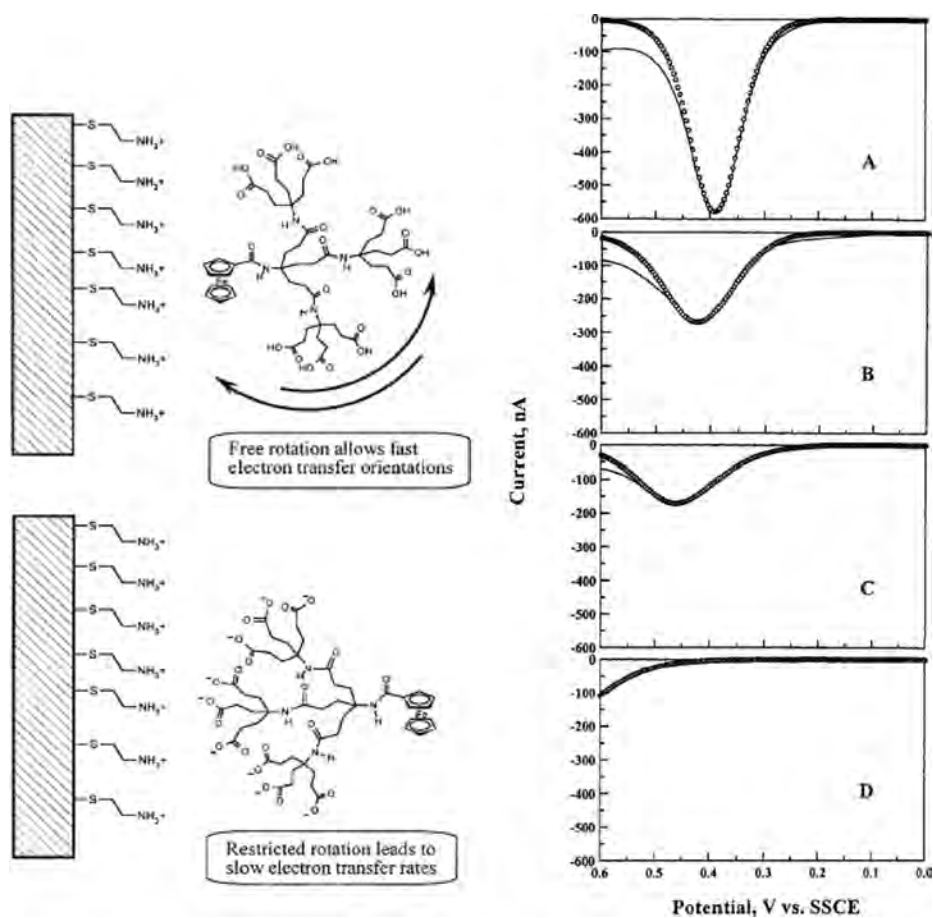
The effects of encapsulation on ligand binding to core molecules have been exhibited in diverse dendrimer–core systems. The principal influence is primarily steric in nature. The type of pockets that a dendrimer architecture establishes around the core is not well understood. Aida and co-workers demonstrated inhibition binding of a dendritic imidazole to a Zn-porphyrin core dendrimer [74]. Suslick and co-workers reported shape selective ligand binding in a series of Zn-porphyrin dendrimers [75, 76]. Pockets are built around the Zn-porphyrins with dendrons, limiting, but not completely eliminating access. Kaifer and co-workers also demonstrated hindrance of cyclodextrin binding for their ferrocene-core offset dendrimers [68, 77]. Pugh et al. reported the ability to discriminate chiral compounds with fluorescent dendrimers [78]. Vinogradov and co-workers showed control of O_2 binding to a Pd-porphyrin core through prudent selection of the encapsulating dendrimer [79]. In this last example, of three different water-soluble dendrimers synthesized, only the Fréchet-style aryl ether dendrimer was capable of inhibiting O_2 quenching of the porphyrin fluorescence emission (Fig. 9). The other two dendrimer architectures permitted O_2 access to the core.


Figure 7. Controlled Encapsulation with an "On-Off" Effect—By controlling the pH of solution, electron transfer to and from the ferrocene core could be controlled. The dendrimer was proposed to control the orientation of the ferrocene with respect to the electrode. Plots A though D are Osteryoung Square Wave Voltammograms obtained at pHs 4.2, 5.3, 6.0, and 7.0, respectively. Reprinted with permission from [67], Y. Wang et al., *J. Am. Chem. Soc.* 121, 9756 (1999). © 1999, American Chemical Society.

Figure 9. Differential Encapsulation—Three series of water-soluble palladium porphyrin core dendrimers with units illustrated by D1, D2, and D3, respectively. Only the aryl-ether-based dendrimers (repeat unit D1) could prevent quenching of emission from the core by O_2. Reprinted with permission from [79], V. Rozhkov et al., *Macromolecules* 35, 1991 (2002). © 2002, American Chemical Society.

3. CONCLUSIONS

Encapsulation has become a significant role that has been studied for dendrimers. A number of architectures have been explored. Several significant phenomena have been illustrated. In the most general sense, the role of the dendrimer in surrounding and encapsulating the core has been rationalized with simple models. However, in each case discussed above, there are examples that do not neatly fit a simple paradigm. Future work to enlarge the number and type of dendrimer architectures studied will facilitate extension of these models and establishment of more general paradigms for dendritic encapsulation.

GLOSSARY

Chromophore   Any chemical moiety that absorbs and/or emits light.

Convergent   A method of chemical synthesis that begins at the edge point of a molecule and builds inwards.

Dendrimer   A macromolecule consisting of a core moiety surrounded by one or more arms known as dendrons.

Dendron   A hyperbranched polymeric arms that form the bulk material of a dendrimer. They are attached to and radiate from the core moiety.

Divergent   A method of chemical synthesis that begins at the center point of a molecule and builds outwards.

Encapsulation   The process of influencing access by surrounding with a material.

Generation   A reference to the number of layers of a dendrimer. A layer is defined by the number of branch points found in the dendrons between the core and the periphery of a dendrimer. Thus, a "generation 4 dendrimer" would have dendrons with four branch points.

Monodisperse   A collection of objects that all have the same size. With regards to dendrimers, all molecules have the same molecular formula and molecular weight.

Nanoenvironment   The immediate surroundings around a moiety defined by molecular structure.

CONTENTS

1. INTRODUCTION

"Diamond," first mined in India thousands of years ago, has been known as the "king of gemstones" by the public for its beauty for centuries. It probably will not be long until in the 21st century the same diamond with a different morphological structure will be known as the "king of materials" to engineers and scientists for its extreme properties with their unique combinations and practical use in manufacturing in the form of films and coatings [1, 2]. The extreme material properties of diamond with some potential applications from their unique combinations can be found in some review articles (for example, see K. V. Ravi in [1] and P. Chalker and S. Lande in [2]), and in addition some new areas of applications such as surface acoustic wave (SAW) devices [2, 3], and micro/nanoelectromechanical systems (MEMS and NEMS, respectively) [4–6] have started emerging. In brief, diamond is very hard and least compressible, is optically transparent from the deep ultraviolet (UV) to the far infrared, has the highest known thermal conductivity of all materials at room temperature, has low thermal expansion coefficient at room temperature (0.8×10^{-6} K) that is comparable to that of invar, exhibits low or "negative" electron affinity, and is biologically compatible and very resistant to chemical

corrosion [1, 2, 7, 8]. Diamond is much more resistant to X-rays, γ radiation, UV light, and nuclear radiation than the other semiconductors such as Si and Ge. Also, it is a very good electrical insulator (with room temperature resistivity of $\sim 10^{16}$ Ω cm). However, its resistivity can be changed over the range 10–10^6 Ω cm by doping, thus becoming a semiconductor with a wide bandgap of 5.5 eV. The great interest in diamond also comes from its applications in electronic devices as it has very high mobility (about 2000 cm^2/V s), breakdown field (10 MV/cm), and saturation velocity (about 2.5×10^7 cm/s) compared to other semiconductors [8]. At the same time, there are other diamond related carbon materials that have properties in between those of diamond and graphite. The properties of these hard carbon materials vary, depending on the concentration of sp^3-(diamond) and sp^2-(graphite) bonded carbon in the films. A classification of diamond and related materials in terms of their structure, resistivity, and energy gap is given in Table 1. The energy difference between thermodynamically stable graphite and metastable diamond is 0.9 kcal/mole. Nanodiamond is a metastable material with intermediate energy, close to *ta*-C having sp^3 bonds more than 90% [9, 10]. Before progressing further let us discuss diamond and related materials in some more detail.

1.1. Synthetic Diamond

Scarcity and cost of the natural diamond led scientists to find means of making diamond in the laboratory. Although there have been several attempts to synthesize diamond from various sources of carbon since it was discovered to be an allotrope of carbon, two main techniques were invented, both in the 1950s; high pressure and high temperature (HPHT) synthesis [1, 7] and chemical vapor deposition (CVD) synthesis [1, 2]. To date, since its discovery, most of the demands to supply diamond for industrial uses, primarily for material cutting, grinding, and polishing, are met by the HPHT technique. In this technique graphite is subjected to tens of thousands of atmosphere and heated to over 2000 K in the presence of some metal catalyst crystallizing it in diamond. However, this process is intrinsically

Table 1. Properties of diamond, graphite, and amorphous carbon.

Material	Structure	Resistivity (Ω cm)	Energy gap (eV)
Diamond	100% sp^3-C	$>10^{10}$	5.5
Nanocrystalline diamond	$>90\%$ sp^3-C	$>10^6$	2–5.5
Tetrahedral amorphous carbon	$>80\%$ sp^3-C	$\sim10^4$	~2
Amorphous carbon	~10–50% sp^3-C	$\sim10^{-1}$	a few meV
Graphite	0% sp^3-C	10^{-4}	0

limited in its ability to cover surfaces in the form of thin film coatings and to produce large sizes. These limitation are overcome by another technique (i.e., CVD synthesis of diamond) in which diamond is grown at subatmospheric pressures in the form of thin films [2]. Although the invention of this technique dates back to 1950s, its early impracticalities in terms of economical viability due to extremely low growth rate and co-deposition of graphitic phase of carbon did not allow it to develop [11]. In late 1960s to early 1980s it was discovered that presence of atomic hydrogen can preferentially etch the co-depositing graphitic phase and can improve the growth rate significantly [12, 13]. The current surge in CVD diamond research can be traced back to 1982 when the Japanese group at the National Institute for Research in Inorganic Materials (now the National Institute of Advanced Industrial Science and Technology) published details of their work clearly indicating the ways and means of generating atomic hydrogen in the growth chamber to grow good quality diamond on nondiamond substrates at significant rates (~1 μm/hr) [14]. Following this the same group came up with another technique in 1983 and this stimulated the worldwide interest in CVD diamond [15].

In general, in this technique, diamond can be nucleated on nondiamond substrates and an oriented or polycrystalline thin film can be deposited by dissociating the precursor gases at low pressures. These polycrystalline films show the same characteristics as natural and synthetic diamond and have high potential for various applications [1, 2, 8]. Generation of atomic hydrogen and the excitation of hydrocarbons can be achieved by various means and can broadly be classified as thermal CVD and plasma CVD. In thermal CVD processes, decomposition of precursor gases is accomplished by thermal activation whereas in plasmas it occurs by electron–molecule reactions. In high temperature plasma torches both mechanisms can be important. Thermal activated CVD includes hot filament and oxyacetylene torches. Plasma CVD includes low and medium pressure microwave (2.45 and 0.915 GHz) and dc plasma, dc plasma jet, low pressure radio frequency (rf) plasma, etc. [2].

1.2. Nanocrystalline Diamond

The high surface roughness of the conventionally grown polycrystalline CVD diamond films prevents their immediate use in spite of having outstanding properties with their unique combinations suitable for many applications. The high surface roughness is a major roadblock using these CVD diamond films for various applications [16, 17] such as machining and wear, optical, and thermal management

applications. For example, diamond is well suited for use as a protective optical coating but diamond films with high surface roughness cause attenuation and scattering of the transmitted signals restricting their use in optical coatings. In order to overcome the problem of surface roughness of diamond films either postpolishing is to be adopted or naturally grown smooth films are to be developed without compromising much of their hardness and other useful properties. However, postpolishing is expensive and time consuming [18–20] and it may be better to concentrate on as-grown smooth diamond films [19–51]. One way to reduce the surface roughness during growth is to control crystalline orientation with (100) facets being parallel to the film plane [52], or by reduction of the grain size (i.e., reduction of grain sizes from micrometers to nanometers) [9, 35, 37, 53].

This is the reason that in the last few years efforts in the area of diamond films grown by CVD have diverted from conventional microcrystalline diamond (MCD) films, having a grain size of a few hundred nanometers to several tens of micrometers [9, 35, 53–55], to nanocrystalline diamond (NCD) films, having a grain size from 2 nm to a few hundred nanometers [9, 19–51, 53, 56–62]. Moreover, this change of perception is a result of NCD films not only being smooth but also being more adaptive to the CVD diamond applications and having enhanced electronics and other properties. This is reflected in their cost effective and superior performances in the areas of electron field emission [63–69], optical transparency and protective coatings [21–23, 28, 38–40, 45, 51, 53, 70–72], tribology [19, 33, 34, 36, 37, 48, 73–75], SAW devices [3], and MEMS [5, 6]. Some of these properties of NCD films and a comparative study with single crystal diamond (SCD)/MCD are listed in Table 2. Moreover, as the size of the grains is changing from micrometer to nanometer, a factor of a million in volume, new properties have started emerging, exploring new areas of applications [76], for example, in X-ray optics, X-ray physics, particle physics, etc.

Some important properties of nanocrystalline diamond films are

- large surface area of diamond and high density of grain boundaries
- drastic increase in surface smoothness relative to microcrystalline diamond
- presence of more defects, however, less disorder in the interface
- better electron emission than conventional diamond films
- less highly oriented grains
- important grain boundary conduction
- enhanced optical transmission.

1.3. Diamond-like Carbon and Tetrahedral Amorphous Carbon

There is another class of hard carbon materials [1, 77, 78], essentially amorphous in nature and consisting of a mixture of sp^2 and sp^3 carbon, broadly termed "diamondlike carbon" (DLC). A significant amount of sp^3 carbon in the films gives them attractive physical and mechanical properties such as high hardness, high wear resistance, low coefficient of friction, chemical inertness, a high optical bandgap, and high

Table 2. Some properties of NCD films.

Properties	SCD/MCD[a]	NCD	Ref.[b]	Potential applications of NCD[c]
Electronic properties				
1. Bandgap (eV)	5.5	2–5.5	[30, 53, 70]	electronic devices
2. Electron affinity	negative	negative	[153]	
3. Onset of field emission (V/μm)	160	3–4	[63]	field emission display
4. Resistivity (Ω cm)	$>10^{10}$	$>10^6$	[56]	
5. Doping	p-type possible	both p- and n-type possible	[56, 162]	electrochemical electrodes
Optical properties				
1. Transmission	transparent from UV to far IR	$\sim$78–84% transmittance beyond 700 nm	[45, 53]	optical coatings
2. Refractive index (@ 633)	2.41	$\sim$2.27–2.35	[53] (@ 830 nm), [201]	IR windows
Mechanical properties				
1. Hardness (GPa)	$\sim$100	>90	[5]	
2. Young's modulus (GPa)	1054	$\sim$1000	[5, 6]	wear resistant, protective coatings
3. Wear resistance	high	high	[19, 34]	
4. Coefficient of friction	<0.1	0.1 (8000 cycles) to 0.01 (2.2×10^6 cycles)	[5]	MEMS/NEMS
Structural properties				
1. Bonding character	100% sp^3-C	$>90\%$ sp^3-C	[5]	
2. Grain size (nm)	—	2–100	this work	
3. Surface roughness (nm)	—	2–50	this work	
4. Hydrogen content (%)	—	<1	[5]	
Other properties

[c] Potential applications are a result of combinations of various properties in most of the cases.

electrical resistivity. These properties in the DLC films vary with the concentration of sp^2 and sp^3 carbon in the films. It has been shown that the properties of DLC films, such as hardness, optical transparency, etc., approach the value of diamond with high concentration of sp^3 carbon [79, 80]. The DLC films with high sp^3 concentration are termed tetrahedral carbon (ta-C) or amorphous diamond (a-D). The term DLC is mostly used to designate the hydrogenated amorphous carbon (a-C:H) whereas the term ta-C is mostly used to designate the nonhydrogenated amorphous carbon (a-C) [78]. The a-C:H films may contain 50% sp^3 carbon whereas it may be as high as 85% in ta-C films. Pulsed laser deposition [72–74, 79, 81, 82], cathodic arc deposition [80, 83], and ion deposition methods [84] have been employed to grow this new class of carbon material.

Considering the smooth surfaces having properties close to diamond, NCD and ta-C have emerged from their respective branches of CVD diamond and DLC, as described, as

the materials for intense current and future activities. As mentioned, it is not only because these films are smooth but also because they are more adaptive to the CVD diamond applications, having enhanced electronics and other properties. This makes the basis of this chapter in which some properties of NCD are discussed, emphasizing, in particular, transport and electronic properties, and are compared with the properties of ta-C. First, various deposition routes of NCD are discussed. Second, transport and electronic properties of NCD will be discussed in detail followed by a discussion on optical and mechanical properties. At the end, various other emerging aspects of NCD are also presented.

2. DEPOSITION ROUTES

A common feature of the majority of the deposition techniques of CVD diamond films is a high concentration of hydrogen gas (H_2) used as one of the constituents with some

hydrocarbon gas such as CH_4. A concentration of H_2 in excess of 99% (of the gas mixture) is required for the growth of high quality MCD films. The high concentration of H_2 results in the generation of a large flux of atomic hydrogen, which is generally believed to play a central role in the various diamond CVD processes. The growth of diamond is said to take place mostly via surface processes of addition and abstraction of radicals from the gas phase [8, 85–87]. Initially, after the nucleation of diamond, the growing diamond surface is to be protected from reconstruction into the graphitelike form. Therefore a high concentration of H is needed to satisfy the dangling bonds left unsatisfied on the growing diamond surface. Subsequently, vacancies are created by hydrogen atoms, which interact with the bonded hydrogen and remove it by converting it into H_2. Methyl radicals (CH_3), also generated by gas-phase hydrogen abstraction by H, are considered as diamond precursors are then placed on the vacancies in order to promote growth. In addition, atomic H preferentially etches the graphitic phase co-depositing with diamond. Generally, before realizing the importance of growing naturally smooth surfaces, the aim in the area of CVD diamond was to maximize the crystalline quality of CVD diamond. However, diamond grown under nonoptimum conditions, such as lower hydrogen concentration or higher carbon activity in the plasma, gives films with small grain size (e.g., several nanometers).

Also, ions are not considered to be good for diamond growth as they enhance lattice disorders and also promote graphitic content in the deposit. On the other hand, in the growth of carbon films by hyperthermal species, ions with energy in the range 40–200 eV produce a high concentration of sp^3 carbon in the films [83, 88, 89]. In this case the growth is dictated by a subplantation mechanism, which relies on the shallow subsurface implantation of the carbon ions [88]. Thus the two routes of growth of carbon films are totally different (i.e., one relies on surface and the other on subsurface processes). Moreover, the deposits are predominantly crystalline and amorphous respectively in the two processes. Interestingly, it was shown recently that both the routes can be coupled not only to generate diamond nuclei in the process called biased enhanced nucleation but can also be used to grow smooth NCD films [41, 42].

In the already existing ways to grow NCD, a number of techniques and conditions have been employed [9, 26, 27, 36, 37, 42, 44, 45, 48, 49, 57, 76]. As the need for as-grown smooth diamond films has been realized in the last few years, new routes have also emerged that mostly aim to grow smooth NCD or NCD embedded in a *ta*-C or *a*-C matrix. Based on the literature, a brief description of these new routes is as follows.

2.1. Hydrogen Deficient Gas Phase

As explained, high hydrogen concentration gives high quality MCD films and one route adopted to reduce the crystalline size to obtain NCD films is to reduce the concentration of hydrogen or increase the carbon activity in the gas phase and on the growing surfaces either by increasing the hydrocarbon constituent in the gas phase or by substituting the hydrogen with other gases, partially or completely. The resultant films vary from phase pure NCD to NCD embedded in *ta*-C or *a*-C matrix.

2.1.1. Hydrogen Deficient CH_4/Ar, C_{60}/Ar, CH_4/N_2, CH_4/He

One such process that has been studied in detail was developed at Argonne National Laboratory, USA [5, 9, 10, 19, 24, 31, 32, 35, 46, 56]. In this process, carbon dimer (C_2) is used as a reactive species in hydrogen deficient (CH_4/Ar or C_{60}/Ar) microwave plasma CVD [9]. C_2 is produced by replacing molecular hydrogen by argon and using CH_4 or C_{60} as precursor gases and also by using N_2/CH_4 as the reactant gases in a microwave plasma CVD system. The NCD films grown on seeded substrates by this technique are composed of 3–15 nm diamond crystallites with up to 1–10% sp^2 carbon residing at the boundaries [9]. Konov et al. [25] also reported growth of smooth NCD films using $CH_4/H_2/Ar$ mixtures with a methane percentage $CH_4/(CH_4 + H_2)$ varied in the range of 10 to 100% in a dc arc plasma deposition system. Their NCD films grown on Si substrates, seeded with ultrafine (5 nm) diamond particles, consisted of 30–50 nm size diamond crystallites. In the partially substituted hydrogen Nistor et al. [29] produced 1–2 μm thick NCD films from $CH_4/H_2/Ar$ mixtures by direct current plasma CVD. The Ar concentration was kept constant at 50% and methane concentration $CH_4/(CH_4 + H_2)$ was varied from 3 to 100%. Similar to Konov et al. [25] they also obtained nanodiamond films without even using hydrogen in the feed gas. Smooth NCD films with grain size of 10–50 nm were obtained on substrates seeded with 5 nm diamond powder. Although their transmission electron microscopy (TEM) studies did not reveal amorphous carbon in significant amounts, the nanocrystallites were found to be highly defective with many twins and other planar defects. The grain boundaries were presumably decorated with disordered sp^3-bonded carbon and sp^2-bonded amorphous carbon. Lin et al. [90] studied the $CH_4/H_2/Ar$ process in a hot filament CVD (HFCVD) system and proposed a compositional map demarcating regions for well-faceted diamond growth, NCD growth, and nondiamond deposition. Well-faceted MCD (2–10 μm) grow using Ar up to 90%. They report a change in microstructure from MCD to NCD, with a grain size smaller than 50 nm, at 95.5% Ar addition. Yang et al. [91] also used the $CH_4/H_2/Ar$ process to grow NCD films and observed decreasing grain size and that the surface morphology of the films changes gradually from faceted to ballastlike diamond with increasing Ar concentration. The formation of NCD was seen when more than 90% Ar was added in the $CH_4/H_2/Ar$ plasma. In another study [92] a low concentration (10–15%) of nonuniform distribution of nanodiamonds in amorphous carbon was detected at temperatures as low as 15 °C from decompositions of CH_4/Ar-rich plasmas generated at 35 kHz.

Amaratunga et al. [93, 94] reported mixed phase films containing diamond crystallites (10–200 nm) embedded in a nondiamond carbon matrix while using CH_4/He plasmas. Bi et al. [3] used Ar, H_2, and CH_4 in the ratios 100:4:1, respectively, to grow thick NCD films for a SAW device. The root mean square (rms) surface roughness in their case was 50 nm while the mean average grain size, estimated by scanning electron microscopy (SEM), was approximately 30 nm.

2.1.2. CH₄-Rich CH₄/H₂ with or without N₂ and O₂

2.1.2. CH$_4$-Rich CH$_4$/H$_2$ with or without N$_2$ and O$_2$

Yoshikawa et al. [48] prepared smooth NCD films having approximately 10 nm size grains, as observed by field emission SEM, by a microwave plasma CVD (MPCVD) system using a high methane concentration (10 vol%) in hydrogen on substrates pretreated by diamond powder of sizes 5 and 250 nm. Heiman et al. [47] used 9.91% methane in hydrogen gas mixture in a dc glow discharge. Smooth NCD films of 1 μm thickness with grain size in the range of 3–5 nm were obtained. Catledge and Vohra [36, 37] reported a new regime for synthesis of nanostructured diamond films on Ti-6Al-4V substrates. They used high pressures (125 Torr) and high methane concentration (5–15%) in balanced hydrogen and nitrogen in a MPCVD system to obtain predominantly diamond nanocrystallites of 13 nm average size, as estimated by X-ray diffraction (XRD) patterns, in a matrix of ta-C. The films are shown to be significantly smooth compared to the conventionally grown MCD films. At these processing conditions the microwave plasma is more highly activated with C$_2$ and atomic hydrogen. In another report they added varying concentrations of nitrogen in the plasma with 15% CH$_4$ and found that the grain size decreases up to the ratio of 0.1 of N$_2$/CH$_4$ before saturating at higher nitrogen concentrations. The amount of ta-C also increases in the same fashion and, as expected, the surface roughness also follows the same trend. It was suggested that the change in the film morphology is not a result of N$_2$ incorporation in the films but is a result of N$_2$ related surface processes such as microtwinning due to changes in gas-phase chemistry and surface kinetics. The same group, in their another study [95], modeled the gas-phase composition for MPCVD grown diamond with H$_2$/CH$_4$/N$_2$ mixtures using a thermodynamic equilibrium package and compared it with their experimental results by growing diamond films using the same mixture with the MPCVD system. A correlation was shown between the calculated composition of CN radical in the gas phase and the experimentally determined nanocrystallinity of the samples grown with different N$_2$ additions in the H$_2$/CH$_4$ plasma indicating the role of CN radical in the nitrogen-induced diamond nanocrystallinity in MPCVD.

Yang et al. [51] grew transparent diamond films with crystallite size below 70 nm in hydrogen and methane microwave plasma CVD on quartz substrates, ultrasonically pretreated by 0.5 μm diamond powder for 30 min. They studied surface morphology and optical and mechanical properties of the films by varying methane concentration in hydrogen plasma in the range of 1 to 4% while introducing 0.2% oxygen after the nucleation and keeping the substrate temperature 500 °C at 4 kPa pressure and 1.5 kW microwave power constant. Grain size and surface roughness were observed to decrease with methane concentration with a significant reduction in grain size occurring at 3% methane, which further reduced at 4% methane though the nanodiamond concentration in the films also goes up. The crystallite size, as estimated by TEM, near the interface was 30 nm and increases to 65 nm near the growth side. A thickness of 1–1.2 μm was obtained in 4 h growth of the films. Chen et al. [38–40, 45] used the MPCVD system to grow NCD films on quartz substrates, ultrasonically pretreated (using 4 nm diamond powder) for 8 h, using CH$_4$/H$_2$/O$_2$ plasmas in which CH$_4$ was varied between 1.5 and 42% while keeping O$_2$ constant at 0.1%. The average surface roughness of their 0.5 to 1 μm film varied between 6 and 13 nm. They showed that the surface roughness of the NCD films decreases with increasing methane concentration and has a great impact on the optical transmittance of the NCD films. Wu et al. [22] demonstrated growth of NCD (20–100 nm grain size) having a surface roughness of ∼15 nm by low pressure (5 Torr) and low microwave power (450 W). Erz et al. [23] used 10% CH$_4$ in hydrogen to grow 800 nm NCD film. Zarrabian et al. [28] used electron cyclotron resonance (ECR) plasma to grow NCD grains of size 4–30 nm embedded in DLC. Jiang et al. [59] showed that NCD can be grown with MPCVD using 5% CH$_4$ on Si ultrasonically pretreated by diamond or SiC powders. The average grain size estimated by TEM analysis revealed a NCD grain size of 30–40 nm. The substrates, mechanically abraded by Al$_2$O$_3$ grit, give NCD embedded in a-C matrix at the same conditions.

Wu et al. [66, 67] grew NCD films using N$_2$/CH$_4$/H$_2$ in a MPCVD system. In the first series the CH$_4$ was varied between 2.1 to 8.4 sccm in 150 sccm of nitrogen without any hydrogen. In the second series hydrogen was introduced and was varied in the range of 0–10 sccm while keeping the methane constant at 3.5 sccm. NCD films with grain size of 8 nm embedded in a-C matrix were obtained without any hydrogen which increases to 20 and 50 nm respectively at 5 and 10 sccm of hydrogen.

In another interesting development, composite diamond films with smooth surfaces, was achieved by alternatively depositing conventional MCD and NCD films in a HFCVD reactor [50]. The structure of the layers was such that the bottom and top layers were respectively MCD and NCD. SEM and atomic force microscopy (AFM) analyses of the films revealed 2–3 μm granules consisting of 10–100 nm diamond grains unlike the well-faceted micrometer size grains observed in conventional MCD films. The surface roughness was less than 100 nm. These films have dielectric properties similar to conventional MCD films with smooth surfaces and are considered to be promising for MEMS devices.

2.1.3. CO-Rich CO/H₂ Mixtures

2.1.3. CO-Rich CO/H$_2$ Mixtures

Lee et al. [26, 27] developed a low temperature process (350 °C < T < 500 °C) for low power but high growth rate (up to 2.5 μm/hr) NCD film by MPCVD. Instead of high methane concentration they used CO-rich CO/H$_2$ mixtures and obtained smooth NCD films consisting of 30–40 nm grain size. They observed an interesting growth trend with respect to substrate temperature while using the CO-rich CO/H$_2$ mixture. There is a narrow temperature window, different for different CO/H$_2$ ratios. The temperature at which the peak growth rate is obtained in this window decreases with increasing CO/H$_2$ ratio. For example, the peak of the growth rate is observed to occur at 500 °C at a ratio of 8 of CO/H$_2$ that decreases to 450 °C at a ratio of 18. Moreover, the growth rate also increases with increasing ratio. Although the growth of NCD was obtained at low temperatures the bulk void fraction also increased significantly compared to the films grown at higher temperatures. Recently,

growth of NCD films of size 20 nm was also reported by Teii et al. [57] at low pressure (80 mTorr) at 700 °C by inductively coupled plasma employing CO/CH$_4$/H$_2$ and O$_2$/CH$_4$/H$_2$. In this case a positive biasing of 20 V was applied to the substrate to reduce the influence of ion bombardment. The films consist of ball shape grains of size 100 nm, which are composed of 20 nm NCD grains.

2.2. Biased Enhanced Growth

As the reader may have noticed, in the growth route for NCD by hydrogen deficient plasmas, mostly the substrates were pretreated externally before deposition ultrasonically or mechanically using diamond or other abrasive powders. There is another well-established method to nucleate diamond internally in conventional growth of MCD films called biased enhanced nucleation (BEN) [96] in which the substrates are biased negatively in a relatively hydrocarbon-rich mixture of hydrocarbon–hydrogen precursor gases. This method, which results in a high density of diamond nucleation (10^{10}/cm^2 or more), is the first step followed by another step or two steps to grow heteroepitaxial diamond films. In order to achieve overgrowth of diamond on these nuclei, the BEN process is followed by conventional growth in which the bias is put off and the growth is continued with lower hydrocarbon percentage in the gas phase. It is found out that in this later stage of growth only the stable parts of the nuclei continue growing with while the remaining getting etched off in the process due to high concentration of hydrogen in the conventional step of growth [97].

To obtain an NCD film, Sharda and Soga [61] considered achieving higher densities of diamond nucleation, similar to the BEN process, followed by their continuous growth in the later stages while maintaining the high density. In order to achieve this they extended the BEN in microwave plasma CVD for the whole growth process and termed their process biased enhanced growth (BEG) in which they obtained diamond nucleation and growth on silicon substrates in a single process [41–43, 76]. They used 5% CH$_4$ in balanced H$_2$ and controlled the bias current density in a special arrangement in a MPCVD system to study the growth in a different combination of conditions (bias current density, bias voltage, and microwave power). A different regime of growth was indeed observed which resulted in NCD films having rms surface roughness of 5–30 nm composed of grains of 2–30 nm with growth rates of 0.5–2 μm/hr at 1000 W microwave power and at substrate temperatures in the range of 400–700 °C. In a similar development, Gu and Jiang [44] also used biasing to not only nucleate diamond but also to grow films. Their growth process, though, uses continuous biasing to grow NCD but in three steps unlike a single step process for both nucleation and growth by Sharda et al. [41–43, 61]. No biasing and methane were used in the first stage for 40 min at 860 °C, which was meant just to remove the oxide layer, followed first by a nucleation stage in which the substrates were biased at −120 V at 5% methane (at 840 °C, 20 mbar pressure, and 800 W microwave power) and second by the growth step in which the substrate was biased up to −140 V while decreasing the methane concentration in the range of 0.5 to 5% and changing other conditions as well. It was observed that the grain size decreases from

0.3 μm at −100 V to 40 nm at −140 V. The growth rate was 0.25 μm/hr and surface roughness, as measured by a surface profilometer, of 1 μm thick film was 5 nm at −140 V. There was a marked difference in the adhesion of the films in case of Sharda et al. [62, 76, 98] and Gu and Jiang [44]. The BEG process by Sharda et al. results in a strong adhesion that allows one to grow any thickness, irrespective of amount of the stress in the films, whereas the NCD films grown by continuous biasing by Jiang and Jia [49] cannot be grown beyond 2 μm due to relatively weak adhesion as the compressive stress in the films make them delaminate from the substrate. Groning et al. [99] grew NCD films on silicon substrates to study their field emission properties with and without biasing. In case of no biasing they used high substrate temperatures (950 and 980 °C) and high methane fraction (5%) and in the case of biasing at −250 V they used a relatively low substrate temperature (850 °C) and lower methane fraction (2%). In the latter case the surface morphology was ballastlike with large ball-like structures of 2–3 μm in diameter consisting of diamond nanocrystallites of size 10–50 nm.

In an effort by Yang et al. [100], the effect of bias in forming NCD in the MPCVD system was studied. The NCD films were grown on scratched substrates unlike the films grown on externally untreated mirrorlike substrates by Sharda et al. or Jiang et al., as described. A continuous dc negative biasing in the range of 0–250 V was applied to the substrates during deposition while using a 1% CH$_4$/H$_2$ mixture for 3 hr to study crystallinity, morphology, and growth rate of the diamond films. The substrate temperature was maintained at 900 °C while using 5.3 kPa chamber pressure and 1000 W microwave power. A change in the morphology with biasing voltage was reported from triangle-faceted grains of 1–3 μm size (up to a bias of 50 V) to square-faceted grains of 1–2 μm size (at 100 and 150 V). Smooth NCD films with grain size of 20–40 nm, as measured by TEM, were obtained at 250 V. The growth rate was reported to decrease with biasing beyond 50 V with the NCD growth rate being 0.3–0.4 μm/hr. It should be noted that the effect of biasing on the growth rate in this study is different than the effect on biasing in the BEG process reported by Sharda et al. [98]. In the later study, the layer thickness in 60 min growth increases from 1 to 2 μm with increasing biasing from 200 to 320 V. In another interesting effort by Yang et al. [101] to grow NCD films, the two main methods to grow NCD, hydrogen deficient argon plasma using methane and fullerene (Section 2.1.1) and biased enhanced growth (Section 2.2), were coupled to study their combined effect on the grain size, microstructure, and growth rate of the diamond films in the MPCVD system. The NCD films with grain size of 50–100 nm were grown using an Ar concentration of 90–99 vol% while continuously biasing the substrate at −50 V. This combination gives a growth rate of 0.7–0.8 μm/hr of NCD films in the MPCVD system, apparently larger than what the authors obtained by individual processes. However, it should again be mentioned that even the maximum growth rate (0.8 μm/hr) of NCD films, with or without Ar addition, reported by Yang et al. [100, 101] is still lower than the maximum growth rate (~1.9 μm/hr) of NCD films by the BEG process reported by Sharda et al. [98].

More studies on the growth of NCD films began appearing, with Zhou et al. [58, 102] reporting growth of nanodiamond *a*-C composite in a HFCVD system. The continuous biasing process was termed as prolong biased enhanced nucleation in which they obtained NCD (∼10 nm) embedded in *a*-C matrix at 1% CH_4 in hydrogen. They obtained 1 μm thick film in 7 h of deposition. The rms surface roughness of their films measured by AFM was ∼20 nm. Nonfaceted granular structures of size 100–200 nm are seen in SEM which consists of ∼10 nm diamond grains embedded in *a*-C matrix, as seen in low magnification TEM.

In another development, growth of smooth nanodiamond films (NCD embedded in *a*-C matrix) on different substrates was reported by Kundu et al. [30] at room temperature using dc magnetron sputtering of vitreous carbon in an argon and hydrogen (0–10%) plasma in the pressure range of 45–90 mTorr. The average grain size, as examined by TEM, was found to be ∼55 nm on quartz and ∼75 nm on Si and Mo substrates. The film surface consists mostly of sp^2-bonded carbon and was removed to see the NCD embedded in the *a*-C matrix by SEM. The sp^3/sp^2 ratio, as estimated by Fourier transform infrared (IR) increased from 4 to 16 with increasing negative bias voltage applied to the substrate.

In an interesting advancement in the synthesis of diamond films, a multilayer structure of MCD and NCD was developed using growth with and without biasing [103]. It was shown in this study that size of the diamond grains could be reduced to a few nm by applying a negative bias during the growth of an MCD film and could again be increased once the bias was put off. This way a layered structure of MCD and NCD can be grown. In this study, the grain size of the initial MCD layer, which was grown for 2 hr, had a grain size of <1 μm that reduced to about 4–5 nm in the overgrown NCD layer while using biasing. The nanometer sized diamond started appearing on the facets of MCD grains right from the growth after 5 min. Application of biasing changed the faceted surface morphology of the MCD layer to a smooth surface morphology in 30 min growth. Putting off the bias after the growth of the NCD layer can again develop a faceted MCD layer on the top of the NCD layer.

2.3. Ion Implantation

A completely different route than those described in Sections 2.1 and 2.2 was adopted by Prawer et al. [104] who showed formation of a pure NCD layer in fused quartz by means of MeV ion implantation followed by annealing at suitable conditions. Unlike the previous two routes or any other route to grow diamond, this process does not require any nucleation or any external high pressure (HPHT process) to develop diamond. In this process, 1 MeV carbon ions with a dose of 5×10^{16} C/cm^2 implanted into fused quartz followed by annealing for 1 h at 1100 °C in 4% hydrogen in argon resulted in the formation of a 60 nm thick layer consisting of 5–7 nm cubic diamond crystallites at 140 nm below the quartz surface. The size of the diamond grains can be controlled by varying the implantation dose and it increases with increasing dose (8–13 nm for 2×10^{17} C/cm^2 and 15–20 nm for 5×10^{17} C/cm^2). In another development Wang et al. [105] formed nanocrystalline diamond with sizes of ∼2–70 nm by Ar$^+$ irradiation of graphite at a fluence of 10^{22}/cm^2.

2.4. Transformation

Yet another unique concept was introduced by Hirari et al. [71] to produce nanocrystalline diamond ceramics not by sintering a raw powder but by transforming C_{60} fullerene by shock compression and rapid quenching. The transformed transparent NCD platelets consist of a few nanometer-sized diamond crystallites, which are connected directly or by a thin modified sp^3 carbon layer, as revealed by TEM and electron energy loss spectroscopy (EELS). Similarly, NCD has been formed by direct transformation of multiwalled carbon nanotubes (MWCNT) under high pressure [106]. MWCNT samples in the form of a platelike shape were subjected to a pressure of 17 GPa and were heated to 2500 K by a CO_2 laser in a diamond anvil cell. The recovered product had the same platelike shape as the starting material and consisted of nanosized octahedral crystals with size less than 50 nm, which was similar to the size of the diameter of the nanotubes. The heated part by the laser was transparent. The Raman spectra of the transparent region of the sample show a broad peak at 1322–1324 cm^{-1} indicating that the converted product is diamond which was confirmed by EELS measurements of the converted sample. No amorphous or graphitic phase could be seen in the transparent region of the converted sample. It should be noted that the unheated part of the sample did not convert to NCD and remained MWCNT. The tubular structure of the unheated part of the sample remained unchanged in spite of the fact that it was subjected to a high pressure of 17 GPa. This is because of high yield strength of the curled graphitic planes.

In another interesting development, Gogotsi et al. [107] reported in the journal *Nature* synthesis of nanocrystalline diamond-structured carbon by conversion of silicon carbide at ambient pressure. In this process silicon was extracted from silicon carbide in chlorine-containing gases at ambient pressure and temperature below 1000 °C. Average crystallite size of the diamond-structured carbon was 5 to 10 nm resulting from a stable conversion from silicon carbide in the presence of hydrogen in the gas mixture.

2.5. Dielectrophoresis/Spraying Coating

A diamond layer can be coated on substrates by dielectrophoresis or a spraying method. Zhu et al. [63] attached thin nanostructured diamond films to silicon substrates by a spraying or brushing technique using commercially available, produced by explosives, 10 to 100 nm size micropolycrystalline diamond particles with each of the particles consisting of 1 to 20 nm crystallites and associated grain boundaries in aqueous suspension. Göhl et al. [65] deposited nanodiamond powder coating by a dielectrophoresis technique. They used nanodiamond powder of 1–10 nm size produced from shock synthesis on a Si tip array, rough Si stumps, and flat standard mirror-polished Si substrates. Xu et al. [108] deposited a nanostructured diamond coating on etched silicon substrates by the dielectrophoresis method using ∼5 nm nanodiamond powder, produced by explosives, by suspending them in ethanol. Mallillard-Schaller et al. [109] deposited 4–5 nm size diamond nanoparticles on flat Si(100) substrates by electrophoresis/dielectrophoresis.

In summary, various routes have been developed or adopted to grow a variety of NCD films varying from phase-pure ultrananocrystalline diamond to nanodiamond embedded in a-C or ta-C matrix. The grain size of these nanocrystals can be controlled and can be varied by different parameters studied in these different routes of their growth. Table 3 gives the range of grain size and surface roughness of NCD films reported by various research groups by adopting different deposition routes, as described in this section. In the following section we shall now discuss in detail transport and electronic properties of this material followed by some discussion of its optical and tribological properties.

3. TRANSPORT PROPERTIES

3.1. High Electrical Conductivity from Diamond and Related Materials

There are different ways to increase conductivity of carbon related materials. One of the easiest methods is to increase the percentage of graphitelike or sp^2-bonded carbon by pyrolysis. It is also observed that application of high hydrostatic pressure can increase the conductivity by a few orders of magnitude [110]. However, controlling the enhanced conductivity by pyrolysis is a very difficult task. Beside, this process gives soft material that is rich in sp^2-bonded carbon. Doping is an elegant way to improve the conductivity of diamond and related materials without changing their structure. Several donors in mono- or di-substitutional sites like Li, F, Cl, I, Xe, S, O, P, N, NO, etc. have been analyzed with calculations. Substitutional P was found to be a better donor than N. Similarly, S and Cl are better donors than O and F, respectively [111]. Interstitial Li atoms are predicted to be shallow donors whereas substitutional Li are predicted to be as acceptors. However, electrical activation by Li-doped diamond was not so high. At the same time, oxygen forms a deep thermal donor and sulfur is a shallower donor than oxygen [111]. Over several years many researchers have been hoping that diamond or diamondlike carbon, with excellent mechanical and thermal properties, would appear as good electronic materials. However, difficulties of doping n-type impurities with low activation energy have hampered their hopes and thus actual diamond devices could not be made yet [112–114]. Due to the smaller atomic radius of carbon compared to that of Si and Ge solubility of different elements in diamond is lower [113]. Nevertheless, several researchers have attempted to incorporate different kinds of dopants, like phosphorous [115], sulfur [116], oxygen [117], etc., and very recently, some reports discussed the possibility of successful n-type doping of diamond [115–120] (see Table 4).

Despite numerous efforts demonstrating that n-type doping can produce shallow donor levels close to the conduction band (CB) of diamond, the levels and the resistivity are still too high (>300 meV and 10^3 Ω cm, respectively) for application of this material at room temperature [115–118] (see Table 4). Also, the conductivity activation energy does not seem to decrease sharply with increase of dopant concentration [116–118]. To apply n-type doped diamond to a real electronic device the resistivity and activation energy should be much smaller than those of boron-doped diamond [120, 121]. In the following we shall concentrate on nitrogen for n-type conduction in diamond.

3.2. n-Type Conduction by Nitrogen Incorporation

3.2.1. Background

Nitrogen has been thought to be an ideal n-type dopant for diamond and related materials. This is because nitrogen has five valence electrons, one more than a carbon atom. This extra electron will be shared by the sp^3- or sp^2-bonded carbon atoms forming σ or π type bonds. Though theoretically

Table 3. Surface roughness and grain size of NCD films obtained by various groups by adopting different routes.

Technique	Route	Grain size (nm)	Roughness[a] (nm)	Ref.
MPCVD	$CH_4/H_2/O_2$	<300	~10	[21]

[a] Roughness is not necessarily an rms value and is also measured by different methods (AFM, profilometer).

Table 4. Comparative study of the electrical properties of doped diamond.

Type of dopant	Conductivity S cm^{-1} (RT)	Activation energy (eV)	Carrier density (cm^3)	Mobility (cm^2/V s)	Ref.
O (n)	high	0.32	5×10^{11}	~40	[117]
S (n)	1.3×10^{-3}	0.38	1.4×10^{13}	597	[116]
P (n)	0.2×10^{-3}	0.46, 0.56, and 0.81	~10^{14}	0.5–5	[115, 118]
N (n-SCD[a])	10^{-16}	1.7	10^7	5000	[113]
N (n-MCD[b])	10^{-6}	1.6		>100	[114]
B (p)	<10	0.36–0	>10^{20}	>10^2	[120]
N (a-C:N)	10^{-2}	0.2	~10^{18}	very low	[121]

[a] SCD = single crystal diamond.
[b] MCD = microcrystalline diamond.

it looks quite simple, in practice it has been quite different because defects dominate the doping effect. Altogether an increase of conductivity can be seen in N-doped materials along with some changes in the structure of the materials.

Nitrogen is a possible donor in diamond with a lower formation energy than that of phosphorous. However, it has been understood that successful nitrogen doping of SCD is quite difficult [112–114]. Because of a high degree of localization of the N wave function, nitrogen behaves as a deep impurity center in diamond, 1.7 eV below the CB. Nitrogen in diamond prefers to form bond with three neighboring carbon atoms occupying a three-coordinated substitutional site distorted along the (111) direction and two of its electrons acting as a lone pair orbital [113]. In CVD polycrystalline diamond also doping of nitrogen has been unsuccessful due to the presence of a large defect density in this material at the surface as well as in the grain boundary that forms π–π^* states in the gap region [114]. Nitrogen creates a natural charge state and remains fourfold coordinated.

Electronic properties of NCD film with ta-C and related materials are compared in the following sections. Apart from structural disorder, the sp^3 percentage of the ta-C films is not found to be different than the sp^3 percentage of the NCD films showing very good mechanical and tribological properties. The ta-C is thought to be a better candidate than other forms of carbon for electronic applications. It is because of its bandgap of about 2 eV and a small activation energy (E_σ, about 0.2 eV) suggesting nitrogen may form a shallow donor level [83, 121]. However, the concept of doping in amorphous materials (here: ta-C) is quite different from the concept of doping in crystallographic forms (e.g., diamond) [122]. The degree of disorder is very high in ta-C which gives tailing of the band in the pseudo-gap region and thus a substitutional doping is found to be difficult [123]. It was understood that the increase of dopant concentration promoted the formation of π-bonded clusters that counteracted the doping phenomena [124]. On the other hand, NCD can be grown as a phase pure diamond where the degree of disorder can be quite low and confined only to quite thin (0.2–0.4 nm) grain boundary (GB) regions and hence the effective defect density of state in the bandgap region should be very low allowing NCD to be doped.

There are several experimental methods (e.g., photoelectron spectroscopy [125], EELS [126, 127]) available to verify doping from the shift of the Fermi level. Although in some cases the Fermi level has been observed to be shifted from the midgap region, the effect of a true substitutional doping could not be seen [121]. This means that the relative shift of the Fermi level appeared due to compensation of defects and graphitization of these materials. From the change of electrical conductivity and Hall voltage, as a function of dopant concentration as well as temperature variation, one can firmly establish doping of a given material. A successful doping increases the conductivity of the material for several orders. The temperature dependent conductivity in this case should show extended state and impurity state conduction. The carrier concentration should be very high and should increase with dopant concentration. If not interfered with by the impurity states, a heavily doped material should behave as a metal. These effects have been observed

in B-doped diamond but have yet to be seen in n-type diamond and related materials. However, B-doped diamond is not considered a good electronic material as the acceptor states lie 0.36 eV above the valence band.

For clear understanding of doping measurement, carrier concentration and mobility and also density of states are very important parameters. Hall measurements are routinely used to understand quality of doping in p-type diamond. The mechanism of current conduction or change over of different types of conduction can also be predicted from temperature dependent Hall measurements. Previously, thermoelectric power (S) was successfully used to understand the type of doping in amorphous carbon films that was found to be very low at room temperature [128]. In order to establish nitrogen doping of ta-C a combined study of low temperature conductivity and thermopower of a-CN$_x$ ($x = 15$–30 at% N) has been performed [122]. A comparative study of thermoelectric power between ta-C and NCD film should be useful to understand n-type conduction.

In this chapter N-doped NCD films will be under focus. Theoretical predictions for nitrogen doping in the NCD films will be discussed first followed by its experimental demonstration and a detailed discussion on the results in the subsequent sections. Although there is not much literature available yet on the nitrogen doping of NCD films, phase-pure NCD films prepared by a MPCVD system from a mixture of argon and methane (1%) using up to 20% nitrogen in the gas phase have been extensively studied by Bhattacharya et al. [56, 129] and provide a sufficient matter to discuss in this chapter. Electrical conductivity and Hall and thermoelectric power measurements of such films as a function of temperature have been carried out [56, 129] and will be a part of the detailed discussion.

3.2.2. Theoretical Predictions

A carbon system including diamond has the ability to change hybridization in a structurally disordered environment. Relatively small bond distortions are capable of locally inducing sp^2 type bonding. This competition between structural disordering and local hybridization change, completely absent in silicon, translate into relatively more ordered GB structures in diamond than in silicon. It has already been predicted that a diamond GB has the potential for becoming electrically conductive. The idea behind this was that the GB was made of graphitelike material with up to 80% of the atoms being three-coordinated whose electrical conductivity is very high. However, because the three-coordinated C atoms are poorly connected to each other, any type of graphitelike electrical conduction through the GBs is not likely making undoped NCD as insulator.

As a representative high energy GB, the (100) $\phi = 43.60°$ ($\Sigma 29$) twist boundary has been chosen by some theoreticians, with a planar unit cell area that is $\Sigma = 29$ times larger than that of the primitive planar unit cell of diamond (100) planes. As a representative low energy GB, the same theoreticians considered that the (111) $\phi = 42.10°$ ($\Sigma 31$) twist GB, with a planar unit cell area $\Sigma = 31$ times larger than that of perfect-crystal (111) planes [10, 130]. Both boundaries are readily generated by a twist rotation of two free (100) or (111) surfaces about the GB plane normal by the respective angle ø.

According to the model developed by Keblinski et al. [131], the degree of connectivity among the three-coordinated carbon atoms clearly showed that like in the unreconstructed free (111) surface individual three-coordinated GB atoms are totally disconnected from each other in the (111) GB because all three of their bonds involve four-coordinated atoms in the same grain. Interestingly, in spite of 80% of the GB carbon atoms being threefold coordinated, other than the sp^2-bonded atom pairs connected across the GB, these atoms are almost completely disconnected from one another. The reasons for this extremely small degree of connectivity are, again, mostly geometrical. Given that within their own (100) planes, the three-coordinated GB atoms are not bonded among themselves, typically two of the three bonds of each of these GB atoms involve four-coordinated atoms within the same grain while only one bond is capable of connecting with another three-coordinated atom, however, across the GB. However, in spite of this relatively low degree of connectivity, one could easily envision dramatic changes in the electrical behavior of diamond GBs, induced, for example, by a small amount of impurities, like nitrogen.

In doped NCD "bridging" by impurities provides the missing connections making it conducting [131]. Zapol et al. [132] reported on nitrogen substitutional impurities in NCD films. They determined the position of GB carbon atoms by energy minimization of structure, where most stable nitrogen was obtained by substituting at a threefold coordinated site (trigonal) with a nonplanar arrangement of the bonds. Nitrogen saturates the original dangling bond and forms a lone pair. This causes no breaking of bonds as opposed to the bulk. Substitution in the planar threefold coordinates results in a slightly puckered nitrogen configuration and movement of the carbon bond partner across the interface into a more pyramidal shape (see the schematic diagram of GB and nitrogen incorporation in [131, 132]). Finally carbon atoms move slightly more out of plane and the bond to the nitrogen lengthens by 10%. It seems that there is a change of bonding character from a double carbon bond to a single carbon bond. As the distortion is very localized, conduction of electrons will not be hampered in the grain boundary regions. Moreover, distribution of bonds caused by the neighboring carbon atoms related to the GB make N available in the GB.

3.2.3. Experimental Demonstration

As mentioned, although not much literature is available, Bhattacharya et al. [56] have experimentally demonstrated high conductivity in their N-doped NCD. The NCD samples were prepared from a mixture of argon (99 sccm) and methane (1 sccm) in a commercial MPCVD system with a varying flow rate of nitrogen (0 to 20 sccm). All films were deposited on n-type Si wafer as well as on fused SiO_2 substrate at 100 Torr pressure, 700 W microwave power, and 800 °C substrate temperature. The deposited films were about 0.5 μm thick. Microstructure of the films was studied by high-resolution TEM (HRTEM) and the nitrogen atomic percentage in the films was determined by secondary ionization mass spectroscopy [56, 129].

HRTEM studies of the films revealed that the films consist of phase pure diamond nanocrystals of 2–4 nm size surrounded by 3–5 Å wide grain boundaries [9, 32] (see Fig. 1a and [56]). In order to distinguish these phase-pure NCD films from other kinds of NCD films that consist of predominantly NCDs embedded in ta-C matrix the former films are termed ultra-NCD (UNCD) [5]. The same term (UNCD) will be used in the remaining part of this chapter to refer the phase-pure NCD films, as described in this section. It is also understood that the GB in the UNCD films is mostly decorated by sp^2-bonded carbon and the estimated value of sp^2-bonded carbon in the films is 5–7%. With the increase of nitrogen concentration the grain size as well as the GB width increases up to 10 times (Fig. 1a and b) [56]. However, the ratio of grain size and width of GB remains fairly constant for different nitrogen concentrations. The near edge X-ray absorption fine structure (NEXAFS) spectroscopy indicated that the sp^2-bonded carbon increases up to 15% when 20% N_2 is introduced in the plasma [133].

In another study, Xu et al. [134] reported change of the microstructure of NCD, implanted with nitrogen, by AFM and XRD. Some cubic-shaped grains that were observed on the surface in the as-deposited film (with grain size in the range 70–400 nm) disappeared with an increase in the implanted fluence, and finally the diamond grains changed into ball-shaped grains, which was caused by the sputtering effect of implanted nitrogen ions. After implantation, the film surface became smooth, owing to the sputtering effect of the nitrogen ions. After nitrogen-ion implantation, the diamond (111) XRD peak broadened and its intensity decreased with increasing fluence. Meanwhile, the value of the crystal lattice increased, but no diffraction peak for graphite was observed. These results indicate that implantation-induced irradiation damage leads to a decline in diamond crystallinity and a swelling of crystal lattice, but no graphitization caused by implantation [134].

The UNCD samples prepared in the nitrogen-free atmosphere were found to be good insulating materials (resistance more than 30 MΩ), and therefore temperature dependent conductivity measurement at low temperature was rather difficult. Upon introduction of nitrogen the conductivity increases very rapidly giving a difference of more than four orders in the samples grown with 0.5 and 20% N_2, as illustrated in Figure 2a [56]. The room temperature

resistivity for the films grown at 20% N_2 was as low as 3.7 mΩ. This value is much lower than the lowest value reported in both *p*- and *n*-type diamond [115, 120]. With the decrease of temperature conductivity of all samples was found to decrease. But the relative change of the value of conductivity between 300 and 4.2 K was shown to decrease with increase of nitrogen concentration with the 20% N_2 sample showing the change as low as 0.66 times (Fig. 2a). Except for the 1% N_2 sample none of the curves were reported to fit in a single exponential decay or power law. The temperature dependency of the conductivity of the NCD films can be analyzed in terms of conduction of diamond grains and conduction of the grain boundary.

3.2.4. True Doping of Diamond Grains

Several researchers demonstrated the temperature dependent conductivity of MCD and SCD in different regions of conduction and a fitting of the complete conductivity versus temperature curve seems not to be possible in many cases [114, 120, 135]. At high temperatures band conduction with activation energy E_1 is dominant whereas in the intermediate region impurity conduction and in the low temperature region hopping conduction are found to be significant. Also, for B-doped diamond the low temperature conductivity was attributed to either impurity or hopping conduction [114] or to hopping conduction [135]. The conductivity as a function of inverse of temperature has been fitted in the entire range of measurements (300 to 4.2 K), in general, as a combination of three exponential decay functions expressed as $\sigma = \sigma_{ext} \exp(-E_1/kT) + \sigma_{imp} \exp(-E_2/kT) + \sigma_{hop} \exp(-E_3/kT)$ or $\sigma_1 \exp(-E_1/kT) + \sigma_2 \exp(-E_2/kT) + \sigma_3 \exp(-E_3/kT)$ using the model of nondegenarately doped semiconductor [120, 136]. The values of σ_1 and σ_2 were found to increase in a similar manner as σ with the increase of nitrogen concentration. The value of σ_1 is always higher than σ_2. The value of σ_3 is very small compared to that of other two terms and it does not change significantly with nitrogen concentration.

In the UNCD films, we find that activation energies E_1 and E_2 are almost same (~0.145 eV) for the films grown with a low amount of nitrogen (1%) in the plasma and,

as the nitrogen concentration in the films increases, E_1 decreases to 0.07 eV for 5% N_2 and thereafter it saturates at 0.016 eV for 10% and 20% N_2 [129]. A plot of variation of activation energies E_1 and E_2 as a function of nitrogen concentration is shown in Figure 2b. Activation energy E_2 decreases much faster than E_1 and ultimately tends to zero (see Fig. 2b). A similar type of variation of different activation energies (both for E_1 and E_2) with dopant concentration has been reported for B-doped diamond where diamond becomes a perfect semiconductor with almost zero activation energy at a boron concentration of more than $(2–3) \times 10^{20}/cm^3$ [135].

For N-doped diamond films the value of E_2 depends on the spacing of the donors and we observe it changing rapidly in the range between 0 and E_1 with doping level. A kink in the slope of the conductivity curve is seen (see Fig. 2a) which moves toward high temperatures with the increase of impurity level. For intermediate concentration (5% N_2), the slope of $\ln \sigma$ vs T^{-1} curve changes at about 33 K, whereas for 10% N_2 this change appears at about 50 K. It seems that for high nitrogen concentration overlapping of impurity (nitrogen) wave functions becomes appreciable and the impurity levels broaden into a band so as to make conduction within the impurity band possible. Impurity conduction at low temperature becomes dominant over the regular band conduction as all the charge carriers squeezed out of the regular band. For high carrier concentration, in 20% N_2 samples, a sharp transition in conductivity is not observed indicating the material tends to become a degenerate semiconductor, as also seen in B-doped diamond [120, 135].

From fitting of conductivity curves the values of E_3 as well as σ_3 are much lower than E_1 and σ_1 and even lower than E_2 and σ_2, suggesting that hopping conduction is negligible in the N-doped UNCD films (Fig. 2a, b). Also, for hopping conduction the value of the activation energy should rise or at least should not decrease with the increase of doping concentration. The activation energies decrease with nitrogen concentration in these samples; thus a major contribution of hopping conduction, as proposed earlier, can be ruled out [137] since hopping conduction strongly depends on the degree of compensation of carriers. As the degree of compensation (defined by $K = N_a/N_d$; N_a, N_d are acceptor and donor concentrations, respectively) is as low as 0.001, transition to hopping conduction at low temperatures may not be seen in the N-doped UNCD films. The possibility of hopping conduction will be discussed using the grain boundary model in the following.

Hall Measurements Carrier concentration and hole mobility of the oriented *p*-type diamond film as a function of temperature from 180 to 440 K have been determined by Hall effect measurements [120, 138]. The carrier concentration at room temperature was shown to be about 5.9×10^{13} cm^{-3}, and the acceptor ionization energy was calculated from the slope of the temperature dependent concentration to be ~0.346 eV. It was shown that the crystallographic morphology of the diamond films plays an important role in the electronic transport properties. The fact that the mobility is still less than that of similar B-doped films grown on single crystals suggests that the low angle grain boundaries do have deleterious effects on transport properties [138].

Hall mobility (μ) and carrier concentration (n) measurements in UNCD samples, grown with 10 and 20% N_2, at several temperatures between 400 and 5 K have been performed confirming electrons as majority carriers [129]. The results showed the highest value of carrier concentration ($\sim10^{20}$) ever found in n-type diamond or related materials indicating that nitrogen is very much soluble in these UNCD films. Therefore, formation of an impurity band at that concentration is feasible. Also noticed was a fairly high value of room temperature mobility (~10 cm^2/V s) for the sample prepared using 20% N_2. This value of room temperature mobility is obviously not comparable to that of SCD [113] because of the size difference of the crystals but is better than a-Si and much better than P-doped diamond [139]. Mobility versus carrier concentration of NCD films showed that both μ and n are increasing with nitrogen concentration. This relationship shows that N_d increases at a higher rate than N_a with nitrogen concentration. And the increase of the mobility with nitrogen concentration at room temperature suggests that μ is more affected by phonon scattering than by impurity scattering. TEM study suggested that the grain size in 20% N_2 samples is two times larger compared to that of the 10% N_2 sample (Fig. 1a and b). Therefore, the increase of mobility within the diamond grains, with the increase of nitrogen concentration, can be explained. This relatively high value of mobility is not possible from hopping conduction. Also, for a particular nitrogen concentration, n increases with temperature whereas μ decreases quite gradually with temperature (see Fig. 3). It is known that the mobility of carriers is strongly dependent on acoustic phonon scattering (at high temperature) as well as on impurity scattering (at low temperature) where the mobility varies as $T^{-3/2}$ and $T^{3/2}$, respectively [7, 140, 141]. In practice, the high temperature mobility due to lattice scattering of diamond was found to vary as $\mu(T) = \mu_0 T^{-s}$ with s varying between 1.5 and 2.8 [7, 138, 140, 141]. However, from this limited number of data points it is difficult to conclude the exact temperature dependence of μ. For the 20% N_2 sample a slight increase of μ between 400 and 50 K confirms the semimetallic nature of the sample where phonon scattering is dominant. The temperature dependence of n is similar to what is seen in boron-doped diamond [135]. The donor activation energy calculated from the carrier concentration is much smaller than that observed from any other N-doped diamond films establishing that nitrogen can create a shallow donor level in NCD.
Impurity Conduction According to the complex conduction model described earlier impurity conduction refers to the direct transfer of holes between impurities without entering into the valence band. Several studies [120, 135, 142, 143] have reported impurity conduction in synthetic single-crystal diamond including very heavily B-doped MCD films. Experimentally, a transition between conduction mechanisms is indicated by a maximum in the plot of Hall coefficient (or a minimum in carrier concentration) versus inverse temperature, occurring at the same temperature as a knee in the plot of resistivity versus inverse temperature. Malta et al. [120] showed a knee in the resistivity curve and corresponding minimum in the carrier concentration. Since the mobility is not the same in different conduction regimes, mobility declined rapidly with decreasing temperature within the impurity conduction regime. It was also observed that conduction transitions always occurred at higher temperatures in the MCD films than homoepitaxial films [120]. At high temperatures, hole concentration was similar to the hole concentration in polycrystalline and homoepitaxial films [120].

Though UNCD films showed a change of slope in the temperature dependent resistivity curve of the 5% N_2 sample, no similar kind of change in Hall mobility and carrier concentration was observed. This is either due to the presence of sp^2 defect levels or no impurity conduction present in the material (unlike true doping in bulk or MCD).

Comparison with Boron-Doped Diamond B-doped type Ib synthetic diamond showed, in the range 10^{18}–10^{19} cm^{-3}, an activation energy of 185 meV between 500 and 1000 K and around 368 meV between 300 and 500 K [142]. For a doping level lower than 10^{19} cm^{-3}, the conduction process is governed by valence band conduction. For 2.5×10^{19} cm^{-3}, a new conduction process increases the conductivity at room temperature that increases strongly with the boron concentration, as seen in the MCD films with a higher doping level, and is attributed due to hopping between ionized and neutral acceptors within the impurity band. It has been suggested that hopping is of the nearest-neighbor hopping (NNH) type. For a doping level of 2.7×10^{20} cm^{-3} or higher, the conductivity decreases with temperature suggesting a metallic behavior, in accordance with the Mott transition expected around 2×10^{20} cm^{-3} [143].

Although above room temperature activated behavior has been seen for boron-doped p-type diamond, in the low temperature region conductivity is hopping type, similar to N-doped UNCD films. However, regarding Hall mobility an important difference was noticed. In P-doped SCD and MCD mobility is found to be decreasing with the increase of carrier concentration [135], whereas for N-UNCD film mobility increases with carrier concentration. Hence the doping of N-UNCD films is not exactly the same as the doping in the P-doped diamond. However, more careful work is needed in this direction.

In the case of N-doped UNCD films the change of conductivity with nitrogen concentration is different. In the low concentration regime conductivity increases with nitrogen concentration in the films. Beyond 5% N_2 in the plasma there is no increase of nitrogen concentration in the

Figure 3. Variation of carrier concentration of NCD film prepared with 20% N_2 was tried to fit with a power law of temperature.

films though conductivity and carrier concentration keep on increasing with increasing gas-phase nitrogen, as shown in Figure 4 [56].

Doping of UNCD films appears to be different from the P-doped diamond where clear distinctions between the band, hopping, and metallic conduction were observed. Therefore, the increase in conduction can be assigned to grain boundary or interface between diamond grains and the grain boundary regions. In the following section we discuss the temperature dependent conductivity by hopping conduction and percolation through the grain boundary.

Effect of Grain Boundary in n-Type Conduction Malta et al. [120] attempted to establish effect of grain boundary on the conductivity in the P-doped diamond. Due to the effect of GB scattering mobility of carriers in MCD can be significantly dropped compared to that in SCD. GBs may act as trapping centers for charge carriers leading to accumulation of charge at the interface of the crystallites thus forming a potential barrier. Traps at GBs deplete the concentration of carriers in the crystallites. Carrier trapping creates a space charge region in GB. As a result, mobility of carriers crossing the grain boundary is significantly reduced and conductivity activation energy may be reduced to a very small value.

In MCD the effective mobility of the carriers was found to change with size of grain as $1/\mu_{eff} = 1/\mu_{GB}(2W/L) + 1/\mu_{Grain}(1 - 2W/L)$, W = depletion width, L = grain size [120]. For the UNCD films both GB and grain are increasing with increase in nitrogen concentration in the plasma but μ_{Grain} is much higher than that of GB as GB is mostly made up of amorphous carbon (a mixture of sp^2- and sp^3-bonded carbon). The ratio W/L can fairly be considered as 0.1 and, therefore, the effective mobility will be dominated by μ_{Grain}. In a carefully carried out analysis by Malta et al. [120] it was observed that the carrier concentration of B-doped MCD does not change from the corresponding homoepitaxial diamond, suggesting almost no depletion of carriers. Moreover, change of mobility cannot be explained by the GB model.

But GB can accommodate some impurities that can increase scattering of the carriers and reduce the mobility.

It was suggested that for heavily doped materials, as in the case of UNCD, doped with nitrogen, the depletion of carriers would be very less and hence diamond GB should have little effect on the transport properties, as also reported by Nihimura et al. [144]. However, as mentioned in the previous sections, the recent calculations, carried out by Kleblinski et al. [131] and Zapol et al. [132], showed GB playing a major role in the NCD films in current conduction. As mentioned before, nitrogen in MCD films usually forms a deep donor level with activation energy of 1.7 eV. Therefore, it is unlikely that the enhanced conductivity in UNCD is due to nitrogen doping of the grains. With the theoretical calculations indicating that nitrogen is favored by 3–5 eV for GB doping, a proposal that the nitrogen in these films is present predominantly in the GBs and not within the grains has been made [132]. In the following we review current conduction in disordered materials.

3.2.5. Transport in Disorder Material (Here Grain Boundary)

Beyond the Mobility Edge In this regime transport is governed by carriers excited beyond a mobility edge into extended state at E_c or E_v (conduction and valence band edge, respectively) giving an activation energy $E_\sigma \cong E_c - E_v$ (or $E_F - E_v$) at high temperatures. This should give an Arrhenious dependence of conductivity $\sigma = \sigma_0 \exp(-E_\sigma/kT)$. As a result, band conduction is seen at high temperatures. The second mechanism is the hopping between localized states at low temperatures.

Hopping through Localized States A number of amorphous semiconductors and amorphous carbon share temperature dependent conductivity as $\sigma = \sigma_0 \exp[-(T_0/T)^{p+1/p+4}]$ where p is a constant and depends on the distribution of states near the Fermi level as $N(E) = N_0 E^p$. For $p = 0$, 1.5, and 2 we get $\exp(-T_0/T)^{1/4}$, $\exp(-T_0/T)^{1/3}$, $\exp(T_0/T)^{1/2} \Rightarrow$ variable range hopping in three, two, and one dimension, respectively.

For the variable range in three dimensions (3D), T_0 can be expanded as $T_0 = 16\alpha^3/[k_B N(E_F)]$, where k_B corresponds to Boltzmann constant and α^{-1} is the decay length of localized states. The average hopping distance R and average energy for hopping W can be expressed as $R = 0.75[3/(2\pi\alpha N(E_F)k_B T)]^{1/4}$ and $W = 3/[4\pi R^3 N(E_F)]$.

Also, the pre-exponential factor in conductivity can be written as $\sigma_0 = e^2 N(E_F) R^2 \gamma_{ph}$ where γ_{ph} is the phonon exchange frequency [145]. From these parameters and fit of conductivity data the Bohr radius was found to be 0.3–0.8 nm at acceptor density corresponding to a resistivity of about 10^3–10^{-2} Ω cm.

Percolation Percolation or network conductivity has been used in many heterogeneous systems to explain conductivity. This type of conduction through a network of resistivity that interconnects the sites of localized states can be a substitute for conduction through a localized state as described previously. From extensive theoretical work it is understood that percolation treatment of hopping predicts behavior similar to the previous ones, like $\sigma = \sigma_0 \exp(-T_0/T)^{1/4}$ or $T^{-1/2}$ for

constant and quadratic density of states, respectively. Moreover an exponential distribution $N(E) = N(E_F) \exp(E/E_0)$ can be used to account for the downward deviation from the linear dependence of $\ln \sigma$ vs $T^{-1/4}$ [145].

In the case of UNCD films [56, 129], grown using 1% N_2, temperature dependent conductivity showed variable range hopping (VRH) in 3D (i.e., $T^{-0.25}$ law) throughout the temperature range (Fig. 5a). This can be explained by opening up some percolation path of the network or bridging by the impurity (suggested by previous models) that just crossed the percolation threshold. Typical hopping distance and density of states $N(E_F)$ for 1% N_2 sample are about 1.2 nm and 6E20 cm^{-3}, respectively. The value of the hopping distance decreases with nitrogen concentration whereas, $N(E_F)$ is found to increase. HRTEM of the sample also showed a little increase of the width of the GB in the films grown using 1% N_2 film compared to the undoped one [56, 129]. For the film grown using 5% N_2 a much wider GB has been noticed. Therefore, the percolation threshold has already been crossed. The $T^{-0.25}$ law works in the low temperature region, namely 15 to 62 K, whereas $T^{-0.5}$ law works over a wider temperature range (15 to 100 K corresponding to VRH with the presence of Coulomb gap). Conductivity of the UNCD films grown with 10 and 20% N_2 has been fitted with $\exp T^{-0.5}$. For the sample grown using 10% N_2 linearity has been found in the range between 5 and 65 K with $\exp T^{-0.5}$ fit though no such linear behavior was observed in the sample grown using 20% N_2 films. Finally, linearity has been searched for T^{β} with ln(conductivity) and it was found to be successful through the range for 10 and 20% N_2 samples with different values of β (Fig. 5b). The values of β is not close to the exponent of VRH conduction. Finally, conductivity of 10% and 20% N_2 samples throughout the temperature range has been successfully fitted as a combination of band and hopping conduction [129]. The fitted model is very much in agreement with grain boundary conduction of UNCD. More work is needed to understand the meaning of current conduction.

Recent tight-binding studies of nitrogen substitution in the GBs show that new electronic states associated with carbon π bonds and dangling bonds are introduced into the fundamental gap and that there are unoccupied states available near the Fermi level [132]. When nitrogen is introduced into the GBs, the associated carbon dangling-bond state is
above the Fermi level and donates electron-to-carbon defect states near the Fermi level, causing it to shift upward (i.e., toward the CB). Thus, it is not unreasonable to imagine that nearest-neighbor hopping or other thermally activated conduction mechanisms could occur in the GB and result in greatly enhanced electron transport. The conduction may occur via the new carbon states in the bandgap. Therefore, a more developed theoretical model should be suggested to explain successful nitrogen doping, especially semimetallic conductivity of UNCD films at high nitrogen concentration and fairly high Hall mobility of the films [56].

Thermoelectric Power An important feature of the UNCD samples prepared with 20% N_2 in the plasma is the high thermoelectric power (S) at room temperature of about -18 μV/K. However, similar value of S with positive sign can be seen in quasi-amorphous (graphitic) carbon that was described by a model based on the series connection of regions with metallic conductivity, hopping conductivity, with variable and constant hopping length [56, 129].

For metallic conductivity, S linearly depends on temperature as $S = k_B/e\pi^2/3k_BT/\Delta(1 + p)$, where Δ is the shift of the Fermi level and p is a parameter, which depends on the predominant mechanism of carrier scattering, which in turn depends on the size of the crystallites.

Thermopower of the regions showing variable range hopping is proportional to the square root of temperature and can be expressed as $S_2 = k_B^2/2e(T_0T)^{0.5}d\ln N(E_F)/dE|_{E=EF}$. This expression does not hold good in the UNCD films reported by Bhattacharyya et al. [129].

For constant range or NNH $\sigma = \sigma_0\exp(-E/k_BT)$, thermoelectric power can be expressed as $S_3 = k_B/2e(E_c - E_F/k_BT + S_0)$ or $S = -1/|e|(E_s/T) + S_0$, where E_c is the CB mobility edge and S_0 corresponds to heat of transfer. The value of E_s is very small and close to E_σ. A shallow donor level close to CB has been suggested from these values.

In the N-doped UNCD films grown by Bhattacharyya et al. [56, 129], S showed negative sign and its temperature dependence is close to a straight line tending to zero at lower temperature [14]. For perfect fitting of the temperature dependence of S different models for metal as well as semiconductors described previously have been tried but were not successful. Finally, keeping in mind the temperature dependence of electrical conductivity, the thermoelectric power of these samples has been fitted as a combination of reciprocal temperature and temperature as follows.

$S(T) = b_1T + b_2/T$ where the first term works for metallic conductivity particularly at a high temperature regime and the second term works at a low temperature regime as observed for semiconductors with small bandgap. However, the overall trend can be attributed to metallic conduction that is more favorable for grain boundary regions. From the sign of S n-type conduction of N-doped films is confirmed. An important difference can be noticed from ta-C films where S was very small and therefore no clear temperature dependence could be observed [122].

3.2.6. Comparison with ta-C

The ta-C films were prepared, in general, by filtered cathodic arc from a graphite target with either flowing nitrogen or bombarding the growing film with nitrogen ions from

Figure 5. (a) Temperature dependent conductivity of NCD film shows variable range hopping for a low amount of nitrogen (1% N_2) in the plasma [$1/T$ is scaled to 1000/T, read abscissa as $(1000/T)^{0.25}$] and (b) temperature dependent conductivity of NCD film shows power law dependence for a high amount of nitrogen (20% N_2) in the plasma.

a Kaufman-ion source. For the discharge voltage of 50 V at the ion source, the ratio of N to C atom arrival rates (Q_r) was found to follow the relationship $Q_r = 1.7 \times j_N/j_C$, where j_N and j_C represent the current densities of nitrogen and carbon ions, respectively. The gas pressure in the chamber was maintained at about 2×10^{-2} Pa. The stoichiometry and density of all the *ta*-C films were determined by elastic recoil-detection analysis [122, 126].

It has been reported that nitrogen incorporation increases the conductivity in *ta*-C [121, 122, 146]. This could be due to either graphitization of the films or nitrogen doping. The thermoelectric power of *ta*-C is positive and acquires a low value (+0.1 mV/K, indicating that current conduction takes place via the valence band extended states), which falls to a few μV/K (a variable range type conduction) when doped by nitrogen. It seems that E_F does not move compared to CB below a doping level of about 10^{-4} where a constant density of states of the CB tail can be found [121]. In addition, it was suggested that beyond an impurity level of approximately 5%, electronic transitions take place through thermally excited electrons in the CB. The problem concerning a small amount of nitrogen incorporated into *ta*-C was investigated mostly by calculations based on schematic models [121]. It was proposed that conductivity increases by a few different routes: the first occurs by the formation of N_4^+, a nondoping configuration with a positive charged state of tetrahedrally bonded nitrogen atoms where hopping conductivity increases. Second, substitution of C in tetragonal configuration by nitrogen atoms creates N_3^0 (i.e., a nondoping and charge neutral state of trigonally bonded nitrogen atom where E_F moves with respect to the band edges, which have high density of localized states). Third, conductivity can also be enhanced by the formation of $N_{3\pi}$ and $N_{4\sigma}$ configurations which means that nitrogen in the doping configuration has three π bonds and four σ bonds, respectively, with one free electron in each case [121]. Although a quantification of doping efficiency is difficult, it is commonly believed to be very low. However, all previous ideas were developed for the low nitrogen and low concentration of sp^2-bonded carbon where the optical gap seems to remain unchanged and the nitrogen doping was suggested to be σ type [121]. It was also proposed that nitrogen doping of *ta*-C is highly compensated (i.e., connected to a large number of dangling bonds, which also need to be compensated by more nitrogen atoms bound in substitutional site) [122].

The conductivity rises by four orders of magnitude (about 4.5 S cm^{-1}) in *a*-CN15 (15% N in the film) compared to *ta*-C and fell to a local minimum in *a*-CN17 (17% N in the film). Conductivity remains almost unchanged in the range between 19% and 23% of nitrogen and increases in *a*-CN26 (26% N in the film) followed by a slight decrease in *a*-CN30 (30% N in the film). Conductivity values measured at 77 K do not change over a wide range of nitrogen concentration. The logarithmic variation of conductivity with inverse of temperature of these samples, as shown in Figure 6, in the temperature range between 80 and 300 K has been fitted with Mott's variable range hopping conduction in three dimensions. This is illustrated in Figure 7. Similar results have been obtained from the nitride carbon films prepared from magnetron sputtering [147]. Due to the high concentration of defects an Arrhenious-like plot seems to be difficult
Figure 6. Temperature dependent conductivity of nitrogen doped *ta*-C films does not show Arrhenious type (activated) behavior.

in these materials. However, there are other reports [148] available where temperature dependent conductivity can be fitted as linearly dependent of inverse of temperature but only in the high temperature region. It is shown that Tauc gap first decreases sharply with nitrogen concentration followed by an increase. It seems that temperature dependent conductivity is very much dependent on the way sample is prepared (i.e., the way defects have been introduced in the materials). Chen et al. [149] also found variable range hopping type temperature dependent conductivity for nitrogen incorporated *ta*-C films where the bandgap was found to decrease from 2.5 to 1.6 eV.

One of the most important features of nitrogen (between 15 and 29%) incorporated *ta*-C is the very small value of *S* at room temperature (1–10 μV/K) for all samples and that they do not show a large change even if the temperature is lowered to 100 K. A change of *S* appears at lower temperatures, either in upward or downward direction, depending on the nitrogen concentration. At low nitrogen concentration (e.g., in *a*-CN15), *S* is negative throughout the temperature range followed by a sharp decrease below about 87 K, suggesting an *n*-type conduction as also discussed earlier. In *a*-CN17, *S* has a value very close to zero. In *a*-CN19 to *a*-CN23, *S* is positive and remains almost unchanged down to the lowest temperature of measurement suggesting a *p*-type conduction. Finally, in *a*-CN26 and *a*-CN30, *S* rises sharply below 100 K (see [122] for the temperature dependence). Only a very small variation of *S* was observed between the
Figure 7. Temperature dependent conductivity of nitrogen doped *ta*-C films obeys variable range hopping in the low temperature regime.

nitrogen percentage of 19 and 30. Like temperature dependent conductivity thermopower, as a function of inverse of temperature, cannot be fitted as a single straight line that is normally seen in doped semiconductors. Also, S is not a linear function of temperature and does not approach to zero while lowering temperature unlike metallic samples [122]. It seems that the mechanism explaining the variation of S in the low temperature regime is quite complicated and more work is needed for a complete understanding.

At the end of this section we can accommodate discussions on the conductivity of amorphous carbon with nanodiamond inclusions where the sp^2 percentage was 60% in the undoped films. These samples are prepared at low pressure (2 mTorr) by ECR plasma from a mixture of methane, argon, and nitrogen. Nitrogen (5 at%), incorporated in the samples, increased the sp^2-bonded carbon in the films to above 80%. As a result conductivity was found to increase up to 50 times compared to the conductivity of the undoped sample. It should be noted that here the conduction takes place due to a large change of film microstructure and defects [150].

Following the approach in the previous section we look into the reasons behind the increase of conductivity in ta-C films after nitrogen incorporation. From EELS measurements, an increase of the π^* peak relative to the σ^* peak has been observed when the nitrogen percentage increases in the ta-C films. This means that graphitization took place in the films as a result of nitrogen incorporation to a large extent. From conductivity, it was shown that graphitization and defects gave rise to relatively high conductivity to doped ta-C films [151].

In summary, from the aforementioned studies we can conclude that in ta-C films conductivity arises from the sp^2-bonded carbon or from the nitrogen related (charge transfer) defects when nitrogen is introduced in the films. No truly activated conduction but only a variable range type hopping conduction can be observed. As a result, the conductivity in the films does not increase drastically with nitrogen concentration in the plasma. Hall mobility also remains very low. This is true for high nitrogen concentration in the films that form CN alloy. However, in the UNCD films the change of conductivity with nitrogen concentration is drastic in spite of the fact that the increase of percentage of sp^2-bonded carbon is very small. For the films grown with low nitrogen concentration, conductivity is explained by the percolation model and variable range hopping. In this case the nitrogen impurity in the films acts as a bridge in the grain boundary region and induces conductivity. For the films grown with higher nitrogen concentration, the grain boundary opens up and contributes to high conductivity. Both variable range hopping and activated band conduction were observed.

4. FIELD EMISSION

Field emission (FE) is considered to be one of the most interesting properties of diamond and related materials. This property can be useful for making cold cathode field emitters and other vacuum microelectronic devices. Though typical metal or semiconductor emitters posses high work functions, a negative electron affinity (NEA) of certain diamond planes allows one to emit electrons with an application of low electric field. Semiconductors and insulators can have a NEA if the minimum energy of their conduction band electrons is above the minimum energy of electrons in vacuum. At the same time, a low threshold energy can also be explained by geometric electric FE, where field can be enhanced up to 100 times. Apart from the electrons tunneling from a metal or semiconductor directly into vacuum, there are also other mechanisms proposed where electrons can tunnel from a metal to diamond surface and can be accelerated to energies sufficient to be ejected into vacuum. If a stable and reproducible emission from diamond or related materials can be obtained it would eliminate the complicated and expensive process of fabricating sharp microtips to provide geometric field enhancement.

For good FE from a diamond surface it should be conductive. Insulating undoped MCD films cannot produce sustained electron emission. MCD films with either none or with a very low percentage of sp^2-bonded carbon emit poorly with threshold emission fields typically of ~30 V/μm and having an unsatisfactory surface uniformity. There should be some conducting path for transportation of electrons. This can be achieved either by n- or p-type doping of this material [115], which could shift the Fermi level to near the CB edge, or by creation of defect states. However, p-type diamond does not emit well because the electron resides deep (>5 eV) below the Fermi level. Therefore, n-type diamond or diamond with defects, where the Fermi level is close to the CB, should be ideal for emission. Although an excellent low FE from diamond and diamondlike materials has been well known, practical application of emission is limited due to lack of reproducibility, consistency, and sustained emission for a long time. Zhu et al. [63] overcame this problem by using hydrogen plasma treated NCD and obtained electron emission of 10 mA/cm^2 at applied field of 3–5 V/μm [63]. It should be noted that the diamonds in this case are undoped and are not separated by grain boundary regions. Thus, the emission was explained to appear from inherently defective structures of nanodiamond.

Coming back to doped diamond films we find some interesting reports on their field emission character. FE of P- and B-doped diamond has been studied and it is found that doping enhances FE much more than the enhancement factor. Also, the type of doping as well as its concentration appears to be very important for the emission [152]. Okano et al. [152] reported N-doped CVD diamond (from urea) with an extremely low threshold voltage. In fact, in N-doped films the emission threshold voltage was found to be much lower than that of P- and B-doped diamond films [152]. They suggested a very low activation energy of the N-doped films. These emission characteristics are attributed mostly to the high defect density of states [63, 152–155].

Nitrogen always been found to enhance the field emission properties of nanodiamond as well [31]. In the case of UNCD, it is illustrated in a plot of variation of field emission current with electric field of UNCD films doped with 0.5 to 20% N_2 in the plasma in Figure 8. Also, in terms of film morphology and structure, NCD was found to be an excellent field emitter [32] showing the lowest onset voltage as well as the highest current density ever reported. Ultimately,
Figure 8. Variation of field emission current with electric field of NCD films doped with 0.5 to 20% N$_2$ in the plasma.

there were efforts to combine both nanostructured carbon (e.g., nanodiamond) and *n*-type conduction to observe excellent field emission in the films. We shall be discussing this effect further in this section.

As discussed, field electron-emission properties in diamond and related materials are strongly dependent on the film structure and on its composition. The emission drastically improves with better uniformity and hysteresis with an increase in *sp*^{2}-bonded carbon content in the diamond films. The best emission properties correspond to a composite structure of an MCD film, where coarse-grained diamond phase coexists with an essential amount of nanocrystalline graphite [156]. Jou et al. [157] and Zhirnov et al. [158] also observed the same phenomenon. Unfortunately, it is difficult to measure quantitative relations between the two carbon phases in the diamond films to determine a relationship between the emission threshold and an exact structure of the film. Pure nanodiamond compacts emit very poorly (thresholds were ∼200 V/μm); the optimized diamond-to-pyrocarbon relationship allows one to observe the emission at fields as low as 1 to 2 V/μm accompanied with satisfactory surface uniformity and the absence of hysteresis of *I–V* curves. From scanning tunneling microscopy it has been understood that the emission zones corresponded to the top of some grains, agglomerated from a number of smaller diamond particles and having no sharp tiplike protrusions. Moreover, the electrical resistivity on the top of the emitting grains demonstrates relatively high ("nongraphite") values, not like for an insulator (diamond), but rather typical for a semiconductor or a thin two-dimensional conducting graphitic layer. A field emission threshold as low as 3 V/μm was observed by Karabutov et al. [156] who found that emission came from the diamond/*sp*^{2}-bonded-carbon interfaces which are very conducting. It is proposed that quantum well effects at thin carbon nanolayers and insulator/graphite interfaces are responsible for the emission.

In other studies, Wang et al. [159] grew uniform NCD film, consisting of diamond grains with an average size of 10–60 nm, by the MPCVD technique using a gas mixture of nitrogen–methane–hydrogen. Field emission results showed that the threshold electric field increased, whereas the emission current density and the number of emission sites decrease with increasing mean diamond grain size. The film with a small grain size of 10 nm has a threshold electric field of 1.5 V/μm and reaches an emission current of

780 μA/cm^2 at electric field of 3.5 V/μm. The field emission characteristics of the NCD films grown on Si substrates in the MPCVD system, simply by replacing the Mo substrate holder with a graphite substrate holder using conventional diamond growth conditions [160], showed that small-grained film has low emission threshold and a high emission current. NCD field emitters were prepared using porous silicon as host matrix by Cai et al. [161]. NCD was deposited on porus Si substrates using 2% CH$_4$/H$_2$, 550 W microwave power, 30 Torr pressure, and 850 °C substrate temperature. SEM studies revealed diamond nucleation occurring at the edges of the etched pores and the nanosized grains partly embedded in the pores of the substrate. Samples with this structure showed excellent electron field emission properties. In the sample, with the smallest NCD grains, the emission current density exceeded 10 mA/cm^2 when the applied electric field was 3 V/μm.

Studies on radiation induced structural changes and electronic properties (i.e., conductivity, optoelectronic properties) of various kinds of films including amorphous carbon films have been going on for a long time. Using ion irradiation there have been efforts to increase or decrease defects in the electronic structure by changing the morphology and structure of diamond and related materials. This in turn can modify the field emission properties of the surfaces of the diamond and related films. It was shown by Jiang et al. [162] in their most recent study that heavy boron incorporation (more than 3000 ppm) using a nontoxic gaseous trimethylborane and hydrogen influences electron field emission properties and intrinsic stress of NCD films. The B-doped NCD films were continuously bombarded by H$^+$ and hydrocarbon ions. As a result of boron incorporation, the B-doped NCD films showed a lower intrinsic compressive stress. Low-field electron emission of 14 V/μm, much lower than that prepared without boron, and high emission current were also the characteristics of the B-doped NCD films consisting of nanosized diamond grains, showing a long-term stability. Gupta et al. [163] tried to improve FE properties of nanocrystalline carbon (graphite) composite by ion irradiation. They prepared MCD and nanocrystalline carbon thin films by MPCVD (a process similar to that described in Section 2) and performed gamma radiation having doses of 1, 5, and 20 Mrads in order to study the radiation-induced structural transformation and the corresponding changes in the electron field emission properties. A dramatic improvement in the emission properties was observed in MCD films only after a cumulative dose of 26 Mrad, while for nanocrystalline carbon a relatively small but systematic decrease in turn-on field was observed from 9 to 4 V/μm with increasing gamma radiation dose. The enhancement in the electron field emission properties of diamond was attributed to the structural defects with their associated electronic defect states produced by the radiation-induced microstructural transformation and *sp*^{2}-bonded carbon channels. In addition, it was observed that the nanocrystalline carbon films underwent much less significant net microstructural changes compared to MCD films upon irradiation. This was explained in terms of two known mechanisms taking place simultaneously: graphitization of diamond and conversion of graphite to diamond, both under high-energy radiation at ambient temperatures. This internal

bonding interconversion between sp^2- and sp^3-bonded carbon appears to be making their nanocrystalline carbon films relatively radiation insensitive. Based on this, the authors proposed fabricating radiation buffer materials to prevent radiations from reaching sensitive materials. Gupta et al. [164] also studied enhancement of field emission by incorporation of sulfur in MCD and nanocrystalline carbon films. The S-assisted films are shown to have lower turn-on fields and steeper rising current as compared to those grown without S addition. The lowest onset voltages achieved were 12 and 4 V/μm respectively in S-assisted MCD and nanocrystalline carbon films.

Now we come to discussion of N-doped UNCD films as described in Section 3.2.4. The highlights of these films, as also can be seen from Figures 8 and 9, are:

- Undoped UNCD films act fairly well in field emission with $V_{th} = 10$ V/μm.
- Threshold voltage of field emission decreases continuously with the increase of N_2 in plasma.
- Stable emission with V_{th} as low as 3.5 V/μm has been obtained with 20% N_2 film.
- The Fowler–Nordheim (F–N) equation, $J = 1.54 \times 10^{-6}(E^2/\phi)\exp(-6.83 \times 10^7 \phi^{3/2}/E)$, has been used to explain the emission, where $E = \beta E_0 = \beta(V/d)$, field enhancement factor $\beta = h/r$, J is current density, E is applied field, and ϕ is work function.
- The F–N equation shows multiple slopes indicating multiple conduction paths with different energy levels.
- This explains formation of more than one energy level, impurity and defect-induced levels (Fig. 9).
- Hopping conduction within the impurity band is possible. This is in agreement with nearest neighborhood hopping of electrical conduction.

There is some controversy [63, 153, 156] related to the origin of FE in diamond films; the electrons are field-emitted preferentially either from boundaries between crystal grains in diamond films or from the crystals themselves. Diamond quantum dots produced by explosive synthesis showed very

Figure 9. Schematic band diagram of conducting diamond shows enhancement of field emission.

important properties such as FE that could be used as cathodes. Combining experimental work on diamond films having nanocrystalline grain size with computations of electron properties at grain boundaries, it has been demonstrated that low threshold fields for electron emission correspond to large enhancements of the interband electronic state density [156]. The minimum threshold field (3–4 V/μm) from UNCD films is found to be the second lowest in different forms of diamond. Tight-binding electronic-structure simulations of a representative high-energy grain boundary in an NCD film show that both extended and localized electronic states are present in the energy gap region, where states are forbidden in bulk diamond [132]. The presence of these states allows significantly increased electronic transport along grain boundaries. It has been shown that hopping through localized π^*-states in sp^2-hybridized grain boundaries is a viable mechanism for transporting electrons from the interiors to the grain surface, where they can be emitted at low voltage. The demonstration of preferential electron emission from grain boundaries shows the importance of nanocrystallinity of diamond in NCD films, which has a high density and uniformity of grain boundaries. This work may have considerable technological impact on the production of materials that are capable of low voltage, uniform, high current density electron emission from large area sources for a wide range of applications, including flat panel displays, high power microwave sources, and ion thrusters for deep space missions.

For practical applications, smoothness of film surface and high mobility of carriers are considered important factors. The N-doped UNCD films prepared at Argonne National Laboratory (ANL) [31] are much more conducting and have smaller crystallites than the samples used by Zhu et al. [63] and Geis et al. [153]. The concentration of nitrogen in the UNCD film grown using 20% N_2 [129] is more than 2×10^{20}/cm³, an equivalent to 0.2% atomic concentration, which is much more than reported by Okano et al. [152, 154]. Moreover, the UNCD films grown by Bhattacharyya et al. [56] have lower surface roughness as well as reasonably good mobility suggesting that these films can offer much better applications.

Field emission of ta-C films is found to be comparable to NCD films and sometimes even better. Ta-C films prepared by filtered cathodic arc started emitting electrons by applying a bias of 250 V to the anode that was kept 60 μm away. Therefore, the threshold voltage was about 4 V/μm for undoped ta-C films. It was also found that ta-C films prepared by ECR plasma showed better field emission properties. Also nitrogen addition to the samples gave even better quality of field emission [165]. At the same time, there are other reports where nitrogen incorporated ta-C showed high threshold voltage in the range between 20 and 25 V/μm. The emitted electrons were suggested to arise from the Fermi energy where no field penetration occurred [166]. It is worth mentioning the improvement of field emission of amorphous carbon by nitrogen incorporation. Amaratunga and Silva found that the nominal onset fields for an emission current density of 10^{-3} mA cm^{-2} is 28 V/μm for 0% N, which decreases to 16 V/μm for 7% to 13 V/μm (11% N), 6 V/μm (14% N), and 4 V/μm (15% N) [167].
5. OPTICAL PROPERTIES

5.1. Raman Spectroscopy and Phonon Confinement

Extensive visible and UV Raman studies of NCD films find different features than bulk diamond and related films [42, 76, 168, 169]. Additional Raman features appear in NCD near 1140 and 1450–1500 cm^{-1}. The intense and sharp feature near 1332 cm^{-1} in visible Raman spectra, an unambiguous signature of cubic crystalline diamond, is found to be either completely missing or to be very weak in the NCD samples compared to single crystal or MCD films. In general, the visible Raman spectra of most of the NCD samples appear to consists of bands near 1150, 1350, 1500, and 1580 cm^{-1} [42]. Raman spectra of as-grown and annealed NCD samples grown by the BEG process (Section 2.2) [170] are shown in Figure 10. The band near 1150 cm^{-1} is mainly assigned to the presence of nanocrystalline phase of diamond [42, 76, 170–173]. It has also been observed as a weak band in the MCD films along with a sharp peak near 1332 cm^{-1} [27, 32, 36, 173]. Various groups have observed it repeatedly in the amorphous and NCD films grown by different techniques [27, 32, 36, 42, 169, 174]. For example, it has been observed in the Raman spectrum of amorphous diamond grown using low energy cluster beam deposition of carbon clusters with size distribution centered around C$_{20}$ [171] and has also been observed in the Raman spectra of NCD films grown using hydrogen deficient plasmas or by the BEG process (Fig. 10) [27, 32, 42, 170]. It was shown in the former study that the clusters keep the memory effect and, as C$_{20}$ clusters are sp^3 hybridized, the deposit turns out to be diamond in amorphous form. As described in Section 2.1.1, the latter method used a high concentration of Ar in Ar/H$_2$/CH$_4$ microwave plasmas [32], or CO/H$_2$ mixtures [27] or biasing [42] for the growth of NCD. At the same time, this Raman structure of the NCD films does not match with the Raman structure of NCD synthesized from transformation of C$_{60}$ [71] (Section 2.4) where only a cubic diamond feature was observed in the transformed
NCD platelets. The Raman intensity of the feature near 1450–1500 cm^{-1} varies proportionally with the intensity of the Raman feature near 1150 cm^{-1} as observed from most such spectra of NCD samples [29, 42, 61] and appears to be related to the disordered sp^3-bonded carbon in the films. The spectra of the samples, annealed at different temperatures, are further discussed in Section 6.

Recently the interest in the two Raman features increased when their assignment to sp^3-bonded carbon became controversial. Ferrari and Robertson argued that these two Raman features (1100–1200 and 1400–1500 cm^{-1}) cannot be related to C–C sp^3 related modes [168] and instead assigned them to *trans*-polyacetylene, or in other words, to sp^2-bonded carbon with the presence of hydrogen [168]. In another recent development, it was shown that nanophase diamond, consisting of diamond crystals of about 5 nm in diameter (Section 2.3) and largely free from aromatic sp^2-bonded carbon, displays a sharp peak near 1090 cm^{-1}, which is assigned to surface phonons of diamond [169]. It was thus concluded in the same report that a Raman feature in the range 1100–1150 cm^{-1} in NCD films, synthesized by CVD, may indicate that these films contain clusters of sp^3-bonded carbon of about 5 nm in diameter. At the same time, Sharda et al. [170] studied Raman spectra of the as-grown and annealed NCD samples (Fig. 10) grown by the BEG process (Section 2.2) and observed that the ratio of the Raman feature near 1150 cm^{-1} to the graphitic band G, which was shown in their various other studies to be related to the structural and mechanical properties of their NCD films, did not change significantly as a function of the annealing temperature. They argued, first, that if these features were related to hydrogen, their intensity should have decreased with annealing temperature, as the hydrogen should have started evolving from the samples after 200 °C [175]. Second, if these features were related to sp^2-bonded carbon, even without having any relation to hydrogen, their intensities should have increased with annealing temperature, as the concentration of sp^2-bonded carbon increases with annealing temperature [175, 176]. However, the plot of the intensity ratio of the Raman features near 1150 cm^{-1} to the graphitic G band, shown in Figure 11, did not follow the expected trends as a function of annealing temperature.

Finally, cubic crystalline diamond features in the XRD patterns of their NCD films, shown in Figure 12, supported to some extent the conjecture that the Raman feature near 1150 cm^{-1} should be related to NCD. The full width at half maximum of the diamond peaks in the NCD films grown by the BEG process [41, 53] was in general observed to be high compared to the MCD films, which was well correlated with the fact that diamond nanocrystallites [32] were present in the films. No XRD peaks associated with graphite or features related to amorphous carbon were observed either in the as-grown films [41, 42, 53] or even in the annealed films in their study (Fig. 12). Therefore, they concluded that their results supported the assignment of the Raman feature near 1150 cm^{-1} to the presence of NCD (i.e., even if not originating solely from nanodiamond). Also, in the case of phase-pure UNCD films, visible Raman (514 nm excitation) shows a similar Raman structure to that described previously. Humps at about 1150 and 1450 cm^{-1} appeared for the entire sample range having different nitrogen concentration (Section 3.2). In general, Raman features in the visible range are very broad and can be analyzed only by deconvolution of the spectra. For example the peak at 1150 cm^{-1} seems to have convoluted with the 1332 cm^{-1} peak. These NCD related Raman features were much more prominent in undoped diamond.

The other bands near 1350 and 1580 cm^{-1} in the NCD samples are popularly known as graphitic D and G bands, respectively, which are related to graphitic islands. The D band appears due to the relaxation in the momentum selection rules of the Raman scattering process due to the small domain size in graphite. In fact, a similar argument is applicable to the appearance of the band near 1140 cm^{-1} due to the nanocrystallinity of diamond [173]. However, the higher or equal intensities of the graphitic bands in the NCD samples, as compared to the intensity of the band near 1140 cm^{-1}, may not represent a high amount of sp^2-bonded carbon in the NCD films. This is because the cross section
of Raman scattering is 50–60 times higher for sp^2-bonded carbon as compared to sp^3-bonded carbon, as reported by Wada and Solin [177]. In the case of the UNCD films the ratio of intensity of G to intensity of the diamond peak (near 1332 cm^{-1}) increases with addition of nitrogen [129, 178]. These results are consistent with the HRTEM picture showing an increase of grain boundary with nitrogen concentration [14, 129].

UV Raman spectroscopy has also been carried out on NCD films using 244 [129] and 257 nm lines [76]. UV-Raman spectroscopy and surface morphology of a film grown by the BEG process (Section 2.2), which shows a high intensity of the NCD related feature (1150 cm^{-1}) in the visible Raman spectroscopy (Fig. 10), are shown in Figure 13. Faceted grains of less than 30 nm in size are evident in the micrograph obtained by a high resolution SEM and the cubic crystalline feature near 1333 cm^{-1} in the UV-Raman spectroscopy is an unambiguous signature of those grains being crystalline diamond. The spectrum also shows a significant amount of the graphitic carbon in the films as evident by the G band at 1580 cm^{-1}. The additional intense feature, as observed in the visible Raman spectra (Fig. 10) of the films near 1140 and 1450–1500 cm^{-1}, was not observed, similar to what was shown by Ferrai and Robertson [168] while arguing that these features should not be assigned to any sp^3-bonded phases. In the case of undoped and doped UNCD films (Section 3.2), undoped films show a prominent diamond peak near 1330 cm^{-1}, the intensity of which is larger than the G peak [129]. The relative intensity of the G peak increases with nitrogen. In fact, the 1332 cm^{-1} peak is hardly observed in the films grown using more than 10% N$_2$. These results suggest that graphitization of the film has occurred by nitrogen incorporation.

Though the presence of the *trans*-polyacetylene at the GB of the samples cannot be verified due to the lack of extensive Raman studies, a similar sp^2 network at the GB of the sp^3-bonded carbon crystallites may be considered as the origin of the additional features observed in the visible Raman spectra of the NCD films.

Another interesting aspect of NCD films is phonon confinement in diamond nanocrystals. Researchers have

attempted to establish quantum confinement in nanodiamond by the upshift of the CB by the displacement of the C1s edge in the EELS spectra [179, 180]. Sun et al. [181] studied Raman spectra of diamond crystals of different sizes, calculated by a phonon confinement model originally proposed by Richter et al. [182] and extended by Campbell and Fauchet [183]. The general idea behind the downshifted and asymmetrically broadened diamond Raman line near 1332 cm^{-1} that they observed is as follows. Diamond nanocrystals should exhibit an asymmetric broadening and shift of the 1332 cm^{-1} diamond Raman peak relative to the diamond Raman peak from the bulk crystal. For an infinite crystal, only phonons near the center of the Brillouin zone ($q \sim 0$) contribute to the Raman spectrum because of momentum conservation between phonons and incident light. In a finite crystal, phonons can be confined in space by crystal boundaries or defects. This results in uncertainty in the phonon momentum, allowing phonons with $q \neq 0$ to contribute to the Raman spectrum.

The Raman line shape is calculated by superimposing Lorentzian line shapes centered at $\omega(q)$, weighted by the wavevector **q** uncertainty caused by the confinement:

$$I(\omega) \sim \int_0^1 4\pi q^2 \, dq \exp(-q^2 L^2/4)/(\omega - \omega(q))^2 + (\Gamma/2)$$

Where Γ represents the Raman line width. Here $\omega(q)$ is an approximate one-dimensional phonon dispersion curve and q can be expressed in units of $2\pi/a$. The crystallite sized L is in units of a, with $a = 3.567$ Å being the lattice constant of diamond. L was assumed to be equal to the particle size. The dispersion curve was assumed to be of the form

$$\omega(q) = A + B\cos(q\pi)$$

where $A = 1193.75$ cm^{-1} and $B = 139.25$ cm^{-1}. The Lorentzian linewidth Γ of the diamond peak was dependent on the particle size and assumed as $\Gamma = \alpha + \beta/L$ where the coefficients were calculated from the diamond peak at 1333 cm^{-1} for standard diamond particles of different sizes by UV-Raman spectroscopy. By changing particle size L, various Raman line shapes were calculated by the previous equation. Based on this, Sun et al. [181] produced, after normalizing, the calculated Raman spectra of diamond particle having sizes of 120, 45, 38, and 23 nm. The theoretical values of diamond particles in various sizes are found to be consistent with the experimental data measured by UV-Raman scattering. It is found that the asymmetric line shape, with some tailing toward low wavenumber, is well explained by the phonon confinement model. Although the scattering from defects can account for the symmetric part of the linewidth, the asymmetry part is much more than expected for a confined phonon line shape calculated according to the Gaussian confinement model for the particle sizes obtained from XRD. An alternative model for the confinement of phonons has also been discussed in the literature that involves the standing waves arising from the reflection of the phonons from the elastic–dielectric boundary [184].

Surface enhanced Raman spectroscopy (SERS) has also been employed to detect the presence of a small amount of nanodiamond in samples. Roy et al. [185] deposited MCD films by HFCVD and found broadening and shift of the 1332 cm^{-1} diamond peak in their SERS. They reported phonon confinement in their study occurring from the nanophase of diamond that was present only at the surface and was not a bulk property. Formation of nanodiamond on the surface of MCD films was confirmed by SEM measurements though the origin of the nanodiamond remained unclear.

5.2. Optical Absorption

MCD films grown by CVD methods are not used widely in the applications for optical devices and coatings because of their rough surfaces. As mentioned before, though diamond is well suited for use as protective optical coatings, diamond films with high surface roughness cause attenuation and scattering of the transmitted signals restricting their uses in optical coatings. The need for deposition of smooth surfaced as-grown CVD diamond films at low temperatures was first realized more than a decade before in 1989 by Ong and Chang [21]. They developed a low temperature process in an MPCVD system, which also resulted in a film with a grain size of less than 300 nm and surface roughness in the range of 5–20 nm (Table 3). They clearly explained in the introduction of their paper the importance of smooth surfaces of diamond films for the purpose of optical coatings with the help of theoretical formulation given by Filinski. The intensity of the transmitted beam has an exponential dependence on the scattering coefficient, which is proportional to the square of the product of rms surface roughness and refractive index. As the index of diamond is 2.4, the rms surface roughness of the films has to be extremely low to give a good intensity of the transmitted light. Ong and Chang [21] obtained over 60% optical transparency in the range 0.6–2 μm wavelength of their $\sim$0.9 μm thick diamond films grown using the different processing method developed by them. It was also shown that their films are adhered well to the quartz substrates. Another publication, realizing the importance of smooth surfaces of as-grown CVD diamond films for optical and tribological applications, appeared in 1992 when Wu et al. [22] showed synthesis of fine-grained diamond films by MPCVD having a grain size in the range of 20–100 nm and surface roughness of 15 nm (Table 3). The measured transmission in the range from 2.5 to 10 μm was found to match with the calculated transmission of $\sim$1 μm thick freestanding diamond with an index of 2.4. The 5% absorption in the films was attributed to the nondiamond carbon and hydrogen content of the film. Erz et al. [23] obtained more than 60% transmittance in their $\sim$1 μm thick NCD films with a surface roughness of 30 nm, grown by optimizing the nucleation density of diamond and methane fraction. They observed a direct correlation between the grain size used for the pretreatment of the substrate and optical transparency of the NCD films (i.e., the bigger the grain size for pretreatment, the bigger the grain size in the grown films which naturally, as explained before, results in lower transparency of the films). It was also shown in their study that the transparency of their films was not dependent on the substrate temperature below 800 °C, used in the growth of the films. Contrary to this, Chen et al. [39, 45] showed that the pretreatment, using a bigger grain size diamond powder, gives

more transparent NCD films and also that the optical transmittance at 700 nm decreases linearly in the temperature range of 600–800 °C [38]. It was shown in different papers published by the same group that the surface roughness of diamond films is the major factor that controls the optical transmittance of the films provided that the graphitic content of the films is negligible. The same group [186] showed a transmittance more than 80% beyond 700 nm in their ~1 μm thick NCD films, grown on quartz in an MPCVD system using high methane concentration (42%), with an average surface roughness of 6–7 nm grown at optimized conditions studied in their work (Table 3). In another study, Yang et al. [51] recently showed an optical transmittance of 65% in the visible light in their ~1 μm thick NCD films, grown on quartz substrate with a average surface roughness of 10 nm.

All the aforementioned studies on the optical transmittance of NCD films are grown on substrates pretreated with diamond powder. In the case of NCD films grown by the BEG process (Section 2.2), Sharda et al. [53] obtained a high transmittance of 78% in the near-IR region in their ~1 μm film, grown on mirror-polished Si substrate, at 600 °C with an rms surface roughness of ~17 nm. In the same study they also compared the optical properties of NCD and MCD films grown in the MPCVD system. Tauc's optical gap for the MCD film was shown to be ~5.5 eV. NCD grown at 700 °C had a high optical absorption coefficient in the whole spectral region and the NCD film grown at 600 °C showed, as mentioned, a high transmittance (~78 %) in the near-IR region, which is close to that of diamond. The high resolution SEM of their MCD and NCD samples showed well-shaped grains with sharp facets in the MCD film with an average grain size of about 1 μm and much smaller grains in the NCD film grown at 600 °C in the range of a few nanometers to a few tens of nanometers. The absorption spectrum of the MCD film showed a quite low absorption coefficient (10^2–10^3 cm^{-1}) in the whole spectral region demonstrating the high quality of the diamond film with the presence of a high sp^3-bonded carbon fraction and a very low sp^2-bonded carbon [53]. The optical energy gap (E_g) of indirect gap material is usually estimated from Tauc's method [187], that is, by extrapolating the linear portion of $(\alpha h\nu)^{1/2}$ vs $h\nu$ plot, where $h\nu$ is the photon energy, to $(\alpha h\nu)^{1/2} = 0$. However, $(\alpha h\nu)^{1/2}$ vs $h\nu$ plots for their NCD films did not exhibit any linear region and Tauc's method could not be applied [53]. Thus, the optical gap was defined in terms of E_{04}, the energy at which the absorption coefficient is 10^4 cm^{-1} [188]. The E_{04} energy for the NCD film grown at 600 °C was found to be around 2 eV. Interestingly, there is no indication of a sharp absorption edge in NCD films. The absorption coefficient appears to vary monotonously with the incident photon [53]. Kundu et al. [30] obtained a high bandgap (~4.2 eV) in their diamond films (predominantly NCD embedded in a-C matrix), grown at low substrate temperature (300 K) by dc magnetron sputtering of vitreous carbon. The bandgap of their films increased to 5 eV when they added 10 vol% hydrogen in the sputtering gas. The NCD ceramics fabricated from C$_{60}$ fullerene by shock compression [71] had absorbance in the wavelength range of 185 to 500 nm matched with the absorbance of natural diamond type IIa with a slightly higher absorbance in

the range of 250 to 350 nm. An abrupt increase in absorption at ~225 nm, at the absorption edge of diamond, indicated the bandgap of NCD platelets was about 5.5 eV. In the case of nitrogen-doped UNCD films (Sections 2.1.1 and 3.2.3), it was observed from the optical absorption spectroscopy that the transmission of the film decreases with nitrogen incorporation [129]. This is possible due to a decrease of the effective bandgap of the material as a result of a change of the film's microstructure. It should be noted that these optical absorption data from the nitrogen-doped UNCD films are very much consistent with the change of electrical conductivity as described in the Section 3.

NCD films were coated on both sides of a silicon wafer to increase its infrared transmission and also as a protective coating [189]. The 54% transmission in the wavenumber range from 1200 to 3600 cm^{-1} of the Si wafer increased to 66% transmission (average), especially in the range of 1500 to 2200 cm^{-1} when coated with a 0.5 μm thick NCD film at one of its surfaces. The tranmission of the one side coated Si wafer in the range of 1500 to 3000 cm^{-1} further improved to an average of 80% after applying a 0.3 μm coating at the other side of the wafer. It was also shown by a sand spraying test that the coatings are strongly adhered and that the coated wafer has better resistance to sand spraying than the Si wafer without coating.

Recently, optical properties of NCD films were obtained by demonstrating the use of a prism-coupling technique to measure the refractive index and thickness together [70]. The prism-coupling technique [190–192] is a proven technique to rapidly and accurately measure both the thickness and refractive index of dielectric and polymer films [193] and, also, has been used widely as a powerful technique to measure the optical constants of AlGaN films [194, 195] and other films [196–199]. It is understood to have unique advantages over other conventional techniques; that is, ellipsometry, spectrophotometry, etc. can be used to measure these thin film parameters as no advance knowledge of film thickness or index is required, measurements of these parameters can be done easily and rapidly (20 seconds) with extremely low standard deviation (typically 0.3% for thickness and 0.1% for index), etc. Although this technique has been used to characterize many kinds of thin films [193–199], diamond and related thin films have not been measured in detail before. The high surface roughness of the MCD films may have been a major problem in characterizing them using this technique. The NCD films grown by the BEG process (Section 2.2) were found to be absorbing for the standard operating wavelength of 633 nm and hence higher wavelengths (i.e., 830 and 1300 nm) were used to obtain sharp guided modes and refractive index and thickness of the films could be measured independently with high accuracy [70]. The index of the NCD films (2.34 at 830 nm and 2.33 at 1300 nm) was found to be homogeneous within the films with negligible changes observed at the film–substrate interface [70]. In general the index of the NCD films was a little lower compared to the index of MCD or natural diamond (2.41 at 633 nm) [200] but was in agreement of the index of fine-grained diamond films measured by the same technique [201]. The refractive index of the film grown for 60 min was also calculated by the reflectance spectrum of the same film using the basic equation for interference fringes

[202]. The index value was found out to be 2.31 ± 0.05 at 790 nm, which matches (within error of measurements) well with the value obtained by the prism-coupling method at 830 nm. Information on absorption was also obtained from the half-width of the guided modes and was correlated to the graphitic concentration in the films measured by Raman spectroscopy [70]. The thickness of the films, measured by the prism-coupling technique, was found to be in agreement with the thickness measured by cross-sectional TEM. The overall results indicated that the prism-coupling technique could be very useful for rapid, easy, and accurate measurements of refractive index and thickness of smooth diamond films [70].

By low temperature high-resolution optical spectroscopy Jelezko et al. [203] investigated individual paramagnetic defect centers in diamond nanocrystals. Optical properties of defects in, for example, diamond compared with those of atomic systems are considerably more complex. In addition to radiative decay, electron–phonon interactions and other matrix-induced relaxation processes contribute to the optical properties of electronic transitions. Previous single center spectroscopy in large diamond crystals at low temperature has revealed unexpected limitations. NCD showed a homogeneous linewidth of a single nitrogen–vacancy (N–V) center. Two sharp zero-phonon lines corresponding to fluorescence emission from single N–V centers were present in the nanocrystal. Diamond nanocrystals show an approximately four times wider spread of the spectral line positions of a single center compared to bulk diamond. The authors are hopeful that the present system may be useful for quantum information processing with individual electron spins.

6. MECHANICAL AND TRIBOLOGICAL PROPERTIES

Wear on machinery is a big problem faced by the industry, as it causes large expenses. Therefore, the wear resistant coating market is growing very fast. Already, 40% of the cutting tools in the market are coated by wear resistant coatings with the market still growing fast [204]. There is an estimated 25 billion US$ market in the United States alone for the high-performance coating industry which includes protective coatings such as thermal barriers and ultrahard or wear-resistant coatings [205]. A high-performance wear resistant coating for high speed dry machining would not only enhance the performance of the automated machines but also would save the high costs of environmentally hazardous coolants being used at present [204].

Diamond is considered to be the best candidate for wear resistant and other tribological applications because of an excellent combination of its high hardness and low friction coefficient with its high thermal conductivity. However, as mentioned in the Section 1 of this chapter, conventional CVD diamond coatings that are deposited at high temperatures have rough surfaces. The high surface roughness is a major problem using diamond films for machining and wear applications [16, 17]. Such rough films cause high friction and high wear losses on the counter surfaces. In order to overcome the problem of surface roughness of diamond films post-polishing can be adopted. The polishing of these

rough diamond surfaces can be done by various methods [16, 19, 20]. As expected, after polishing their friction coefficient becomes comparable to natural diamond [206, 207]. Another way to overcome the problem is to grow naturally smooth films without compromising their hardness and other useful properties. As the postpolishing is expensive, time consuming [18–20], and also not possible in the case of complex shapes, it might therefore be advisable to pursue the growth of naturally smooth films [19, 33, 34, 36, 37, 48, 73–75]. At the same time, a high layer adhesion to the substrate is a necessary condition to obtain a high performance of the coating in the tribological applications [208].

On the other hand, although DLC and *ta*-C films are much smoother, are equally hard as conventional diamond, and can be grown at lower temperatures [79, 209, 210], these films contain a high level of compressive stress (2–15 GPa) within the planes of the films [83, 211–216]. The stress in the films directly affects their adhesion and causes them to delaminate from the substrate [214] thus, in turn, restricting the film thickness only to a few tens of nanometers to keep the film stable on the substrate. This thickness is too low to use the films for tribological applications and also higher stress cannot be developed beyond 10–12 GPa for fundamental studies or other recently proposed related applications [76]. The high compressive stress and adhesion have been key problems, especially in their uses in tribological applications. The current research in this area in various laboratories and universities is aimed at reducing this stress and, at the same time, improving adhesion of these films to the substrate. The stresses in the DLC films are reduced by incorporating N, Si, O, or metals [78]. In *ta*-C films the stresses can be reduced by incorporation of metals [217] or boron [210], by building multilayer structure [218], or by annealing the films [209].

NCD films have superb tribological properties, meeting all the technical requirements to be an ideal wear-resistant coating material, such as smooth surfaces with their hardness being quite close to MCD or natural diamond, improved interface toughness, and material stability [5, 19, 37, 174]. Moreover, depending on the growth route the amount of stress can be controlled to grow films with low or almost no stress [5, 42]. Also, some growth routes described in Section 2 are capable of developing strong adhesion without any additional effort of engineered interfaces [62, 76]. In addition, the NCD films can be grown on a variety of substrates such as silicon, SiC, Ti-6Al-4V, Mo, W, WC, Si_3N_4, quartz, etc. [9, 30, 33, 34, 36, 38, 51, 61]. Moreover, there is a growing interest in the scientific community in the mechanical properties of the grain boundaries in nanostructured materials including NCD [131, 204, 219–222]. It is worth mentioning some interesting observations in the area of nanoscience and nanotechnology that are related to mechanical properties; highly compressed diamond grain boundaries can be harder than diamond [221], carbon nanocomposite structure films with nanometer-sized dense *a*-C regions embedded in 5–10% lower density *a*-C film shows 15% more hardness than the same higher density *a*-C film without the dense nanoregions in the film [223], and nanocrystalline TiN/SiN_x nanocomposites have been prepared with a hardness of 105 GPa [204]. We shall now look at the hardness and surface roughness of the NCD films

grown by different routes as classified in Section 2 followed by a review of their tribological properties in this section. Table 3 gives an overview of surface roughness and grain sizes of the NCD films grown by various groups.

The phase-pure UNCD, composed of randomly oriented grains of whose size distribution maximizes at 3–5 nm prepared at ANL, had a surface roughness of 20–40 nm and average hardness value of 88 GPa [5]. The NCD films prepared by Konov et al. [25] had a surface roughness of 20 nm while having a maximum hardness of 85 GPa. NCD films grown on Si by the MPCVD system using 10% methane by Yoshikawa et al. [48] showed Vickers hardness in the range of 82–99 GPa and had a rms surface roughness of 8.4 nm, as measured by AFM in a 1×1 μm^2 area. The friction coefficient of their films will be discussed while discussing tribological properties of the NCD films in the same section.

The NCD films grown by Catledge and Vohra [36] on titanium alloy (Ti-6Al-4V), a technologically important material, used in aerospace, biomedical, and chemical engineering, and on Mo substrates by MPCVD had a rms surface roughness of 50 nm, hardness of ∼90 GPa (90% that of natural diamond), and elastic modulus of 750 GPa. In another study, Catledge and Vohra [37] showed enhancement in the interface toughness with addition and increase of nitrogen in the growth process. Grogler et al. [224] showed a coating of CVD diamond using a high methane concentration of 4–10% CH_4 in balanced H_2 in the process gases in the MPCVD system exhibiting superior solid-particle erosion resistance of Ti-6Al-4V. The mass loss of Ti-6Al-4V coated with a CVD diamond layer using 6% CH_4 in balanced H_2 is shown to have decreased by a factor of 100 compared to the uncoated specimen. However, the films grown with lower and higher methane concentration showed only a modest reduction in wear. This behavior of the erosion resistance of the CVD diamond coating at different methane concentrations was explained in terms of the structural changes of the films with methane concentration as assessed by Raman spectroscopy and SEM. The high erosion resistance was explained in terms of good interconnection of diamond grains in the films grown at intermediate methane concentration. It was interpreted that at these intermediate methane concentrations twin formation is favorable which facilitates secondary nucleation resulting in good film cohesion. The coatings with a highly ordered columnar growth, at 1% methane, and the NCD coatings with a high amount of nondiamond carbon, grown at a higher methane concentrations (12% and above), showed poor erosion resistance. In another study Catledge et al. [225] showed that for a fixed flow rate of N_2, increasing the methane from 5 to 15% in hydrogen resulted in an increase in diamond crystallinity, a decrease in nondiamond carbon, and an increase in film hardness from 43 to 90 GPa. This effect of obtaining a better diamond crystallinity and higher hardness with increase in methane concentration is similar to what was reported by Sharda et al., that increasing methane in BEG growth of NCD increased NCD concentration in the films [98], and is quite a contrast to the effect of increasing methane without any nitrogen addition (i.e., in a conventional CVD diamond growth). It is quite advantageous in the case of nonconventional methods to grow NCD, as higher methane concentration not only gives higher growth rates but also results

in better adhesion of the NCD films. In the same study [225], the authors reported that at a fixed flow of methane of 88 sccm, increasing nitrogen from 0 to 26.4 sccm resulted in decreasing diamond crystallinity, increasing nondiamond carbon, and decreasing film hardness from 100 to 50 GPa. Nevertheless, a concentration of 15% CH_4 with a ratio of N_2/CH_4 of 0.10 results in a roughness of 15–30 nm, good adhesion, and a high hardness of 90 GPa. Beyond this ratio no significant changes were observed either in the diamond crystallinity or in the surface roughness of the films, which is explained in terms of saturation of concentration of CN radical beyond this ratio [95, 225]. These results of NCD coatings on metallic surfaces are quite interesting and have a great potential for use in designing articulating medical implant devices as hard and low-friction wear resistant coatings. The same group reported growth of nanostructured diamond film, as a wear resistant coating, on curved surfaces of Ti-6Al-4V alloy machined to simulate the shape of a temporomandibular joint dental implant to extend implant service lifetime [226]. It was shown that the coatings, consisting of a significant volume fraction of NCD, are hard (60 ± 5 GPa) and are uniform in composition.

The NCD films (∼1 μm thick) grown on quartz substrate by the MPCVD system for transparent protective coatings showed a Vicker's hardness of 73–93 GPa with a surface roughness of 9 nm, measured by AFM [51]. Kundu et al. [30] obtained a hardness of 50 GPa in the NCD films embedded in a-C matrix with surface roughness ∼9 nm at 300 K temperature on quartz substrate by dc magnetron sputtering of vitreous carbon.

The NCD films grown by the BEG process by Sharda et al. [42, 61, 170] had a hardness in the range of 70–90 GPa at optimized conditions with rms surface roughness, measured in an area of 5×5 μm^2 by AFM, varying in the range of 10–30 nm and a low amount of stress (<1 GPa). They were shown to have achieved a strong adhesion in their NCD films on silicon substrates that their films did not delaminate even at intentionally induced enormous amounts of in-plane stress [62, 98]. The strong adhesion may be the result of implanted carbon ions, with suitable energy, into the substrate in the initial stages of growth. Interestingly, the reduction of the grain size from micrometer to nanometer brings up unusual properties of the thin films that were never observed before. Si wafers having thicknesses in the range of 300–700 μm have been shown spherically bent up to a radius of curvature of 0.02 m by a coating of highly stressed 1–2 μm thick NCD films. The increase in the stress was correlated to the decrease in the grain size of diamond in the films [62]. The radius of curvature of the NCD/Si samples can be controlled and new applications have been proposed in the areas of X-ray physics, particle physics, etc., where bent wafers are used [76]. This subject is further discussed in Section 7.4. On the other hand, the NCD films, grown adopting the same route of biasing (Section 2.2), in multisteps, have been shown to have average surface roughness as low as 5 nm with adhesion reported to be good enough to prepare film with thickness only up to 2 μm [49]. A high amount of compressive stress and a comparatively weak thickness in the films restrict preparation of thicker films.

The nanocrystalline diamond ceramics fabricated by Hirari et al. [71] from C_{60} fullerene by shock compression have comparable hardness to type IIa diamond. It was reported that the NCD platelets were too hard to measure by the conventional micro-Vicker's method. Nanocrystalline diamond coatings by conversion of silicon carbide also show promising mechanical properties, with hardness in excess of 50 GPa and Young's moduli up to 800 GPa [107].

Thermal stability of NCD films has also been investigated by a few groups. It has been shown that the NCD films can be stable up to a temperature as high as 950 °C [47]. Heiman et al. [47] annealed their NCD samples up to a temperature of 950 °C in vacuum for 10 min and observed no change in the EELS spectrum of the film in spite of the fact that the films contained high hydrogen content. Sharda et al. [170] annealed their NCD samples up to a temperature of 800 °C in Ar ambient for one hour and, as discussed in Section 5.1, observed no or little change in the Raman spectra of their films shown in Figure 10. As shown in Figure 14, the rms surface roughness (20–25 nm) and hardness (55–75 GPa) of the NCD samples annealed at different temperatures remained fairly constant to temperatures as high as 800 °C.

Tribological properties of NCD films have also been investigated by a few research groups. Erdemir et al. [19] found out that the phase-pure NCD films, grown by MPCVD using Ar and fullerene with rms surface roughness of 20–40 nm, has tribological properties superior to the conventionally grown rough MCD films, which are even comparable to the tribological properties of the natural diamond. The sliding friction coefficients of their NCD films against Si_3N_4 balls were ~0.05 and ~0.1, respectively, in dry N_2 and air, lower by a factor of 5–10 than that of rough MCD films with rms roughness of 0.35 μm. The initial friction is always observed to be high which decreases rapidly to stabilize at lower values. In the long duration tests for 22,000 cycles of friction in dry N_2 some occasional fluctuations were observed in which the friction increases and comes back to the same value. However, such fluctuations were not observed in the tests in air. Wear rates of SiC pins and Si_3N_4 balls against the NCD films were found to be two orders of magnitude lower than the wear rates against rough MCD films. Hollman et al. [34] grew NCD films on spherical cemented carbide rock drilling

Figure 14. Plot of hardness and rms surface roughness as a function of annealing temperature. Hardness data presented in the graph are averaged from a few sets of five indents on the samples and the error bar is taken from the minimum and maximum hardness observed. bits with a spherical top of 6 mm radius and tested them in dry and lubricated sliding against cemented carbide, ball-bearing steel, stainless steel (CC, BBS, and SS, respectively), titanium, and aluminum. These NCD films, grown by a hot-flame method in which the samples are negatively biased to 500 V, showed an average surface roughness of 30 nm, measured by a profilometer, and 6–10 nm, measured by AFM in an 8×8 μm^2 area. After a light polishing these NCD samples show a smoother surface with an average surface roughness in the area of 1×1 μm^2 in AFM decreased to 2.5 nm. The friction coefficient of the NCD films under dry sliding conditions was high initially, similar to what was observed by Erdemir et al. [19], and reduced after traveling a sliding distance of 5–10 m to low values (0.06–0.1) against CC, BBS, and SS. Lubrication with water and oil brought a little change in friction. There was no change in friction of CC while using oil lubrication and rather increased in the case of SS and decreased in the case of BBS. Water lubrication reduced the friction against all the materials. The friction coefficient of as-grown NCD films against Ti and Al was high (0.5–0.6) and soon resulted in seizure. The seizure occurred even with the lubrication against Ti. However, a light polishing of the NCD films gave a friction of 0.1, which further reduced to the values of 0.03–0.055 when water and oil lubrications were used. In comparison, the self-mated BBS gave a friction of 0.8, 0.4, and 0.14, respectively, in dry, water-, and oil-lubricated conditions. In the case of wear tests, the NCD films had a low wear whereas countersurfaces had almost no wear. The wear resistance of the NCD films in dry sliding against SS is shown to be 100 times higher than that of self-mated BBC with oil lubrication. This gives an idea of how excellent NCD is for wear-resistant coating. The friction coefficient of the NCD films grown at high methane concentration using the MPCVD system by Yoshikawa et al. [48] was 0.02, again after having an initial high value of approximately 0.2, similar to what was observed in the previous two cases. Hong et al. [227] studied tribological properties of their NCD film synthesized on silicon substrates using 10% CH_4/H_2 microwave plasmas. The NCD film, grown for 20 hours, consisted of 30–50 nm size diamond grain and had a surface roughness of 10 nm. The friction coefficient, measured using a SiC ball of 6.35 mm diameter with 0.5 N load, was in the range of 0.05–0.07 in dry air.

Investigations from the aforementioned studies revealed that smooth NCD films have superb tribological properties and show low friction and wear even against materials, which normally behave poorly as sliding contacts in the countersurfaces such as stainless steel, Ti, and Al. A superior performance as compared to the rough MCD films is obviously a result of the smooth surfaces of NCD films. Friction and wear can be defined, respectively, as the resistance experienced in the motion when a solid body is moving tangentially against another in contact and the damage occurring or removal of the material from one or both of the solid surfaces because of this motion. This resistance in the motion of diamond and diamondlike films has been shown to arise mainly from a combination of two main factors; physical/chemical attraction or adhesion and mechanical ploughing at the two surfaces in motion [9, 19, 34]. As mentioned, the conventionally grown MCD films have
rough surfaces with sharp crystal edges. These sharp asperity tips on the rough diamond surfaces result in abrasive cutting and ploughing of the softer counterfaces giving high friction and wear from these MCD films [19]. In the case of smooth diamond surfaces the ploughing effect minimizes and thus the friction is low which is defined largely by physical/chemical interactions between the sliding surfaces or in other words by the adhesive component of the friction. There is another factor which makes NCD films superior to MCD films for tribological applications. That is its ability to become more smooth during sliding [19, 34, 48]. It can be seen while observing the initial high friction coefficient of NCD films, which rapidly decreases to stabilize at lower values [19, 34, 48]. This initial high friction comes from the as-deposited NCD surface roughness, which is still in the range of 20–40 nm. However, soon after the sliding starts these surfaces become ultrasmooth (3–6 nm [19], 0.6 nm [34]), reducing the friction coefficient, which is now purely defined by the adhesive component of the friction. The adhesive component is also minimized when the diamond surfaces are passivated. This is indeed the reason given for the low friction of smooth or cleaved diamond surfaces [228, 229]. It has been shown (Gardos in [1]) that the friction coefficient of self-mated diamond increases when adsorbed gases are desorbed. Hollman et al. [34] showed that their NCD diamond films have a higher concentration of hydrogen than the MCD films and that may have contributed to improved tribological properties. The large fluctuations of the former in the long duration sliding in dry nitrogen were attributed to the phase transformation of the moving asperity of NCD films generating micromechanical wear from the graphitic debris accumulating at the sliding interfaces. When this debris is removed by mechanical means as the sliding continues the friction again comes back to the same lower value.

In addition to modifying structural and electronic properties, as described in Section 4, ion implantation has also been employed to improve mechanical properties of NCD films. Xu et al. [230] studied the influence of nitrogen ion implantation on the friction and wear properties of NCD films. They found that the friction coefficient of their 800 nm thick NCD film on Si substrate in ambient conditions, while rubbing against a ruby ball and without any implantation, was 0.7. A wear scar of 12 mm diameter can be seen on the ruby ball in only 10 cycles of rubbing against NCD film. The friction coefficient reduces a little with sliding cycles, however, still resulting in a severe wear of the ruby ball. The NCD film broke after 250 cycles when the wear scar diameter on the ruby ball was 0.32 mm. The N ion implantation of the NCD film significantly decreased the friction coefficient and wear of the ruby ball. The friction coefficient decreased to 0.08 when the implanted fluency reached to 1×10^{17} ions/cm^2. In this case, even after 1000 cycles of rubbing against NCD films the wear scar diameter of the ruby ball was only about 0.05 mm. The adhesive component of the friction was shown to be the main reason for such a high friction between ruby ball and NCD surfaces. The N ion implantation with a typical fluency of 1×10^{17} ions/cm^2 changes the surface chemical state of NCD film thus reducing the adhesion between the two sliding surfaces resulting in improvement in the tribological properties of the NCD films. Moreover, transformation

of some part of diamond crystallites into amorphous sp^3-rich bonds and a highly disordered sp^2-rich structure, which also attributed to the decrease of the friction coefficient and wear of the ruby ball, may also contribute to decreasing the friction and wear of the ruby ball.

In summary, the NCD films have superior mechanical and tribological properties compared to the rough MCD films. The former can therefore be a superior replacement to rough MCD films in tribological applications because the as-grown smooth surfaces not only save time and cost of polishing the rough MCD surfaces but also are able to become ultrasmooth soon after the sliding starts.

7. APPLICATIONS

7.1. MEMS

MEMS is one of the most rapidly growing technologies which involves miniaturized mechanical components and devices. It has a broad range of commercial applications with a diverse collection of evolving MEMS sensors and actuators for applications in transportation, medicine, industry, and aerospace. The MEMS devices, already on the market, are sensors that trigger car airbags, nozzles for ink-jet printers, and tiny blood-pressure monitors that can be implanted in the human body.

Currently silicon is the main material used in MEMS devices because of the already available Si surface machining technology. However, because of its poor friction and wear properties it is not considered suitable for different micromachines with fast-moving parts. Thus the future MEMS applications demands a different material that possesses excellent mechanical and tribological properties and additionally that should be able to perform well in extreme environments in order to realize the range of its potential applications. Diamond with its exceptional mechanical and tribological properties in combination with high chemical inertness and high thermal conductivity has all that is needed to be an ideal tribomaterial for MEMS components, especially where significant rolling and sliding contact under harsh conditions are involved. MCD films have rough surfaces with granular morphology not suitable for MEMS applications and instead smooth NCD films will be the best suitable diamond films for MEMS applications. Krauss et al. [5] have demonstrated fabrication methods, some unique to diamond and some related to existing Si fabrication technology, to fabricate MEMS components based on their phase-pure UNCD. Butler and co-workers [6] recently demonstrated fabrication of MEMS resonators from conformal NCD coatings on Si and device processed Si wafers. They [6] reported fabrication of nanomechanical resonant structures in NCD. A different method of pretreatment was adopted in which the substrate was first exposed to the deposition conditions in the MPCVD system for 20 min followed by ultrasonic bath treatment of nanodiamond powder suspended in ethanol. Single-crystal silicon wafers were thermally oxidized to obtain a 1 μm thick silicon dioxide film before using them as substrates to grow the NCD films. The NCD films, grown at 750 °C using 3 sccm of methane and 900 sccm of hydrogen at a microwave power of 800 W, consisted of columnar grains that range in size from 5 to 15 nm

near the substrate interface to 10% of the thickness of the film at growing surface. NCD films as thin as 80 nm were obtained and by using standard lithographic and semiconductor processing techniques, NCD structures with a lateral dimensions as small as 50 nm were fabricated with the measured mechanical resonant frequencies up to 640 MHz.

7.2. SAW Devices

SAW devices that typically consist of piezoelectric substrates (quartz, lithium niobate) on which thin metal film integrated transducers are fabricated using photolithiography have key applications in microwave and rf electronics. High frequency SAW devices can be obtained with relaxed lithography criteria if diamond can be used as a substrate because of its high SAW velocity [2]. However, as-grown MCD film cannot be used because of its high surface roughness and its uses after polishing may not be considered practical since the existing SAW devices are very competitive and price sensitive [2]. Recently Bi et al. [3] showed that the NCD films could be a superior replacement to MCD films for high frequency SAW devices. NCD films have smooth surfaces that save processing time and money that are needed to polish the rough MCD films for their uses in SAW devices. In addition, interestingly, the NCD films grown in MPCVD system were shown to have superior SAW properties as well, in terms of elastic isotropy and absence of grain boundary scattering.

7.3. Electrochemical Electrodes

Diamond is an attractive material for applications in electrochemical analyses and synthesis. This attractiveness arises from its extreme electrochemical window (>3 V) and chemical inertness [231]. Some of these applications are qualitative and quantitative electrochemical analyses, water purification and disinfection, reduction of oxidants and heavy metals, synthesis of powerful oxidants like chlorine, etc. [9]. Boron-doped MCD film electrochemical electrodes exhibit superior properties in aqueous solutions compared to other material electrodes such as platinum electrodes that have a potential span of 1.5 eV. However, because of the surface morphology of the MCD films it requires a thick film of several micrometers to obtain pinhole-free films. NCD films will be advantageous to MCD films in this area mainly because doping may not be needed and also a much smaller thickness should be good enough for the corrosion protection of the underlying substrate.

7.4. DNA Modified NCD Substrates

In the most recent advancements in the area of nanocrystalline diamond, it was shown that the NCD films could be a near ideal substrate for integrating microelectronics to biological modification and sensing [232]. Two types of NCD samples, grown on silicon substrates in the MPCVD system, were investigated in this study. One of the two samples was grown using the routes described in Sections 2.1.1 and 3.2.3 with a thickness of 0.75 μm at 150 Torr using 99% Ar and 1% CH$_4$. Another NCD sample was 0.5 $\pm$ 0.2 μm thick and was grown using 900 sccm hydrogen and

1 sccm CH$_4$ at 15 Torr, also by the MPCVD system. Sequential steps taken to attach DNA to a NCD surface are illustrated in Figure 15 [232]. Initially H-terminated NCD surfaces (Fig. 15a) were chemically modified to produce a layer of amine groups using a photochemical scheme. A DNA-modified NCD surface (Fig. 15e) was produced by reacting the amine-terminated NCD surface with a heterobifunctional cross-linker sulphosuccinimidyl-4-(N-maleimidomethyl) cyclohexane-1-carboxylate (SSMCC) followed by a reaction with thiol-modified DNA (Fig. 15b–d). Hybridization studies, carried out using two different oligonucleotides attached to the surface and two fluorescently tagged complementary and noncomplementary oligonucleotides, showed no detectable nonspecific adsorption, with extremely good selectivity between matched and mismatched sequences. To demonstrate diamond's unique ability to achieve extremely high stability and sensitivity, stability studies of NCD and other commonly used surfaces for biological modification, such as gold, silicon, glass, and glassy carbon, were performed and compared. All the DNA-modified surfaces were prepared with nearly identical chemistry and were subjected to 30 successive cycles of hybridization and
Figure 15. Sequential steps in DNA attachment to NCD surface. Reprinted with permission from [232], W. Yang et al., *Nature Mater.* 1, 253 (2002). © 2002, Macmillan Magazines Ltd.

denaturation. The fluorescence image was obtained after every cycle of hybridization and also after every cycle of denaturation. Figure 16 [232] shows no measurable decrease in the signal intensity of the UNCD sample even after 30 cycles of hybridization–denaturation, whereas there are a small but steady decrease in DNA-modified silicon surfaces and rapid degradation in DNA-modified gold and commercially available amine-terminated glass. In addition, two types of commercially available glassy carbon, prepared at 1000 and 3000 °C, respectively, showed 30% degradation and stability over 30 cycles of hybridization and denaturation. However, the latter material is not compatible with silicon microelectronics technology because of the high temperatures involved in its fabrication. This clearly demonstrated the superiority of DNA-modified NCD over others in its ability to achieve very high stability and sensitivity and, as diamond has the potential advantage of being compatible with microelectronics, the findings of this report on NCD thin film should be an important breakthrough in the development of completely integrated biological sensing systems.

Earlier in the same year, in the conference "Diamond 2002" (Granada, Spain), Takahashi [233] demonstrated in his presentation that CVD diamond is a good material to solidify and preserve DNA. A diamond chip of dimensions 3 mm × 3 mm × ∼0.3 mm was chemically modified by the amino linkage with the carboxylation. Not only was ∼4 pmole/mm^2 of oligonucleotide fixed with the amide linkage, as compared to ∼0.5 pmole/mm^2 for a silicon chip; DNA fixed on a diamond chip was also shown to be more stable than the DNA fixed on a silicon chip. Covalently bound complementary DNA libraries on diamond chips
Figure 16. Stability of DNA-modified UNCD film and other materials during 30 successive cycles of hybridization and denaturation. All the DNA-modified substrates were amine-modified and then linked to thiol-terminated DNA using SSMCC as a covalent linker, as described in Section 7.4 and Figure 14. The fluorescence intensities after hybridization with perfectly matched, fluorescently labeled complements are shown. For each substrate, the fluorescence was measured after each denaturation step and was confirmed to be zero. Reprinted with permission from [232], W. Yang et al., *Nature Mater.* 1, 253 (2002). © 2002, Macmillan Magazines Ltd.

were reported to be stable for two years after solidification. DNA preservation using diamond chips was said to become the most important postgenome technology.

7.5. NCD Coated Bent Si Wafers

As mentioned in the Section 6, some interesting and unusual results were reported to emerge when NCD films were grown on Si substrates by providing controlled and continuous bias current density (BCD) in a MPCVD system [62, 98]. It was reported that NCD films grown by the BEG process can contain an enormous amount of stress when grown at high BCD. The interesting point to note was that the samples bend dramatically due to stress without delaminating. Such bending of the wafers was possible to demonstrate experimentally due to having developed strong adhesion in the films that can sustain an enormous amount of stress, which bent the whole sample. As the films show characteristics of NCD, their large grain boundary area, accommodating nondiamond carbon impurities, and the hydrogen content of the films were hypothesized to be the origin of the large stress in the films [98]. A high amount of stress in the films may cause bending of the substrates such as silicon [62]. The curved crystals find potential applications in the area of X-ray optics and particle physics [76]. A bent silicon wafer can be used in place of a magnet to deflect a beam of charged particles and ions [234–236]. In fact, this area of deflection of beams of charged particles by bent crystals has now become a mature field, both with respect to fundamental investigations as well as applications. However, to date, a heavy mechanical mechanism (crystal bender) is being used to mechanically bend the crystal to the desired radius of curvature depending upon the application [234–237]. The stress and hence the curvature of the films on silicon substrates were shown to vary by changing the BCD [61, 76]. Different growth conditions result in films with a wide range of radius of curvature (0.02 to 3.5 m). It was proposed to use these bent Si substrates in place of crystal benders, a cumbersome mechanical arrangement used for bending silicon in those areas. Data on the range of radius of curvature used in X-ray optics and particle physics were compared with the radius of curvature obtained by inducing stress in the NCD films on Si wafers. Interestingly, the radius of curvature of the NCD coated Si wafers obtained in this work falls in the range of the radius of curvature of bent crystals used in X-ray optics and particle physics experiments [76]. Therefore, these freestanding bent wafers may replace the cumbersome mechanism of crystal benders, used in the area of X-ray optics and particle physics experiments. It should be noted that this was just a proposal and can be verified only when the NCD coated bent wafers could be tested practically.

7.6. Search for Extraterrestrial Diamond

Some of the features of natural diamond are different from synthetic ones. For example, on the atomic level, natural diamonds can include paired nitrogen atoms whereas synthetic diamonds (HPHT—Section 1.1) that begin with a diamond seed have single nitrogen atoms and also metal catalysts that absorb nitrogen. These differences are the basis of the idea

of the presolar origin of natural diamond. Some researchers believe that diamond carbon came from supernovas (explosive, dying stars) that released carbon into our solar system about 5 billion years ago. From spectroscopic data on presolar diamonds and observations of dense molecular clouds, it is estimated that 10 to 20% of cosmic carbon is nanodiamond in the dense media. Meteorites transported the carbon to earth, where extreme heat and pressure transformed it into diamonds. However, neither diamonds nor fullerenes have been detected in space so far unlike in meteorites, but their presence has been predicted. Let us discuss this subject in more detail.

7.6.1. Meteoritic Diamonds

Diamond was first reported in a meteorite in 1888 from two fireballs seen to land in Siberia. The field blossomed in 1987 when John Wacker and Tang Ming, working in the laboratory of Edward Anders at the University of Chicago, discovered minuscule diamonds, only a few nanometers across, from a type of meteorite called carbonaceous chondrites.

Two types of meteorite contain diamond: stony and iron. Sometimes a large amount of diamond is collected from meteorites. The sintered, polycrystalline microdiamond from meteorites aggregates has a porous ceramic texture and ranges up to 3167 carats, which is 61 carats heavier than Cullinan, the largest single crystal diamond.

Nanodiamonds recovered from meteorites, which originate in asteroids, have been thought to be the most abundant type of presolar grain. Diamonds account for more than 99% of the identified presolar meteoritic material, with an abundance that can exceed 0.1% (1000 ppm) of the matrix, corresponding to more than 3% of the total amount of carbon in the meteorite. Presolar diamonds have been isolated from ordinary, carbonaceous, and enstatite chondrites, and the proportion of C diamond is between 3 and 4% [238]. Diamonds of meteorite and presolar origin are mostly nanocrystalline (~2 nm) but are in extraordinary high concentrations (120 to 1600 ppm) in meteorites. Such diamond is more abundant than presolar SiC (~10 ppm), graphite (~2 ppm), and other minerals. Because of the extremely fine grain sizes, analytical measurements on chondritic nanodiamond, unlike graphite and SiC, can only be obtained on aggregates and not single crystals. N concentrations in presolar diamonds range from 2000 to 12,000 ppm: an exotic source for N in presolar diamonds [238].

In addition to diamond and graphite, a-C has also been seen in meteorites. However, recent observation shows that their abundance decreases with heliocentric distance, in which large-scale transport and circulation within the early solar system is depleted [238]. Apart from presolar origin meteorite impacts on earth could have transformed carbon and graphite into diamond and lonsdaleite though there is no proof. On the other hand formation of nanodiamond in space is thought to be similar to that of passive CVD diamond and carried by meteorites to earth.

7.6.2. Presolar Diamonds

Laboratory conditions in which CVD diamonds are produced are considered to be broadly similar to stellar atmospheres in H/C and C/O ratios and temperature. If C/O > 1,

which is attained in the helium shell of massive stars, diamond is expected to condense. The CVD model is consistent with hydrogen bonding on the surfaces of presolar diamonds and with the prediction, from remote spectroscopy, that grain surfaces in C-rich circumstellar envelopes are saturated in -C–H-.

The prevailing theory for the origin of presolar diamond is that it condenses by a CVD-like process in stellar atmospheres or in atmospheric outflows from red giant stars [with solar masses (M sun) = 8 to 12] in the evolutionary sequence of becoming type II supernovae (SN). Type I SN have also been suggested as sources of diamond that involves binary stars, one of which is a dense white dwarf that gravitationally accretes material from a companion, 1 to 8 M sun C star (C/O > 2) and ultimately incinerates [238].

In the type I SN, the disruptive explosion results from the sequestering of matter from a companion star by a dense white dwarf. In a type II SN, a single star, usually a supergiant in the evolutionary sequence, undergoes a gradual and then a catastrophic collapse as core fuels in sequential layers are expended. On final implosion and rebounding, the outermost envelopes are blasted into the interstellar media. It is in these outermost expanding and cooling envelopes of type I and type II SN that nanodiamonds nucleate, perhaps a month or so after a SN event. Thermonuclear reactions in SN take place at several million Kelvin and are far in excess of temperatures of C condensation as diamond. Hence, diamond nucleation is governed by expansion and cooling of SN envelopes, which may only reach critical diamond condensation temperatures in a year or so after an SN event. C availability may also increase by ionization and dissociation of inert CO into C and O [239].

7.6.3. Experimental Evidence

Infrared stretching of an interstellar CH band (at 2880 cm^{-1}) of NGC 7538 IRS 9 indicated the presence of diamond or related material in the dense interstellar molecular cloud. The abundance of diamond in other nebula (like in the Egg nebula) and meteorites is believed that to have been produced by a shock wave of interstellar medium [240]. UV light from nearby stars suggests that diamond dust drifts in the vast spaces among stars. Diamond grains may concentrate in the cocoons of dust enshrouding young stars, because the meteorite diamonds absorb infrared light in a pattern similar to the light absorbed by grains around young stars.

8. CONCLUSIONS

This chapter reviews several aspects of nanocrystalline diamond and also presents a comparative study of related materials at relevant places. Starting from the classification of diamond and related materials, various new synthesis routes that have been developed by different groups over the last few years since realizing the importance of nanocrystalline diamond films have been described elaborately. A variety of growth from phase-pure NCD to NCD embedded in ta-C or a-C matrix is possible.

The transport property of phase-pure UNCD films is addressed in detail, as one major issues of the chapter,

with special emphasis placed on their nitrogen doping. A successful *n*-type doping, which has been quite elusive in MCD diamond, is demonstrated in nitrogen incorporated NCD films. It is shown that nitrogen is very much soluble in NCD films and that it forms a conducting percolation path through the grain boundary and a shallow donor level quite close to the CB. As a result, a very high conductivity of *n*-type diamond has been achieved. While reviewing other nitrogen-doped diamond and related materials, it was found that such an improvement in the transports properties is unique to NCD. At high doping levels this material becomes a semimetal. The low temperature dependent conductivity is explained in terms of hopping conduction and impurity conduction similar to that of boron-doped MCD diamond. Hall measurements identified electrons as majority carriers with a very high concentration as well as reasonably good mobility. With the increase of nitrogen concentration the structure of UNCD films appears to change a little making the grain boundaries wider. Theoretical prediction agrees with the results of transport properties. The nitrogen doping in the UNCD films is also shown to have enhanced their field emission properties opening up various potential applications. Optical, mechanical, and tribological properties of NCD films were reviewed. Additional features start appearing in the Raman spectroscopy of the films when the diamond grain size changes from micrometer to nanometer. The origin of these features with another interesting phenomena of phonon confinement in nanodiamond grains is discussed. Excellent optical, mechanical, and tribological properties of the NCD films with naturally grown much smoother surfaces and additional advantageous properties appear to be a superior replacement for MCD films in potential applications in areas such as optical windows, wear-resistant coatings, SAW devices, MEMS, etc. Some other aspects of NCD, such as electrochemical electrodes and DNA modified NCD substrates, are also discussed in brief. DNA-modified NCD appears to be superior to other DNA-modified materials in its ability to achieve very high stability and sensitivity and, while diamond being compatible with microelectronics, this advancement may help in the development of completely integrated biological sensing systems. Some other interesting and unique features of NCD films are also reviewed that arise when the grain size reduces to nanometers. One such feature is generation of enormous stress in a micrometer thick NCD thin film that bent Si wafers (several hundreds of micrometers thick) to a radius of curvature as low as 0.02 m. Finally, NCD in meteorites coming from deep space including a brief description of the presolar origin of nanodiamond is also reviewed.

GLOSSARY

Chemical vapor deposition (CVD)   A method to deposit thin film onto a substrate in which the deposited species are formed by chemical reactions between gaseous reactants at elevated temperature in the vicinity of the substrate.

Deoxyribonucleic acid (DNA)   A macromolecule consisting of one or two strands of linked deoxyribonucleotides.

Dielectrophoresis   It is defined as the lateral motion imparted on uncharged particles as a result of polarization induced by non-uniform electric fields.

DNA hybridization   Formation of a duplex structure by two complementary single strands of DNA.

Field emission   Emission of electron from the surface of a material by application of electric field.

Fluorescence   The emission of light by a substance immediately after the absorption of energy from light of usually shorter wavelength.

Friction and wear   Friction is the resistance to motion experienced when a solid body is moving tangentially against another in contact. Wear is the damage occurring or removal of the material from one or both the solid surfaces because of this motion (sliding, rolling or impact).

Grain boundary   Boundary between grains in polycrystalline materials.

Micro/nanoelectromechanical systems (MEMS/NEMS) The miniaturized mechanical components and devices.

Negative electron affinity   Similar to a work function, the electron affinity is defined as the energy required for an electron to escape from the conduction band edge to vacuum. The case of having vacuum level below the conduction band is termed as negative electron affinity which results in easy emission of electron from the surface of a material.

Plasma chemical vapor deposition (Plasma CVD) The chemical reactions between gaseous reactants are activated in plasma.

Surface acoustic waves (SAW)   A device in which acoustic waves propagating on the surface of a piezo-electric crystal transfer a signal between two transducers.

Thermal chemical vapor deposition (Thermal CVD)   The chemical reactions between gaseous reactants are activated using thermal energy.

Dielectric Properties of Nanoparticles

S. Berger

Technion, Haifa, Israel

CONTENTS

1. INTRODUCTION

Dielectric properties of solids are determined by electric dipoles having a length scale of a few angstroms. A local change in microstructure or composition within this length scale affects the type and intensity of the dipole. As the particle size decreases to the nanometer scale local microstructure and composition changes relative to the bulk state are greatly increased especially at the particle surfaces and may reach 50% of the total material volume. Consequently, the dielectric properties of nanometer-sized particles are unique and different than those of bulk-sized particles. Fabrication methods of nanometer-sized particles have been developed to a mature state where high control on size and composition is achievable which enables efficient usage of their unique dielectric properties. Indeed, nanometer-sized particles are being used in various dielectric-based applications such as capacitors, electronic memories, and optical filters. In addition, intensive studies of further exploitation of their unique dielectric properties in future high-tech devices are being carried out.

In spite of the significant experimental data and knowledge gathered on dielectric properties of nanometer-sized particles the level of their understanding and modeling is far from being satisfactory. Even in simple nanostructures the theoretical models succeed in describing only qualitatively the dielectric behavior. Quantitative theoretical expressions usually depend on immeasurable parameters and fail in evaluating the experimental results. In more complicated nanostructures there is not even basic understanding of their dielectric properties due to the difficulty in identifying the different types of electric dipoles at the particle surfaces and in evaluating the contribution of each type of these dipoles to the macro dielectric properties of the materials.

This chapter makes a first attempt to review the current knowledge and understanding of dielectric properties of nanometer-sized particles. It is divided into two main sections; the first one refers to linear and the second one refers to nonlinear dielectric materials. Each section is subdivided to homogeneous and inhomogeneous systems. Each system is first defined according to microstructure and composition characteristics. The dielectric properties of each system are then summarized by presenting experimental results on the effect of decreasing the particles from bulk to nanometer size as well as changing their microstructure and composition on the dielectric permittivity, dielectric loss, and temperature-dependent dielectric response. In some cases, unique preparation methods of the particles and their technological applications are detailed. Finally, the dielectric behavior of each system is explained by presenting various theoretical models and emphasizing the limitations of each model in predicting the dielectric properties.

2. LINEAR DIELECTRICS

2.1. Homogeneous Materials

The dielectric behavior of homogeneous linear dielectric materials is changed as the particle size decreases from a typical bulk value into a nanometer scale. Experimental studies have reported that nanometer-sized particles have a higher dielectric permittivity than that of their bulk-sized particles especially at low frequencies. For example, in nanometer-sized amorphous SiO_2 particles having an average size of about 20 nm, the relative dielectric permittivity (dielectric constant $k' = \varepsilon'/\varepsilon_0$) is equal to about 13 at 1 kHz, which is higher by a factor of 3.3 than that of the bulk particles [1]. Another example shows that the dielectric constant of nanometer-sized amorphous silicon nitride particles is equal to 380 at 10 kHz, which is higher by a factor of about 48 compared to that of the micron-sized particles [2]. A similar dielectric enhancement was also reported in other materials such as Al_2O_3 [3], Si [3], and TiO_2 [4]. This dielectric enhancement is attributed to dipoles associated with the interfaces of the nanometer-sized particles. These dipoles result from different types of point defects at the particle interfaces such as dangling bonds, twisted

bonds, and bonds with adsorbed foreign polar molecules. Interface dipoles associated with dangling bonds were identified in nanometer-sized SiO_2 particles by using electron paramagnetic resonance (EPR) spectroscopy [1]. The density of these dipoles was reduced by thermal annealing, without changing the particles size, which results in a decrease of the dielectric constant [1]. A similar thermal annealing effect was observed in nanometer-sized SiC particles [5]. Interface dipoles associated with adsorbed polar molecules were identified in nanometer-sized Fe_2O_3 particles [6]. Interface dipoles have different relaxation times than those of bulk dipoles. For example, two different relaxation times that differ from each other by almost an order of magnitude were measured for two different types of interface dipoles in nanometer-sized Fe_2O_3 particles [6].

The dielectric permittivity of nanometer-sized particles can be described by the Havriliak–Negami (HN) expression [7],

$$\varepsilon^* = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)}{[1 + (i\omega\tau_0)^\beta]^\alpha} \qquad (1)$$

where ε_s is the static permittivity, ε_∞ is the high frequency permittivity, ω is the angular frequency, τ_0 is the mean relaxation time, and β and α are parameters that vary between 0 and 1 and describe the symmetric and asymmetric broadening of the relaxation process. The dependence of ε' and ε'' on the applied field frequency can be obtained by rearranging Eq. (1). For example, in the case of a symmetric broadening of the relaxation process ($\alpha = 1$) the dependence of ε' and ε'' on ω is as follows:

$$\varepsilon'(\omega) = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)(1 + (\omega\tau_0)^\beta \cos(\beta\pi/2))}{1 + 2(\omega\tau_0)^\beta \cos(\beta\pi/2) + (\omega\tau_0)^{2\beta}} \qquad (2)$$

$$\varepsilon''(\omega) = \frac{(\varepsilon_s - \varepsilon_\infty)(\omega\tau_0)^\beta \cos(\beta\pi/2)}{1 + 2(\omega\tau_0)^\beta \cos(\beta\pi/2) + (\omega\tau_0)^{2\beta}} \qquad (3)$$

The dielectric behavior of bulk-sized particles is usually characterized by a dominant polarization mechanism of bulk dipoles having a narrow distribution of relaxation times ($\beta \sim 1$). In this case, the plot of ε' vs. ω, according to Eq. (2), shows the Debye behavior characterized by a sharp decrease of ε' from ε_s to ε_∞ within a narrow range of frequencies around $\omega = \tau_0^{-1}$ (Fig. 1a). The mean dielectric loss, ε''_{mean}, is

generally composed of three contributions that depend on frequency and temperature,

$$\varepsilon''_{mean}(\omega, T) = \varepsilon''_{pol}(\omega, T) + \varepsilon''_{inter}(\omega, T) + \varepsilon''_{dc}(\omega, T) \qquad (4)$$

where $\varepsilon''_{pol}(\omega, T)$ results from dipolar reorientation, $\varepsilon''_{inter}(\omega, T)$ is associated with interface polarization, and $\varepsilon''_{dc}(\omega, T)$ results from the dc electrical conductivity. The first component of Eq. (4) is detailed by Eq. (3) for $\beta = 1$, the second component of Eq. (4) is also included in Eq. (3) for the case of $\beta < 1$, and the third component of Eq. (4) depends on the dc electrical conductivity as

$$\varepsilon''_{dc}(\omega, T) = \sigma_{dc}(T)/(\varepsilon_0\omega^{1-K}) \qquad (5)$$

where $0 \leq k \leq 1$. In the case of bulk-sized particles, the second and third components of Eq. (4) are negligible compared to the first component due to the low density of interfaces and small dc electrical conductivity ($\sigma_{dc} < 10^{-10}\ \Omega^{-1}\,m^{-1}$). In this case the plot of ε'' vs. ω according to Eq. (3) for $\beta \sim 1$ shows a peak that spans over a narrow range of frequencies and reaches its maximum value at $\omega = \tau_0^{-1}$ (Fig. 2a). At the maximum point of the peak the oscillating charges are coupled directly with the oscillating field, which results in a maximum absorption of the electrical energy. In the case of nanometer-sized particles, β is closer to zero than to one, due to a large distribution of relaxation times owing to different types of interface dipoles. The plot of ε' vs. ω for this case (Fig. 1b) shows a continuous decrease of ε' over a wide range of frequencies from few mHz up to tens of KHz as observed experimentally. In nanometer-sized particles, the contribution of $\varepsilon''_{inter}(\omega, T)$ and $\varepsilon''_{dc}(\omega, T)$ to $\varepsilon''_{meas}(\omega, T)$ is not negligible as in bulk-sized particles but rather dominant. For example [6], in nanometer-sized F_2O_3 particles, the dc electrical conductivity was found to be about $10^{-7}\ \Omega^{-1}\,m^{-1}$ which is higher by 3 orders of magnitude compared to their bulk value. The relatively high dc electrical conductivity of nanometer-sized particles is attributed to the high density of interface states. These states can contribute charge carriers due to ionization and can also function as conduction centers for the transport of charge carriers. This interface contribution to the dielectric loss is dominant at low frequencies and decreases monotonously with increasing frequency (Fig. 2b). The dielectric differences between nanometer-sized and bulk-sized particles can also be seen in the graphical presentation of ε'' vs. ε' (Cole–Cole plot). In the case of bulk-sized particles the plot of ε'' vs. ε' results in a perfect semicircle curve which indicates a single polarization mechanism of dipoles having a narrow distribution of relaxation times (Fig. 3a). However, the Cole–Cole plot for nanometer-sized particles (Fig. 3b) shows a major deviation from a perfect semicircle especially at low frequencies which indicates a large distribution of relaxation times.

2.2. Heterogeneous Materials

Heterogeneous dielectric systems consist of components having different dielectric permittivity and electrical conductivity. The presence of different types of constituents enables
Figure 1. The dielectric constant as a function of applied field frequency for (a) bulk-sized particles and (b) nanometer-sized particles.
Figure 2. The dielectric loss as a function of applied field frequency for (a) bulk-sized particles and (b) nanometer-sized particles.

more degrees of freedom to change the dielectric properties and obtain unique dielectric behavior compared to homogeneous materials. At the interfaces between dissimilar particles space charges are built up and induce interfacial polarization. As the size of the particles decreases to the nanometer range and the volume fraction of the particles increases, the mechanism of interface polarization becomes more dominant in determining the dielectric behavior of the material. There is no general theoretical model that can predict the magnitude of interface polarization in heterogeneous materials due to the difficulty of defining quantitatively the particles interfaces. Current models of dielectric behavior include parameters that refer to different types of interface dipoles that can be evaluated only from experimental results. Most of the experimental studies and theoretical models of heterogeneous dielectric materials have focused on binary systems composed of metal particles embedded in an insulating matrix. These systems provide enhanced dielectric permittivity compared to the pure matrix over a wide range of metal compositions. More recently, an opposite trend has arisen, where heterogeneous systems having a dielectric permittivity lower than that of the matrix are fabricated and modeled especially for microelectronic applications. In the following section the properties of both types of heterogeneous systems are reviewed for nanometer-sized particles and compared with bulk-sized particles.
Figure 3. The Cole–Cole plot for (a) bulk-sized particles and (b) nanometer-sized particles.

2.2.1. Nanocomposites

A nanocomposite dielectric material is a heterogeneous system where at least one of the components has nanometer-sized particles. In this section the term nanocomposites will refer to a system composed of either nanometer-sized metal particles dispersed in an insulating matrix or metal particles surrounded by nanometer-sized dielectric particles. The dielectric behavior of nanocomposites can be manipulated by changing the size, shape, and composition of the particles. The effect of each of these parameters on the dielectric behavior is described in this section.

The effect of composition on the dielectric behavior of nanocomposites is characteristic of a percolation system. At the percolation threshold, there is a sharp rise of the dielectric permittivity which follows a power law dependence on the metallic phase concentration, x [8, 9],

$$\varepsilon_{\text{ef}} \propto \left| \frac{(x - x_c)}{x_c} \right|^{-q} \tag{6}$$

where q is a critical exponent and x_c is the percolation threshold. The critical exponent, q, and the percolation threshold, x_c, depend on many parameters including the particle size. Experimental studies show a large distribution of percolation threshold values for nanocomposites. For example, the percolation threshold of Au–SiO$_2$ and Ag–SiO$_2$ nanocomposites was found to be at about $x_c = 0.50$ [10, 11], which is higher than that of randomly packed bulk-sized particles [13]. On the other hand, the percolation threshold of W–SiO$_2$ nanocomposites (micron-sized W particles surrounded by nanometer-sized SiO$_2$ particles) was found to be at about $x_c = 0.2$ [12], which is lower than that of randomly packed bulk-sized particles [13]. There is no theoretical model that can predict the percolation threshold of nanocomposites, even for a relatively simple geometrical configuration of equal metal spherical particles uniformly dispersed in an insulating matrix, due to probably a strong interfacial interaction of the metal particles [10].

Below the percolation threshold, the dielectric permittivity of nanocomposites was found to be higher than that of pure bulk-sized particles of the matrix [10, 14]. For example, the dielectric constant of Au–SiO$_2$ nanocomposites was found to be higher by a factor of 10 compared to that of bulk-sized SiO$_2$ particles [15]. This finding was obtained for a composition below the percolation threshold, where the Au particles have an ellipsoidal shape, a nanometer size (80 nm length and 30 nm width), a random distribution in the SiO$_2$ matrix, and a distance of 30–200 nm between neighboring particles. ESCA measurements showed that the surfaces of the nanometer-sized Au particles are electrically charged which explains the dielectric permittivity enhancement due to an interface polarization mechanism.

Below the percolation threshold, the interface polarization contribution to the total dielectric polarization becomes more dominant as the concentration of the nanometer-sized metal particles increases which results in an increase of the dielectric permittivity [10, 14].

The dielectric loss of nanocomposites is higher than that of their bulk-sized particles. For example, in the case of Au–SiO$_2$ and Ag–SiO$_2$ nanocomposites, the dielectric loss was found to be higher by a factor of 3–7 compared to that of

their bulk-sized particles [16]. In addition, the dielectric loss increases with increasing concentration of the nanometer-sized metal particles. This result is accompanied with an increase of the ac electrical conductivity within the range of values characteristic to an insulator and not to a metal. The enhanced dielectric loss and ac electrical conductivity of nanocomposites indicate the role of the interfaces between the metal and insulator particles as charge carrier supplier and charge carrier transport medium. Another characteristic property to nanocomposites is a strong resonance in the dielectric loss, which is shifted to lower energy as the size of the particles decreases. For example, a resonance of dielectric loss was observed near 2.4 eV in Au–SiO$_2$ nanocomposites and not in their individual constituent phases [10, 17]. The resonance position was shifted to a lower energy with decreasing particle size from 6.3 to 2 nm while keeping constant their spherical shape, volume fraction, and uniform distribution in the SiO$_2$ matrix.

The effect of temperature on the dielectric behavior of nanocomposites was studied on several systems. In the case of Ag–SiO$_2$ nanocomposites [18] two different temperature dependent dielectric behaviors were observed. Below 200 K, the dielectric permittivity remains constant with decreasing temperature to 100 K. This behavior was attributed to an electronic polarization mechanism. Above 200 K, the dielectric permittivity and dielectric loss were found to increase with increasing temperature up to 300 K. A similar thermally activated behavior of the dielectric permittivity was found in W–SiO$_2$ nanocomposites at temperatures between 300 and 500 K [19]. This behavior is attributed to a thermal activation of dipoles at the interfaces of the particles. Consequently, the interface polarization, which is the dominant polarization mechanism of nanocomposites at low frequencies, increases.

The dielectric behavior of nanocomposites can be explained by theoretical models, which were originally developed for bulk-sized particles and later corrected for small-sized particles. In general, these theories consider a composite material as a medium having an effective dielectric permittivity. They present expressions for the effective dielectric permittivity as a function of dielectric permittivity, volume fraction, and shape of the particle constituents. The theoretical models refer to two cases of nanocomposites: a statistical mixture (type 1) and a matrix inclusion (type 2) systems. In the case of the type 1 system, both components are embedded in an effective medium with properties of a mixture. This system is characteristic of compacted powders, interpenetrating network structures, and heterogeneous polymer mixtures especially at high applied-field frequencies. The effective dielectric permittivity of this system can be expressed as [20]

$$\varepsilon^{1-2A} = x_1(\varepsilon_1)^{1-2L_m} + x_2(\varepsilon_2)^{1-2L_m} \qquad (7)$$

where ε_i and x_i are the permittivity and volume fraction of a component i and L_m is the depolarization factor.

In the case of the type 2 system, various models [21–26] have been presented and tested experimentally and the most widely accepted one is the Maxwell–Garnett (MG) theory [26]. The MG theory takes into account the modification of the applied electric field at any point within the medium by the dipole fields of individual polarizable entities. The theory assumes that the metal particles have spherical shape, equal size, uniform distribution in the matrix, and no interaction between them. Based on these assumptions the MG expression for the effective dielectric permittivity of the composite system is [26]

$$\varepsilon(\omega) = \varepsilon_i(\omega)\frac{(1+2xZ)}{(1-xZ)} \qquad Z = \frac{\varepsilon_m - \varepsilon_i}{\varepsilon_m + \varepsilon_i} \qquad (8)$$

where m refers to the metal and i to the insulator particles, and x is the volume fraction of the metal particles. The effect of the particle shape is taken into consideration in Eq. (9) by referring to ellipsoidal metal particles and adding a depolarization factor L_m to Eq. (8) [27]:

$$\varepsilon(\omega) = \varepsilon_i \frac{\varepsilon_i(1-x)(1-L_m) + \varepsilon_m(x+L_m(1-x))}{\varepsilon_i + L_m(1-x)(\varepsilon_m - \varepsilon_i)} \qquad (9)$$

L_m varies between 0 (perpendicular orientation) and 1 (parallel orientation) of the principal axis of the ellipsoid relative to the direction of the applied electric field. The model shows a change of dielectric permittivity for different shapes of particles. In the case of $L_m = 0$, the dielectric permittivity is equal to a weighted average of the dielectric permittivities of the components. The case of $L_m = 1$ is equivalent to an array of capacitors connected in series and the dielectric permittivity is calculated respectively. A distribution of L_m values for randomly oriented ellipsoidal particles is observed in nanocomposites by a distribution of relaxation times of the interface dipoles. The effect of particle size is hidden in Eq. (9) in the value of ε_m. A separation of the real and imaginary parts from Eq. (9) leads to the Debye-type equations with a mean relaxation time, τ_M [22]:

$$\varepsilon = \varepsilon_\infty + \frac{\varepsilon - \varepsilon_\infty}{1 + (\omega\tau_M)^2} \qquad (10)$$

$$\varepsilon'' = (\varepsilon_S - \varepsilon_\infty)\frac{\omega\tau_M}{1 + (\omega\tau_M)^2} \qquad (11)$$

τ_M, ε_S, and ε_∞ depend on volume fraction, depolarization factor, electrical conductivity, and dielectric permittivity of the metal and insulator components. This dependence leads to a decrease of ε' with increasing frequency over a wide range of frequencies due to the presence of various types of interface dipoles having different relaxation times. This behavior was observed experimentally in nanocomposites such as Au–SiO$_2$ [15] and W–SiO$_2$ [12] systems. The dielectric loss of these nanocomposites was also found to decrease with increasing frequency, and its lowest value compared to the dielectric permittivity was found at high frequencies in the range of few MHz [15].

The MG theory as expressed in Eq. (9) agrees well with the experimental results in the case of a small volume fraction ($x < 0.2$) of nanometer-sized metal particles [10, 11]. It predicts qualitatively the enhancement of the dielectric permittivity and the dielectric loss, the presence of a resonance in the dielectric loss, and the thermally activated behavior of the dielectric permittivity [26]. As the volume fraction of the nanometer-sized metal particles increases, the MG theory overestimates the dielectric permittivity and dielectric loss due to interactions between the metal particles. Other

theories [28–30], which include the interactions between the metal particles, show worse results than those obtained by the MG theory.

2.2.2. Nanoporous Materials

Nanoporous dielectric materials are heterogeneous systems composed of an insulating matrix with embedded nanometer-sized pores. The dielectric behavior of nanoporous material can be manipulated by changing the size and shape of the pores as well as by adding adsorbed polar molecules to the pore surfaces. The dielectric behavior of nanoporous materials strongly depends on the applied field frequency. At high frequencies (in the range of MHz and up) the dielectric permittivity, which is determined by bulk dipoles, decreases with increasing the concentration of pores, due to a decrease of the material density. This property is utilized in applications that require low dielectric permittivity. For example, ultra-large-scale-integration (ULSI) devices require low dielectric permittivity (low-k) materials in order to reduce the signal transition times, the power consumption, and the cross-talk. Suitable materials should have a dielectric constant of about 1.5. The pore diameter has to be about 20 nm in order to satisfy many requirements such as good mechanical and electrical strength, sufficient thermal conductivity, low adsorption of humidity, and good gap-fill capabilities [31, 32]. Nanoporous silica represents an example of a material that can be fabricated with high (50–90%) closed porosity for low dielectric constant (low-k) applications. The dielectric constant of silica can be reduced from about 4 to about 1.3 by introducing a high density of closed nanometer-sized pores and thus reducing its density from 2.2 to about 0.4 gr/cm^3 [33]. The most widely used technique to prepare nanoporous silica is the sol–gel method. This method is suitable for conventional spin-on techniques used by the microelectronic industry. Nanometer-sized pores having a narrow size distribution can be prepared by controlling the precursor chemistry, temperature, pH, reaction time, fluid, and drying conditions [34]. A different approach for the fabrication of nanopores consists of insertion of organic templates, such as surfactant arrays, emulsion droplets, or latex spheres, into various oxides during their fabrication process. In this way pores with different sizes between 5 nm and 1 μm are formed [35]. Nanoporous polyimide thin film is another example of a low-k material at high frequencies aimed for interlevel dielectrics in microelectronic packaging devices [36]. The dielectric constant of these films was found to decrease with increasing porosity from 2.9 for 0% porosity to 2.3 for 19% porosity [37].

At low frequencies, (in the range of mHz up to KHz) the dielectric permittivity of nanoporous materials, which is determined by interface dipoles, increases with increasing pore concentration, due to an increase of the pore/matrix interfaces density [38]. In this frequency range the dielectric permittivity is higher than that of the fully dense matrix. The dielectric permittivity is affected by any parameter that changes the nature of the pore/matrix interface such as temperature [37, 38].

In general, the MG theory [26] can describe the dielectric behavior of nanoporous materials as in the case of nanocomposites. However, there are discrepancies in the values of the dielectric permittivity and dielectric loss between the experimental results and the MG theory predictions, which are attributed to inaccurate approximations of the theory with regard to the effect of size and shape of pores as well as to the local electric field at the pore/matrix interfaces [25, 37].

The dielectric behavior of nanoporous materials is very sensitive to adsorbed dipolar molecules or ions on the pore/matrix interfaces [39, 40] because of the large surface-to-volume ratio, the chemical interfacial bonds, and the structural orientation of the adsorbed molecules. The adsorbed molecules can contribute to the dielectric polarization through two mechanisms: interfacial polarization and bulklike polarization [41]. The interface polarization is affected by a surface bound layer of molecules and is dominant at low frequencies. The bulklike polarization results from molecules inside a pore that are not connected directly to the pore surface. The bulklike polarization shows dielectric relaxation processes at frequencies higher than those associated with the interface polarization. An example of the effect of adsorbed molecules inside pores on the dielectric behavior can be seen in nanoporous silica. In this case, the presence of adsorbed water molecules on the surface of nanopores results in an increase of the dielectric permittivity and dielectric loss compared to those of dry pores especially at low frequencies between 100 Hz and 1 kHz [42]. Four dielectric relaxation processes associated with the adsorbed water molecules were observed at different temperatures [42]. The first relaxation process was observed at low temperatures (from −100 to +10 °C). It is characterized by a thermally activated Arrhenius behavior and a non-Debye frequency dependence. It is attributed to reorientation of adsorbed water molecules in icelike structures on the pore surfaces [39]. The second relaxation process was observed at about 60 °C. It is characterized by a non-Arrhenius behavior and is attributed to glass-forming liquids [43]. The third relaxation process was observed at low frequencies at temperatures between 20 and 80 °C. The amplitude of this process decreases with increasing frequency and the dielectric loss factor reaches a maximum value, which is independent of temperature. This relaxation process is attributed to a percolation of charge carriers within the fractal structure of connected pores [42]. The fourth relaxation process was observed at temperatures above 150 °C and is characterized by enhanced dielectric loss at low frequencies. This process is attributed to interfacial polarization due to trapping of free charge carriers at the pore/matrix interfaces causing a buildup of space charge with a relatively long relaxation time [44].

The first, second, and third relaxation processes can be fitted to a superposition of two theoretical expressions. The first one is the HN expression [Eq. (1)] [7] and the second expression is Jonscher's empirical formula [45],

$$\varepsilon(\omega) = B_1 \omega^{n-1} - i B_2 \omega^{n-1} \tag{12}$$

where B_1 and B_2 are the coefficients of asymptotic expansion, and n is the Jonscher parameter for the high frequency part of the relaxation process. The fourth relaxation process can be described by the MG theory [Eq. (9)] [26].

3. NONLINEAR DIELECTRICS

3.1. Homogeneous Materials

3.1.1. Particle Size Effect on Ferroelectric Domain Structure

A reduction of particles size into the nanometer scale changes the domain structure and consequently the dielectric behavior of ferroelectric materials. The particles size effect can be divided into three size regions [46]. The first region is characterized by multidomain crystallites having a bulk ferroelectric behavior. The second region occurs at a smaller particle size, where single-domain crystallites are present, and is characterized by a loss of spontaneous polarization, an absence of the hysteresis loop, and a nonlinear dielectric behavior. The third region is found in the smallest particles and is characterized by a disappearance of the nonlinear dielectric behavior.

The first size region, where multidomain crystallites are present, is characteristic of bulk-sized particles. In this region a decrease of the crystallites size is accompanied with a decrease of 90° domain width, as formulated in [47, 48]

$$w \propto d^m \tag{13}$$

where w is the domain width, d is the crystallite size, and m is a factor that depends on a crystallite size ($m > 1/2$ for crystallites smaller than 1 μm) [49]. Equation (13) is determined by minimizing the energies associated with the electrical and strain fields inside the domains and the domain walls [50]. In this size region the dielectric permittivity is determined by a sum of a volume contribution, $\varepsilon_{r,\mathrm{vol.}}$, which is based on the single-crystal dielectric permittivity and a domain walls contribution, $\varepsilon_{r,\mathrm{dom}}$:

$$\varepsilon_r(T) = \varepsilon_{r,\mathrm{vol.}}(T) + \varepsilon_{r,\mathrm{dom}}(T) \tag{14}$$

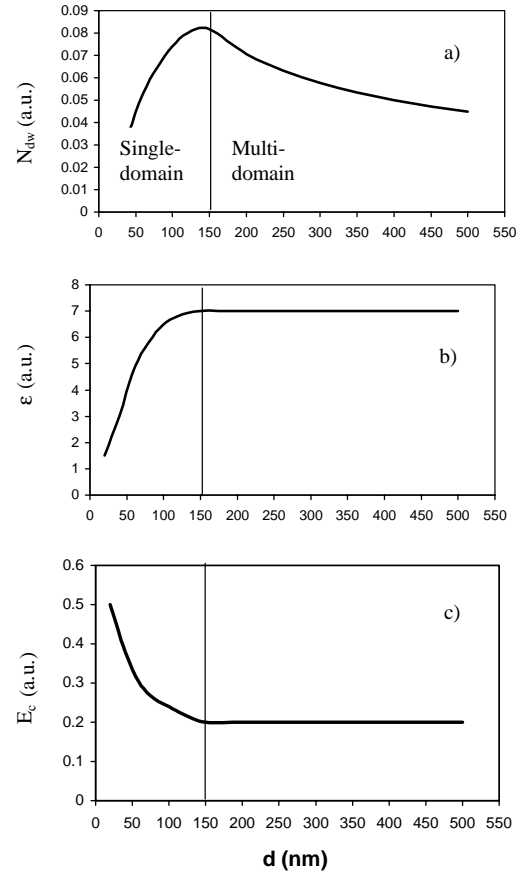
As the crystallite size decreases the density of 90° domain walls increases and consequently $\varepsilon_{r,\mathrm{dom}}$ increases [50]. For example [51], in BaTiO$_3$ crystallites having an average crystallite size of about 10 μm, $k_r = \varepsilon_r/\varepsilon_0 \sim 1700$ where $k_{r,\mathrm{vol.}} \sim 1000$ and $k_{r,\mathrm{dom}} \sim 700$. A decrease of the crystallite size to about 2 μm results in an increase of the dielectric constant to 2500. Based on these experimental results an expression was formulated that relates the crystallite size, d, and the contribution of the domain walls to the dielectric constant, $k_{r,\mathrm{dom}} = 2200/(d)^{0.5}$. A similar relationship was found for Pb$_{1-x}$La$_x$Zr$_{1-y}$Ti$_y$O$_3$ crystallites [52]. The number of variants determining the domain structure [53] decreases with decreasing crystallites size. At a critical size a transition from multidomain to single-domain crystallites occurs. Experimental studies show a critical size of 30 nm in PbTiO$_3$ crystallites [54] and 80 nm in BaTiO$_3$ crystallites [55]. The transition from multidomain to single-domain crystallites is accompanied by an abrupt increase of coercive field, a drop in dielectric permittivity, and a sharp decrease of domains density (Fig. 4). The increase of the coercive field is explained by a greater difficulty to form new domains in single-domain compared to multidomain crystallites by applying an external electric field [56]. This explanation is supported by an experimental observation of a smaller acti-


Figure 4. The effect of grain size, d, on the (a) domain wall density, N_{dw}, (b) dielectric permittivity, ε, and (c) coercive field, E_c, of a ferroelectric material.

vation energy for domain reorientation in multidomain than in single-domain PbTiO$_3$ crystallites [57]. The decrease of dielectric permittivity with decreasing crystallite size below the critical value is attributed to a lack of domain walls that can contribute to dielectric polarization via a domain wall motion mechanism. This behavior is opposite to that observed in multidomain crystallites, where the domain density increases with decreasing crystallite size according to a square-root dependence ($N_d \sim d^{-1/2}$) (Fig. 4). The transition from multidomain to single-domain crystallites can be explained by thermodynamic considerations with the aid of a schematic description (Fig. 5) [55]. The explanation starts with a reference state for the crystallites, which is a paraelectric phase. Below T_c, these crystallites transform first into single-domain crystallites. This transformation is associated with a free energy change that consists of a reduction of a volume free energy, ΔG_v, and addition of surface, ΔG_s, and strain, ΔG_ε, free energies:

$$\Delta G = -\Delta G_v + \Delta G_s + \Delta G_\varepsilon \tag{15}$$

The strain free energy in single-domain crystallites results from a volume expansion associated with a phase transformation and from clamping forces applied by the surrounding crystallites. It depends on the crystallite size and domain
Figure 5. Schematic description of the crystallite size effect on the transition stages from a paraelectric to a multidomain ferroelectric phase.

width according to the expression [48]

$$\Delta G_\varepsilon = \frac{\sigma_{90}}{w} + \frac{2k_c \beta^2 w}{d} \qquad (16)$$

where σ_{90} is a 90° domain wall energy per unit area, k_C is a strain energy associated with the change of the crystallographic unit cell, β is the unit cell deformation ($c/a - 1$), w is the domain width, and d is the crystallite size. The dependence of the domain width on the crystallite size [Eq. (17)] is obtained by minimizing the free energy of the crystallite, ΔG:

$$w = \left(\frac{\sigma_{90} d}{2k_c \beta^2} \right)^{1/2} \qquad (17)$$

The transition from single-domain to multidomain crystallites occurs above a critical crystallite size, d_c, which is equal to the domain width at the minimum free energy state of the crystallite [Eq. (18)] (Fig. 6). This transition is accompanied with strain relaxation by a formation of twins and domain walls:

$$d_c = \frac{\sigma_{90}}{2kc\beta^2} \qquad (18)$$

Calculated values [using Eq. (18)] of the critical crystallite size were found to be in a good agreement with experimental values for $BaTiO_3$ and $PbTiO_3$ crystallites [54].

The third size region is found in the smallest crystallites and is characterized by a disappearance of the nonlinear behavior below another critical crystallite size. Various critical crystallite sizes were observed experimentally in different materials such as a 9 nm size in $PbTiO_3$ crystallites
Figure 6. The effect of crystallite size, d, on domain width, w, in solid perovskites according to Eq. (17).

[58], a 150 nm size in KDP crystallites [59], and a 30 nm size in $BaTiO_3$ crystallites [55]. The transition point, which is marked by the critical size, is attributed to a surface effect, which becomes dominant as the size of the crystallites decreases into the nanometer size scale. The surface effect can be divided into two main sources: surface energy and depolarization energy. The surface energy can completely suppress the ferroelectric behavior below a critical size L_c that depends on a correlation length, ζ, and correlation factors D and α as follows [60]:

$$L_c \approx 0.85\zeta = 0.85\sqrt{\frac{D}{|\alpha|}} \qquad (19)$$

The depolarization energy can also suppress the ferroelectric behavior. It results from an accumulated charge at interfaces of neighboring crystallites and at interfaces of crystallites with external conductive electrodes. This accumulated charge partially screens the spontaneous polarization of the crystallites due to its distribution over a finite length. It becomes dominant when the polarization vector is perpendicular to the crystallite surface. In this case, L_c can be calculated as [60]

$$L_c = \frac{2\alpha C}{T_{cb} \varepsilon_0} l_s \qquad (20)$$

where α is the polarizability of the material, C is the Curie–Weiss constant, T_{cb} is the Curie temperature of the bulk ferroelectric material, ε_0 is the vacuum permittivity, and l_s is the screening length of the accumulated charge.

Calculations of L_c according to Eq. (20) result in different values than those observed experimentally. For example, L_c for $BaTiO_3$ crystallites in contact with gold electrodes [61] was calculated to be 0.53 nm, which is below the experimentally observed value (30 nm) [55]. For polyvinyliden fluoride (PVDF) copolymers, L_c was calculated to be about 0.1 nm. Crystallites with such a size cannot be fabricated and tested. The thinnest film for which full ferroelectric switching has been reported is a 0.9 nm PVDF copolymer prepared by the Langmuir–Boldgett technique [62]. The discrepancy between the calculated and experimental values of L_c in these examples indicates that the ferroelectric suppression at a critical crystallite size is not done solely by the depolarization energy but with a contribution of the surface energy.

3.1.2. Two-Dimensional Ferroelectric Behavior

Two-dimensional ferroelectric behavior means that the dielectric properties are determined by dipole interaction within a plane rather between planes in the film. It is characterized by an absence of finite size effect below a critical film thickness. Two-dimensional ferroelectric behavior was found only in ultrathin films (1–15 nm thick) of the copolymer vinyliden fluoride with trifluoroethylene, P(VDF-TrFE, 70:30) [62]. The polymer has a very high crystallinity [63, 64] due to ordered $-((CF_2\text{-}CH_2)_x\text{-}(\text{-}CF_2\text{-}CHF)_{1-x})_{n-}$ chains having a regular intrachain period of 0.26 nm controlled by C–C bonds between fluorine pairs (Fig. 7). In the ferroelectric phase, the chains are arranged in parallel rows having quasi-hexagonal close packing with an orthorhombic $mm2$
Figure 7. Schematic description of a fragment of the PVDF molecular structure having an intrachain period of 0.26 nm and dipole moments oriented from the fluorine atom side to the hydrogen atom side of the molecule chain.

structure [65]. This structure exhibits preferred polarization orientation in a direction perpendicular to the film plane. Ultrathin films of P(VDF-TrFE) were fabricated by the horizontal Schaefer variation of the Langmuir–Boldgett monolayer transfer technique, which enables precise control of the film nanostructure [66, 67]. The films show a combination of regular (bulk) and irregular ferroelectric properties. Their regular ferroelectric properties include a first-order ferroelectric–paraelectric phase transition at about 80 °C, polarization hysteresis loops with good saturation values, and complete reversible polarization switching below 80 °C [62]. The irregular properties of these films are an absence of finite size effect between 15 and 1 nm, an absence of apparent critical thickness in films as thin as 1 nm, which is much thinner than any previously reported ferroelectric film, a presence of very large coercive fields ($E_c =$ 0.6–0.9 $GV m^{-1}$) [68], and an appearance of a new phase transition at temperature of about 20 °C [62]. The absence of finite size effect and critical size in two-dimensional ferroelectric films is in contradiction to theoretical models of three-dimensional ferroelectricity. The coercive fields of two-dimensional films are much higher than in those of other ferroelectric materials; they do not depend on the film thickness and are very close to the theoretical intrinsic coercive field (~ 1 $GV m^{-1}$). This means that the switching mechanism does not depend on nucleation and growth of domains but rather on a new mechanism, which is still unknown. The new ferroelectric phase transition at 20 °C was determined as a first-order transition due to the presence of thermal polarization hysteresis loops and peaks in both dielectric constant and pyroelectric response [62]. It is attributed to a surface effect since the surface band structure is changed at about the same temperature of 20 °C [69].

Currently, there is no theoretical model that can explain the two-dimensional ferroelectric behavior of ultrathin films. It is suggested [70] to use the Ising model [71] for this purpose, since it describes restricted movement of dipoles. In the P(VDF-TrFE) case, the dipole movement is restricted to only partial rotation about the polymer chain axis due to interchain steric interactions and interchain dihedral

stiffness. The model should take into consideration the anisotropic dipole coupling within a plane in the film (strong parallel to and weak perpendicular to the plane) or the weak dipole coupling between planes in the film.

3.1.3. Effect of Crystallite Size on the Curie Temperature

The effect of crystallite size on the Curie temperature of ferroelectric materials has been investigated for a long time since 1953 [59] and the experimental results do not show a clear dependence between them. For example, one study [72] reported an increase while another study [73] reported a decrease of the Curie temperature as the crystallite size of the same material, BaTiO$_3$, decreases. However, many experimental studies reported a shift of the Curie temperature compared to its bulk value as the crystallite size decreases to the nanometer size scale [74–78]. For example, a change of a few degrees of the bulk Curie temperature was observed in the case of NaNO$_2$ nanocrystals ($d \sim$ 5–20 nm) [75] while on the other hand a change of almost 80 degrees was observed in PbTiO$_3$ nanocrystals ($d \sim$ 30 nm) [76]. An empirical expression was given in the case of PbTiO$_3$ crystallites [76] to describe the dependence between Curie temperature and crystallite size, which consists of three material-related constants, c_1, c_2, c_3:

$$T_c = c_1 - \frac{c_2}{(d - c_3)} \tag{21}$$

Equation (21) cannot describe all the observed experimental results and currently, there is no theoretical expression that can evaluate the change of T_c with crystallite size based on measurable parameters. However, there are theoretical expressions that describe this dependence on the basis of immeasurable parameters such as surface interaction strength and surface extrapolation length. These theoretical expressions, which refer to a change of order in the vicinity of the film or crystallite surface, result from two main models. The first one is known as the Ising model under a transverse field (IMTF) [78]. This model refers to a ferroelectric behavior determined by hydrogen bonds. Each bond has a double potential well for the proton. Above the Curie temperature, the protons have a random distribution between the two sides of the double potential well, while below T_c they prefer one side of it. In this way the ferroelectric phase transition becomes associated with a transition from random to ordered occupancy of the double potential wells and can be described in terms of the spin 1/2 IMTF Hamiltonian [79],

$$H = -\Omega \sum_i S_i^x - \frac{1}{2} \sum_{i,j} J_{i,j} S_i^z S_j^z \tag{22}$$

where i and j are two sites of a double potential well of the hydrogen bond, Ω is the transverse field, S_i^x and S_i^z are the x and z components of the pseudo-spin [S^z differs between occupancy of site i ($S_i^z = +\frac{1}{2}$) and site j ($S_i^z = -\frac{1}{2}$)], and J_{ij} is an effective exchange constant which represents the interaction between the ith and jth sites. The first component of Eq. (22), $\Omega \sum_i S_i^x$, corresponds to a tunneling of protons between neighboring sites

and it serves as a parameter of disorder in the material. If $\Omega \sum_i S_i^x > \frac{1}{2} \sum_{i,j} J_{i,j}$ then there is no ferroelectric phase. The second component of Eq. (22), $\frac{1}{2} \sum_{i,j} J_{i,j} S_i^z S_j^z$, is associated with the interaction between neighboring potential wells sites. Both components of Eq. (22) are affected by crystallite surfaces or interfaces, where the density and type of nearest neighbor atomic sites differ than those in the crystallite bulk regions. As the crystallite size decreases to the nanometer scale, the density of interfaces between crystallites increases, leading to a pronounced contribution of interface sites to the effective exchange constant, J_{ij} [Eq. (22)]. According to the Ising model, the relative contribution of crystallite interfaces to the overall effective exchange constant of the material, J_s/J, determines the Curie temperature.

For example [79], Eqs. (23) and (24) show the dependence of T_c on the ratio J_s/J for one and two interface layers respectively in a relatively simple case with the conditions $J_{i,j} \neq 0$ only for nearest-neighbors sites i and j, $J_{i,j} = J_s$ (if both sites are at an interface), and otherwise $J_{i,j} = J$ (nearest interactions), and the spins lie on a simple cubic lattice with the coordination axes parallel to the cube edges,

$$\text{for } n=1 \quad x=4\frac{J_s}{J} \quad \left(x=2\frac{\Omega}{J}\right)\coth\left(\frac{\Omega}{2k_B T_c}\right) \quad (23)$$

$$\text{for } n=2 \quad x=1+4\frac{J_s}{J} \quad \left(x=2\frac{\Omega}{J}\right)\coth\left(\frac{\Omega}{2k_B T_c}\right) \quad (24)$$

where n is the number of surface layers, and k_B is the Boltzman constant.

Equations (23) and (24) are compared with the bulk Curie temperature expression [Eq. (25)] obtained for a second-order phase transition, by using the Hamiltonian [Eq. (22)] under the mean-field approximation [79],

$$\tanh\left(\frac{\Omega}{2k_B T_b}\right) = 2\left(\frac{\Omega}{n_0 J}\right) \quad (25)$$

where n_0 is the coordinate number.

Curves of T_c/T_b vs. J_s/J based on Eqs. (23)–(25) show that there is a critical surface interaction strength, J_{sc}, which is higher than that of the bulk value ($J_{sc}/J = 1.25$ for a single surface layer and $J_{sc}/J = 1.08$ for two surface layers). If $J_s > J_{sc}$ then the Curie temperature increases as the size of the crystallite decreases. Otherwise, the Curie temperature decreases with decreasing the crystallite size. For a weak surface interaction, there will be no ferroelectric behavior, which was reported for nanometer-sized crystallites and ultrathin films. For a strong surface interaction, an optimum crystallite size with a maximum Curie temperature is obtained.

A second model on the effect of crystallite size on the Curie temperature of ferroelectric materials is based on the Landau–Devonshire theory [61, 80, 81]. The theory describes the free energy, F, of the bulk material as a function of polarization, P, in a formalism of a Taylor series,

$$F = \frac{1}{2}AP^2 + \frac{1}{4}BP^4 + \frac{1}{6}GP^6 \cdots \quad (26)$$

where A is a coefficient associated with a Curie temperature of a bulk material, T_b, as follows:

$$A = A_0(T - T_b) \quad (27)$$

The coefficients B and G in Eq. (26) are associated with the type of the ferroelectric phase transition. A first-order transition occurs when $B < 0$ and $G > 0$, while a second-order transition appears when $B > 0$. The effect of the particle surfaces adds more terms into Eq. (26) as detailed in

$$F = S\left\{\int d^3r\left[\frac{1}{2}AP^2 + \frac{1}{4}BP^4 + \frac{1}{6}GP^6 + \frac{1}{2}C|\nabla P|^2\right] + \frac{1}{2}C\delta^{-1}\int dS(nP)^2\right\} \quad (28)$$

where n is the number of surfaces with area S, and δ is a surface parameter. In the case of a second-order phase transition and a stationary F, Eq. (28) is changed into the following differential equation [82–84]:

$$C\frac{d^2P}{dz^2} - AP - BP^3 = 0 \quad (29)$$

The solution of Eq. (29) under the boundary condition of Eq. (30) for plane surfaces gives criteria [Eq. (31)] for the effect of the crystallite size or film thickness, d, on the Curie temperature:

$$\frac{dP}{dz} \pm \frac{1}{\delta}P = 0 \quad \text{at } z = \pm\frac{1}{2d} \quad (30)$$

$$\begin{aligned}\text{If } \delta < 0 \quad &\text{then } T_c > T_b \\ \text{If } \delta > 0 \quad &\text{then } T_c < T_b\end{aligned} \quad (31)$$

The surface parameter δ plays the same role as the normalized surface interaction strength, J_s/J, in the IMTF model. In the case of $\delta > 0$ the spontaneous polarization decreases, most pronouncedly at the crystallites surfaces, and the Curie temperature decreases with decreasing crystallite size. The opposite case occurs when $\delta < 0$, where the spontaneous polarization and Curie temperature increase with decreasing crystallite size. The dependence of T_c on the crystallite size or film thickness is usually presented by dimensionless variables of T_c/T_b vs. $1/\zeta_0$ where $\xi_0 = [CT_b/A_0]^{0.5}$ [85]. The criteria given in Eq. (31) were developed for a second-order ferroelectric phase transition. In the case of a first-order phase transition the term P^6 in Eq. (28) cannot be neglected and the model does not provide criteria for the effect of crystallite size on Curie temperature but only shows a discontinuous polarization change at the Curie temperature [85].

3.2. Heterogeneous Materials

3.2.1. Ferroelectric Relaxors

Ferroelectric relaxors (FRs) are complex oxides that belong to the family of disordered materials and most particularly to the group of mixed-cation ferroelectrics having a perovskite structure with a general chemical formula $A_{1-x} - A'_x B_{1-y} B'_y O_3$. The most intensively studied FR materials are $PbMg_{1/3}Nb_{2/3}O_3$ (PMN), $PbSc_{1/2}Ta_{1/2}O_3$, $PbSc_{1/2}Nb_{1/2}O_3$,

Pb$_2$KTa$_5$O$_{15}$ (PKT), and Pb$_{1-x}$La$_x$Zr$_{1-y}$Ti$_y$O$_3$ (PLZT). FR materials consist of nanometer-sized ferroelectric domains (10–50 nm) dispersed in a paraelectric matrix. The presence of nanometer-sized domains was verified by X-ray diffraction, neutron diffraction, and transmission electron microscopy (TEM) studies on various FR materials [86–91].

The dielectric behavior of FRs has been studied experimentally [92–94] and was found to be different than that of conventional ferroelectric materials. FRs usually exhibit high dielectric permittivity and low dielectric loss. Their dielectric permittivity has a peak-shaped dependence on temperature with a maximum value at a temperature called T_{max} (Fig. 8a) [95]. T_{max} increases with increasing applied field frequency. For example [96], in La-modified lead-based FR, an increase in frequency by one order of magnitude lead to a shift of T_{max} by about 10 °C. Below T_{max}, the dielectric permittivity shows a non-Debye dispersion over a wide range of frequencies (usually between 10 Hz and 10 MHz). The dielectric loss of FRs also has a peak-shaped dependence on temperature with a sharp rise at a temperature lower than T_{max} (Fig. 8b). The dielectric losses show frequency dependent dispersion above T_{max}, which is opposite to the direction observed for the dielectric permittivity. The dielectric loss of different frequencies merges together at low temperatures. FR materials show a diffuse phase transition from the paraelectric to the ferroelectric phase [92] and an absence of macroscopic polarization at temperatures below T_{max}. The dependence of the dielectric susceptibility, $\chi_0(T)$, on temperature in FR materials cannot be described by the known Curie–Weiss law but rather by a special quadratic law as

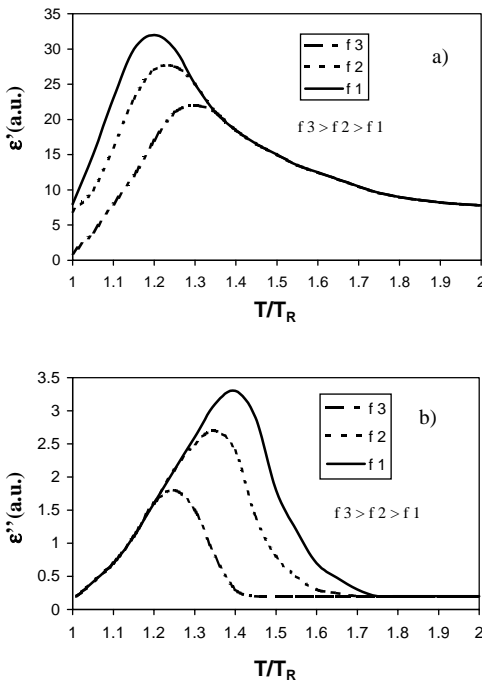
$$\chi_0(T) = \frac{C}{(T - T_c)^2} \tag{32}$$


Figure 8. The effect of temperature on the dielectric permittivity [real (a) and imaginary (b) parts] of ferroelectric relaxors at different frequencies (TR is a reference temperature).

where C is the Curie constant and T_c is the Curie temperature.

The dielectric polarization of FR material was found to strongly depend on the applied field orientation relative to the crystallographic orientation. For example, an abrupt jump in polarization was found in the PMN materials by applying an electric field of about 1.7 kV/cm in the $\langle 111 \rangle$ direction. The polarization saturates at higher applied fields in this direction. Applying an electric field in the $\langle 110 \rangle$ direction resulted in a polarization jump at a higher electric filed and a lower saturation value than those observed in the $\langle 111 \rangle$ direction. Neither polarization jump nor saturation value was found when the electric field was applied in the $\langle 100 \rangle$ direction but rather a continuous increase of polarization with increasing applied field up to 6 kV/cm. Different phases have been observed in FR materials depending on the intensity and orientation of the applied field as well as on temperature. For example, in the PMN materials three different phases (paraelectric, glass, and ferroelectric) were observed when an electric field was applied in the $\langle 111 \rangle$ direction [97]. The paraelectric phase, which is controlled by a dynamic disorder, was obtained at temperatures higher than 206 K (field-free depoling temperature) under applied dc fields between 0 and 2.7 kV/cm. This phase shows a pronounced dispersive peaks of ε' and ε'' with a major maximum value at about 206 K and a minor maximum value at about 217 K in the high field regime (above 1.7 kV/cm). The amplitudes of these maxima are frequency dependent and they disappear under dc fields below 1.7 kV/cm. The glassy phase was obtained at temperatures below 206 K and under dc applied fields lower than 1.7 kV/cm. The glassy phase, which is characterized by a metastable polarization, is explained by the presence of a large distribution of dipole relaxation times. The metastable polarization increases nonlinearly with increasing applied field up to 1.7 kV/cm and can be described by the expression [97]

$$P^{ms} = \chi_0^{ms}(T)E + \frac{1}{3}\chi_2^{ms}(T)E^3 \tag{33}$$

where P^{ms} is the metastable polarization, χ is the static susceptibility, and E is the applied field. Ferroelectric phases in the PMN materials were observed at temperatures below 206 K and under dc applied fields higher than 1.7 kV/cm. The phases are classified in three groups. The first group is characterized by a ferroelectriclike behavior with a higher polarization than that of the glassy phase and it appears at lower temperatures. The second group is characterized by a field-independent value of polarization that can be reversed by an applied field. It is obtained at higher temperatures and applied fields than those of the first group. The third group shows a hysteresis loop and a usual first-order ferroelectric phase transition.

The relatively high permittivity over a wide temperature range and low sintering temperatures of FR materials make them attractive for multilayer capacitors. They are also attractive to piezoelectric applications due to their high piezoelectric coefficients [98] compared to conventional piezoelectric ceramics.

Various models have been proposed to explain the mechanism of formation and the nature of the nanometer-sized

domains that determine the unique dielectric behavior of FR materials. One model [86] suggests a unique local polarization in nanometer-sized domains without any global polarization in the crystal. The model distinguishes between short-range and long-range order effects. The short-range effect is associated with a local polar symmetry, which is correlated with local atomic shifts. The small polar regions are part of the host lattice and therefore depend on it. The structure of a polar region differs from that of the host lattice only in the atomic shifts. Thus, the crystal does not behave as a polar homogeneous structure, because the coherence length of the polar zones is spatially limited, nor does it behave as a perfectly cubic crystal because of the strong deviation from a cubic symmetry. The nanopolar regions may appear in at least two configurations. One configuration consists of islands of polar ordered nanodomains (first phase) immersed in a disordered paraelectric host lattice (second phase). Another configuration consists of an array of nanodomains (first phase) surrounded by interdomain regions (second phase). In both configurations the crystal is considered as a two phase system. The long-range effect is associated with a variation of the local polarization fields in such a way that no global polarization exists in the material. This model was tested experimentally with neutron and X-ray diffraction studies of PMN-based FR materials during cooling from 1000 to about 5 K [86, 99, 100]. The studies revealed a mean cubic structure of the matrix down to 5 K with, however, the presence of nanometer-sized rombohedral polar domains (atomic shifts along $\langle 111 \rangle$ direction of the cube, which is the rhombohedral axis). The size of the polar domains grew with increasing temperature and the correlation length was estimated to be of about 10 nm at 5 K.

Another model, called the superparaelectric model, of FR materials is based on high-resolution TEM studies that revealed nanometer-sized polar domains dispersed in a paraelectric matrix [100]. The model claims that the domains are superparaelectric regions with thermally fluctuating polarization vectors between equivalent potential wells [95]. This model was used in a phenomenological approach [101] that analyzes the behavior of FR materials throughout four stages. The first stage regards the FR as an ensemble of independent, identical, monosized superparaelectric domains. The second stage introduces a distribution of the domain size. The third stage takes into account a temperature dependence of the domain size, and the fourth stage treats the dipolar interaction of neighboring domains. This phenomenological approach was used to build a model that quantitatively describes the dielectric behavior of FR materials [102]. It is well known that the first nucleation of domains occurs hundreds of degrees above T_{max} [103]. In the case of the PMN material, it has been shown that the nucleation temperature is at about 600 K, far above $T_{max} = 265$ K [99]. At T_{max}, the size distribution of the domains is relatively narrow and the dielectric relaxation follows the Debye expressions [Eqs. (10), (11)]. Below T_{max}, the size of the domains begins to strongly increase and their size distribution is broadened upon cooling. The present model assumes homogeneous nucleation and exponential size distribution of the domains for temperatures sufficiently below T_{max}. The model also claims that the domains fluctuate under a thermal energy higher than the required polarization activa-

tion energy, E_a. E_a depends linearly on the domain volume, which means that as the domain size increases it becomes more difficult to thermally fluctuate it. The relaxation time of the domain increases exponentially with increasing E_a. The presence of a size distribution of domains below T_{max} results in a multiple relaxation times and an asymmetric dielectric response (in contrast to the Debye-type response) of FR materials. The model formulates a dependence of dielectric permittivity and dielectric loss on frequency of FR materials as

$$\varepsilon_r' \cong k_c \left[1 - \frac{n\pi}{2\sin(n\pi/2)} (\omega\tau_c)^n \right] \tag{34}$$

$$\varepsilon_r'' \cong k_c \frac{n\pi}{2\cos(n\pi/2)} (\omega\tau_c)^n \tag{35}$$

where ε_r' and ε_r'' are the real and imaginary parts of the complex dielectric permittivity, ω is the angular frequency of the applied field, k_c and τ_c are the static dielectric constant and the relaxation time of the domains, respectively, and n is a dimensionless parameter that spans between 0 and 1 and is equal to the ratio between the thermal energy and the polarization activation energy of the domains. The expression $[1 - (n\pi/2\sin(n\pi/2))(\omega\tau_c)^n]$ in Eq. (34) is known as the dispersion factor which indicates quantitatively (between 0 and 1) the degree of dielectric permittivity dispersion. The parameter n is inversely proportional to the width of the domain size distribution. Consequently, a small variation in domain size induces a dielectric dispersion over several orders of frequency magnitude. For example, a small change of the domain size from 4.5 to 5.5 nm results in a dispersion of the relaxation time over 4 orders of magnitude [104]. Equation (34) shows that the dielectric permittivity is proportional to $[1 - (\omega\tau_c)^n]$ which means that at the same temperature and domain size distribution, the dielectric permittivity increases with decreasing frequency. However, at the same frequency a decrease of temperature is associated with an increase of both n and τ_c, which results in a decrease of the dielectric permittivity. The parameter n decreases linearly from 1 to almost 0 with decreasing temperature according to Eq. (36) due to growth of domains and broadening of their size distribution,

$$n = \alpha(T - T_0) \tag{36}$$

where α and T_0 are constants. T_0 corresponds to the transition temperature from the paraelectric to the ferroelectric phase of the pure host system [105]. However, in FR materials, the nanometer-sized domains cannot grow into macrodomains without an applied electric field. Consequently, the parameter n deviates from its linear dependence on temperature below T_0, which results in a slow down of the dielectric dispersion at temperatures much lower than T_{max}. The model also claims that the dielectric permittivity peak is not associated with a true ferroelectric phase transition. The presence of the peak is explained by a growth of domains to a size where they begin to fail in following the alternating applied field. It is therefore expected that T_{max} will increase with increasing frequency. The peak of the

dielectric loss is also not associated with a true phase transition but rather corresponds to a temperature where the dielectric dispersion reaches a maximum value. This model was tested experimentally on the PMN and PKT-based FR materials and was found to be in a good agreement with the experimental results [102].
